1986). These two forms of coping sometimes work together. For example, you might deal with the problem of noise from a nearby airport by forming a community action group to push for tougher noise regulations and, at the same time, calm your anger when noise occurs by mentally focusing on the group's efforts to improve the situation (e.g., Hatfield et al., 2002). As mentioned earlier, coping efforts may not always be so adaptive. In the face of a financial crisis or impending exams, for example, some people rely on emotion-focused methods such as using alcohol or other drugs to ease anxiety but take no problem-focused steps to get out of debt or learn difficult material. These emotion-focused strategies may reduce distress in the short run, but the long-term result may be a financial or academic situation that is worse than it was before. Susan Folkman and Richard Lazarus (1988) have devised a widely used questionnaire to assess the specific ways in which people cope with stressors; Table 13.3 shows some examples of responses to their questionnaire.

Particularly when a stressor is difficult to control, it is sometimes helpful to express fully, and think about, the emotions you are experiencing in relation to the stressful event (Langens & Schüler, 2007; Niederhoffer & Pennebaker, 2002). The benefits of this cognitive strategy have been observed among many individuals whose religious beliefs allow them to bring meaning to the death of a loved one, or the devastation of a natural disaster, events that might otherwise seem to be senseless tragedies (Heppner et al., 2006; Powell, Shahabi, & Thoresen, 2003; VandeCreek et al., 2002). And when cancer patients are encouraged to express their feelings about their diagnosis and to search for positive aspects of their illness (such as bringing their family closer together), they experience fewer symptoms, need fewer medical visits, and adjust better to their disease (Antoni et al., 2001; Low, Stanton, & Danoff-Burg, 2006). Humor may also play a role. Some individuals who use humor to help them cope show better adjustment and lower physiological reactivity to stressful events (Martin, 2001; Moran, 2002).

● Social Support

If you have ever benefited from the comforting presence of a good friend during troubled times, you know about another factor that mediates the impact of stressful events—*social support*. Social support consists of resources provided by other

TABLE 13.3 Ways of Coping

TRY THIS  Coping is defined as the cognitive and behavioral efforts to manage specific demands that people perceive as taxing their resources (Folkman et al., 1986). This table illustrates two major approaches to coping measured by the Ways of Coping questionnaire: problem-focused and emotion-focused coping. To get an idea of your own coping style, rank-order the skills listed under each major approach in terms of how often you tend to use each of them. Do you rely on just one or two, or do you adjust your coping strategies to fit different kinds of stressors?

| Coping Skills | Example |
|-------------------------------------|--|
| Problem-focused coping | |
| Confronting | "I stood my ground and fought for what I wanted." |
| Seeking social support | "I talked to someone to find out more about the situation." |
| Planful problem solving | "I made a plan of action, and I followed it." |
| Emotion-focused coping | |
| Self-controlling | "I tried to keep my feelings to myself." |
| Distancing | "I didn't let it get to me; I tried not to think about it too much." |
| Positive reappraisal | "I changed my mind about myself." |
| Accepting responsibility | "I realized I brought the problem on myself." |
| Escape/avoidance (wishful thinking) | "I wished that the situation would go away or somehow be over with." |

Source: Adapted from Folkman et al. (1986); Taylor (2002).

You've Got a Friend Even when social support cannot eliminate stressors, it can help people, such as these breast cancer survivors, to feel less anxious, more optimistic, more capable of control, and more willing to try new ways of dealing with stressors (Trunzo & Pinto, 2003). Those who provide social support may feel better, too (Brown et al., 2003).

people. The friends and social contacts on whom you can depend for support constitute your **social support network** (Burlleson, Albrecht, & Sarason, 1994). Social support may take many forms, from eliminating the stressor (as when a friend helps you fix your car) to easing its impact with companionship, ideas for coping, or reassurance that you are cared about and valued and that everything will be all right.

The stress-reducing effects of social support have been documented for a wide range of stressors, including cancer, heart disease, military combat, loss of loved ones, natural disasters, arthritis, AIDS, and even ethnic discrimination (e.g., Antoni & Lutgendorf, 2007; Boden-Albala et al., 2005; Gonzalez et al., 2004; Mookadam & Arthur, 2004; Penner, Dovidio, & Albrecht, 2001). Social support can have health benefits, too. For example, students who get emotional support from friends show better immune system functioning than those with less adequate social support (Cohen & Herbert, 1996). This may be why people in strong social support networks are less vulnerable to colds and flu during exams and other periods of high academic stress (Kop et al., 2005; Pressman et al., 2005; Taylor, Dickerson, & Klein, 2002). Having strong social support is also associated with faster recovery from surgery or illness, possibly because helpful friends and family members encourage patients to follow medical advice (Brummett et al., 2005; Krohne & Slangen, 2005; Taylor, 2002). Stronger social networks are even associated with better mental functioning in old age (Barnes et al., 2004). According to some researchers, having inadequate social support can be as dangerous as smoking, obesity, or lack of exercise in that it nearly doubles a person's risk of dying from disease, suicide, or other causes (House, Landis, & Umberson, 1988; Kiecolt-Glaser & Newton, 2001; Rutledge et al., 2004).

However, the relationship between social support and the impact of stressors is more complex than it might appear. First, just as the quality of social support may influence people's ability to cope with stress, the reverse may also be true: People's ability to cope may determine the quality of social support they receive (McLeod, Kessler, & Landis, 1992). For example, people who complain endlessly about stressors but never try to do anything about them may discourage social support, whereas those with an optimistic, action-oriented approach may attract support.

- **social support network** The friends and social contacts on whom one can depend for help and support.

Second, *social support* refers not only to relationships with others but also to the recognition that others care and will help (Demaray & Malecki, 2002). Some relationships in a social support network may be stormy and fragile, resulting in interpersonal conflicts that can have an adverse effect on health (Ben-Ari & Gil, 2002; Malarkey et al., 1994).

Finally, having too much support or the wrong kind of support can be as bad as not having enough (Reynolds & Perrin, 2004). For example, people whose friends and family are overprotective may actually put less energy into coping efforts. And in one study of people with physical disabilities, nearly 40 percent of them were found to have experienced emotional distress in response to the well-intentioned help they received from their spouses. This distress, in turn, was a predictor of depression nearly a year later (Newsome & Schulz, 1998). Similarly, people living in crowded conditions might at first perceive the situation as providing lots of social support, but these conditions may eventually become an added source of stress (Lepore, Evans, & Schneider, 1991). Further, the value of social support may depend on the kind of stressor being encountered. So although having a friend present might reduce the impact of some stressors, it might amplify the impact of others. In one study, for example, participants faced with speaking in public experienced it as more threatening—and showed stronger physical and psychological stress responses—when a friend was watching than when they were alone (Stoney & Finney, 2000). In short, the efforts or presence of members of a social support network can sometimes become annoying, disruptive, or interfering, thereby increasing stress and intensifying psychological problems (Newsome, 1999; Ruiz et al., 2006). It has even been suggested that among people under intense stress, the benefits of having a large social support network may be offset by the dangers of catching a cold or the flu from people in that network (Hamrick, Cohen, & Rodriguez, 2002).

● Stress, Personality, and Gender

The impact of stress on health appears to depend not only on how people think about particular stressors but, to some extent, on how they think about and react to the world in general. For instance, stress-related health problems tend to be especially common among people whose “disease-prone” personalities lead them to (1) try to ignore stressors when possible; (2) perceive stressors as long-term, catastrophic threats that they brought on themselves; and (3) be pessimistic about their ability to overcome stressors (e.g., Penninx et al., 2001; Peterson et al., 1988; Segerstrom et al., 1998; Suinn, 2001).

Other cognitive styles, such as those characteristic of “disease-resistant” personalities, help insulate people from the ill effects of stress. These people tend to think of stressors as temporary challenges to be overcome, not catastrophic threats, and they do not constantly blame themselves for bringing them about. Among the most important components of the disease-resistant personality are sociability (e.g., Cohen et al., 2003b) and *dispositional optimism*, the belief or expectation that things will work out positively (Folkman & Moskowitz, 2000; Rosenkranz et al., 2003; Taylor, Kemeny, et al., 2000). Optimistic people tend to live longer (Giltay et al., 2004, 2006), to experience fewer health consequences following major stressors, and to have more resistance than pessimists to colds and other infectious diseases (Cohen et al., 2003a, 2003b; Kivimaki et al., 2005; Pressman & Cohen, 2005). These data help to explain why optimistic students experience fewer physical symptoms at the end of the academic term (Aspinwall & Taylor, 1992; Ebert, Tucker, & Roth, 2002). Optimistic coronary bypass surgery patients tend to heal faster and stay healthier than pessimists (Scheier et al., 1989) and to experience a higher quality of life following coronary surgery than those with less optimistic outlooks (Fitzgerald et al., 1993). And among HIV-positive men, dispositional optimism has been associated with less psychological distress, fewer worries, and lower perceived

risk of developing full-blown AIDS (Johnson & Endler, 2002; Taylor et al., 1992). All these effects appear to be due in part to optimists' tendency to use challenge-oriented, problem-focused coping strategies that attack stressors directly, in contrast to pessimists' tendency to use emotion-focused coping, such as denial and avoidance (Bosompra et al., 2001; Brenes et al., 2002). They also tend to be happier than pessimists, a tendency associated not only with less intense and less dangerous physiological responses to stressors but also with greater success in life (e.g., Lyubomirsky, King, & Diener, 2005; Steptoe, Wardle, & Marmot, 2005).

Indeed, like optimism, happiness and other positive emotions, such as hope and curiosity, have been associated with better health and longer life (Cohen et al., 2003a; Ong et al., 2006; Ostir et al., 2006; Richman et al., 2005). For example, a long-term study of Catholic nuns found that those who wrote with the most positive emotional style when they were young lived longer than those whose writing contained less positive emotions (Danner, Snowden, & Friesen, 2001). Studies like these represent a new line of research in health psychology that focuses on investigating and promoting the positive emotions, behaviors, and cognitive styles associated with better health (Seligman et al., 2005).

Gender may also play a role in responses to stress. In a review of two hundred studies of stress responses and coping methods, Shelley Taylor and her colleagues found that males under stress tended to get angry, avoid stressors, or both, whereas females were more likely to help others and to make use of their social support networks (Taylor, Klein, et al., 2000). Further, in the face of equally intense stressors, men's physiological responses, including changes in heart rate and blood pressure, tend to be more intense than women's (Stoney et al., 1988). This is not true in every case, of course, but why should a significant difference show up at all? The gender-role learning discussed in the chapter on human development surely plays a part (Eagly & Wood, 1999). But Taylor also proposes that women's "tend-and-befriend" style differs from the "fight-or-flight" pattern so often seen in men because of gender differences in how hormones combine under stress. Consider oxytocin (pronounced "ox-see-TOE-sin"), a hormone released in both sexes as part of the general adaptation syndrome (Taylor et al., 2006; Uvnas-Moberg, Arn, & Magnusson, 2005). Oxytocin may interact differently with male and female sex hormones, producing a greater stress reduction effect in women than in men (Grewen et al., 2005). These differences could lead to the more intense emotional and behavioral stress responses often seen among men, responses that may be partly responsible for their greater vulnerability to heart disease and other stress-related illnesses (Kajantie & Phillips, 2006). If that is the case, gender differences in stress responses may help to explain why women in North America live an average of 5.3 years longer than men (Hoyert, Kung, & Smith, 2005). The role of gender-related hormones in stress responding is supported by the fact that there are few, if any, gender differences in children's stress responses. Those differences begin to appear only around adolescence, when sex hormone differences become pronounced (Allen & Matthews, 1997).

FOCUS ON RESEARCH METHODS

Personality and Health

LINKAGES (a link to Personality, p. 561)

The way people think and act in the face of stressors, the ease with which they attract social support, and their tendency to be optimists or pessimists are but a few aspects of their *personalities*.

■ What was the researchers' question?

Are there other personality characteristics that protect or threaten people's health? This was the research question asked by Howard Friedman and his associates (Friedman et al., 1995a, 1995b). In particular, they attempted to identify aspects of

personality that increase the likelihood that people will die prematurely from heart disease, high blood pressure, or other chronic diseases.

■ How did the researchers answer the question?

Friedman suspected that an answer might lie in earlier research—specifically, in the Terman Life Cycle Study of Intelligence, named after Louis Terman, author of the Stanford-Binet intelligence test. As described in the chapter on cognitive abilities, the study was originally designed to document the long-term development of 1,528 gifted California children (856 boys and 672 girls)—nicknamed the “Termites” (Terman & Oden, 1947). Friedman and his colleagues found ways of using data from this study to explore the relationship between personality and health.

Starting in 1921, and every five to ten years thereafter, Terman’s research team had gathered information about the Termites’ personality traits, social relationships, stressors, health habits, and many other variables. The data were collected through questionnaires and interviews with the Termites themselves, as well as with their teachers, parents, and other family members. When, by the early 1990s, about half of the Termites had died, Friedman realized that the Terman Life Cycle Study could serve as a longitudinal study in health psychology. As in most such studies, the independent variable (in this case, personality characteristics) was not actually manipulated (the Termites had obviously not been randomly assigned different personalities by the researchers), but the various personality traits identified in these people could still be related to a dependent variable (namely, longevity—how long they lived). So Friedman and his colleagues gathered the death certificates of the Termites, noted the dates and causes of death, and then looked for associations between personality and longevity.

■ What did the researchers find?

One of the most important predictors of long life turned out to be a personality dimension known as *conscientiousness*, or social dependability (described in the chapter on personality). Termites who, in childhood, had been seen as truthful, prudent, reliable, hard-working, and free from vanity tended to live longer than those whose parents and teachers had identified them as impulsive and lacking in self-control.

Friedman and his colleagues also used the Terman Life Cycle Study to investigate the relationship between social support and health. They compared the life spans of Termites whose parents had divorced or who had been in unstable marriages themselves with those who grew up in stable homes and who had stable marriages. The researchers found that people who had experienced parental divorce during childhood or who themselves had unstable marriages died an average of four years earlier than those whose close social relationships had been less stressful.

■ What do the results mean?

The research of Friedman and his co-workers was based mainly on the analysis of correlations, so it is difficult to draw conclusions about whether differences in personality traits and social support actually caused some Termites to live longer than others. Nevertheless, Friedman and his colleagues searched the Terman data for clues to mechanisms through which personality and other factors might have exerted a causal influence on longevity (Peterson et al., 1998). For example, they evaluated the hypothesis that conscientious, dependable Termites who lived socially stable lives might have followed healthier lifestyles than their impulsive and socially stressed age-mates. People in the latter group did indeed tend to eat less healthy diets and were more likely to smoke, drink to excess, or use drugs. However, these behaviors alone did not fully account for their shorter average life spans. Another possible explanation is that conscientiousness and stability in social relationships create a general attitude of caution that goes beyond eating right and avoiding substance

abuse. The researchers found some support for this idea in the Terman data. Termites who were impulsive or low on conscientiousness were somewhat more likely to die from accidents or violence than those who were less impulsive. (A similar finding is reported in the Focus on Research Methods section of the personality chapter.)

■ What do we still need to know?

Although the Terman Life Cycle Study cannot provide definite answers about the relationship between personality and health, it has generated some important clues and a number of intriguing hypotheses to be evaluated in future research with more representative samples of people. Some of that research has already taken place and tends to confirm Friedman's findings about conscientiousness (Hampson et al., 2006). Further, Friedman's decision to reanalyze a set of data on psychosocial development as a way of exploring issues in health psychology stands as a fine example of how a creative researcher can pursue answers to complex questions that are difficult or impossible to study via controlled experiments. ■

Our review of personality and other factors that can alter the impact of stressors should make it obvious that what is stressful for a particular individual is not determined simply by predispositions, coping styles, or situations. (See "In Review: Stress Responses and Stress Mediators.") Even more important are interactions between the person and the situation, the mixture of each individual's coping resources and the specific characteristics of the situations encountered.

in review Stress Responses and Stress Mediators

| Category | Examples |
|------------------------------|--|
| Responses | |
| Physical | Fight-or-flight syndrome (increased heart rate, respiration, and muscle tension; sweating; pupillary dilation); SAM and HPA activation (involving release of catecholamines and corticosteroids); eventual breakdown of organ systems involved in prolonged resistance to stressors. |
| Psychological | <i>Emotional:</i> anger, anxiety, depression, and other emotional states. <i>Cognitive:</i> inability to concentrate or think logically, ruminative thinking, catastrophizing. <i>Behavioral:</i> aggression and escape/avoidance tactics (including suicide attempts). |
| Mediators | |
| Appraisal | Thinking of a difficult new job as a challenge will create less discomfort than focusing on the threat of failure. |
| Predictability | A tornado that strikes without warning may have a more devastating emotional impact than a long-predicted hurricane. |
| Control | Repairing a disabled spacecraft may be less stressful for the astronauts doing the work than for their loved ones on Earth, who can do nothing to help. |
| Coping resources and methods | Having no effective way to relax after a hard day may prolong tension and other stress responses. |
| Social support | Having no one to talk to about a rape or other trauma may amplify the negative impact of the experience. |

- **psychoneuroimmunology** A field of research on the interaction of psychological, social, behavioral, neural, hormonal, and immune system processes that affect the body's defenses against disease.

The Physiology and Psychology of Health and Illness

We have mentioned several studies showing that people under stress are more likely than less stressed people to develop infectious diseases. These studies are part of a much larger body of research in health psychology that sheds light on the relationship between stress and illness. In the following sections we focus on some of the ways in which stress can, directly or indirectly, lead to physical illnesses by affecting the *immune system* and the *cardiovascular system*.

● Stress, Illness, and the Immune System

As described in the chapter on biological aspects of psychology, components of the immune system act as the body's first line of defense by killing or deactivating foreign or harmful substances in the body, such as viruses and bacteria (Simpson, Hurtley, & Marx, 2000).

The role of physiological stress responses in altering the body's ability to fight disease was demonstrated more than a century ago. On March 19, 1878, at a seminar before the Académie de Médecine de Paris, Louis Pasteur showed his distinguished audience three chickens. One was a healthy bird that had been raised normally. A second bird had been intentionally infected with bacteria but given no other treatment; it was also healthy. The third chicken Pasteur presented was dead. It had been infected with the same bacteria as the second bird, but it had also been stressed by being exposed to cold temperatures. As a result, the bacteria had killed it (Kelley, 1985).

Research conducted since Pasteur's time has greatly expanded knowledge about how stressors affect the body's reaction to disease. **Psychoneuroimmunology** is the field that examines the interaction of psychological, social, behavioral, neural, hormonal, and immune system processes that affect the body's ability to defend itself against disease (Ader, 2001).

● **The Immune System and Illness** If the immune system is impaired—by stressors, for example—a person is left more vulnerable to colds, mononucleosis, and many other infectious diseases (Potter & Zautra, 1997). It is by disabling the immune system that HIV infection leads to AIDS and leaves the HIV-infected person defenseless against other infections or cancers.

There are many facets to the human immune system. One important component is the action of immune system cells, especially white blood cells, called *leukocytes* (pronounced “LU-koh-sites”), which are formed in the bone marrow and serve as the body's mobile defense units. Leukocytes are called into action when foreign substances are detected. Among the varied types of leukocytes are *B-cells*, which mature in the bone marrow, and *T-cells*, which mature in the thymus. Generally, T-cells kill other cells, and B-cells produce *antibodies*, which are circulating proteins that bind to specific toxins and other foreign cells and begin to deactivate them. *Natural killer cells*, another type of leukocyte, destroy a wide variety of foreign organisms, but they have particularly important antiviral and antitumor functions. Yet another type of immune system cell is the *macrophage* (pronounced “MACK-row-fayj). Macrophages engulf foreign cells and digest them in a process called *phagocytosis*, or “eating cells.” These scavengers are able to squeeze out of the bloodstream and enter organs, where they destroy foreign cells.

The activity of immune system cells can be either strengthened or weakened by a number of systems, including the endocrine system and the central and autonomic nervous systems. It is through these connections that stress-related psychological and emotional factors can affect the functioning of the immune system (see Figure 3.24 in the chapter on biological aspects of psychology). The exact mechanisms by which

LINKAGES (a link to Biological Aspects of Psychology, p. 102)

The First Line of Defense A patrolling immune system cell sends out an extension known as a *pseudopod* (pronounced “SUE-doh-pod”) to engulf and destroy a bacterial cell before alerting more defenders. Psychological stressors can alter immune system functions through a number of mechanisms. For example, they can activate neural connections between the sympathetic nervous system and organs of the immune system through response systems that have direct suppressant effects on immune function. These suppressant effects are due largely to the release of cortisol and other corticosteroid hormones from the adrenal cortex (see Figure 13.3).

the nervous system affects the immune system are not yet fully understood, but they appear to involve both indirect and direct connections (Rosenkranz et al., 2003). The brain can influence the activity of the immune system indirectly by altering the secretion of hormones (including cortisol secretion by the adrenal gland) that stimulate receptors in circulating T-cells and B-cells. More direct influences occur as nerves affect immune organs, such as the thymus, where T-cells and B-cells are stored (Felten et al., 1991; Maier & Watkins, 2000).

● **The Immune System and Stress** Researchers have found that people under stress are more likely than less stressed people to develop infectious diseases and to experience flare-ups of latent viruses responsible for oral herpes (cold sores) or genital herpes. For example, Sheldon Cohen and his colleagues in the United Kingdom (Cohen et al., 1995) exposed 394 healthy adult volunteers either to one of five respiratory viruses or to a placebo. The participants were then isolated and asked about the number and severity of life stresses they had experienced in the previous year. After controlling for factors such as prior history of colds, exposure to other viruses, and health practices, the researchers found that the more stress the participants had experienced, the greater was the likelihood that their exposure to a virus would result in colds and respiratory infections.

These findings are supported by other research showing that a variety of stressors lead to suppression of the immune system. The effects are especially strong in the elderly (Penedo & Dahn, 2004), but they occur in everyone (Kiecolt-Glaser et al., 2002). For example, one study found that as first-year law students participated in class, took exams, and experienced other stressful aspects of law school, they showed a decline in several measures of immune functioning (Segerstrom et al., 1998). Similarly, reduction in natural killer cell activity has been observed in both men and women following the deaths of their spouses (Irwin et al., 1987), and a variety of immune system impairments have been found in people suffering the effects of separation, divorce, unemployment, lack of social support, and loneliness (Cohen et al., 2007; Kiecolt-Glaser & Glaser, 1992). Providing care for an elderly relative who is mentally or physically incapacitated is a particularly stressful circumstance that has been reliably shown to diminish immune function (Kiecolt-Glaser et al., 2003, 2005; Vitaliano, Zhang, & Scanlan, 2003).

The relationship between stress and the immune system is especially important in persons who are HIV-positive but do not yet have AIDS. Because their immune systems are already seriously compromised, further stress-related impairments could be life-threatening. Research indicates that psychological stressors are associated with the progression of HIV-related illnesses (e.g., Heckman et al., 2004). Unfortunately, people with HIV (and AIDS) face a particularly heavy load of immune-suppressing psychological stressors, including bereavement, unemployment, uncertainty about the future, and daily reminders of serious illness. A lack of perceived control and resulting depression can further amplify their stress responses (Sewell et al., 2000).

● **Moderators of Immune Function** The effects of social support and other stress-moderating factors can be seen in the activity of the immune system. For example, immune system functioning among students who are able to get emotional assistance from friends during stressful periods appears better than among those with less adequate social support (Cohen & Herbert, 1996).

James Pennebaker (2002) suggests that social support may help prevent illness by providing the person under stress with an opportunity to express pent-up thoughts and emotions. Suppressing the emotions associated with stressors, says Pennebaker, is itself a stressor that can lead to further impairment of the immune system (Petrie et al., 1995; Petrie, Booth, & Pennebaker, 1998). For example, the spouses of suicide or accidental-death victims who do not or cannot confide their feelings to others are

Fighting a Deadly Disease The impact of psychological factors on immune system functioning can be seen in the progression of HIV/AIDS. Sustained depression, concealment of gay identity, negative expectancies, and reliance on passive, emotion-focused coping methods such as denial have all been related to faster disease progression. Openly expressing emotions, collaborating closely with doctors, having optimistic expectations, remaining involved in normal activities, finding meaning in the situation, and other active, problem-focused coping strategies have all been associated with slower disease progression (Balbin, Ironson, & Solomon, 1999).

You Can't Fire Me—I Quit! For a time, researchers believed that anyone who displayed the pattern of aggressiveness, competitiveness, and nonstop work known as “Type A” behavior was at elevated risk for heart disease (Friedman & Rosenman, 1974). More recent research shows, however, that the danger lies not in these characteristics alone, but in hostility, a pattern seen in some, but not all, Type A people.

the ones most likely to develop physical illnesses during the year following the death (Pennebaker & O’Heeron, 1984). Disclosing, even anonymously, the stresses and traumas one has experienced is associated with enhanced immune functioning, reduced physical symptoms, and decreased use of health services (Campbell & Pennebaker, 2003; Niederhoffer & Pennebaker, 2002; Rosenberg et al., 2002). This may explain why support groups for problems ranging from bereavement to overeating to alcohol and drug abuse tend to improve participants’ quality of life and, to some extent, their physical health status (Taylor, Dickerson, & Klein, 2002). Future research in psychoneuroimmunology promises to reveal more about the complex chain of mental and physical events that determine whether people become ill or stay healthy.

● Stress, Illness, and the Cardiovascular System

Earlier we discussed the role of the sympatho-adreno-medullary (SAM) system in mobilizing the body’s defenses during times of threat. Because the SAM system is linked to the cardiovascular system, its repeated activation in response to stressors has been associated with the development of coronary heart disease (CHD), high blood pressure (hypertension), and stroke. The link appears especially strong in people who show intense physiological reactivity to stressors (Ming et al., 2004; Treiber et al., 2001). For example, among healthy young adult research participants, those whose blood pressure rose most dramatically in response to a mild stressor, or a series of stressors, were the ones most likely to develop hypertension later in life (Light et al., 1999; Matthews et al., 2004).

As also mentioned earlier, these physiological reactions to stressors—and the chances of suffering stress-related health problems—depend partly on personality, especially on how people tend to think about stressors and about life in general. For example, the trait of *hostility*—particularly when accompanied by irritability and impatience—has been associated with the appearance of coronary heart disease (Bunde & Suls, 2006; Day & Jreige, 2002; Krantz & McCeney, 2002; Smith, 2003a).

THINKING CRITICALLY

Does Hostility Increase the Risk of Heart Disease?

Health psychologists see hostility as characterized by suspiciousness, resentment, frequent anger, antagonism, and distrust of others (Krantz & McCeney, 2002; Stoney & Engebretson, 1994; Williams, 2001). The identification of hostility as a risk factor for coronary heart disease and *myocardial infarction*, or *MI* (commonly known as heart attack), could be an important breakthrough in better understanding the chief cause of death in the United States and most other Western nations (Centers for Disease Control and Prevention, 2001; Hu et al., 2000). But is hostility as dangerous as health psychologists suspect?

■ What am I being asked to believe or accept?

Many researchers claim that individuals displaying hostility are at increased risk for coronary heart disease and heart attack (e.g., Bleil et al., 2004; Boyle et al., 2004). This risk, they say, is independent of other risk factors such as heredity, diet, smoking, and drinking.

■ What evidence is available to support the assertion?

The precise mechanism underlying the relationship between hostility and heart disease is not clear, but there are several possibilities. The risk of CHD and MI may be elevated in hostile people because these people tend to have an unusually strong reaction to stressors, especially when challenged. During interpersonal conflicts, for example, people predisposed to hostile behavior display not only overt hostility but also unusually large increases in blood pressure, heart rate, and other aspects of SAM reactivity (Brondolo et al., 2003; Suls & Wan, 1993). In addition, it takes hostile individuals longer than normal to get back to their resting levels of SAM functioning (Gerin et al., 2006). Like a driver who damages a car by flooring the accelerator and applying the brakes at the same time, these “hot reactors” may create excessive wear and tear on the arteries of the heart as their increased heart rate forces blood through tightened vessels. Increased sympathetic nervous system activation not only puts a strain on the coronary arteries but also leads to surges of stress-related hormones from the adrenal glands, including the catecholamines (adrenaline and noradrenaline). High levels of these hormones are associated with increases in cholesterol and other fatty substances that are deposited in arteries and contribute to atherosclerosis (hardening of the arteries) and CHD (Bierhaus et al., 2003; Stoney & Hughes, 1999). And in fact, cholesterol and triglycerides do appear to be elevated in hostile people, even when they are not under stress (Dujovne & Houston, 1991; Engebretson & Stoney, 1995).

Hostility might also affect heart disease risk less directly, through its impact on social support. Some evidence suggests that hostile people take less advantage of their social support networks than other people do (Lepore, 1995). Some may not have much social support available, possibly because they have offended potential supporters. Whatever the case, failure to use the support they do have may intensify the impact of stressful events on hostile people. The result may be increased anger, antagonism, and, ultimately, additional stress on the cardiovascular system.

■ Are there alternative ways of interpreting the evidence?

Studies suggesting that hostility causes CHD or MI are not true experiments. Researchers cannot manipulate the independent variable, hostility, by creating it in some people but not others, nor can they create experimental conditions in which individuals who differ only in terms of hostility are compared on heart disease, the dependent variable. So although the available evidence suggests an association between

hostility and heart disease, it cannot confirm that hostility is causing heart disease. Accordingly, we have to consider other possible explanations of the hostility–heart disease relationship.

Some researchers suggest that higher rates of heart problems among hostile people are due not to the impact of hostility on autonomic reactivity and hormone surges but, rather, to a third variable that accounts for the other two. Specifically, genetically determined autonomic reactivity might increase the likelihood of both hostility and heart disease (Krantz et al., 1988). Supporting this alternative interpretation is evidence that people with an inherited predisposition toward strong physiological responses to the stressors of everyday life not only have a higher risk for CHD but also tend to be more hostile (Cacioppo et al., 1998). It is at least plausible, then, that some individuals are biologically predisposed to exaggerated autonomic reactivity and to hostility, each of which is independent of the other.

It has also been suggested that hostility may be only one of many traits linked to heart disease. Depressiveness, hopelessness, pessimism, and anxiety may be involved, too (Frasure-Smith & Lespérance, 2005; Kubzansky, Davidson, & Rozanski, 2005; Nicholson, Fuhrer, & Marmot, 2005; Suls & Bunde, 2005).

■ What additional evidence would help to evaluate the alternatives?

One way of testing whether hostile people's higher rates of heart disease are related to their hostility or to a more general tendency toward intense physiological arousal is to examine how hostile individuals react to stressors under circumstances in which their hostility is deactivated. Researchers have done exactly this by observing the physiological reactions of hostile people as they endure the stress of surgery under general anesthesia. The results indicate that, even while unconscious, hostile people show unusually strong autonomic reactivity (Krantz & Durel, 1983). So it is more likely that oversensitivity to stressors, not hostile thinking, is causing this exaggerated response. This possibility is supported by research showing that, compared with other people, individuals who have strong blood pressure responses to stressors also show different patterns of brain activity during stress (Gianaros et al., 2005).

To more fully illuminate the role of hostility in the development of heart disease, future research will have to take into account a number of important possibilities: (1) Some individuals may be biologically predisposed to react to stress and challenge with hostility and increased cardiovascular activity, which in turn may contribute to heart disease; (2) hostile people may amplify and perpetuate their stress through aggressive thoughts and actions, which in turn may provoke others and elicit additional stressors; and (3) people high in hostility may harm their health to a greater extent than less hostile people by smoking, drinking, overeating, failing to exercise, and engaging in other high-risk behaviors (Houston & Vavac, 1991).

■ What conclusions are most reasonable?

Although there is some inconsistency among various studies, most researchers continue to find that hostile individuals have a higher risk of heart disease and heart attacks than do other people (Krantz & McCeney, 2002; Stansfeld & Marmot, 2002). However, the causal relationship is probably more complex than researchers first thought; it appears that many interacting factors affect the relationship between hostility and CHD.

We must also keep in mind that the relationship between heart problems and hostility may not be universal. The relationship does appear to hold for women, as well as for men, and for individuals in various ethnic groups (e.g., Nakano & Kitamura, 2001; Olson et al., 2005; Stoney & Engebretson, 1994; Yoshimasu et al., 2002). However, final conclusions must await further research that examines the impact of gender, culture, and ethnicity on the link between hostility and heart disease (Finney, Stoney, & Engebretson, 2002). ■

● Risking Your Life: Health-Endangering Behaviors

As we have seen, many of today's major health problems are caused or amplified by preventable behaviors such as those listed in Table 13.1.

● **Smoking** Smoking is the single most preventable risk factor for fatal illnesses in the United States (U.S. Surgeon General, 2004). It accounts for 440,000 deaths each year—which is 20 percent of all U.S. deaths and more than those caused by all other drugs, car accidents, suicides, homicides, and fires combined (Centers for Disease Control and Prevention, 2002a; U.S. Department of Health and Human Services, 2001b; Mokdad et al., 2004). Even nonsmokers who inhale second-hand smoke face an elevated risk for respiratory diseases, including lung cancer, and for cardiovascular diseases as well (Menziez et al., 2006; Vineis et al., 2005; Wen et al., 2006), a fact that has fueled a militant nonsmokers' rights movement in North America and in some European countries.

Although smoking is declining in the United States overall—only about 23.5 percent of adults now smoke—the rate is higher (almost 28 percent) for those between the ages of eighteen and twenty-four and much higher (40.8%) among American Indians and Alaskan Natives (American Lung Association, 2002; Centers for Disease Control and Prevention, 2002a). In North America, only about 4 percent of smokers who try to quit on their own remain abstinent, and only 27 to 30 percent of those using nicotine replacement and/or behavior modification programs achieve long-term success (American Lung Association, 2002; Lancaster et al., 2006). Still, persistence can pay off: There are more than 45 million former smokers in the United States alone (Niaura & Abrams, 2002). Improving this success rate and preventing adolescents from taking up smoking remain among health psychology's greatest challenges.

● **Unsafe Sex** About 40 million people worldwide are HIV-positive, and about 21 million have died from AIDS (Sepkowitz, 2006; World Health Organization, 2003). About a million people in the United States have AIDS or HIV (Centers for Disease Control, 2005), though as many as 300,000 HIV victims are unaware of being infected (Glynn & Rhodes, 2005; Sepkowitz, 2006). With growing public awareness that using condoms can prevent HIV infection, and with the availability of better treatment methods, the number of new AIDS cases and AIDS deaths began to fall in the United States during the 1990s. AIDS deaths are continuing to fall somewhat, but the number of new HIV/AIDS cases is again on the rise. Current estimates are that about 40,000 HIV infections occur each year, many of which stem from heterosexual contact with people who don't know they are infected (Centers for Disease Control and Prevention, 2005; Sepkowitz, 2006).

In short, not everyone is getting the HIV/AIDS prevention message. Like smoking and many other health-threatening behaviors, unprotected sex is disproportionately common among low-income individuals, many of whom are members of ethnic minority groups. As a result, African American women's risk of contracting HIV is fifteen times higher than that of European American women. African American men are three times more likely than European American men to contract HIV; in fact, AIDS is the leading cause of death among African American men between the ages of twenty-five and forty-four (Centers for Disease Control and Prevention, 2005).

Promoting Healthy Behavior

Health psychologists are deeply involved in the development of smoking cessation programs, in campaigns to prevent young people from taking up smoking, in obesity-prevention efforts, and in the fight against the spread of HIV infection and AIDS

Doctor's Orders Despite their physicians' instructions, many patients fail to take their blood pressure medication and continue to eat unhealthy diets. Noncompliance with medical advice is especially common when cultural values and beliefs conflict with that advice. Aware of this problem, health psychologists are developing culture-sensitive approaches to health promotion and disease prevention (Kazarian & Evans, 2001).

(e.g., Carey et al., 2004; Durantini et al., 2006; Morisky et al., 2006; Stice, Shaw, & Nathan, 2006). They have also helped promote early detection of disease. Encouraging women to perform breast self-examinations and men to do testicular self-examinations are just two examples of health psychology programs that can save thousands of lives each year (Taylor, 2002). Health psychologists have also explored the reasons behind some people's failure to follow treatment regimens that are vital to the control of diseases such as diabetes, heart disease, HIV/AIDS, and high blood pressure (Bartlett, 2002; Gonzalez et al., 2004). Understanding these reasons and devising procedures that encourage greater adherence to medical advice could speed recovery, prevent unnecessary suffering, decrease costs, and save many lives (Barclay et al., 2007; Simpson et al., 2006).

Health psychologists' efforts to prevent, reduce, or eliminate behaviors that pose health risks and to increase healthy behavior patterns are called **health promotion** (Smith, Orleans, & Jenkins, 2004). For example, they have developed many of the health promotion programs now used in school systems to teach children and adolescents the skills necessary to turn down cigarettes, drugs, and unprotected sex. To meet the more difficult challenge of modifying existing health-threatening behaviors, health psychologists go into workplaces and communities with the goal of altering diet, smoking, and exercise patterns, promoting safe driving habits, helping elderly people to avoid falling, and teaching stress-management techniques (Langenberg et al., 2000; Lisspers et al., 2005; Tuomilehto et al., 2001). These programs may have the added advantage of creating savings in future medical treatment costs (Blumenthal et al., 2002; Schneiderman et al., 2001).

● Health Beliefs and Health Behaviors

Health psychologists are also trying to understand the thought processes that lead people to engage in health-endangering behaviors and that can interfere with efforts to adopt healthier lifestyles. Their research has led to intervention programs that seek to change these patterns of thinking, or at least take them into account. In one study, for example, women who avoid thinking about the risks of breast cancer were more likely to get a mammogram screening after receiving health information that was tailored to their cognitive styles (Williams-Piehotka et al., 2005).

This cognitive approach to health psychology is embodied in various *health-belief models*. One of the most influential of these models was developed by Irwin

- **health promotion** The process of altering or eliminating behaviors that pose risks to health, as well as encouraging healthy behavior patterns.

© Steve Kelley/Copley News Service.

Rosenstock (1974). This model is based on the assumption that people's decisions about health-related behaviors (such as smoking) are guided by four main factors:

1. Perceiving a *personal threat* of, or susceptibility to, developing a specific health problem. (Do you believe that *you* will get lung cancer from smoking?)
2. Perceiving the seriousness of the illness and the consequences of having it. (How serious do *you* think lung cancer is, and what will happen if you get it?)
3. The belief that changing a particular behavior will reduce the threat. (Will giving up smoking prevent *you* from getting lung cancer?)
4. A comparison of the *perceived costs* of enacting a health-related behavior change and the *benefits expected* from that change. (Will the reduced chance of getting cancer in the future be worth the discomfort and loss of pleasure associated with not smoking?)

This health-belief model suggests that the people most likely to quit smoking would be those who believe that they are at risk for getting cancer from smoking, that cancer is serious and life-threatening, that quitting will reduce their chances of getting cancer, and that the benefits of preventing cancer clearly outweigh the difficulties associated with quitting.

Other cognitive factors not included in Rosenstock's model may also be important, however. For example, people are unlikely to try to quit smoking unless they believe they can succeed. So *self-efficacy*, the belief that one is able to perform some behavior, is an additional consideration in decisions about health behaviors (Armitage, 2005; Bandura, 1992). A related factor is the person's intention to engage in a behavior designed to improve health or protect against illness (Albarracín et al., 2001; Schwarzer, 2001; Webb & Sheeran, 2006).

Health-belief models have been useful in predicting a variety of health behaviors, including exercise (McAuley, 1992), safe-sex practices (Fisher, Fisher, & Rye, 1995), following doctors' orders (Bond, Aiken, & Somerville, 1992), and having vaccinations and routine mammograms (Brewer et al., 2007; Champion & Huster, 1995). These models have also shaped health promotion efforts. For example, interventions with individuals at high risk for AIDS, particularly adolescents and African American women, include programs to improve knowledge about the disease and skill in demanding safe sex (e.g., DiClemente et al., 2004).

● Changing Health Behaviors: Stages of Readiness

Changing health-related behaviors depends not only on a person's health beliefs but also on that person's readiness to change. According to James Prochaska and his colleagues, the process of successful change occurs in five stages (Prochaska, DiClemente, & Norcross, 1992; Schumann et al., 2005):

1. *Precontemplation*. The person does not perceive a health-related problem and has no intention of changing in the foreseeable future.

2. *Contemplation.* The person is aware of a health-related behavior that should be changed and is seriously thinking about changing it. People often get stuck here. Smokers, for example, have been known to spend years “thinking about” quitting.
3. *Preparation.* The person has a strong intention to change; has specific plans to do so; and may already have taken preliminary steps, such as cutting down on smoking.
4. *Action.* The person at this stage is engaging successfully in behavior change. Because “backsliding,” or relapse, is so common when trying to change health-related behaviors, people must remain successful for up to six months before they officially reach the final stage.
5. *Maintenance.* The person uses skills learned along the way to continue the healthy behavior and to prevent relapse.

These stages may actually overlap somewhat; for example, some “precontemplators” might actually be starting to contemplate change (Herzog & Blagg, 2007). In any case, the path from precontemplation through maintenance may not be a smooth one. Usually, people relapse and repeat one or more of the previous stages before finally achieving stability in the healthy behavior they desire (Polivy & Herman, 2002). For example, smokers typically require three to four cycles through the stages and up to seven years before they finally reach the maintenance stage (Piasecki, 2006).

Taking Time Out The workplace is the number one source of stress for many people in the United States. On January 1, 2000, Raymond Fowler, who was then chief executive officer of the American Psychological Association, joined the ranks of those whose elevated blood pressure, heart problems, and other physical stress responses necessitated a temporary leave of absence from highly stressful jobs (Fowler, 2000). The National Institute for Occupational Safety and Health (1999) suggests a wide range of other behavioral coping options for stressed employees who cannot afford to take time off.

● Programs for Coping with Stress and Promoting Health

An important part of health psychologists' health promotion work has been to improve people's stress-coping skills (e.g., Keogh, Bond, & Flaxman, 2006). Let's consider a few specific procedures and programs associated with this effort.

● **Planning to Cope** Just as people with money in the bank have a better chance of weathering a financial crisis, those with effective coping skills may escape some of the more harmful effects of intense stress. Like family money, the ability to handle stress appears to come naturally to some people, but coping can also be learned (Lewis Claar & Blumenthal, 2003).

The first step in learning to cope with stress is to make a systematic assessment of the degree to which stress is disrupting your life. This assessment involves (1) identifying the specific events and situations, such as conflicts or life changes, that are operating as stressors, and (2) noting the effects of these stressors, such as headaches, lack of concentration, or excessive drinking. Table 13.4 lists the other steps in a program to cope with stress. Notice that the second step is to select an appropriate goal. Should you try to eliminate stressors or try to change your response to them? Knowing the difference between changeable and unchangeable stressors is important. Stress-related problems are especially common among people who either exhaust themselves trying to change unchangeable stressors or miss opportunities to change stressors that can be changed (Folkman, 1984).

Bear in mind that no single method of coping with stressors is right for everyone, or every stressor. As mentioned earlier, for example, denying the existence of an uncontrollable stressor may be fine in the short run but may eventually lead to problems if no other coping method is used (Suls & Fletcher, 1985). Similarly, people who rely exclusively on an active problem-solving approach may handle controllable stressors well but find themselves nearly helpless in the face of uncontrollable ones (Murray & Terry, 1999). The most successful stress managers may be those who can adjust their coping methods to the demands of changing situations and differing stressors (Taylor, 2002).

TABLE 13.4 Stages in Coping with Stress

Many successful programs for systematically coping with stress guide people through several stages and are aimed at removing stressors that can be changed and at reducing responses to stressors that cannot be changed (Taylor, 2002).

| Stage | Task |
|-----------------|--|
| 1. Assessment | Identify the sources and effects of stress. |
| 2. Goal setting | List the stressors and stress responses to be addressed. Designate which stressors are and are not changeable. |
| 3. Planning | List the specific steps to be taken to cope with stress. |
| 4. Action | Implement coping plans. |
| 5. Evaluation | Determine the changes in stressors and stress responses that have occurred as a result of coping methods. |
| 6. Adjustment | Alter coping methods to improve results, if necessary. |

Dealing with Chemotherapy

Progressive relaxation training can be used to ease a variety of health-related problems. For example, one study found that this training resulted in significant reductions in anxiety, physiological arousal, and nausea following cancer chemotherapy (Burish & Jenkins, 1992).

- **progressive muscle relaxation training**
A procedure for learning to relax that involves tensing muscles and then releasing the tension in those muscles.

● **Developing Coping Strategies** Like stress responses, strategies for coping with stress can be cognitive, emotional, behavioral, or physical. *Cognitive coping strategies* involve changing how we think about stressors. For example, students with heavy course loads may experience anxiety, confusion, discouragement, lack of motivation, and the desire to run away from it all. Frightening, catastrophizing thoughts about their tasks (for example, “What if I fail?”) magnify these stress responses. Cognitive coping strategies replace catastrophic thinking with thoughts in which stressors are viewed as challenges rather than threats (Ellis & Bernard, 1985). This substitution process is called *cognitive restructuring* (Lazarus, 1971; Meichenbaum, 1977). It can be done by practicing calmer, more rational and constructive thoughts such as “All I can do is the best I can.” Cognitive coping does not eliminate stressors, but it can help people perceive them as less threatening and thus make them less disruptive while generating a more hopeful emotional state (Antoni et al., 2001; Chesney et al., 2003).

Seeking and finding social support from others are effective *emotional coping strategies*. The perception that you have such support and that you are cared for and valued by others tends to be an effective buffer against the ill effects of many stressors (Taylor, 2002; Taylor, Klein, et al., 2000). Research suggests that having enhanced social support is associated with improved immune function (Kiecolt-Glaser & Newton, 2001) and more rapid recovery from illness (Taylor, 2002).

Behavioral coping strategies involve changing behavior in ways that minimize the impact of stressors. Time management is one example. If it seems that you are always pressed for time, consider developing a time management plan. The first step is to use a calendar or day planner to record how you spend each hour of each day in a typical week. Next, analyze the information to locate when and how you might be wasting time and how you might use your time more efficiently. Then set out a schedule for the coming week and stick to it. Make adjustments in subsequent weeks as you learn more realistic ways to manage your time. Time management can’t create more time, but it can help control catastrophizing thoughts by providing reassurance that there is enough time for everything and a plan for handling everything you have to do.

Physical coping strategies are aimed at directly altering the undesirable physiological responses that occur before, during, or after the appearance of stressors. The most common physical coping strategy is some form of drug use. Prescription medications are sometimes an appropriate coping aid, especially when stressors are severe and acute, such as the sudden death of one’s child. But if people depend on prescriptions or other drugs, including alcohol, to help them face stressors, they often attribute any success to the drug, not to their own skill. Furthermore, the drug effects that blunt stress responses may also interfere with the ability to apply coping strategies. The resulting loss of perceived control over stressors may make those stressors even more threatening and disruptive.

in review Methods for Coping with Stress

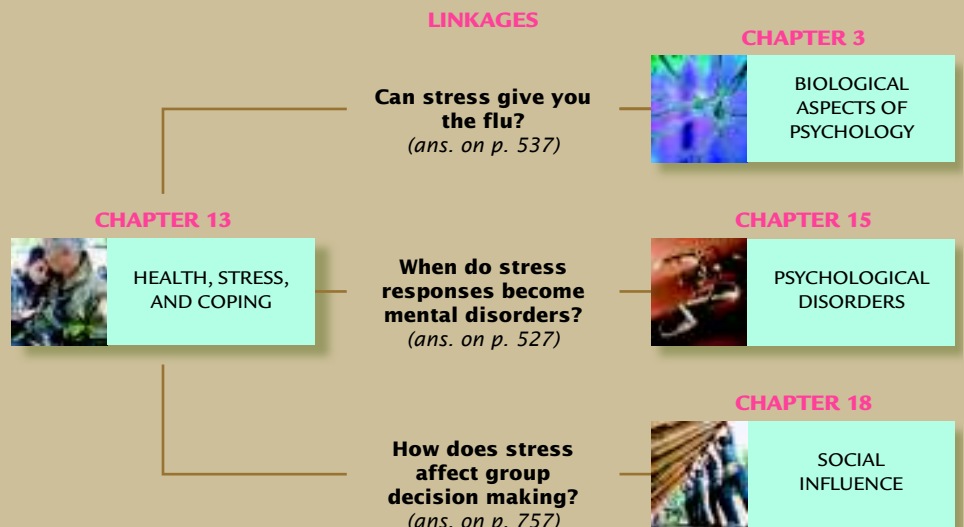

| Type of Coping Method | Examples |
|-----------------------|--|
| Cognitive | Thinking of stressors as challenges rather than as threats; avoiding perfectionism. |
| Emotional | Seeking social support; getting advice. |
| Behavioral | Implementing a time-management plan; where possible, making life changes to eliminate stressors. |
| Physical | Progressive relaxation training; exercise; meditation. |

Nonchemical methods of reducing physical stress reactions and improving functioning include progressive muscle relaxation training (Bernstein, Borkovec, & Hazlett-Stevens, 2000; Scheufele, 2000), physical exercise (Anshel, 1996), biofeedback (Sarafino & Goehring, 2000), and meditation and tai chi (Li et al., 2001), among others (Taylor, 2002).

Progressive muscle relaxation training is one of the most popular physical methods for coping with stress. Edmund Jacobson developed the technique during the 1930s (Jacobson, 1938). Today, progressive muscle relaxation is learned by tensing a group of muscles (such as the hand and arm) for a few seconds, then releasing the tension and focusing on the resulting feelings of relaxation. This procedure is repeated for each of sixteen muscle groups throughout the body (Bernstein et al., 2000). Once people develop some skill at relaxation, they can use it to calm themselves down anywhere and anytime, often without lying down. (“In Review: Methods for Coping with Stress” summarizes our discussion of stress-coping methods.)

LINKAGES

As noted in the chapter on introducing psychology, all of psychology’s many subfields are related to one another. Our discussion of posttraumatic stress disorder illustrates just one way in which the topic of this chapter, health, stress, and coping, is linked to the subfield of psychological disorders (which is the focus of the chapter by that name). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and help you better appreciate the big picture that is psychology.

SUMMARY

Health Psychology

The development of *health psychology* was prompted by recognition of the link between stress and illness, as well as the role of behaviors such as smoking, in elevating the risk of illness. Researchers in this field explore how psychological factors are related to physical disease and vice versa. Health psychologists also help people to behave in ways that prevent or minimize disease and promote health.

Stress and Stressors

The term *stress* refers in part to *stressors*, which are events and situations to which people must adjust. More generally, stress is viewed as an ongoing, interactive process that takes place as people adjust to and cope with their environment. Stressors may be physical or psychological.

Psychological Stressors Psychological stressors include life changes and strains, catastrophic events, acute stressors, daily hassles, and chronic stressors.

Measuring Stressors Stressors can be measured by tests such as the Social Readjustment Rating Scale (SRRS) and the Life Experiences Survey (LES), as well as by surveys of daily hassles, but scores on such tests provide only a partial picture of the stress in an individual's life.

Stress Responses

Responses to stressors can be physical or psychological. They can occur alone or in combination, and the appearance of one response can stimulate others.

Physical Responses Physical stress responses include changes in sympatho-adreno-medullary (SAM) activation, such as increases in heart rate, respiration, and many other processes, as well as hypothalamic-pituitary-adrenocortical (HPA) activation, including the release of corticosteroids. These responses are part of a pattern known as the *general adaptation syndrome*, or *GAS*. The GAS has three stages: alarm, resistance, and exhaustion. The GAS helps people resist stress, but if present too long, it can lead to depletion of physiological resources, as well as to physical illnesses, which Hans Selye called *diseases of adaptation*.

Psychological Responses Psychological stress responses can be emotional, cognitive, and behavioral. Cognitive stress reactions include ruminative thinking; catastrophizing; and disruptions in the ability to think clearly, remember accurately, and solve problems efficiently. Behavioral stress responses include irritability, aggression, absenteeism, and even suicide attempts. Extreme or chronic stressors can lead to *burnout* or *posttraumatic stress disorder (PTSD)*.

Stress Mediators: Interactions Between People and Stressors

The fact that different individuals react to the same stressors in different ways can be explained in part by stress mediators, such as the extent to which individuals can predict and control their stressors, how they interpret the threat involved, the social support they get, and their stress-coping skills.

How Stressors Are Perceived Many stressors are not inherently stressful; their impact depends partly on how people perceive them. In particular, stressors appraised as threats are likely to have greater impact than those appraised as challenges.

Predictability and Control Knowing that a particular stressor might occur but being uncertain whether it will occur tends to increase the stressor's impact, as does lack of control over stressors.

Coping Resources and Coping Methods The people most likely to react strongly to a stressor are those whose coping resources and coping methods are inadequate.

Social Support Social support, which consists of resources provided by other persons, can lessen the impact of stressors. The friends and social contacts on whom a person can depend for support constitute that person's *social support network*.

Stress, Personality, and Gender Certain personality characteristics help insulate people from the ill effects of stress. One such characteristic appears to be dispositional optimism, the belief or expectation that things will work out positively. Gender can also play a role in stress responses.

The Physiology and Psychology of Health and Illness

Stress, Illness, and the Immune System *Psychoneuroimmunology* is the field that examines the interaction of psychological and physiological processes that affect the body's ability to defend itself against disease. When a person is under stress, some of the hormones released from the adrenal gland, such as cortisol, reduce the effectiveness of the cells of the immune system (for example, T-cells, B-cells, natural killer cells, and macrophages) in combating foreign invaders such as viruses.

Stress, Illness, and the Cardiovascular System Heart disease is a major cause of death in most Western countries, including the United States. People who are hostile appear to be at greater risk for heart disease than other people, possibly because their heightened reactivity to stressors can damage their cardiovascular system.

Risking Your Life: Health-Endangering Behaviors Many of the major health problems in Western cultures are related to preventable behaviors such as smoking and having unsafe sex.

Promoting Healthy Behavior

The process of altering or eliminating health-risky behaviors and fostering healthy behavior patterns is called *health promotion*.

Health Beliefs and Health Behaviors People's health-related behaviors are partly guided by their beliefs about health risks and what they can do about them.

Changing Health Behaviors: Stages of Readiness The process of changing health-related behaviors may involve several

stages, including precontemplation, contemplation, preparation, action, and maintenance. Understanding which stages people are in and helping them move through these stages are important tasks in health psychology.

Programs for Coping with Stress and Promoting Health

To cope with stress, people must recognize the stressors affecting them, note their effects, and develop ways of handling them. Important coping skills include cognitive restructuring, as well as using emotional and behavioral means to minimize the intensity and impact of stressors. *Progressive muscle relaxation training* and other physical coping strategies can reduce physical stress reactions. These coping procedures are often part of health psychologists' disease-prevention and health-promotion efforts.

Personality

If you've ever been stuck in a traffic jam, you've probably noticed that some people are tolerant and calm. Others become so fearful and cautious that they worsen the congestion. Still others get so impatient and angry that they may trigger a shouting match or cause an accident. How people handle frustration is just one aspect of their personalities. In this chapter, we examine the concept of personality, review some of the tests that psychologists have developed to measure it, and look at how personality theories and research are being applied in everyday life. Here's how we have organized the material:

SUMMARY

It has been estimated that U.S. businesses lose more than \$60 billion each year as a result of employee theft (Gatewood & Feild, 2001). Millions more are spent on security and surveillance designed to curb these losses, but it would be far better if companies could simply avoid hiring dishonest employees in the first place. Some firms have tried to screen out potential thieves by requiring prospective employees to take “lie detector” polygraph tests. As described in the chapter on motivation and emotion, however, these tests may not be reliable or valid. In fact, the federal government has banned their use in most kinds of employee selection.

Thousands of companies have turned instead to paper-and-pencil “integrity” tests designed to identify job applicants who are likely to steal or behave in other dishonest or irresponsible ways (Wanek, Sackett, & Ones, 2003). Some of these tests simply ask applicants if they have stolen from previous employers and if they might steal in the future. Such questions can screen out people who are honest about their stealing, but most people who steal would probably also lie to conceal previous crimes or criminal intentions. Accordingly, some companies now use tests to assess applicants’ general psychological characteristics and compare their scores with those of current or past employees. Applicants whose characteristics are most like the company’s honest employees are hired; those who appear similar to dishonest employees are not hired.

Can undesirable employee behaviors be predicted on the basis of such tests? To some extent, they can. For example, scores on the *Reliability Scale*—which includes questions about impulsivity and disruptive behavior during school years—are significantly correlated with a broad range of undesirable activities in the workplace (Hogan, 2005). But psychological tests are far from perfect predictors of those activities (Mumford et al., 2001). Although better than polygraph tests, psychological tests still fail to detect dishonesty in some people, and worse, they may falsely identify some honest people as potential thieves. The best that companies can hope for is to find tests that will help reduce the overall likelihood of hiring dishonest people.

The use of psychological tests to help select honest employees is a more formal version of the process that most of us use when we meet someone new. We observe the person’s behavior, form impressions, and draw conclusions—often within just a few seconds (Borkenau et al., 2004)—about how that person will act at other times or under other circumstances. Like the employer, we are looking for clues to *personality*. Although there is no universally accepted definition, psychologists generally view **personality** as the unique pattern of enduring thoughts, feelings, and actions that characterize a person. Personality research, in turn, focuses on understanding the origins or causes of the similarities and differences among people in their patterns of thinking, emotion, and behavior.

With such a large agenda, personality researchers must incorporate information from many other areas of psychology. In fact, personality psychology lies at the crossroads of all psychological research (Funder, 2004). It is the merging, in a particular individual, of all the psychological, behavioral, and biological processes discussed in this book. To gain a full understanding of anyone’s personality, for example, you must know something about that person’s developmental experiences (including cultural influences), genetic and other biological characteristics, perceptual and other information-processing habits and biases, typical patterns of emotional expression, and social skills. Psychologists also want to know about personality in general, such as how it develops and changes across the life span, why some people are usually optimistic whereas others are usually pessimistic, and how consistent or inconsistent people’s behavior tends to be from one situation to the next.

- 
- **personality** The pattern of psychological and behavioral characteristics by which each person can be compared and contrasted with others.

In this chapter we describe four approaches to the study of personality and some of the ways in which personality theory and research are being applied. We begin by presenting the *psychodynamic approach*, which was developed by Sigmund Freud and later modified by a number of people he influenced. Next, we describe the *trait approach*, which focuses on the consistent patterns of thoughts, feelings, and actions that form individual personalities. Then we present the *social-cognitive approach*, which explores the roles of learning and cognition in shaping human behavior. Finally, we consider the *humanistic approach*, with its emphasis on personality as a reflection of personal growth and the search for meaning in life. After reviewing these approaches, we describe how psychologists measure and compare people's personalities. We also give some examples of how psychological tests are being used in personality research and in other ways as well.

The Psychodynamic Approach

Some people think they can understand personality by simply watching people. Someone with an “outgoing personality,” for example, shows it by acting friendly and sociable. But is that all there is to personality? Not according to Sigmund Freud. Trained as a medical doctor in the late 1800s, Freud spent most of his life in Vienna, Austria, treating patients who displayed “neurotic” disorders, such as blindness or paralysis, for which there was no physical cause. Freud's experience with these patients, as well as his reading of the works of Charles Darwin and other scientists of his day, led him to believe that our personalities, behavior, and behavior disorders are determined mainly by basic drives and past psychological events (Allen, 2006). He agreed, too, with Sir Francis Galton and other nineteenth-century writers when he proposed that people may not know why they feel, think, or act the way they do, because these activities are partly controlled by the unconscious part of the personality—the part of which we are not normally aware (Funder, 2004). From these ideas Freud created the **psychodynamic approach** to personality, which assumes that our thoughts, feelings, and behavior are determined by the interaction of various unconscious psychological processes (Schultz & Schultz, 2005).

Founder of the Psychodynamic Approach Here is Sigmund Freud with his daughter, Anna, who became a psychoanalyst herself and eventually developed a revised version of her father's theories.

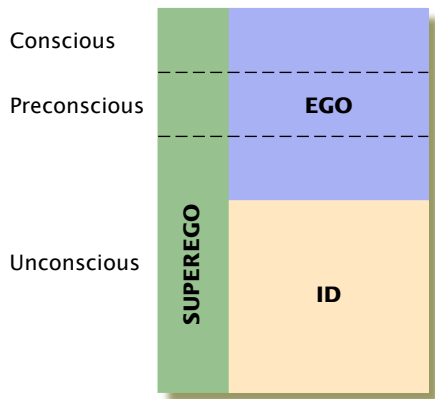

FIGURE 14.1

Freud's Model of Personality

According to Freud, some parts of the personality are conscious, whereas others are unconscious. Between these levels is the *preconscious*, which Freud saw as the location of memories and other material not usually in awareness but that can be brought into consciousness with little or no effort.

- **psychodynamic approach** Freud's view that personality is based on the interplay of unconscious mental processes.
- **id** The unconscious portion of personality that contains basic impulses and urges.
- **libido** The psychic energy contained in the id.
- **pleasure principle** The id's operating principle, which guides people toward whatever feels good.
- **ego** The part of the personality that mediates conflicts between and among the demands of the id, the superego, and the real world.
- **reality principle** The operating principle of the ego that creates compromises between the id's demands and those of the real world.
- **superego** The component of personality that tells people what they should and should not do.
- **defense mechanism** A psychological response that helps protect a person from anxiety and guilt.
- **psychosexual stages** Periods of personality development in which, according to Freud, conflicts focus on particular issues.

● The Structure and Development of Personality

Freud believed that people have certain basic impulses or urges—related not only to food and water, but also to sex and aggression. In most translations of his writings, the term *instinct* is used to describe these impulses and urges, though Freud did not believe that they are all inborn and unchangeable, as the word *instinct* might imply (Schultz & Schultz, 2005). He did believe, though, that our desires for love, knowledge, security, and the like arise from these more basic impulses. He said that each of us faces the task of figuring out how to satisfy basic urges. Our personality develops, he claimed, as we struggle with that task, and it is reflected in the ways we go about satisfying a range of urges.

● **Id, Ego, and Superego** As shown in Figure 14.1, Freud described the structure of personality as having three major components: the id, the ego, and the superego (Allen, 2006).

He saw the **id** as the unconscious portion of personality, in which two kinds of “instincts” reside. There are life instincts, which he called *Eros*. They promote positive, constructive behavior and reflect a source of energy (sometimes called *psychic energy*) known as **libido**. There are also death instincts, or *Thanatos*, which Freud saw as responsible for aggression and destructiveness (Hergenhahn & Olson, 2007). The id operates on the **pleasure principle**, seeking immediate satisfaction of both kinds of instincts, regardless of society's rules or the rights or feelings of others. The hungry person who pushes to the front of the line at Burger King would be satisfying an id-driven impulse.

Parents, teachers, and others soon begin to place more and more restrictions on children's expression of their id impulses. In the face of these restrictions, a second part of the personality—the **ego**—develops from the id. The ego tries to find ways to get what a person wants in the real world, as opposed to the fantasy world of the id. Operating on the **reality principle**, the ego makes compromises between the id's unreasoning demands for immediate satisfaction and the practical limits imposed by the social world. The ego would lead that hungry person at Burger King to wait in line and think about what to order rather than risk punishment by pushing ahead.

As children learn about the rules and values of society, they tend to adopt them. This process of *internalizing* parental and cultural values produces the third component of personality. It is called the **superego**, and it tells us what we should and should not do. The superego becomes our moral guide, and it is just as relentless and unreasonable as the id in its demand to be obeyed. It would make the hungry person at Burger King feel guilty for even thinking about violating society's rules.

● **Conflicts and Defenses** Freud described the inner clashes among the three personality components as *intrapsychic* or *psychodynamic conflicts*. He believed that each person's personality is shaped by the number, nature, and outcome of these conflicts. Freud said that the ego's primary function is to prevent the anxiety or guilt we would feel if we became aware of our socially unacceptable id impulses or if we thought about violating the superego's rules (Engler, 2003). Sometimes, the ego motivates sensible actions, as when a parent asks for help in dealing with impulses to abuse a child. However, the ego may also use **defense mechanisms**, which are unconscious tactics that protect against anxiety and guilt by either preventing threatening material from surfacing or disguising it when it does (Porcerelli et al., 2004) (see Table 14.1).

● **Stages in Personality Development** Freud proposed that personality develops during childhood in a series of **psychosexual stages**. Failure to resolve the problems and conflicts that appear at a given stage can leave a person *fixated*—that is, unconsciously preoccupied with the area of pleasure associated with that stage. Freud believed that the stage at which a person became fixated in childhood can be seen in adult personality characteristics.

TABLE 14.1 Ego Defense Mechanisms

TRY THIS  According to Freud, defense mechanisms deflect anxiety or guilt in the short run, but they sap energy. Further, using them to avoid dealing with the source of problems can make those problems worse in the long run. Try listing some incidents in which you or someone you know might have used each of the defenses described here. What questions would a critical thinker ask to determine whether these behaviors were unconscious defense mechanisms or actions motivated by conscious intentions?

| Defense Mechanism | Description |
|--------------------|--|
| Repression | Unconsciously pushing threatening memories, urges, or ideas from conscious awareness: A person may experience loss of memory for unpleasant events. |
| Rationalization | Attempting to make actions or mistakes seem reasonable: The reasons or excuses given (e.g., “I spank my children because it is good for them”) sound rational, but they are not the real reasons for the behavior. |
| Projection | Unconsciously attributing one’s own unacceptable thoughts or impulses to another person: Instead of recognizing that “I hate him,” a person may feel that “He hates me.” |
| Reaction formation | Defending against unacceptable impulses by acting opposite to them: Sexual interest in a married co-worker might appear as strong dislike instead. |
| Sublimation | Converting unacceptable impulses into socially acceptable actions, and perhaps symbolically expressing them: Sexual or aggressive desires may appear as artistic creativity or devotion to athletic excellence. |
| Displacement | Deflecting an impulse from its original target to a less threatening one: Anger at one’s boss may be expressed through hostility toward a clerk, a family member, or even a pet. |
| Denial | Simply discounting the existence of threatening impulses: A person may vehemently deny ever having had even the slightest degree of physical attraction to a person of the same sex. |
| Compensation | Striving to make up for unconscious impulses or fears: A business executive’s extreme competitiveness might be aimed at compensating for unconscious feelings of inferiority. |

In Freud’s theory, a child’s first year or so is called the **oral stage**, because the mouth—which infants use to eat and to explore everything from toys to their own hands and feet—is the center of pleasure during this period. Freud said fixation at the oral stage can stem from weaning that is too early or too late and may result in adult characteristics ranging from overeating or childlike dependence (late weaning) to the use of “biting” sarcasm (early weaning).

TRY THIS  Which of Freud’s ego defense mechanisms is operating here? (Check the answer at the bottom of page 556.)

The Oral Stage According to Freud, personality develops in a series of psychosexual stages. At each stage, a different part of the body becomes the primary focus of pleasure. This baby would appear to be in the oral stage.

- **oral stage** The first of Freud's psychosexual stages, in which the mouth is the center of pleasure and conflict.
- **anal stage** The second of Freud's psychosexual stages, usually occurring during the second year of life, in which the focus of pleasure and conflict shifts from the mouth to the anus.
- **phallic stage** The third of Freud's psychosexual stages, in which the focus of pleasure and conflict shifts to the genital area.
- **Oedipus complex** A pattern described by Freud in which a boy has sexual desire for his mother and wants to eliminate his father's competition for her attention.
- **Electra complex** A pattern described by Freud in which a young girl develops an attachment to her father and competes with her mother for his attention.
- **latency period** The fourth of Freud's psychosexual stages, in which sexual impulses lie dormant.
- **genital stage** The last of Freud's psychosexual stages, which begins during adolescence, when sexual impulses appear at the conscious level.

The **anal stage** occurs during the second year, when the child's ego develops to cope with parental demands for socially appropriate behavior. For example, in most Western cultures, toilet training clashes with the child's freedom to have bowel movements at will. Freud said that if toilet training is too harsh or begins too early, it can produce an anal fixation that leads, in adulthood, to stinginess or excessive neatness (symbolically withholding feces). If toilet training is too late or too lax, however, the result could be a kind of anal fixation that is reflected in adults who are disorganized or impulsive (symbolically expelling feces).

According to Freud, between the ages of three and five, the child's focus of pleasure shifts to the genital area. Because he emphasized male psychosexual development, Freud called this period the **phallic stage** (*phallus* is another word for penis). He believed that during this stage, a boy experiences sexual desire for his mother and a desire to eliminate, or even kill, his father, with whom the boy competes for the mother's affection. (Freud named this pattern of impulses the **Oedipus complex** because it reminded him of the plot of *Oedipus Rex*, the classical Greek play in which Oedipus, upon returning to his homeland, unknowingly slays his father and marries his mother.) The boy's fantasies make him fear that his powerful "rival" (his father) will castrate him. To reduce this fear, the boy's ego represses his incestuous desires and leads him to "identify" with his father and try to be like him. It is during this stage that the male's superego begins to develop.

According to Freud, a girl begins the phallic stage with a strong attachment to her mother. When she realizes that boys have penises and girls don't, though, she supposedly develops *penis envy* and transfers her love to her father. This pattern has become known as the **Electra complex** because it parallels the plot of another classical Greek play, but Freud himself never used that label. To avoid her mother's disapproval, the girl identifies with and imitates her, thus forming the basis for her own superego.

Freud believed that unresolved conflicts from the phallic stage can lead to many problems in adulthood, including difficulties in dealing with authority figures and an inability to maintain a stable love relationship.

As the phallic stage draws to a close and its conflicts are dealt with by the ego, a peaceful interval begins. During this **latency period**, which lasts through childhood, sexual impulses stay in the background as the youngster focuses on education, same-sex peer play, and the development of social skills. In adolescence, when sexual impulses reappear at a conscious level, the genitals again become the focus of pleasure. Thus begins what Freud called the **genital stage**, which he saw as lasting for the rest of a person's life.

● Variations on Freud's Personality Theory

Freud's ideas—especially those involving the Oedipus and Electra complexes and the role of infantile sexuality—were, and still are, controversial. Even many of Freud's followers did not entirely agree with him. Some of them have been called *neo-Freudian* theorists, because they maintained many of the basic ideas in Freud's theory but developed their own approaches. Others are known as *ego psychologists*, because their ideas focused more on the ego than on the id (Larsen & Buss, 2005).

● **Jung's Analytic Psychology** Carl Jung (pronounced "yoong") was the most prominent of Freud's early followers to chart his own theoretical course. Jung (1916) emphasized that libido is not just sexual instinct but rather a more general life force that includes an innate drive for creativity, for growth-oriented resolution of conflicts, and for the productive blending of basic impulses with real-world demands. Jung did not identify specific stages in personality development. He suggested instead that people gradually develop differing degrees of *introversion* (a tendency to reflect on one's own experiences) or *extraversion* (a tendency to focus on the social world), along with differing tendencies to rely on specific psychological functions, such as thinking

versus feeling. Combinations of these differing tendencies, said Jung (1933), create personalities that display distinctive and predictable patterns of behavior.

Jung also claimed there is a *collective unconscious*, which contains the memories we have inherited from our human and nonhuman ancestors (Hergenhahn & Olson, 2007). According to Jung, we are not consciously aware of these memories, but they are responsible for our innate tendencies to react in particular ways to certain things. For example, Jung believed that our collective memory of mothers influences how each of us perceives our own mother. Although the notion of a collective unconscious is widely accepted by followers of Jung, there is no empirical evidence that it exists. In fact, Jung himself acknowledged that it would be impossible to objectively demonstrate the existence of a collective unconscious (Feist & Feist, 2002).

● **Other Neo-Freudian Theorists** Jung was not the first or the only theorist to challenge Freud. Alfred Adler, once a loyal follower of psychoanalysis, came to believe that the power behind the development of personality comes not from id impulses but from an innate desire to overcome infantile feelings of helplessness and to gain some control over the environment. Adler (1927/1963) referred to this process as *striving for superiority*, by which he meant a drive for fulfillment as a person, not just a desire to do better than others. Other prominent neo-Freudians, including Erik Erikson, Erich Fromm, and Harry Stack Sullivan, focused on how people's personalities are shaped by those around them. They argued that once our biological needs are met, the attempt to meet social needs (to feel protected, secure, and accepted, for example) is the primary influence on personality. And according to these theorists, the strategies people use to meet these social needs, such as by dominating others or being dependent on them, become central features of their personalities.

The first feminist personality theorist, Karen Horney (pronounced “HORN-eye”), disputed Freud's view that women's lack of a penis causes them to envy men and feel inferior to them. Horney (1937) argued that, in fact, it is men who envy women: Realizing that they cannot bear children and that they often play only a small role in raising them, males see their lives as having less meaning or substance than women's. Horney called this condition *womb envy*. She argued further that when women feel inferior, it is because of the personal and political restrictions that men have placed upon them, not because of penis envy (Larsen & Buss, 2005). Horney's position on this issue reflected her strong belief that cultural factors, rather than instincts, play a major role in personality development (Hergenhahn & Olson, 2007). This greater emphasis on cultural influences is one of the major theoretical differences between Freud and the neo-Freudians generally.

An Early Feminist After completing medical school at the University of Berlin in 1913, Karen Horney (1885–1952) trained as a Freudian psychoanalyst. She accepted some aspects of Freud's views, including the idea of unconscious motivation, but she eventually developed her own neo-Freudian theory. She saw the need for security as more important than biological instincts in motivating infants' behavior. She also rejected Freud's notion that the psychological development of females is influenced by penis envy.

● Contemporary Psychodynamic Theories

Some of the most influential psychodynamic approaches to personality now focus on *object relations*—that is, on how people's perceptions of themselves and others influence their view of, and reactions to, the world (Pervin, Cervone, & John, 2005). Early object relations theorists such as Melanie Klein (1991), Otto Kernberg (1984), Heinz Kohut (1984), and Margaret Mahler (1968), saw the first relationships between infants and their love objects—usually the mother and other primary caregivers—as vitally important in the development of personality (Klein, 1975; Kohut, 1984; Sohlberg & Jansson, 2002). In their view, these relationships shape a person's thoughts and feelings about social relationships later in life (Pervin et al., 2005).

Today, object relations theory finds its clearest expression in research on the kinds of relationships, or *attachments*, that infants form with their primary caregivers. Ideally, infants form a secure early bond to their mothers or other caregivers,

The defense mechanism illustrated in the cartoon on page 554 is displacement.

tolerate gradual separation from this “attachment object,” and eventually develop the ability to relate to others as independent, secure individuals (Ainsworth, 1989; Bowlby, 1973). As described in the chapter on human development, however, some infants do not develop this *secure attachment*. Instead, they may display various kinds of *insecure attachments*. There is indeed evidence that the nature of early child-parent attachments is associated with differences in self-image, identity, security, and social relationships in adolescence, adulthood, and even old age (Consedine & Magai, 2003; Mattanah, Hancock, & Brand, 2004; Rholes, Simpson, & Friedman, 2006). In one study, people who had insecure attachment showed much stronger physiological stress reactions to interpersonal conflicts than did people whose attachments were secure (Powers et al., 2006). Another study found that people with insecure attachments were much less likely to be helpful when they encountered a person in distress (Mikulincer & Shaver, 2005). A third study found that children who, because of abuse, neglect, or rejection, miss the opportunity to become securely attached to their mothers or other adults may suffer severe disturbances in their later relationships (Aizawa, 2002).

● Evaluating the Psychodynamic Approach

Freud’s personality theory is probably the most comprehensive and influential psychological theory ever proposed, and it has influenced modern Western thinking about medicine, literature, religion, sociology, and anthropology. It has also shaped a wide range of psychotherapy techniques and stimulated the development of several personality assessments, including the projective tests described later in this chapter. Some of Freud’s ideas have received support from research on cognitive processes. For example, psychologists have found that people do employ several of the defense mechanisms Freud described (Cramer, 2003), although it is unclear whether these always operate at an unconscious level. As mentioned in the chapter on consciousness, there is also evidence that people’s thoughts and actions can be influenced by unrecalled events and experiences (Andersen & Miranda, 2000; Andersen & Chen, 2002; Ferguson & Bargh, 2004) and perhaps by emotions that are not consciously felt (Winkielman & Berridge, 2004). Some researchers believe that unconscious processes may affect people’s health (Goldenberg et al., 2005).

However, Freud’s psychodynamic theories have several weaknesses. For one thing, they are based almost entirely on case studies of a few individuals. As discussed in the chapter on research in psychology, conclusions drawn from case studies may not apply to people in general. Nor was Freud’s sample representative of people in general. Most of his patients were upper-class Viennese women who not only had psychological problems but also were raised in a culture in which discussion of sex was considered to be uncivilized. Moreover, Freud’s thinking about personality reflected Western European and North American values, which may or may not be helpful in understanding people in other cultures (Schultz & Schultz, 2005). For example, the concepts of ego and self that are so central to Freud’s personality theory (and those of his followers) are based on the self-oriented values of individualist cultures. These values may be less central to personality development in the more collectivist cultures of, say, Asia and South America (Matsumoto, 2000).

Freud’s conclusions may have been distorted by other biases as well. Freudian scholars suggest for example, that Freud might have modified reports of what happened during therapy to better fit his theory (Esterson, 2001; Schultz & Schultz, 2005). He may also have asked leading questions that influenced patients to “recall” events from their childhood that never really happened (Esterson, 2001). Today, there are similar concerns that some patients who recover allegedly repressed memories about childhood sexual abuse by parents may actually be reporting false memories implanted by their therapists (Loftus, 2004).

Freud’s focus on male psychosexual development and his notion that females envy male anatomy have also caused both female and male feminists to reject some

or all of his ideas. In the tradition of Horney, some contemporary female neo-Freudians have proposed theories that focus specifically on the psychosexual development of women (Sayers, 1991).

Finally, as judged by today's standards, Freud's theory is not very scientific. His definitions of id, ego, unconscious conflict, and other concepts lack the precision required for scientific measurement and testing (Stanovich, 2004). His belief that human beings are driven mainly by unconscious desires ignores evidence that much human behavior goes beyond impulse gratification. The conscious drive to reach personal, social, and spiritual goals is also an important determinant of behavior, as is learning from others.

Some of the weaknesses in Freudian theory have been addressed by those who have altered some of Freud's concepts and devoted more attention to social influences on personality. Attempts have also been made to increase precision and objectivity in the measurement of psychodynamic concepts (e.g., Barber, Crits-Christoph, & Paul, 1993). Research on concepts from psychodynamic theory is, in fact, becoming more sophisticated and increasingly reflects interest in subjecting psychodynamic principles to experimental tests (e.g., Betan et al., 2005; Wegner, Wenzlaff, & Kozak, 2004; Westen, 2005). Still, the psychodynamic approach is better known for generating hypotheses about personality than for scientifically testing them. Accordingly, this approach to personality is now much less influential in mainstream psychology than it was in the past (Allen, 2006; Carver & Scheier, 2004).

The Trait Approach

If you were to describe the personality of someone you know, it would probably take the form of a small number of descriptive statements. Here is an example:

She is a truly caring person, a real extravert. She is generous with her time, and very conscientious about everything she does. Yet sometimes she is not very assertive or confident. She always gives in to other people's demands because she wants to be accepted by them.

In other words, most people describe others by referring to the kind of people they are ("extravert," "conscientious"); to the thoughts, feelings, and actions that are most typical of them ("caring," "not very assertive," "generous"); or to their needs ("wants to be accepted"). Together, these statements describe personality *traits*—the inclinations or tendencies that help to direct how a person usually thinks and behaves (Pervin et al., 2005).

The **trait approach** to personality makes three basic assumptions:

1. Personality traits are relatively stable and therefore predictable over time. So a gentle person tends to stay that way day after day, year after year (Costa & McCrae, 2002).
2. Personality traits are relatively stable across situations, and they can explain why people act in predictable ways in many different situations. A person who is competitive at work will probably also be competitive on the tennis court or at a party.
3. People differ in how much of a particular personality trait they possess; no two people are exactly alike on all traits. The result is an endless variety of unique human personalities.

● **Traits Versus Types** Theories about enduring differences in people's personality characteristics go back at least as far as Hippocrates, a physician of ancient Greece. He suggested that a certain temperament, or basic behavioral tendency, is associated with each of four bodily fluids, or humors: blood, phlegm, black bile, and

● **trait approach** A perspective in which personality is seen as a combination of characteristics that people display over time and across situations.

Selecting a Jury Some psychologists employ type and trait theories of personality as they advise prosecution or defense attorneys about which potential jurors are most likely to be sympathetic to their side of a court case.

yellow bile. Personality, said Hippocrates, depends on how much of each humor a person has. His terms for the four humor-based personalities—sanguine (optimistic), phlegmatic (slow, lethargic), melancholic (sad, depressive), and choleric (angry, irritable)—still survive today.

Notice that Hippocrates was describing personality *types*, not traits. Traits involve *quantitative* differences among people—such as how much of a certain characteristic they possess. Types involve *qualitative* differences, such as whether someone possesses a certain characteristic at all. When people are “typed,” they are said to belong to one class or another—such as male or female. Modern type theories of personality try to do the same by placing people in one category or another (Funder, 2004). For example, Avshalom Caspi and his colleagues claim to have identified three qualitatively different basic personality types (Caspi, 1998; Robins, John, & Caspi, 1998). These include the *well-adjusted person*, who is flexible, resourceful, and successful with other people; the *maladjusted overcontrolling person*, who is too self-controlled to enjoy life and is difficult for others to deal with; and the *maladjusted undercontrolling person*, whose excessive impulsiveness can be dangerous both for the person and for others. (This chapter’s Focus on Research Methods section contains more information on these and other types.)

Type theories have recently gained acceptance among some personality researchers, but the majority of researchers doubt that it’s possible to compress the dazzling range of human characteristics into a just few discrete types (McRae et al., 2006). Accordingly, the trait approach to personality remains much more influential. Trait theorists are interested in measuring the relative strength of the many personality characteristics that they believe are present in everyone (see Figure 14.2). Most of today’s trait theories of personality have their origins in the work of Gordon Allport, Raymond Cattell, and Hans Eysenck.

● Allport’s Trait Theory

Gordon Allport spent thirty years searching for the traits that combine to form personality. He found nearly 18,000 dictionary terms that can be used to describe human behavior (Allport & Odbert, 1936), but he noticed that many of these terms referred to the same thing (e.g., *hostile*, *nasty*, and *mean* all convey a similar meaning). So if you were to jot down the personality traits that describe a close friend or relative, you would probably be able to capture that individual’s personality using only about seven

FIGURE 14.2

Two Personality Profiles

TRY THIS  Trait theory describes personality in terms of the strength of particular dimensions, or traits. Here are trait profiles for Rodney, an inner-city social worker, and James, a sales clerk. Compared with James, Rodney is about equally industrious; more generous; and less nervous, extraverted, and aggressive. Just for fun, mark this figure to indicate how strong you think you are on each of the listed traits. Trait theorists suggest that this should be easy for you to do because, they say, virtually everyone displays a certain amount of almost any personality characteristic.

trait labels. Allport believed that the set of labels chosen to describe a particular person reflects that person's *central traits*—those that are usually obvious to others and that organize and control behavior in many different situations. Central traits are roughly equivalent to the descriptive terms used in letters of recommendation (*reliable* or *distractible*, for example) that are meant to convey what can be expected from a person most of the time (Schultz & Schultz, 2005). Allport also believed that people possess *secondary traits*—those that are more specific to certain situations and control far less behavior. “Dislikes crowds” is an example of a secondary trait.

Allport's research helped to lay the foundation for modern research on personality traits. However, his emphasis on the uniqueness of each individual personality made it difficult to draw conclusions about the structure of human personality in general (McAdams, 1997).

● The Big-Five Model of Personality

In recent years, trait approaches have continued to focus on identifying and describing the core structure of personality. This work owes much to Allport and also to a British psychologist named Raymond Cattell. Cattell asked people to rate themselves and others on many of the trait-descriptive terms that Allport had identified. He then used a mathematical technique called *factor analysis* to study which of these terms were related to one another. Factor analysis can reveal, for example, whether someone who is moody is also likely to be anxious, rigid, and unsociable. Cattell believed that the sets of traits clustering together in this analysis would reflect a set of basic personality *factors* or dimensions. His analyses eventually identified sixteen such factors, including shy versus bold, trusting versus suspicious, and relaxed versus tense. Cattell believed that these factors are found in everyone, and he measured their strength using a test called the *Sixteen Personality Factor Questionnaire*, or 16PF (Cattell, Eber, & Tatsuoka, 1970).

More recent factor analyses by researchers such as Paul Costa and Robert McCrae have led many trait theorists to believe that personality is organized around

TABLE 14.2 The Big-Five Personality Dimensions

| Dimension | Defining Descriptors |
|------------------------|---|
| Openness to experience | Artistic, curious, imaginative, insightful, original, wide interests, unusual thought processes, intellectual interests |
| Conscientiousness | Efficient, organized, planful, reliable, thorough, dependable, ethical, productive |
| Extraversion | Active, assertive, energetic, outgoing, talkative, gesturally expressive, gregarious |
| Agreeableness | Appreciative, forgiving, generous, kind, trusting, noncritical, warm, compassionate, considerate, straightforward |
| Neuroticism | Anxious, self-pitying, tense, emotionally unstable, impulsive, vulnerable, touchy, worrying |

Here is a list of the adjectives that define the big-five personality factors. You can more easily remember the names of these factors by noting that their first letters spell the word *ocean*.

Source: Adapted from McCrae & John (1992).

only five basic factors (McCrae & Costa, 2004). The components of this so-called **big-five model**, or five-factor model, of personality are *openness to experience*, *conscientiousness*, *extraversion*, *agreeableness*, and *neuroticism* (see Table 14.2). The importance of the big-five model is suggested by the fact that different investigators find these factors (or a set very similar to them) when they factor-analyze data from personality inventories, peer ratings of personality characteristics, checklists of descriptive adjectives, and many other sources (Costa & McCrae, 1995; John & Srivastava, 1999). The fact that some version of the big-five factors reliably appears in many countries and cultures—including Canada, China, the Czech Republic, Germany, Greece, Finland, India, Japan, Korea, the Philippines, Poland, and Turkey (Allik & McCrae, 2004; Ashton et al., 2004; Yamagata et al., 2006)—provides further evidence that these few dimensions may represent the most important components of human personality (McCrae & Terracciano, 2005).

Many trait theorists believe that the big-five model represents a major breakthrough in examining the personalities of people who come from different backgrounds, differ in age, and live in different parts of the world (Carver & Scheier, 2004). It has certainly enabled psychologists to provide a comprehensive description of the basic similarities and differences in people's personalities and to explore how these factors are related to everything from attachment styles and personality disorders to subjective well-being and even future weight gain (e.g., Brummett et al., 2006; Diener, 2000; Lynam & Widiger, 2001; Nofle & Shaver, 2006).

● Biological Trait Theories

Some personality theorists are interested not only in what traits form the core of human personality but also in why people differ on these traits. Their research suggests that trait differences reflect the operation of some important biological factors.

● **Eysenck's Biological Trait Theory** Like Cattell, British psychologist Hans Eysenck (pronounced "EYE-sink") used factor analysis to study the structure of personality and thus helped lay the groundwork for the big-five model. Eysenck suggested that most people's traits could be described using two main dimensions—*introversion-extraversion* and *emotionality-stability* (Eysenck 1990a, 1990b; see Figure 14.3):

1. *Introversion-extraversion*. Extraverts are sociable and outgoing, enjoy parties and other group activities, take risks, and love excitement and change.

- **big-five model** A view based on factor-analytic studies suggesting the existence of five basic components of human personality: openness, conscientiousness, extraversion, agreeableness, and neuroticism; also called the five-factor model.

Animal Personalities The idea that personality can be described in terms of five main dimensions seems to hold for some animals as well as humans. The five animal dimensions vary from, but are still related to, human traits. For example, hyenas differ from one another in terms of dominance, excitability, agreeableness (toward people), sociability (toward each other), and curiosity. Some of these same traits have been observed in other species, including dogs, horses, orangutans, and chimpanzees (Gosling, 2001; Gosling, Kwan, & John, 2003; King, Weiss, & Farmer, 2005; Weiss, King, & Perkins, 2006; Wolf et al., 2007). Cat lovers often report such traits in their pets, too.

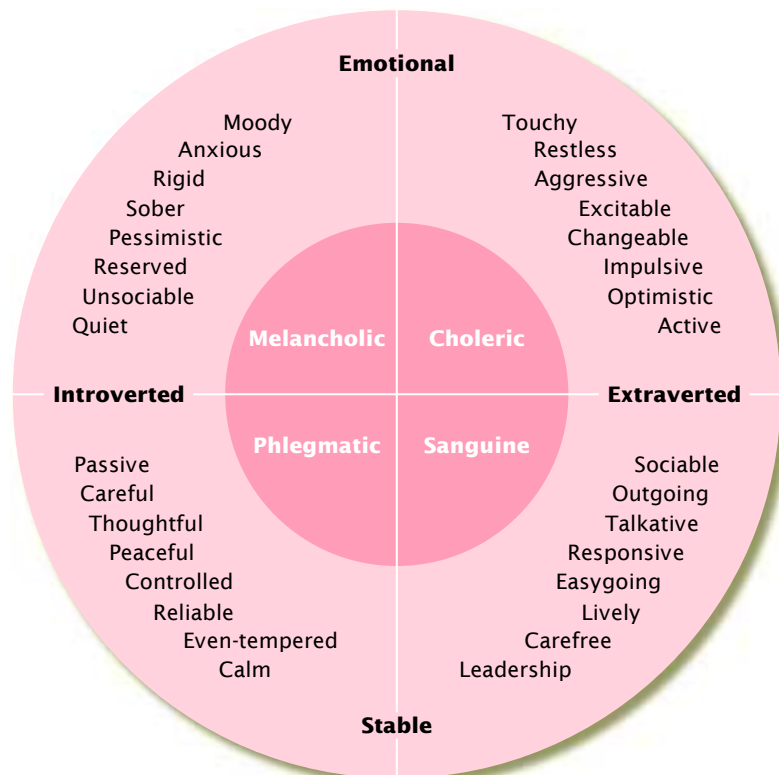

Introverts tend to be quiet, thoughtful, and reserved, enjoying solitary pursuits and avoiding excitement and social involvement.

2. *Emotionality-stability*. At one extreme of the emotionality-stability dimension are people who display such characteristics as moodiness, restlessness, worry, anxiety, and other negative emotions. Those at the opposite extreme are calm, even-tempered, relaxed, and emotionally stable. (This dimension is also often called *neuroticism*.)

FIGURE 14.3

Eysenck's Main Personality Dimensions

TRY THIS According to Eysenck, varying degrees of emotionality-stability and introversion-extraversion combine to produce predictable trait patterns. Notice that an introverted but stable person is likely to be controlled and reliable, whereas an introverted emotional person is likely to be rigid and anxious. (The traits appearing in the quadrants created by crossing these two personality dimensions correspond roughly to Hippocrates' four temperaments.) Which section of the figure do you think best describes your personality traits? How about those of a friend or a relative? Did you find it any easier to place other people's personalities in a particular section than it was to place your own personality? If so, why do you think that might be?

Eysenck argued that the variations in personality characteristics that we see among individuals can be traced to inherited differences in their nervous systems, especially in their brains. These biological differences, he said, create variations in people's typical levels of physiological arousal and in their sensitivity to stress and other environmental stimulation. For example, as mentioned in the motivation and emotion chapter, people who inherit a nervous system that normally operates below their optimum arousal level will always be on the lookout for excitement, change, and social contact in order to increase their arousal. As a result, these people will be *extraverted*. In contrast, people whose nervous system is normally "overaroused" will tend to avoid excitement, change, and social contact in order to reduce arousal to their optimum level. In short, they will be *introverted*. What about the emotionality-stability dimension? Eysenck said that people who score toward the stability side have nervous systems that are relatively insensitive to stress; those who are more emotional have nervous systems that react more strongly to stress.

● **Gray's Approach-Inhibition Theory** Jeffrey Gray, another British psychologist, agrees with Eysenck about the two basic dimensions of personality, but he offers a different explanation of the biological factors underlying them (Gray, 1991; Gray & McNaughton, 2000). According to Gray, differences among people in introversion-extraversion and emotionality-stability stem from two related systems in the brain: the behavioral approach system and the behavioral inhibition system. The *behavioral approach system*, or *BAS*, is made up of brain regions that affect people's sensitivity to rewards and their motivation to seek those rewards (Pickering & Gray, 1999). The BAS has been called a "go" system, because it is responsible for how impulsive or uninhibited a person is. The *behavioral inhibition system*, or *BIS*, involves brain regions that affect sensitivity to potential punishment and the motivation to avoid being punished. The BIS is a "stop" system that is responsible for how fearful or inhibited a person is. People with an active behavioral approach system tend to experience positive emotions; people with an active behavioral inhibition system are more likely to experience negative ones (Zelenski & Larsen, 1999).

In explaining Eysenck's personality dimensions, Gray sees extraverts as having a sensitive reward system (BAS) and an insensitive punishment system (BIS). Introverts are just the opposite—they are relatively insensitive to rewards but highly sensitive to punishment. Similarly, emotionally unstable people are much more sensitive to both rewards and punishments than are those who are emotionally stable.

Gray's theory has its critics (e.g., Corr, 2002), but it is now more widely accepted than Eysenck's theory—primarily because it is being supported by other research (e.g., Johnson, Ruggero, & Carver, 2005; Mitchell & Nelson-Gray, 2006) and because it is more consistent with what neuroscientists know about brain structures, neurotransmitters, and how they operate (Franken, Muris, & Georgieva, 2006; Reuter et al., 2006; Wacker, Chavanon, & Stemmler, 2006).

THINKING CRITICALLY

Are Personality Traits Inherited?

Gray's approach-inhibition theory is one of several new biologically oriented explanations of the origins of personality traits (e.g., Zuckerman, 2004). A related approach involves investigating the genetics of these traits. Consider the case of identical twins who were separated at five weeks of age and did not meet again for thirty-nine years. Both men drove Chevrolets, chain-smoked the same brand of cigarettes, had divorced women named Linda, were remarried to women named Betty, had sons named James Allan, had dogs named Toy, enjoyed similar hobbies, and had served as sheriff's deputies (Tellegen et al., 1988).

■ What am I being asked to believe or accept?

Case studies like these have helped focus the attention of behavioral geneticists on the possibility that some core aspects of personality might be partly, or even largely, inherited (Bouchard, 2004; Ebstein, 2006; Noble & Coccaro, 2005; Yamagata et al. 2006).

■ What evidence is available to support the assertion?

The evidence and the arguments regarding this assertion are much like those presented in the chapter on cognitive abilities, in which we discuss the origins of differences in intelligence. Stories about children who seem to “have” their parents’ or grandparents’ bad temper, generosity, or shyness are often presented in support of the heritability of personality. And in fact, family resemblances in personality do provide an important source of evidence. Several studies have found moderate but significant correlations between children’s personality test scores and those of their parents and siblings (Davis, Luce, & Kraus, 1994; Loehlin, 1992).

Even stronger evidence comes from studies conducted around the world comparing identical twins raised together, identical twins raised apart, nonidentical twins raised together, and nonidentical twins raised apart (Grigorenko, 2002). Whether they are raised apart or together, identical twins (who have exactly the same genes) tend to be more alike in personality than nonidentical twins (whose genes are no more similar than those of other siblings). This research also shows that identical twins are more alike than nonidentical twins in general temperament, such as how active, sociable, anxious, and emotional they are, their positive attributes, and where they fall on the big-five dimensions (Borkenau et al., 2002; Yamagata et al., 2006). On the basis of such twin studies, behavioral geneticists have concluded that at least 30 percent, and perhaps as much as 60 percent, of the differences among people in terms of personality traits are due to genetic factors (Caspi, Roberts, & Shiner, 2005).

■ Are there alternative ways of interpreting the evidence?

Family resemblances in personality could reflect genetic or social influence. So an obvious alternative interpretation of this evidence might be that family similarities come not from common genes but from a common environment, especially from the examples set by parents and siblings. Children learn many rules, skills, and behaviors

Family Resemblance Do children inherit personality traits in the same direct way as they may inherit facial features, coloration, and other physical characteristics? Research in behavioral genetics suggests that personality is the joint product of genetically influenced behavioral tendencies and the environmental conditions each child encounters.

by watching those around them; perhaps they learn their personalities as well (Funder, 2004). The fact that siblings who aren't twins are less alike than twins are may well result from what are called *nonshared environments* (Plomin, 2004). A child's place in the family birth order, differences in the way parents treat each of their children, and accidents and illnesses that alter a particular child's life or health are examples of nonshared factors that can have a differential impact on each individual (Loehlin, Neiderhiser, & Reiss, 2003). Nontwins are more likely than twins, especially identical twins, to be affected by nonshared environmental factors.

■ What additional evidence would help to evaluate the alternatives?

One way to evaluate the idea that personality is inherited would be to locate genes that are associated with certain personality characteristics (Ebstein, 2006). Genetic differences have already been tentatively associated with certain behavior disorders, but most behavioral genetics researchers doubt that there are direct links between specific genes and particular personality traits (Caspi et al., 2005; Reif & Lesch, 2003).

Another way to evaluate the role of genes in personality is to study people in infancy, before the environment has had a chance to exert its influence. If the environment were entirely responsible for personality, all newborns should be essentially alike. However, as discussed in the chapter on human development, they show immediate differences in *temperament*—varying markedly in activity, sensitivity to the environment, tendency to cry, and interest in new stimuli (Rothbart & Derryberry, 2002). These differences suggest biological and perhaps genetic influences.

To evaluate the relative contributions of nature and nurture beyond infancy, psychologists have examined the characteristics of adopted children. If adopted children are more like their biological parents than their adoptive parents, this suggests the influence of heredity in personality. If they are more like their adoptive families, a strong role for environmental factors in personality would be suggested. In actuality, adopted children's personalities tend to resemble the personalities of their biological parents and siblings more than those of the families in which they are raised (Plomin et al., 1998).

Further research is needed to determine more clearly what aspects of the environment are most important in shaping personality. So far, the evidence suggests that elements in the shared environment that affect all children in the family to varying degrees (socioeconomic status, for example) are probably not the main reason that identical twins show similar personalities. As mentioned earlier, however, nonshared environmental influences may be very important in personality development (Harris, 2000; Loehlin et al., 2003). In fact, some researchers believe that nonshared influences must be considered even when trying to explain the greater similarities between identical twins reared apart than among nontwin siblings reared together. Additional research on the role of nonshared factors in personality development and the ways in which these factors might differentially affect twin and nontwin siblings' development is obviously vital. It will also be important to investigate the ways in which the personalities of individual children may affect the nature of the environment in which they are raised (Krueger, Markon, & Bouchard, 2003; see also the behavioral genetics appendix).

■ What conclusions are most reasonable?

Even those researchers, such as Robert Plomin, who support genetic theories of personality caution that we should not replace "simple-minded environmentalism" with the equally incorrect view that personality is almost completely biologically determined (Plomin & Crabbe, 2000). As with cognitive abilities, it is pointless to talk about heredity *versus* environment as causes of personality, because nature and nurture always intertwine to exert joint and simultaneous influences. For example, we know that genetic factors affect the environment in which people live (e.g., their families) and how they react to their environment, but it also turns out that environmental factors can influence which of a person's genes are activated and how much those genes affect the person's behavior (Cacioppo et al., 2000; Pickering & Gray, 1999).

With these findings in mind, we would be well advised to draw rather tentative conclusions about the sources of differences in people's personalities. The evidence available so far suggests that genetic influences do appear to contribute significantly to personality differences. However, it is important to understand the implications of this statement. As noted earlier, there is no evidence of a single gene for any specific personality trait (Plomin, 2002). The genetic contribution to personality most likely comes through the influence of sets of genes that shape people's nervous systems and their general predispositions toward certain temperaments (Arbelle et al., 2003; Ebstein, 2006; Grigorenko, 2002). Temperamental factors—such as how active, emotional, and sociable a person is—then combine with environmental factors, such as a person's interactions with other people, to produce specific features of personality (Caspi et al., 2005). For example, children who inherit a tendency toward emotionality might play less with other children, withdraw from social interactions, and thereby fail to learn important social skills (Eisenberg, Fabes, & Murphy, 1995). These experiences and tendencies, in turn, might lead to the self-consciousness and shyness seen in introverted personalities.

Notice, though, that genetic predispositions toward particular personality characteristics may or may not appear in behavior, depending on whether the environment supports or suppresses them. Changes in genetically influenced traits are not only possible but may actually be quite common as children grow (Cacioppo et al., 2000). So even though there is a strong genetic basis for shyness, many children learn to overcome this tendency and become rather outgoing (Rowe, 1997). In summary, it appears that rather than inheriting specific traits, people inherit the raw materials out of which personality is shaped by the world. ■

● Evaluating the Trait Approach

The trait approach, especially the big-five model, has gained such wide acceptance that it tends to dominate contemporary research in personality. Yet there are several problems and weaknesses associated with this approach.

For one thing, trait theories seem better at describing people than at understanding them. It is easy to say, for example, that Marilyn is nasty to others because she has a strong hostility trait; but other factors, such as the way people treat her, could also be responsible. Indeed, trait theories have typically focused more on *how* people behave than on *why* they act as they do (Mischel, 2004a, 2004b). Nor do trait theories say much about how traits are related to the thoughts and feelings that precede, accompany, and follow behavior. Do introverts and extraverts decide to act as they do, can they behave otherwise, and how do they feel about their actions and experiences? Some personality psychologists are now linking their research to that of cognitive psychologists in an effort to better understand how thoughts and emotions influence, and are influenced by, personality traits (e.g., Shoda & LeeTiernan, 2002). And as suggested in the previous section, other psychologists have become interested in the role of genes, brain structures, and neurotransmitters as causes of the individual differences we see among people's personality traits (e.g., DeYoung, Peterson, & Higgins, 2005; Netter, 2006).

Still, the trait approach has been faulted for offering a short list of traits that provides, at best, a fixed and superficial description of personality that fails to capture how traits combine to form a complex and dynamic individual (Block, 2001; Funder, 2004). Also, some people have questioned whether there are exactly five core dimensions of personality. Some research suggests, for example, that there might be a sixth dimension, namely honesty and humility (Lee, Ogunfowora, & Ashton, 2005). Others have questioned whether the factors are exactly the same in all cultures (Cross & Markus, 1999). But even if the big-five model is correct and universal, its factors are not all-powerful, because situations also affect behavior. For example, people high in extraversion are not always sociable. Whether they behave sociably depends, in part, on where they are and who else is present.

In fairness, early trait theorists, such as Allport, did implicitly acknowledge the importance of situations in influencing behavior, but it is only recently that consideration of person-situation interactions has become an explicit part of trait-based approaches to personality. This change is largely the result of research conducted by psychologists who have taken a social-cognitive approach to personality, which we describe next.

The Social-Cognitive Approach

The **social-cognitive approach** to personality differs from the psychodynamic and trait approaches in two important ways. First, social-cognitive theorists look to *conscious* thoughts and emotions for clues to how people differ from one another and what guides their behavior (Mischel, 2004b). Second, the social-cognitive approach did not grow out of clinical cases or other descriptions of people's personalities. It was based instead on the principles of animal and human learning described in the chapter on learning. In fact, the founders of the social-cognitive approach were originally known as *social-learning theorists* because of their view that what we call *personality* consists mainly of the thoughts and actions we learn through observing and interacting with family and others in social situations (Bandura & Walters, 1963; Funder, 2004).

● Roots of the Social-Cognitive Approach

Elements of the social-cognitive approach can be traced back to the behaviorism of John B. Watson. As described in the chapter on introducing psychology, Watson (1925) used research on classical conditioning to support his claim that all human behavior, from mental disorder to scientific skill, is determined by learning. B. F. Skinner broadened the behavioral approach by emphasizing the importance of operant conditioning in learning. Through what he called **functional analysis**, Skinner tried to understand behavior in terms of the function it serves in obtaining rewards or avoiding punishment. For example, if observations show that a schoolboy's aggressive behavior occurs mainly when a certain teacher is present, it may be that aggression is tolerated by that teacher, and might even be rewarded with special attention. Rather than describing personality traits, then, functional analysis summarizes what people find rewarding, what they are capable of doing, and what skills they lack.

The principles of classical and operant conditioning launched social-learning explanations of personality, but because they were focused on observable behavior, they were of limited usefulness to researchers who wanted to explore the role of thoughts in guiding behavior. As the social-learning approach evolved into the social-cognitive approach, it incorporated learning principles but also went beyond them.

Today, proponents of this very popular approach to personality seek to assess and understand how learned patterns of thoughts and feelings contribute to behavior and how behavior and its consequences alter cognitive activity, as well as future actions. In dealing with that aggressive schoolboy, for example, social-cognitive theorists would want to know not only what he has learned to do in certain situations (and how he learned it) but also what he thinks about himself, his teachers, his behavior—and his expectations about each (Shoda & Mischel, 2006).

- **social-cognitive approach** An approach in which personality is seen as the patterns of thinking and behavior that a person learns.

- **functional analysis** Analyzing behavior by studying what responses occur under what conditions of operant reward and punishment.

● Prominent Social-Cognitive Theories

Julian Rotter, Albert Bandura, and Walter Mischel have presented the most influential social-cognitive personality theories.

**FIGURE 14.4****Reciprocal Determinism**

Bandura's notion of reciprocal determinism suggests that personal factors (such as cognitions, or thoughts), behavior, and the environment are constantly affecting one another. For example, a person's hostile thoughts may lead to hostile behavior, which creates even more hostile thoughts. At the same time, the hostile behavior offends other people, which creates a threatening environment that causes the person to think and act in even more negative ways. As increasingly negative thoughts alter the person's perceptions of the environment, that environment seems to be more threatening than ever (Bushman et al., 2005).

● **Rotter's Expectancy Theory** Julian Rotter (1982) argued that learning creates cognitions, known as *expectancies*, that guide behavior. Specifically, he said that a person's decision to engage in a behavior is determined by (1) what the person expects to happen following the behavior and (2) the value the person places on the outcome. For example, people spend a lot of money on clothes to be worn at a job interview because (1) past learning leads them to expect that doing so will help get them the job, and (2) they place a high value on having the job. To Rotter, then, behavior is determined not only by the kinds of consequences that Skinner called *positive reinforcers* but also by the expectation that a particular behavior will result in those consequences (Mischel, 2004b).

Rotter himself focused mainly on how expectations shape particular behaviors in particular situations, but several of the researchers he influenced also examined people's more general expectations about what controls life's rewards and punishments. Those researchers noticed that some people (*internals*) are inclined to expect events to be controlled by their own efforts. These individuals assume that what they achieve and the reinforcements they receive are due to efforts they make themselves. Others (*externals*) are more inclined to expect events to be determined by external forces over which they have no control. When externals succeed, they are likely to believe that the success was due to chance or luck.

Research on differences in generalized expectancies does show that they are correlated with differences in behavior. For example, when threatened by a hurricane or other natural disaster, internals—in accordance with their belief that they can control what happens to them—are more likely than externals to buy bottled water and make other preparations (Sattler, Kaiser, & Hittner, 2000). When confronted with a personal problem, internals are more likely than externals to work to solve this problem. Externals are more likely to see it as being unsolvable (Gianakos, 2002). Internals also tend to work harder than externals at staying physically healthy, and as a result may lower their risk of cancer and heart disease (Stürmer, Hasselbach, & Amelang, 2006). They are less likely to drink alcohol, or—if they do drink—less likely to drive while intoxicated (Cavaola & Desordi, 2000). Internals tend to be more careful with money (Lim, Teo, & Loo, 2003), and internal college students tend to be better informed about the courses they take, including what they need to do to get a high grade. Perhaps as a result, internals tend to get better grades than externals (Dollinger, 2000).

● **Bandura and Reciprocal Determinism** In his social-cognitive theory, Albert Bandura (1999; 2006) sees personality as shaped by the ways in which thoughts, behavior, and the environment interact and influence one another. He points out that whether people learn through direct experience with rewards and punishments or through the observational learning processes described in the chapter on learning, their behavior creates changes in their environment. Observing these changes, in turn, affects how they think, which then affects their behavior, and so on in a constant web of mutual influence that Bandura calls *reciprocal determinism* (see Figure 14.4).

According to Bandura, an especially important cognitive element in this web of influence is perceived **self-efficacy**—the learned expectation of success. Bandura says that what we do, and what we try to do, is largely controlled by our perceptions or beliefs about our chances of success at a particular task or problem. The higher our perceived self-efficacy in relation to a particular situation or task, the greater our actual accomplishments in that situation or task (Zimmerman & Schunk, 2003). So going into a job interview with the belief that you have the skills necessary to be hired may lead to behaviors that help you get the job.

Perceived self-efficacy about a specific behavior can interact with a person's expectancies about the consequences of behavior in general, thus helping to shape the person's psychological well-being (Maddux & Gosselin, 2003; see Figure 14.5). For example, if a person has low perceived self-efficacy and also expects that nothing

● **self-efficacy** According to Bandura, learned expectations about the probability of success in given situations.

FIGURE 14.5**Self-Efficacy and Psychological Well-Being**

According to Bandura, if people with high self-efficacy perceive the environment as unresponsive to their best efforts, they may become resentful and socially active protesters. If they perceive the environment as responsive to their efforts, they are more likely to be both active and self-assured.

| | | Outcome expectation | |
|------------------------|---|--|---------------------------------|
| | | - | + |
| Self-efficacy judgment | + | Social activism Protest Grievance Milieu change | Assured opportune action |
| | - | Resignation Apathy | Self-devaluation Despondency |

anyone does has much effect on the world, the result may be apathy. But if a person with low perceived self-efficacy also believes that other people are enjoying the benefits of their efforts, the result may be self-criticism and depression.

● **Mischel's Cognitive/Affective Theory** Social-cognitive theorists argue that learned beliefs, feelings, and expectancies characterize each individual and make that individual different from other people. Walter Mischel calls these characteristics *cognitive person variables*, and he believes that they outline the dimensions along which individuals differ (Mischel, 2004b).

According to Mischel, the most important cognitive person variables are (1) *encodings* (the beliefs the person has about the environment and other people), (2) *expectancies* (what the person expects to follow from various behaviors and what the person believes he or she is capable of doing), (3) *affects* (feelings, emotions, and affective responses), (4) *goals and values* (the things a person believes in and wants to achieve), and (5) *competencies and self-regulatory plans* (the thoughts and actions the person is capable of, as well as the ability to engage in planned, self-controlled, and goal-directed behavior (Shoda & Mischel, 2006).

To predict a person's behavior in a particular situation, says Mischel, we need to know about these cognitive person variables, as well as about the features of the situation the person will face. In short, the person and the situation interact to produce behavior. Mischel's view has been called an "if-then" theory, because he proposes that *if* people encounter a particular situation, *then* they will engage in the characteristic behaviors (called *behavioral signatures*) they have learned to display in that situation (Kammrath, Mendoza-Denton, & Mischel, 2005).

Mischel was once highly critical of trait theories of personality, but now sees his own theory as generally consistent with that approach. In fact, the concept of behavioral signatures is quite similar to the concept of traits. However, Mischel still argues that trait theorists underestimate the power of situations to alter behavior and do not pay enough attention to the cognitive and emotional processes that underlie people's overt actions. Despite their remaining differences, most advocates of the trait and social-cognitive approaches are now focusing on the similarities between their views (Cervone, 2005; Fleeson, 2004). This trend toward reconciliation has helped to clarify the relationship between personal and situational variables and how they affect behavior under various conditions. Many of the conclusions that have emerged are consistent with Bandura's concept of reciprocal determinism:

1. Personal dispositions (which include traits and cognitive person variables) influence behavior only in relevant situations. The trait of anxiousness, for example, may predict anxiety, but only in situations in which an anxious person feels threatened.
2. Personal dispositions can lead to behaviors that alter situations that, in turn, promote other behaviors. For example, a hostile child can trigger aggression in others and thus start a fight.

The Impact of Situations Like the rest of us, Arnold Schwarzenegger behaves differently in different situations, including when acting in his *Terminator* movies and when serving as the governor of California. Mischel's theory of personality emphasizes that person-situation interactions are important in determining behavior.

3. People choose to be in situations that are in tune with their personal dispositions. Introverts, for instance, are likely to choose quiet environments, whereas extraverts tend to seek out livelier, more social circumstances.
4. Personal dispositions are more important in some situations than in others. Under circumstances in which many different behaviors would all be appropriate—a company picnic, for example—what people do may be predicted from their dispositions (extraverts will probably play games and socialize while introverts watch). However, in situations such as a funeral, in which fewer options are socially acceptable, personal dispositions will not differentiate one person from another; everyone is likely to be quiet and somber.

Today, social-cognitive theorists devote much of their research to examining how cognitive person variables develop, how they are related to stress and health, and how they interact with situational variables to affect behavior.

● Evaluating the Social-Cognitive Approach

The original behavioral view of personality appealed to many people. It offered an objective, experimentally oriented approach that operationally defined its concepts, relied on empirical data for its basic principles, and based its applications on the results of empirical research (Pervin et al., 2005). However, its successor, the social-cognitive approach, has gained even wider acceptance because it blends theories from behavioral and cognitive psychology and applies them to such socially important areas as aggression, the effects of mass media on children, and the development of self-regulatory processes that enhance personal control over behavior. The popularity of this approach also stems from the ease with which its principles can be translated into treatment procedures for many types of psychological disorders (O'Donohue, Fisher, & Hayes, 2003; see the chapter on treatment of psychological disorders).

Still, the social-cognitive approach has not escaped criticism. Psychodynamic theorists point out that social-cognitive theories leave no role for unconscious thoughts and feelings in determining behaviors (e.g., Westen, 1998). Some advocates of trait theory complain that social-cognitive theorists have focused more

on explaining why traits are unimportant than on why situations are important and that they have failed to identify what it is about specific situations that brings out certain behaviors (Friedman & Schustack, 2003; Funder, 2004). The social-cognitive approach has also been faulted for failing to present a general theory of personality, offering instead a set of more limited theories that share certain common assumptions about the nature of personality (Feist & Feist, 2002). Most generally, the social-cognitive approach is considered incapable of capturing the complexity, richness, and uniqueness that some critics see as inherent in human personality (Carver & Scheier, 2004). According to these critics, a far more attractive alternative is provided by the humanistic approach to personality.

The Humanistic Approach

Unlike theories that emphasize the instincts and learning processes that humans seem to share with other animals, the **humanistic approach** to personality focuses on mental capabilities that set humans apart: self-awareness, creativity, planning, decision making, and responsibility. Those who adopt the humanistic approach see human behavior as motivated mainly by an innate drive toward growth that prompts people to fulfill their unique potential. And like the planted seed whose natural potential is to become a flower, people are seen as naturally inclined toward goodness, creativity, love, and joy. Humanistic psychologists also believe that to explain people's actions in any particular situation, it is more important to understand their view of the world than their instincts, traits, or learning experiences. To humanists, that world view is a bit different for each of us, and it is this unique *phenomenology* (pronounced “feh-naw-men-ALL-oh-gee”), or way of perceiving and interpreting the world, that shapes personality and guides behavior (Kelly, 1980). From this perspective, then, no one can understand another person without somehow perceiving the world through that person's eyes. All behavior, even seemingly weird behavior, is presumed to be meaningful to the person displaying it. Because it emphasizes the importance of looking at people's perceptions, this approach is sometimes called the *phenomenological approach*.

What Is Reality? Each of these people has a different perception of what happened during the play that started this argument—and each is sure he is right! Disagreement about the “same” event illustrates phenomenology, each person's unique perceptions of the world. The humanistic approach sees these perceptions as shaping personality and guiding behavior. As described in the perception chapter, our perceptions are often influenced by top-down processing. In this case, expectations and motivation stemming from differing loyalties are likely to influence reality—and reactions—for each team's players, coaches, and fans.

- **humanistic approach** A view in which personality develops through an actualizing tendency that unfolds in accordance with each person's unique perceptions of the world.

The humanistic approach to personality has many roots. The idea that each person perceives a different reality reflects the views of existential philosophers such as Søren Kierkegaard and Jean-Paul Sartre. The idea that people actively shape their own reality stems in part from the Gestalt psychologists, whose work is described in the chapter on perception, and from George Kelly, a psychologist who also influenced social-cognitive theorists. We can also hear echoes of Alfred Adler and other psychodynamic theorists who emphasized the positive aspects of human nature and the importance of the ego in personality development. Humanistic theories of personality have, themselves, helped to fuel research in positive psychology, which focuses on character strengths such as wisdom, courage, and humanity, as well as on happiness, thriving, and other aspects of human experience associated with maximum personal development and functioning (Peterson, 2006; Ryan & Deci, 2000; Seligman, 2002).

● Prominent Humanistic Theories

By far, the most prominent humanistic theories of personality are those of Carl Rogers and Abraham Maslow.

● **Rogers’s Self Theory** In his extensive writings, Carl Rogers (e.g., 1961, 1970, 1980) emphasized the **actualizing tendency**, which he described as an innate inclination toward growth and fulfillment that motivates all human behavior and is expressed in a unique way by each individual (Raskin & Rogers, 2001). Rogers saw personality as the expression of that actualizing tendency as it unfolds in each individual’s uniquely perceived reality (Hergenhahn & Olson, 2007). The centerpiece of Rogers’s theory is the *self*, the part of experience that a person identifies as “I” or “me.” According to Rogers, those who accurately experience the self—with all its preferences, abilities, fantasies, shortcomings, and desires—are on the road to what Kurt Goldstein (1939) had called *self-actualization*. The progress of people whose experiences of the self become distorted, however, is likely to be slowed or stopped.

Rogers saw personality development beginning early, as children learn to need other people’s approval, or as he called it, *positive regard*. Evaluations by parents, teachers, and others soon begin to affect children’s self-evaluations. When these

Seeking Self-Actualization According to Rogers, conditions of worth can make it harder for children to become aware of and accept aspects of themselves that conflict with their parents’ values. Progress toward self-actualization can be enhanced by associating with those whose positive regard is less conditional on displaying any particular pattern of behavior.

● **actualizing tendency** According to Rogers, an innate inclination toward growth that motivates all people.

Parents are not usually this obvious about creating conditions of worth, but according to Rogers, the message gets through in many more subtle ways.

“Just remember, son, it doesn't matter whether you win or lose—unless you want Daddy's love.”

evaluations are in agreement with a child's own self-evaluations, the child reacts in a way that matches, or is *congruent* with, self-experience. The child not only experiences positive regard but also evaluates the self as “good” for having earned approval. This positive self-experience becomes part of the **self-concept**, which is the way one thinks of oneself. But what if a positive self-experience is evaluated negatively by others, as when a little boy is teased by his father for having fun playing with dolls? In this case, the child must either do without a parent's positive regard or, more likely, reevaluate the self-experience—deciding perhaps that “I don't like dolls” or “Feeling good is bad.”

In other words, said Rogers, personality is shaped partly by the actualizing tendency and partly by evaluations made by others. In this way, people come to like what they are “supposed” to like and to behave as they are “supposed” to behave. This socialization process is adaptive, because it helps people to function in society, but it often requires that they suppress their self-actualizing tendency and distort their experience. Rogers argued that psychological discomfort, anxiety, or even mental disorder can result when the feelings people experience or express are *incongruent*, or at odds, with their true feelings.

Incongruence is likely, said Rogers, when parents and teachers act in ways that lead children to believe that their worth as people depends on displaying the “right” attitudes, behaviors, and values. These **conditions of worth** are created whenever *people* are evaluated instead of their behavior. For example, parents who find their toddler smearing finger paint on the dog are unlikely to say, “I love you, but I don't approve of this particular behavior.” They are more likely to shout, “Bad boy!” or “Bad girl!” This reaction sends a subtle message that the child is lovable and worthwhile only when well behaved. As a result, the child's self-experience is not “I like painting Fang, but Mom and Dad don't approve,” but instead, “Playing with paint is bad, and I am bad if I like it, so I don't like it,” or “I like it, so I must be bad.” The child may eventually display overly neat and tidy behaviors that do not reflect the real self but, rather, are part of the ideal self dictated by the parents.

- **self-concept** The way one thinks of oneself.
- **conditions of worth** According to Rogers, the feelings an individual experiences when the person, instead of the person's behavior, is evaluated.

The Joys of a Growth Orientation

According to Maslow's theory of personality, the key to personal growth and fulfillment lies in focusing on what we have, not on what we don't have or on what we have lost. Rachel Barton could have let the accident that took her leg destroy her career as a concert violinist, and with it, her joy in life—but she didn't. Researchers in the field of positive psychology are studying the development of resilience, as well as other character strengths, as part of an effort to understand and promote all the things that can go right in human life (Peterson, 2006).

As with Freud's concept of superego, conditions of worth are first set up by external pressure but eventually become part of the person's belief system. So Rogers saw rewards and punishments as important in personality development not just because they shape overt behavior but also because they can so easily create distorted self-perceptions and incongruence.

● **Maslow's Growth Theory** Like Rogers, Abraham Maslow (1954, 1971) considered personality to be the expression of a basic human tendency toward growth and self-actualization. In fact, Maslow believed that self-actualization is not just a human capacity but a human need. As described in the motivation and emotion chapter, he placed self-actualization as the highest in a hierarchy of motives, or needs. Yet, said Maslow, people are often distracted from seeking self-actualization because they focus on needs that are lower on the hierarchy.

Maslow saw most people as controlled by a **deficiency orientation**, the preoccupation with perceived needs for material things, especially things they do not have. Ultimately, he said, deficiency-oriented people come to see life as a meaningless exercise in disappointment and boredom, and they may begin to behave in problematic ways. For example, in an attempt to satisfy the need for love and belongingness, people may focus on what love can give them (security), not on what they can give to another. This deficiency orientation may lead a person to be jealous and to focus on what is missing in relationships. As a result, the person will never truly experience either love or security.

In contrast, people with a **growth orientation** do not focus on what is missing but draw satisfaction from what they have, what they are, and what they can do. This orientation opens the door to what Maslow called *peak experiences*, in which people feel joy, even ecstasy, in the mere fact of being alive, being human, and knowing that they are utilizing their fullest potential.

● Evaluating the Humanistic Approach

The humanistic approach to personality is consistent with the way many people view themselves. It gives a central role to each person's immediate experiences and emphasizes the uniqueness of each individual. The humanistic approach and its phenomenological perspective inspired the person-centered therapy of Rogers and other forms of psychotherapy (see the chapter on treatment of psychological disorders). This approach also underlies various short-term personal growth experiences—such as sensitivity training and encounter groups designed to help people become more

- **deficiency orientation** According to Maslow, a preoccupation with perceived needs for things a person does not have.
- **growth orientation** According to Maslow, a tendency to draw satisfaction from what is available in life, rather than to focus on what is missing.

aware of themselves and the way they relate to others (e.g., Cain & Seeman, 2002). It has also led to programs designed to teach parents how to avoid creating conditions of worth while maximizing their children's potential. And as already mentioned, the humanistic approach has helped to promote research in positive psychology, which studies what and how things go right in human development (Diener, 2003; Peterson, 2006; Snyder & Lopez, 2006).

Yet to some, the humanistic view is naive, romantic, and unrealistic. Are people all as inherently good and growth-oriented as this approach suggests? Critics wonder about that, and they also fault humanistic personality theories for paying too little attention to the importance of inherited characteristics, learning, situational influences, and unconscious motivation in shaping personality. The idea that everyone is directed only by an innate growth potential is viewed by these critics as an oversimplification. So, too, is the assumption that all human problems stem from blocked actualization. Like the trait approach, humanistic theories seem to do a better job of describing personality than explaining it. And like many of the concepts in psychodynamic theories, humanistic concepts seem too vague to be tested empirically. Accordingly, the humanistic approach per se has not been very popular among psychologists who rely on empirical research to learn about personality (Friedman & Schustack, 2003). This may be changing, though, as the explosion of research in positive psychology leads to new humanistically oriented theories that lend themselves to empirical evaluation (e.g., Burton et al., 2006; Deci & Ryan, 2000; Ryan & Deci, 2000).

Even so, humanists' tendency to define ideal personality development in terms of personal growth, independence, and self-actualization has been criticized for emphasizing culture-specific ideas about mental health that may not apply outside North America and other Western cultures (Heine, 2003). As described in the next section, the individualist foundations of humanistic personality theories may be in direct conflict with the values of non-Western, collectivist cultures.

"In Review: Major Approaches to Personality" summarizes key features of the humanistic approach, along with those of the other approaches we have described. Which approach is most accurate? There is no simple answer to that question, partly because each approach emphasizes different aspects of personality. Accordingly, it has been suggested that a full understanding of the origins and development of personality will come only by recognizing the roles of all the factors that various approaches have shown to be important. Some psychologists are now working on theoretical models that take this promising integrative approach (Mayer, 2005; McAdams & Pals, 2006).

in review Major Approaches to Personality

| Approach | Basic Assumptions About Behavior | Typical Research Method |
|------------------|---|---|
| Psychodynamic | Determined by largely unconscious intrapsychic conflicts | Case studies |
| Trait | Determined by traits or needs | Analysis of tests for basic personality dimensions |
| Social-cognitive | Determined by learning, cognitive factors, and specific situations | Analysis of interactions between people and situations |
| Humanistic | Determined by innate growth tendency and individual perception of reality | Studies of relationships between perceptions and behavior |

LINKAGES Personality, Culture, and Human Development

 LINKAGES (a link to Human Development, p. 501)

In many Western cultures, it is common to hear people encourage others to “stand up for yourself” or to “blow your own horn” in order to “get what you have coming to you.” In middle-class North America, for example, the values of achievement and personal distinction are taught to children, particularly male children, very early in life (Kitayama, Duffy, & Uchida, 2007). North American children are encouraged to feel special, to want self-esteem, and to feel good about themselves, partly because these characteristics are associated with happiness, popularity, and superior performance in school. Whether self-esteem is the cause or the result of these good outcomes (Baumeister et al., 2003), children who learn and display these values nevertheless tend to receive praise and encouragement for doing so.

As a result of this cultural training, many people in North America and Europe develop personalities that are largely based on a sense of high self-worth. In a study by Hazel Markus and Shinobu Kitayama (1997), for example, 70 percent of a sample of U.S. students believed they were superior to their peers, and 60 percent believed they were in the top 10 percent on a wide variety of personal attributes! This tendency toward self-enhancement is evident as early as age four.

It is no wonder that many Western personality theorists see a sense of independence, uniqueness, and self-esteem as fundamental to mental health. Psychoanalyst Erik Erikson included the appearance of personal identity and self-esteem as part of normal psychosocial development (see the chapter on human development). Middle-class Americans who fail to value and strive for independence, self-promotion, and unique personal achievement may be seen as displaying a personality disorder, some form of depression, or other psychological problems.

Do these ideas reflect universal truths about personality development or, rather, the influence of the cultures that generated them? It is certainly clear that people in many non-Western cultures develop personal orientations very different from those of North Americans and Europeans (Lehman, Chiu, & Schaller, 2004). In China and Japan, for example, an independent, unique self is not emphasized (Ho & Chiu, 1998). Children there are encouraged to develop and maintain harmonious relations with others and

The goal of esteem building is clear these days in many children’s activities at school, and in some team sports, too, which are designed either to eliminate competition or, as in this case, assure that everyone feels like winners. The same goal is reflected in day-care centers, summer camps, and other children’s programs with names such as Starkids, Little Wonders, Superkids, and Precious Jewels.

Culture and Personality

In individualist cultures, most children learn early that personal distinction is valued by parents, teachers, and peers. In cultures that emphasize collectivist values, a strong sense of personal self-worth tends to be seen as a less important characteristic. In other words, the features of “normal” personality development vary from culture to culture. Make a list of the core values you have learned. Which of them are typical of individualist cultures, which are typical of collectivist cultures, and which reflect a combination of both?

not to stand out from the crowd, because doing so might make others seem inferior by comparison. In fact, the Japanese word for “different” (*tigau*) also means “wrong” (Kitayama & Markus, 1992). So whereas children in the United States hear that “the squeaky wheel gets the grease,” Japanese children are warned that “the nail that stands out gets pounded down” (Markus & Kitayama, 1997). From a very young age, they are taught to be modest, to play down the value of personal contributions, and to appreciate the joy and value of group work (Kitayama & Uchida, 2003).

In contrast to the *independent* self-system prevalent in individualist cultures (e.g., the United States, the United Kingdom, and Switzerland), countries characterized by a more collectivist orientation (e.g., Japan, China, Brazil, and Nigeria) promote an *interdependent* self-system through which people see themselves as a small fraction of a social whole. Each person has little or no meaningful definition without reference to the group. These differences in self-systems may produce differences in what gives people a sense of well-being and satisfaction (Tsai, Knutson, & Fung, 2006). In the United States, a sense of personal well-being is typically associated with the feeling of *having positive attributes*, such as intelligence, creativity, competitiveness, persistence, and so on. In Japan and other Asian countries it is more likely to be associated with the feeling of *having no negative attributes* (Eliot et al., 2001). Similarly, the results of studies conducted around the world indicate that in collectivist cultures, life satisfaction is associated with social approval and harmonious relations with others, whereas in individualist cultures, life satisfaction is associated with high self-esteem and feeling good about one’s own life (Uchida et al., 2001).

Given that cultural factors shape notions about ideal personality development, it is important to evaluate various approaches to personality in terms of how well they apply to cultures other than the one in which they were developed (Cross & Markus, 1999). Their applicability to males and females must also be considered. Even within North American cultures, for example, there are gender differences in the development of self-esteem. Females tend to display an interdependent self-system, achieving their sense of self and self-esteem from attachments to others. By contrast, males’ self-esteem tends to develop in relation to personal achievement, in a manner more in keeping with an independent self-system (Cross & Madson, 1997). Cross-gender and cross-cultural differences in the nature and determinants of a sense of self underscore the pervasive effects of gender and culture on the development of many aspects of personality (Zakriski, Wright, & Underwood, 2005). ■

**FOCUS ON
RESEARCH METHODS**

**Longitudinal Studies of Temperament
and Personality**

Studying the development of personality over the life span requires longitudinal research, in which the same people are followed from infancy to adulthood so that their characteristics can be assessed at different points in their lives. A number of studies have used longitudinal methods to explore a variety of questions about changes in personality over time.

■ What was the researchers' question?

The specific question addressed by Avshalom Caspi and his colleagues was whether the temperament children display at birth and in their early years predicts their personality and behavior as adults (Caspi, 2000; Caspi & Silva, 1995; Caspi et al., 1997; Caspi et al., 1995; Caspi, Harrington, et al., 2003). As discussed in the chapter on human development, it is generally agreed that differences in temperament are influenced more by heredity than by the environment (Saudino, 2005).

■ How did the researchers answer the question?

Caspi's research team studied all the children born in Dunedin, New Zealand, between April 1972 and March 1973—a total of about a thousand individuals. When the children were three years old, an examiner gave each of them a test of their cognitive abilities and motor skills and, using a 3-point scale, rated their reactions to the testing situation. Some of the children displayed uncontrolled behaviors; some interacted easily; some were withdrawn and unresponsive. (To avoid bias while making their ratings, the examiners were told nothing about the children's typical behavior outside of the testing room.) These observations were used to place each child into one of five temperament categories: *undercontrolled* (irritable, impatient, emotional), *inhibited* (shy, fearful, easily distracted), *confident* (eager to perform, responsive to questions), *reserved* (withdrawn, uncomfortable), and *well adjusted* (confident, friendly, well controlled). The children were observed and categorized again when they were five, seven, and nine years old. On each occasion, a different person did the ratings, thus ensuring that the observers' ratings would not be biased by earlier impressions. Almost all correlations among the independent ratings made at various ages were positive and statistically significant, indicating that the temperament classifications were stable across time.

When the participants were eighteen years old, they completed a standard personality test, and then, at twenty-one, they were interviewed about the degree to which they engaged in risky and unhealthy behaviors such as excessive drinking, violent crime, unprotected sexual activity, and unsafe driving habits. To avoid bias, the interviewers were given no information about the participants' temperament when they were children or about their scores on the personality test. Finally, at the age of twenty-six, the participants again took a standard personality test and were also rated by their friends on the big-five personality dimensions.

■ What did the researchers find?

Several significant differences were found among the average personality scores for the five original temperament categories. For example, the average test scores of twenty-six-year-olds who had been classified as “undercontrolled” in childhood showed that they were more alienated, uninhibited, and stressed than any other temperament group. Further, people who had been classified as “confident” or “well adjusted” as children tended to be better adjusted and more extraverted at twenty-six than people who had been classified as “inhibited” or “reserved” when they were children. Young adults who, as children, had been classified as “well adjusted” tended to be effective individuals who were likely to assume leadership roles. These findings held true for males and females alike.

Caspi and his colleagues also found small but significant correlations between early temperament and health-risky and criminal behaviors (Caspi et al., 2003). For example, people classified as “overcontrolled” were more likely to avoid dangerous and exciting activities at the age of twenty-one than were those who had been classified as “undercontrolled.” In fact, participants classified as “undercontrolled” were significantly more likely than any of the other groups to engage in risky behaviors and to have criminal records. The relationship between temperament in childhood and health-risky behaviors in young adulthood was not a direct one, though. Statistical analyses revealed that temperament at age three affected personality at age eighteen, which in turn affected later behavior patterns.

■ What do the results mean?

The results of Caspi’s studies provide persuasive empirical support for a hypothesis long endorsed by personality psychologists, namely that we can make relatively accurate predictions about adult personality and behavior if we know about childhood temperament. However, the strength of these results should not be overstated. The relationships between temperament and personality, and between temperament and various problematic behaviors, though statistically significant, were also relatively modest. For example, not all the participants classified as “undercontrolled” at age three turned out to be aggressive or violent at age twenty-one. The implication is that personality is influenced and shaped by temperament, but not completely determined by it (Hampson & Goldberg, 2006; Roberts, Walton, & Viechtbauer, 2006).

The results of these studies also confirm a point made in the chapter on health, stress, and coping—that personality plays a significant role in health. Specifically, personality characteristics predispose people to engage in behaviors that can affect their mental and physical health.

■ What do we still need to know?

Caspi’s research has revealed some consistency between temperament in childhood and personality in adulthood, but it also leaves some unanswered questions (Roberts & Delvecchio, 2000). For example, what factors underlie this consistency? The fact that there are individual differences in adult behavior within temperament groups shows that a child is not simply biologically programmed to display certain personality traits later. One explanation offered by Caspi and his colleagues draws heavily on social-cognitive theories, particularly on Bandura’s notion of reciprocal determinism. These researchers believe that long-term consistencies in behavior result from the mutual influence that temperament and environmental events have on one another. They propose, for example, that people tend to put themselves in situations that reinforce their temperament. So “undercontrolled” people might choose to spend time with people who accept and even encourage rude or impolite behavior. And when such behavior brings negative reactions, the world seems that much more hostile, and they become even more aggressive and negative. Caspi and his colleagues see the results of their studies as evidence that this process of mutual influence between personality and situations can continue over a lifetime (Caspi et al., 2003). ■

Assessing Personality

Psychologists describe people’s personalities using information from four main sources: *life outcomes* (such as level of education, income, or marital status); *situational tests* (laboratory measurements of behavioral, emotional, and physiological reactions to conflict, frustration, and the like); *observer ratings* (judgments about a person made by family or friends); and *self-reports* (responses to interviews and personality tests). The data gathered through these methods are used for many purposes, including diagnosing psychological disorders, predicting dangerousness,

selecting new employees, and even choosing astronaut candidates best suited to space travel (Bernstein, Kramer, & Phares, 2008; Meyer et al., 2001).

Observer ratings and situational tests allow direct assessment of many aspects of behavior, including how often, how effectively, and how consistently various actions occur. *Interviews* provide a way to gather information about personality from the person's own point of view. Some interviews are *open ended*, meaning that questions are tailored to the intellectual level, emotional state, and special needs of the person being interviewed. Others are *structured*, meaning that the interviewer asks a fixed set of questions about specific topics in a particular order. Structured interviews are routinely used in personality research because they are sure to cover matters of special interest to the researcher.

Personality tests offer a way of gathering self-report information that is more standardized and economical than interviews. To be useful, however, a personality test must be reliable and valid. As described in the chapter on cognitive abilities, reliability refers to how stable or consistent the results of a test are; validity reflects the degree to which test scores are interpreted appropriately and used properly in making inferences about people. The many personality tests available today are traditionally classified as either *objective* or *projective*.

● Objective Personality Tests

Objective personality tests contain clearly stated items that relate to a person's thoughts, feelings, or behavior (such as "Do you like parties?"). The most common kind of objective personality test is similar in format to the multiple-choice or true-false examinations used in many classrooms. Like those exams, self-report personality tests can be administered to many people at the same time. They can also be machine scored. However, whereas there is only one correct answer for each item on a classroom exam, the "correct" answers to an objective personality test depend on who is taking it. Each person is asked to respond in a way that best describes him or her.

The person's responses to an objective test's items are combined into a score. That score can be used to draw conclusions about the individual's personality, but only after it has been compared with the responses of thousands of other people who have taken the same test. For example, before interpreting your score on a self-report test of extraversion, a psychologist would compare that score with *norms*, or average scores from other individuals of your age and gender. Only if you were well above these averages would you be considered unusually extraverted.

Some self-report tests focus on one personality trait, such as optimism (Carver & Scheier, 2002). Others measure a set of related traits, such as empathy and social responsibility (Penner, 2002). Still others measure the strength of a wider variety of traits to reveal general psychological functioning. For example, the *Neuroticism Extraversion Openness Personality Inventory, Revised*, or NEO-PI-R (Costa & McCrae, 1992), is designed to measure the big-five personality traits described earlier. Table 14.3 shows how the test's results are presented. One innovative feature of the NEO-PI-R is its "private" and "public" versions. The first version asks for the respondent's self-assessment. The second version asks a person who knows the respondent to rate him or her on various dimensions. Personality descriptions based on the two versions are often quite similar, but discrepancies may indicate problems. For example, if a person's self-ratings are substantially different from those of a spouse, marital problems may be indicated. The nature of the discrepancies could suggest a focus for marital therapy.

The NEO-PI-R is quite reliable (Viswesvaran & Ones, 2000), and people's scores on its various dimensions have been successfully used to predict social status (Anderson et al., 2001) as well as a number of behaviors, including success in business, performance in specific jobs (Conte & Gintoft, 2005; Zhao & Seibert, 2006), and the likelihood of engaging in criminal activities and risky sexual behaviors (Miller et al., 2004).

- **objective personality test** A test containing direct, unambiguous items relating to the individual being assessed.

TABLE 14.3 Sample Summary of Results from the NEO-PI-R

The NEO-PI-R assesses the big-five personality dimensions. In this example of the results a respondent might receive, the five factors scored are, from the top row to the bottom row, neuroticism, extraversion, openness, agreeableness, and conscientiousness. Because people with different NEO profiles tend to have different psychological problems, this test has been used to aid in the diagnosis of personality disorders (Trull & Sher, 1994).

Compared with the responses of other people, your responses suggest that you can be described as:

| | | |
|--|---|---|
| <input type="checkbox"/> Sensitive, emotional, and prone to experience feelings that are upsetting. | <input checked="" type="checkbox"/> Generally calm and able to deal with stress, but you sometimes experience feelings of guilt, anger, or sadness. | <input type="checkbox"/> Secure, hardy, and generally relaxed even under stressful conditions. |
| <input type="checkbox"/> Extraverted, outgoing, active, and high-spirited. You prefer to be around people most of the time. | <input type="checkbox"/> Moderate in activity and enthusiasm. You enjoy the company of others, but you also value privacy. | <input checked="" type="checkbox"/> Introverted, reserved, and serious. You prefer to be alone or with a few close friends. |
| <input type="checkbox"/> Open to new experiences. You have broad interests and are very imaginative. | <input type="checkbox"/> Practical but willing to consider new ways of doing things. You seek a balance between the old and the new. | <input checked="" type="checkbox"/> Down-to-earth, practical, traditional, and pretty much set in your ways. |
| <input type="checkbox"/> Compassionate, good-natured, and eager to cooperate and avoid conflict. | <input checked="" type="checkbox"/> Generally warm, trusting, and agreeable, but you can sometimes be stubborn and competitive. | <input type="checkbox"/> Hardheaded, skeptical, proud, and competitive. You tend to express your anger directly. |
| <input checked="" type="checkbox"/> Conscientious and well organized. You have high standards and always strive to achieve your goals. | <input type="checkbox"/> Dependable and moderately well organized. You generally have clear goals but are able to set your work aside. | <input type="checkbox"/> Easygoing, not very well organized, and sometimes careless. You prefer not to make plans. |

 LINKAGES (a link to Psychological Disorders, p. 597)

When the goal of personality testing is to diagnose psychological disorders, the most commonly used objective test is the *Minnesota Multiphasic Personality Inventory*, or *MMPI* (Butcher & Rouse, 1996). This 566-item true-false test was originally developed during the 1930s at the University of Minnesota by Starke Hathaway and J. C. McKinley. It has since been revised and updated to become the *MMPI-2* (National Computer Systems, 1992). The *MMPI*'s items are organized into ten *clinical scales*. These are groups of items that, in earlier research, had drawn a characteristic pattern of responses only from people who displayed particular psychological disorders or personality characteristics.

Interpreting the *MMPI* is largely a matter of using computer programs to compare test profiles—such as those shown in Figure 14.6—to the profiles of people already known to display certain personality characteristics. It is presumed that people share characteristics with the group whose profile most closely resembles their own. But although a very high score on one scale, such as depression, might indicate a problem in the dimension measured by that scale, *MMPI* interpretation usually focuses on the overall pattern in the clinical scales—particularly on the combination of two or three scales on which a person has unusually high scores.

There is considerable evidence for the reliability and validity of *MMPI* clinical scales, but even the latest editions of the test are far from perfect measurement tools (Carr, Moretti, & Cue, 2005; Munley, 2002). The validity of *MMPI* interpretations may be particularly suspect when—because of cultural factors—the perceptions, values, and experiences of a respondent are notably different from those of the test developers and the people to whom the respondent's results are compared. A profile that looks typical of people with a certain disorder might actually reflect the culture-specific way the respondent interpreted the test items, not a mental problem (Groth-Marnat, 1997). Even though the *MMPI-2* uses comparison norms that represent a

FIGURE 14.6

MMPI Clinical Scales and Sample Profiles

A score of 50 on the clinical scales of the MMPI is average. Scores at or above 65 mean that the person's responses on that scale are more extreme than at least 95 percent of the normal population. The green line represents the profile of Jeffrey Dahmer, the infamous Milwaukee, Wisconsin, man who was sentenced to life in prison in 1992 for murdering, dismembering, and partially cannibalizing seventeen young men and boys. His profile would be interpreted as characteristic of people who are "odd and peculiar in thinking and behavior and distant and mistrustful in relations with others despite strong needs for attention and affection. They see others as hostile, rejecting, and unreliable. Sexual deviation, the confusion of sexuality with aggression, defective empathy, and difficulties in the expression and control of anger are chronic problems" (Nichols, 2006). The profile in purple comes from a more normal man, but it is characteristic of someone who is self-centered, passive, unwilling to accept personal responsibility for his behavior, and, when under stress, complains of numerous vague physical symptoms.

The clinical scales abbreviated in the figure are as follows:

1. Hypochondriasis (Hs; concern with bodily functions and symptoms).
2. Depression (D; pessimism, hopelessness, slowed thinking).
3. Hysteria (Hy; use of physical or mental symptoms to avoid problems).
4. Psychopathic deviate (Pd; disregard for social customs, emotional shallowness).
5. Masculinity/femininity (Mf; interests associated with a particular gender).
6. Paranoia (Pa; delusions, suspiciousness).
7. Psychasthenia (Pt; worry, guilt, anxiety).
8. Schizophrenia (Sc; bizarre thoughts and perceptions).
9. Hypomania (Ma; overactivity, excitement, impulsiveness).
10. Social introversion (Si; shy, insecure).

more culturally diverse population than did those of the original MMPI, psychologists must always use caution when interpreting profiles of people who are members of minority subcultures (Butcher, 2004).

● Projective Personality Tests

Unlike objective tests, **projective personality tests** contain relatively unstructured stimuli, such as inkblots, which can be perceived in many ways. Those who favor projective tests tend to take a psychodynamic approach to personality. They believe that people's responses to the tests' ambiguous stimuli are guided by unconscious needs, motives, fantasies, conflicts, thoughts, and other hidden aspects of personality. Some projective tests ask people to draw items such as a house, a person, or a tree (see Figure 14.7); to fill in the missing parts of incomplete pictures or sentences; or to say what they associate with a particular word. Projective techniques are sometimes used in basic personality research, but they are far more popular among clinical psychologists, who use them in the assessment of psychological disorders (Garb et al., 2005).

One prominent projective test, developed by Henry Murray and Christina Morgan, is called the *Thematic Apperception Test*, or TAT. As described in the chapter on motivation and emotion, the TAT is used to measure need for achievement (see Figure 11.6 in that chapter). It is also used to assess other needs (e.g., for power or affiliation) that Murray and Morgan saw as the basis for personality. Another widely used projective test, the *Rorschach Inkblot Test*, asks people to say what they see in a series of inkblots similar to the one in Figure 14.8.

- **projective personality test** A test made up of unstructured stimuli that can be perceived and responded to in many ways.

**FIGURE 14.7****A Draw-a-Person Test**

These drawings were done by an eighteen-year-old male who had been caught stealing a television set. A psychologist interpreted the muscular figure as the young man's attempt to boast of masculine prowess but saw the muscles' "puffy softness" as suggesting feelings of inadequacy. The drawing of the baby-like figure was seen to reveal vulnerability, dependency, and a need for affection. Appealing as these interpretations may be, research does not generally support the value of projective tests in personality assessment (Lilienfeld, Wood, & Garb, 2000).

Source: Hammer (1968).

Those who support the use of projective tests claim that ambiguous test items make it difficult for respondents to detect what is being measured and what the "best" answers would be. They argue, therefore, that these tests can measure aggressive and sexual impulses and other personality features that people might otherwise be able to hide. However, in comparison with the results of objective tests, responses to projective tests are much more difficult to translate into numerical scores for scientific analysis. In an effort to reduce the subjectivity involved in projective-test interpretation, some psychologists have developed more structured—and thus potentially more reliable—scoring systems for instruments such as the Rorschach (Erdberg, 1990; Exner, 2003). And there are in fact specific instances—as in studies assessing implicit social motives with the TAT—in which projective tests show acceptable reliability and validity (Meyer, Mihura, & Smith, 2005; Schultheiss & Rohde, 2002). Overall, though, projective personality tests are substantially less reliable and valid than objective tests (Hunsley, Lee, & Wood, 2003; Lilienfeld, Wood, & Garb, 2000). Because of their generally low predictive power, projective tests often add little information beyond what might be inferred from life outcome data, interviews, and objective personality tests (Hunsley et al., 2003). ("In Review: Personality Tests" summarizes the characteristics of objective and projective tests, along with some of their advantages and disadvantages.)

● Personality Tests and Employee Selection

How good are personality tests at selecting people for jobs? Most industrial/organizational psychologists believe these tests are valuable tools in the selection of good employees. The MMPI (and even some projective tests) are occasionally employed for such purposes (e.g., Matyas, 2004), but the majority of personality tests used by large organizations are those that measure the big-five personality dimensions or related characteristics (Borman, Hanson, & Hedge, 1997; Costa, 2001). Several researchers have found significant relationships between scores on these characteristics and measures of overall job performance and effective leadership (Kieffer, Schinka, & Curtiss, 2004; Lim & Ployhart, 2004; Silverthorne, 2001).

FIGURE 14.8**The Rorschach Inkblot Test**

TRY THIS  The Rorschach test consists of ten patterns similar to this one, some in color, some in black and white. People taking the test are asked to say what each pattern might be and to explain why. Jot down what you see in this inkblot, and why, and then compare your responses to those of some friends. Most scoring methods focus on (1) what part of the blot the person responds to; (2) what details, colors, or other features appear to determine each response; (3) the content of responses (such as seeing animals, maps, or body parts); and (4) the popularity or commonness of the responses.

in review Personality Tests

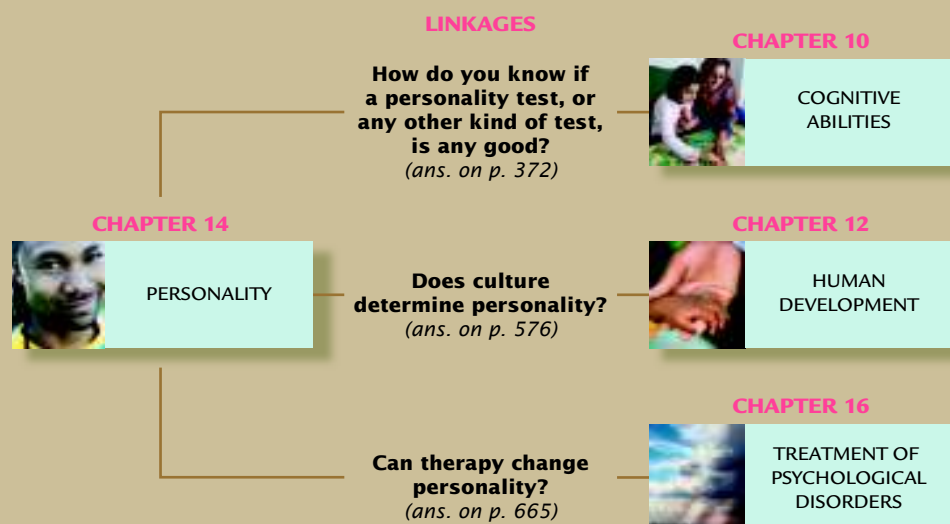

| Type of Test | Characteristics | Advantages | Disadvantages |
|--------------|---|---|--|
| Objective | Asks direct questions about a person; quantitatively scored | Efficiency, standardization | Subject to deliberate distortion |
| Projective | Unstructured stimuli create maximum freedom of response; scoring is subjective, though some objective methods exist | “Correct” answers not obvious; designed to tap unconscious impulses; flexible use | Reliability and validity lower than those of objective tests |

A more general review of studies involving thousands of people has shown that objective personality tests are of value in helping businesses reduce thefts and other disruptive employee behaviors (Ones & Viswesvaran, 2001).

Still, personality tests are not perfect, and as noted earlier, they sometimes lead to incorrect predictions about behavior. Many tests measure traits that may be too general to predict specific aspects of job performance (Furnham, 2001). Often, features of the work situation are better predictors of employee behavior than are personality tests (Mumford et al., 2001). Further, some employees see personality tests as an invasion of their privacy. They worry also that test results in their personnel files might later be misinterpreted and hurt their chances for promotion or for employment by other companies. Lawsuits have resulted in a ban on the use of personality tests in the selection of U.S. federal employees. Concerns about privacy and other issues surrounding personality testing have also led the American Psychological Association and other organizations to publish joint ethical standards relating to procedures for the development, dissemination, and use of all psychological tests (American Educational Research Association, American Psychological Association, and National Council on Measurement in Education, 1999; American Psychological Association, 2002b). The goal is not only to improve the reliability and validity of tests but also to ensure that their results are properly used and do not infringe on individuals' rights (Turner et al., 2001).

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of cultural factors and personality illustrates just one way in which the topic of this chapter, personality, is linked to the subfield of developmental psychology (which is the focus of the chapter on human development). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

SUMMARY

Personality refers to the unique pattern of psychological and behavioral characteristics by which each person can be compared and contrasted with other people. The four main theoretical approaches to personality are psychodynamic, trait, social-cognitive, and humanistic.

The Psychodynamic Approach

The *psychodynamic approach*, first proposed by Sigmund Freud, assumes that personality arises out of the interplay of various unconscious psychological processes.

The Structure and Development of Personality Freud believed that personality has three components—the *id*, which has a reservoir of *libido* and operates according to the *pleasure principle*; the *ego*, which operates according to the *reality principle*; and the *superego*, which internalizes society's rules and values. The ego uses *defense mechanisms* to prevent unconscious conflicts among these components from becoming conscious and causing anxiety or guilt. Freud proposed that the focus of conflict changes as the child passes through *psychosexual stages* of development, called the *oral stage*, the *anal stage*, the *phallic stage* (during which the *Oedipus complex* or the *Electra complex* arises), the *latency period*, and the *genital stage*.

Variations on Freud's Personality Theory Many of Freud's early followers developed new theories that differed from his. Among these theorists were Carl Jung, Alfred Adler, and Karen Horney. These and other theorists tended to downplay the role of instincts and the unconscious, emphasizing instead the importance of conscious processes, ego functions, and social and cultural factors. Horney also challenged the male-oriented nature of Freud's original theory.

Contemporary Psychodynamic Theories Current psychodynamic theories are derived from the neo-Freudians' emphasis on family and social relationships. According to object relations and attachment theorists, personality development depends mainly on the nature of early interactions between individuals and their caregivers.

Evaluating the Psychodynamic Approach Despite evidence in support of some psychodynamic concepts and recent attempts to test psychodynamic theories more precisely and objectively, critics still fault the approach for its lack of a scientific base and for its view of human behavior as driven by unmeasurable forces.

The Trait Approach

The *trait approach* to personality assumes that personality is made up of stable internal characteristics that appear at varying strengths in different people and guide their thoughts, feelings, and behavior.

Allport's Trait Theory Gordon Allport believed that personality is created by a small set of central traits and a larger number of secondary traits in each individual. He analyzed language to try to identify those traits, thus laying the foundation for modern research on personality traits.

The Big-Five Model of Personality Building on the work of Allport and Raymond Cattell, contemporary researchers have used factor analysis to identify five basic dimensions of personality, collectively referred to as the *big-five model*, or five-factor model. These dimensions—openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism—have been found in many different cultures.

Biological Trait Theories Hans Eysenck believed that differences in nervous system arousal are responsible for differences in core dimensions of personality, especially introversion-extraversion and emotionality-stability. Newer biological theories have largely replaced Eysenck's theory, and they suggest instead that these differences are due to biological differences in the sensitivity of brain systems involved with responsiveness to rewards and to punishments.

Evaluating the Trait Approach The trait approach has been criticized for being better at describing personality than at explaining it, for failing to consider mechanisms that motivate behavior, and for underemphasizing the role of situational factors. Nevertheless, the trait approach—particularly the big-five model—currently dominates the field of personality.

The Social-Cognitive Approach

The *social-cognitive approach* to personality focuses on the thoughts and feelings that influence people's behavior and assumes that personality is a label that summarizes the unique patterns of thinking and behavior that a person learns in the social world.

Roots of the Social-Cognitive Approach With roots in research on classical and operant conditioning (including Skinner's *functional analysis* of behavior), the social-cognitive approach has expanded on traditional behavioral approaches by emphasizing the role of cognitive factors, such as observational learning, in personality development.

Prominent Social-Cognitive Theories Julian Rotter's theory focuses on cognitive expectancies that guide behavior, and it generated interest in assessing general beliefs about whether rewards occur because of personal efforts (internal control) or chance (external control). Albert Bandura believes that personality develops largely through cognitively mediated learning, including observational learning. He sees personality as reciprocally determined by interactions among cognition, environmental stimuli, and behavior. Perceived *self-efficacy*—the belief in one's ability to accomplish a specific task—is an

important determinant of behavior. Walter Mischel emphasizes the importance of cognitive person variables and their interactions with the characteristics of particular situations in determining behavior. According to Mischel, we must look at both cognitive person variables and situational variables in order to understand human consistencies and inconsistencies.

Evaluating the Social-Cognitive Approach The social-cognitive approach has gained wide acceptance because it has merged theories from behavioral and cognitive psychology and used them to explain a wide range of important social behaviors. However, the approach has been criticized for failing both to provide one coherent theory of personality and to capture the complexity, richness, and uniqueness of human personalities.

The Humanistic Approach

The *humanistic approach* to personality is based on the assumption that people are primarily motivated by a desire to fulfill their natural potential in a uniquely perceived version of reality. So to understand a person, you have to understand the person's view of the world, which serves as the basis for personality and guides behavior.

Prominent Humanistic Theories Carl Rogers believed that personality development is driven by an innate *actualizing tendency*, but also that one's *self-concept* is shaped by social evaluations. He proposed that when people are free from the effects of *conditions of worth*, they are more likely to be psychologically healthy and to achieve self-actualization. Abraham Maslow saw self-actualization as the highest in a hierarchy of needs. Personality development is healthiest, he said, when people have a *growth orientation* rather than a *deficiency orientation*.

Evaluating the Humanistic Approach Although it has an intuitive appeal, the humanistic approach is faulted for being too idealistic, for failing to explain personality development, for being vague and unscientific, and for underplaying cultural differences in "ideal" personalities.

Assessing Personality

The information used in personality assessment comes from four main sources: life outcomes, situational tests, observer ratings, and self-reports. To be useful, personality assessments must be both reliable and valid.

Objective Personality Tests *Objective personality tests* contain clearly worded items relating to the individual being assessed; their scores can be compared with group norms. The MMPI and the NEO-PI-R are examples of objective tests.

Projective Personality Tests Based on psychodynamic theories, *projective personality tests* present ambiguous stimuli in an attempt to tap unconscious personality characteristics. Two popular projective tests are the TAT and the Rorschach Inkblot Test. In general, projective personality tests are less reliable and valid than objective personality tests.

Personality Tests and Employee Selection Objective personality tests are often used to identify the people best suited for certain occupations. Although such tests can be helpful in this regard, those who use them must be aware of the tests' limitations and take care not to violate the rights of test respondents.

Psychological Disorders

Many people pursue what other people consider odd hobbies, such as collecting string, but when does oddness become abnormality? In this chapter, we discuss the ways in which society answers that question. We also describe the main types of psychological disorders, their possible causes, their legal status, and how they have been explained over the centuries. We have organized our presentation as follows:

Defining Psychological Disorders 589

SUMMARY

During his first year at college, Mark began to worry about news stories describing the deadly diseases resulting from HIV, the virus that causes AIDS. He took a blood test for HIV and was relieved when it showed no infection. But then he wondered if he might have contracted HIV after he took the test. Internet research revealed that HIV antibodies may not appear until six months after infection. Mark took another blood test, also negative, but he still worried when he learned that the AIDS virus can live outside of the human body for anywhere from ten minutes to several hours or even days.

Given this uncertainty, Mark concluded that HIV can live indefinitely outside of the body and could therefore be anywhere and everywhere. He decided that the only safe course was not just sexual abstinence but absolute cleanliness. Mark began to scrub himself whenever he touched doorknobs, money, walls, floors—anything. People with HIV, he thought, could have touched these things, or they might have bled on the street and he might have tracked their infected blood into his car and house and bathroom. Eventually he felt the need to scrub everything around him up to forty times in each direction; it took him several exhausting hours just to shower and dress. He washed the shower knobs before touching them and, once in the shower, felt that he had to wash his body in cycles of thirteen strokes. If his feet touched the bare floor, he had to wash them again before putting on his underwear to ensure that his feet would not contaminate the fabric. He was sure that his hands, rubbed raw from constant washing, were especially susceptible to infection, so he wore gloves at all times except in the summer, when he wrapped his fingers in flesh-colored bandages. The process of protecting himself from infection was wearing him out and severely restricting his activities; he could not go anywhere without first considering the risk of infection.

Mark's case provides an example of someone who suffers from a psychological disorder, also called a *mental disorder* or *psychopathology*. **Psychopathology** is generally defined as patterns of thought, emotion, and behavior that result in personal distress or a significant impairment in a person's social or occupational functioning. Surveys reveal that in any given year in the United States alone, about 30 percent of adults—about 60 million people—display some form of mental disorder and that about half of all Americans can expect to experience a disorder by age seventy-five (Kessler, Berglund, et al., 2005; Kessler, Chiu, et al., 2005; National Institute of Mental Health, 2006; World Health Organization Mental Health Survey Consortium, 2004; see Figure 15.1). These overall rates of mental disorder are found, with only minor variations, in all segments of U.S. society, including males and females in all ethnic groups and in the young and old. Many of these disorders appear quite early in life. In any given year, about 20 percent of U.S. children display significant mental disorders (Costello et al., 2003; U.S. Surgeon General, 1999), and about three-quarters of adult disorders first appear by age twenty-four; half begin as early as fourteen (Egan & Asher, 2005; Kessler, Berglund, et al., 2005).

Bear in mind, though, that the prevalence of psychological disorders may be even higher than the percentages just cited. For one thing, major survey studies have examined fewer than half of all known psychological disorders. Further, these studies count each case only once, even though about 45 percent of people who are diagnosed with one disorder actually display *comorbidity*, meaning that they are diagnosed as having two or even three disorders (Kessler, Chiu, et al., 2005; National Institute of Mental Health, 2006). Finally, surveys fail to count people whose symptoms are not quite severe enough to be labeled as a disorder, but who

● **psychopathology** Patterns of thinking, feeling, and behaving that are maladaptive, disruptive, or uncomfortable for those who are affected or for those with whom they come in contact.

FIGURE 15.1**Incidence of Specific Psychological Disorders**

Several large-scale surveys of adults in the United States revealed that about 30 percent of them experience some form of mental disorder in any given year and that almost half of them have displayed a disorder at some time in life. Indeed, one recent survey suggested that only about 20 percent of adults in the U.S. are both free of any form of mental disorder and flourishing (Keyes, 2007). The data shown here summarize the lifetime findings by category of disorder. The same general patterns appear among the more than 400 million people worldwide who suffer from some form of psychological disorder (Andrade et al., 2002; Bjil et al., 2003; Liu et al., 2002; World Health Organization Mental Health Survey Consortium, 2004).

are nevertheless suffering and whose functioning is somewhat impaired (Faravelli et al., 2006).

Psychological disorders are enormously costly in terms of human suffering, wasted potential, and lost resources (e.g., Adler et al., 2006; Kessler, Adler, et al., 2006). They are the leading cause of disability in the United States and Canada for persons aged fifteen to forty-four (National Institute of Mental Health, 2006), and a similar pattern appears around the world. One study found that psychological disorders ranked second (after cardiovascular disease) in producing disability and shortened life expectancy in industrialized economies (World Health Organization Mental Health Survey Consortium, 2004). The impact of these disorders is even greater in less-developed countries where treatment is less available (Druss, Rosenheck, & Sledge, 2000; Gureje et al., 2006; Kawakami et al., 2005; Medina-Mora et al., 2005; Miller, 2006; Stewart et al., 2003).

Beyond causing personal suffering and disability, psychological disorders also impose a huge financial burden on families, communities, and society (Druss et al., 2000; Lyons & McLoughlin, 2001; Marcotte & Wilcox-Goek, 2001; Stewart et al., 2003). Let's consider how these disorders are defined and classified.

Defining Psychological Disorders

A California woman's husband dies, and in her grief she stays in bed all day, weeping, refusing to eat, at times holding "conversations" with him. In India, a Hindu holy man on a pilgrimage rolls along the ground across a thousand miles of deserts and mountains, pelted by monsoon rains, until he reaches the sacred place he seeks. In the Middle East, a young man straps explosives to his body and detonates them in a crowded market, killing himself and dozens of others. In London, a British artist randomly scratches parked cars as part of his "creative process." Eight percent of adults in the United States say they have seen a UFO (CNN/Time, 1997), and hundreds of people around the world claim to have been abducted by space aliens (Clancy, 2005). These examples and countless others raise the question of where to draw the line between normality and abnormality, between eccentricity, criminality, and mental disorder.

Is This Man Abnormal? Whether unusual individuals are labeled “abnormal” and perhaps given treatment for psychological disorder depends on a number of factors, including how *abnormality* is defined by the culture in which they live, who is most directly affected by their behavior, and how much distress they suffer or cause.

● What Is Abnormal?

There are several criteria for judging whether people’s thinking, emotions, or behaviors are abnormal. Each criterion has value but also some flaws.

● **Infrequency** If we define *normality* as what most people do, an obvious criterion for abnormality is *statistical infrequency*—that which is unusual. By this criterion, the few people who believe that space aliens are stealing their thoughts would be judged abnormal, and the many people who worry about crime or terrorism would not. But statistical infrequency alone is a poor criterion for abnormality, because some characteristics that appear only rarely—such as creative genius or world-class athletic ability—may be highly valued. Further, this definition implies that only those who conform to all aspects of the majority’s standards are normal. Equating nonconformity with abnormality can result in the oppression of those who express minority views in a society. Finally, just how rare must a behavior be to warrant the designation of “abnormal”? The dividing line is not easy to locate.

● **Norm Violation** Abnormality can also be defined in terms of whether someone violates social norms—the cultural rules that tell us how we should and should not behave in various situations, especially in relation to others (see the chapter on social influence). According to this *norm violation* criterion, when people behave in ways that are bizarre, unusual, or disturbing enough to violate social norms, they may be described as abnormal. From this perspective, identifying psychopathology and deciding who “has it” depends in part on how a society defines *normal* and *abnormal* (Castillo, 1997).

Like infrequency, though, norm violation alone is an inadequate measure of abnormality. For one thing, some norm violations are better characterized as eccentric or illegal than as abnormal. People who seldom bathe or who stand too close during conversation violate social norms, but are they abnormal or merely annoying? Further, whose norms are we talking about? Social norms vary across cultures, subcultures, and historical eras, so actions that qualify as abnormal in one part of the world might be perfectly acceptable elsewhere.

● **Personal Suffering** Another criterion for abnormality is *personal suffering*. In fact, experiencing distress is the criterion that people often use in deciding that their psychological problems are severe enough to require treatment. But personal suffering alone is an inadequate criterion for abnormality. It does not take into account the fact that people are sometimes distressed about characteristics (such as being gay or lesbian) that are not mental disorders. Further, people can display psychological disorders without experiencing distress if the disorders have impaired their ability to recognize how maladaptive their behavior is. Those who sexually abuse children, for example, create far more distress in victims and their families than they suffer themselves.

 LINKAGES (a link to Social Influence, p. 723)

● Behavior in Context: A Practical Approach

Because no single criterion is entirely adequate for identifying abnormality, mental health practitioners and researchers tend to adopt a *practical approach* that combines aspects of all the criteria we have discussed. They consider the *content* of behavior (what the person does); the sociocultural *context* in which the person’s behavior occurs; and the *consequences* of the behavior for that person, as well as for others. This practical approach pays special attention to whether a person’s thoughts, behavior, or emotions cause **impaired functioning**—that is, difficulty in fulfilling appropriate and expected family, social, and work-related roles (U.S. Surgeon General, 1999; Wakefield, 1999).

● **impaired functioning** Difficulty in fulfilling appropriate and expected family, social, and work-related roles.

Situational Factors in Defining Abnormality

When men in Delhi, India, need a restroom, they can take advantage of outdoor urinals like this one. In some countries, it is even acceptable for men to urinate against buildings on city streets. In the United States and many other places, though, males who urinate anywhere other than the relative privacy of a men's room are considered to be deviant and might even be arrested for indecent exposure. In other words, situational factors can determine whether a particular behavior is labeled “normal” or “abnormal.” Make a list of the reasons you would give for, or against, calling these men “abnormal.” Which criteria for abnormality did you use?

What is “appropriate” and “expected” depends on age, gender, and culture, as well as on the particular situation and historical era in which people find themselves. For example, the same short attention span that is considered normal in a two-year-old would be considered inappropriate and problematic in an adult. There are gender-specific norms as well. In some countries, for example, it is more appropriate for women than for men to display emotion. Kisses, tears of happiness, and long embraces are common when women greet each other after a long absence. Men tend to simply shake hands or, at most, hug briefly. Because of cultural differences, hearing a dead relative’s voice calling from the afterlife would be more acceptable in certain North American Indian tribes than among, say, the families of suburban Toronto. Situational factors are important, too. Falling to the floor and speaking an unintelligible language is considered appropriate, even desirable, during the worship services of certain religious groups, but the same behavior would be seen as inappropriate, and a sign of disorder, in a college classroom. Finally, judgments about behavior are shaped by changes in social trends and cultural values. For example, the American Psychiatric Association once listed homosexuality as a mental disorder but dropped this category from its *Diagnostic and Statistical Manual of Mental Disorders* in 1973. In taking this step, it was responding to changing views of homosexuality that were prompted in part by the political and educational efforts of gay and lesbian rights groups.

In summary, it is difficult, and probably impossible, to define a specific set of behaviors that everyone, everywhere, will agree constitutes abnormality. The practical approach defines abnormality as including those patterns of thought, behavior, and emotional reaction that significantly impair people’s functioning within their culture (Wakefield, 1992).

Explaining Psychological Disorders

Since the dawn of civilization, people throughout the world have tried to understand the causes of psychological disorder. The earliest explanations of abnormal behavior focused on possession by gods or demons. Disordered people were seen either as innocent victims of spirits or as social or moral deviants suffering supernatural

An Exorcism The exorcism being performed by this Buddhist monk in Thailand is designed to cast out the evil forces seen as causing this child's disorder. Supernatural explanations of mental disorder remain influential among religious groups in many cultures and subcultures around the world (Fountain, 2000). Awareness of this influence in the United States and Europe has increased recently following cases in which people have died during exorcism rituals (e.g., Christopher, 2003; Radford, 2005).

punishment. In Europe during the late Middle Ages, for example, people who displayed threatening or unusual behavior were seen as controlled by the devil or other evil beings. Supernatural explanations of psychological disorders are still invoked today in many cultures around the world—including certain ethnic and religious subcultures in North America (Glazer et al., 2004; Nickell, 2001; Tagliabue, 1999).

● The Biopsychosocial Model

More generally, however, researchers in Western cultures attribute psychopathology to three other causes: biological factors, psychological processes, and sociocultural contexts. For many decades, there was controversy over which of these three causes is most important, but it is now widely agreed that they can all be important. Accordingly, researchers have adopted a **biopsychosocial model** in which mental disorders are seen as caused by the combination and interaction of biological, psychological, and sociocultural factors, each of which contributes in varying degrees to particular problems in particular people (Krueger & Markon, 2006; Nater et al., 2006; U.S. Surgeon General, 1999).

● **Biological Factors** The *biological factors* thought to be involved in causing mental disorders include physical illnesses, disruptions or imbalances in bodily processes, and genetic influences. This *medical model* of psychopathology has a long history. For example, the ancient Greek physician Hippocrates said that psychological disorders resulted from imbalances among four *humors*, or bodily fluids (blood, phlegm, black bile, and yellow bile). According to Hippocrates, depression (“melancholia”) resulted from an excess of black bile. In ancient Chinese cultures, psychological disorders were seen as resulting from an imbalance of *yin* and *yang*, the dual forces of the universe flowing in the physical body.

As the medical model gained prominence in Western cultures after the Middle Ages, specialized hospitals for the insane were established throughout Europe. Treatment in these early asylums consisted mainly of physical restraints, laxative purges, bleeding of “excess” blood, and induced vomiting. Cold baths, fasts, spinning chairs, and other physical discomforts were also used in efforts to “shock” patients back to normality.

● **biopsychosocial model** A view of mental disorders as caused by a combination of interacting biological, psychological, and sociocultural factors.

Visiting Bedlam As shown here in William Hogarth's portrayal of "Bedlam" (slang for London's St. Mary's of Bethlehem hospital), most asylums of the 1700s were little more than prisons. Notice the well-dressed visitors; in those days, people could buy tickets to tour the cells and gawk at the patients.

The medical model led to a view of abnormality as *mental illness*, and in fact, most people in Western cultures today still tend to seek medical doctors and hospitals for the diagnosis and treatment of psychological disorders (Wang et al., 2006). The medical model is now more properly called the **neurobiological model**, because it explains psychological disorders in terms of particular disturbances in the anatomy and chemistry of the brain and in other biological processes, including genetic influences (e.g., Kendler, 2005; Plomin & McGuffin, 2003). Neuroscientists and others who adopt a neurobiological approach study the causes and treatment of these disorders as they would study any physical illness, seeing problematic symptoms stemming primarily from an underlying neurological disturbance that can be diagnosed, treated, and cured.

The importance of biological factors in psychopathology has been demonstrated in many psychological disorders. *Dementia*, for example, is characterized by a loss of mental functions, including disturbances in memory, personality, and cognitive abilities. The most frequent causes of dementia are progressive deterioration of the brain as a result of aging or long-term alcohol abuse; acute diseases and disorders such as encephalitis, brain tumors, or head injury; and drug intoxication. Alzheimer's disease is a severe form of dementia seen mostly in the elderly. Research in neuroscience and behavioral genetics has also identified biological factors in a number of other psychological disorders to be described later, including schizophrenia, bipolar disorders, some forms of anxiety disorder, and autism and attention deficit disorder (Kendler, 2001).

● **Psychological Processes** If biological factors provide the “hardware” of mental disorders, the “software” includes psychological factors, such as our wants, needs, and emotions; our learning experiences; our attachment history; and our way of looking at the world. The roots of this **psychological model** of mental disorders can be seen in ancient Greek literature and drama dealing with the *psyche*, or mind—especially with the mind's struggles to resolve inner conflicts or to overcome the effects of stressful events. These ideas took center stage in the late 1800s, when Sigmund Freud challenged the assumption that psychological disorders had only physical causes. As described in the personality chapter, Freud's explanations of

- **neurobiological model** A modern name for the medical model, in which psychological disorders are seen as reflecting disturbances in the anatomy and chemistry of the brain and in other biological processes.
- **psychological model** A view in which mental disorder is seen as arising from psychological processes.

LINKAGES (a link to Learning, p. 204)

mental disorders were part of his *psychodynamic approach*. He believed that those disorders are the result of unresolved, mostly unconscious conflicts that begin in childhood. These conflicts pit people's inborn impulses against the limits placed on those impulses by society. More recent psychodynamic explanations—such as *object relations* theory—focus less on unconscious urges and more on the role of attachment and other early interpersonal relationships (Bienenfeld, 2005; Schultz & Schultz, 2005).

Other theories discussed in the personality chapter suggest other psychological processes that can contribute to the development of mental disorders. For example, *social-cognitive* theorists, also known as *social learning* theorists, see most psychological disorders as resulting from the interaction of past learning and current situations. Just as people learn to avoid hot grills after being burned, say these theorists, bad experiences in school or a dental office can “teach” people to fear such places. Social-cognitive theorists also emphasize that learned expectations, schemas, and other mental processes discussed in the chapter on cognition and language can influence the development of disorders (e.g., Johnson-Laird, Mancini, & Gangemi, 2006). Depression, for example, is seen as stemming from negative events, such as losing a job, but also from the irrational or maladaptive thoughts that people have learned in relation to these events—thoughts such as “I never do anything right.”

Finally, the *humanistic* approach to personality suggests that behavior disorders appear when a person's natural tendency toward healthy growth is blocked, usually by a failure to be aware of, and to express, true feelings. When this happens, the person's perceptions of reality become distorted. The greater the distortion, the more serious the psychological disorder. Humanistic psychologists also focus on the meanings that people attach to events and how those meanings can lead to adaptive or maladaptive reactions.

● **Sociocultural Context** Together, neurobiological and psychological factors go a long way toward explaining many forms of mental disorder. Still, these factors relate mainly to causes residing within the individual. The **sociocultural model** of disorder suggests that we cannot fully explain all forms of psychopathology without also looking outside the individual—especially at the social and cultural factors that form the background of abnormal behavior. Looking for causes of disorders in this *sociocultural context* means paying attention to factors such as gender, age, and marital status; the physical, social, and economic situations in which people live; and the cultural values, traditions, and expectations in which they are immersed (Evans et al., 2000; Lim, 2006; Martinez-Taboas, 2005). Sociocultural context influences not only what is and is not labeled “abnormal” but also who displays what kind of disorder and how likely they are to receive treatment for it.

Consider gender, for instance. The greater tolerance in many cultures for the open expression of emotional distress among women, but not men, may contribute to the higher rates of depression seen in women compared with men (Hightower, 2005; Wupperman & Neumann, 2006). Similarly, the view held in many cultures that excessive alcohol consumption is less appropriate for women than for men is a sociocultural factor that may help explain higher rates of alcohol abuse among men in those cultures (Helzer et al., 1990; Timko, Finney, & Moos, 2005).

Sociocultural factors can influence the overall prevalence of disorders, too. For instance, anxiety disorders and depression tend to be less common in Japan than in Western countries, including the United States (Kawakami et al., 2005). And many kinds of psychological disorders increase in frequency among people living in countries ravaged by wars or other stressful conditions (Karam et al., 2006).

Sociocultural factors also influence the form that abnormality takes. For example, depression is a *culture-general* disorder—appearing virtually everywhere in the world—but the symptoms that sufferers report tend to differ depending on cultural background (Falicov, 2003; Hopper & Wanderling, 2000). In Western cultures, emotional and physical components of disorders are generally viewed separately, so

- **sociocultural model** A way of looking at mental disorders in relation to gender, age, ethnicity and other social and cultural factors.

symptoms of depression tend to revolve around despair and other signs of emotional distress. But in China, Japan, and certain other Asian cultures, emotional and physical experiences tend to be viewed as one, so a depressed person is as likely to report stomach or back pain as to complain of sadness (Karasz, 2005; Kleinman, 2004; Nakao & Yano, 2006).

There are also culture-specific forms of disorder. For instance, Puerto Rican, Guatemalan, Mexican, and Dominican Hispanic women sometimes experience *ataques de nervios* (“attack of nerves”), a unique way of reacting to stress that includes heart palpitations, shaking, shouting, nervousness, depression, and, on occasion, fainting or seizure-like episodes (Baer, Weller, et al., 2003; Spiegel, 1994). Another example can be found in Southeast Asia, southern China, Malaysia, and West African nations where a disorder called *koro* is occasionally observed. Victims of this condition, who are usually male, fear that their penis will shrivel, retract into the body, and cause death (in females, the fear relates to shriveling of the breasts). Epidemics of *koro*, often triggered by economic hard times, appear only in cultures that hold the specific supernatural beliefs that explain it (Dzokoto & Adams, 2005; Tseng et al., 1992).

In short, sociocultural factors create differing stressors, social roles, opportunities, experiences, and avenues of expression for different groups of people. They also help shape the disorders and symptoms to which certain categories of people are prone, and they even affect responses to treatment. For example, among people diagnosed with schizophrenia, those living in a developing country such as India are much more likely to improve than those living in a more developed country, such as the United States (Hopper & Wanderling, 2000). We don’t yet know for certain what is responsible for this difference, but it may have something to do with the ways in which schizophrenia is understood in different cultures. In the West, schizophrenia is considered a chronic, debilitating, potentially dangerous, long-term illness. As a result, many people diagnosed with schizophrenia find themselves left on the fringes of society. In some non-Western societies, the disorder is seen as less severe and less resistant to treatment. Perhaps this more optimistic view encourages more intense efforts at socialization and, as a result, better outcomes (Mathews, Basily, & Mathews, 2006). Whatever the explanation, these data highlight the fact that any attempt to fully explain psychological disorders must take sociocultural factors into account.

● Diathesis-Stress as an Integrative Explanation

The biopsychosocial model is currently the most comprehensive and influential approach to explaining psychological disorders. It is prominent partly because it encompasses so many important causal factors, including biological imbalances, genetically inherited characteristics, brain damage, enduring psychological traits, socioculturally influenced learning experiences, stressful life events, and many more.

But how do all these factors interact to actually create disorder? Most researchers believe that inherited characteristics, biological processes, and early learning experiences combine to create a predisposition, or *diathesis* (pronounced “dye-A-thuh-sis”), for a psychological disorder. Whether or not a person actually develops symptoms of a disorder depends on the nature and amount of stress the person encounters (Turner & Lloyd, 2004; U.S. Surgeon General, 1999). For example, a person may have inherited a biological tendency toward depression or may have learned depressing patterns of thinking, but these predispositions may not be expressed as a depressive disorder unless the person is faced with a financial crisis or suffers the loss of a loved one. If such major stressors don’t occur, or if the person has adequate skills for coping with them, depressive symptoms may never appear or may be relatively mild (Canli et al., 2006).

This way of thinking about the biopsychosocial model is known as the **diathesis-stress approach**. It assumes that biological, psychological, and socio-cultural factors can predispose us toward a disorder but that it takes a certain amount of stress to actually trigger that disorder. People with a strong diathesis

- **diathesis-stress approach** Viewing psychological disorders as arising when a predisposition for a disorder combines with sufficient amounts of stress to trigger symptoms.

TABLE 15.1 The Biopsychosocial Model of Psychopathology

Here are the factors that would be considered by the biopsychosocial model, and combined in the diathesis-stress approach, to explain the case of José, a fifty-five-year-old electronics technician. A healthy and vigorous father of two adult children, he was recently forced to take medical leave because of a series of sudden, uncontrollable panic attacks in which he experienced dizziness, heart palpitations, sweating, and fear of impending death. The attacks also kept him from his favorite pastime, scuba diving, but he has been able to maintain a part-time computer business out of his home. (Panic disorder is discussed in more detail later in this chapter; the outcome of this case is described in the chapter on treatment of psychological disorders.)

| Explanatory Domain | Possible Contributing Factors |
|---------------------------------|---|
| Neurobiological/medical | José may have organic disorders (e.g., genetic tendency toward anxiety; brain tumor, endocrine dysfunction; neurotransmitter imbalance). |
| Psychological: psychodynamic | José has unconscious conflicts and desires. Instinctual impulses are breaking through ego defenses into consciousness, causing panic. |
| Psychological: social-cognitive | Physical stress symptoms are interpreted as signs of serious illness or impending death. Panic is rewarded by avoidance of work stress and the opportunity to stay home. |
| Psychological: humanistic | José fails to recognize his genuine feelings about work and his place in life, and he fears expressing himself. |
| Sociocultural | A culturally based belief that “a man should not show weakness” amplifies the intensity of stress reactions and delays José’s decision to seek help. |
| Diathesis-stress summary | José has a biological (possibly genetic) predisposition to be overly responsive to stressors. The stress of work and extra activity exceeds his capacity to cope and triggers panic as a stress response. |

are more vulnerable, so even relatively mild stress might be enough to create a problem. People whose diathesis is weaker might not show signs of a disorder until stress becomes extreme or prolonged. Another way to think about the notion of diathesis-stress is in terms of *risk*: The more risk factors for a disorder a person has—whether in the form of genetic tendencies, personality traits, cultural traditions, or stressful life events—the more likely it is that the person will display a form of psychological disorder associated with those risk factors.

Table 15.1 provides an example of how the diathesis-stress approach and the factors contained in the biopsychosocial model of disorder might explain a particular case of psychopathology. Throughout this chapter, you’ll see how these concepts are being applied in an effort to understand the causes of several other psychological disorders (Hankin & Abela, 2005; Hastings & Nuselovici, 2006).

Classifying Psychological Disorders

Although definitions of abnormality differ somewhat within and across cultures, there is a set of culture-general and culture-specific behavior patterns that characterize what most mental health professionals consider to be psychopathology. Most of these behavior patterns qualify as disorders because they result in impaired functioning, a main criterion of the practical approach to defining abnormality. It has long been the goal of those who study abnormal behavior to organize these patterns into a system of diagnostic categories.

The main purpose of diagnosing psychological disorders is to determine the nature of people’s problems. Once the characteristics of the problems are understood, the most appropriate method of treatment can be chosen. Diagnoses are also important for research on the causes of mental disorders. If researchers can accurately and

reliably classify people into particular disorder categories, they will have a better chance of spotting genetic flaws, biological abnormalities, cognitive processes, and environmental experiences that people in the same category might share. Finding that people in a certain diagnostic category share a set of features that differs from those seen in other categories could provide clues about which features are related to the development of each disorder. In short, proper classification can lead to the discovery of causes.

In 1952 the American Psychiatric Association published the first edition of what has become the official North American diagnostic classification system, the *Diagnostic and Statistical Manual of Mental Disorders (DSM)*. Each new edition of the *DSM* has included more categories of disorders. The latest editions, *DSM-IV* and *DSM-IV-TR* (which contains some text revisions), include more than three hundred specific diagnostic labels (American Psychiatric Association, 1994, 2000). Each of these editions was designed to further improve the quality of the diagnostic system by taking into account the results of the most recent research on psychopathology.

Mental health professionals outside North America diagnose mental disorders using the classification systems that appear in the tenth edition of the World Health Organization's *International Classification of Diseases (ICD-10)* and its companion volume, the second edition of the *International Classification of Impairments, Disabilities and Handicaps (ICIDH-2)*. To facilitate international communication about—and cross-cultural research on—psychopathology, *DSM-IV* was designed to be compatible with these manuals, and efforts are under way to remove inconsistencies existing between the systems (Helzer & Hudziak, 2002; Regier et al., 2005; Widiger et al., 2006).

● A Classification System: *DSM-IV*

DSM-IV describes the abnormal patterns of thinking, emotion, and behavior that define various mental disorders. For each disorder, *DSM* provides specific criteria outlining the conditions that must be present before a person can be given that diagnostic label. Diagnosticians using *DSM-IV* can evaluate troubled people on as many as five dimensions, or *axes* (the plural of *axis*). In keeping with the biopsychosocial model, evaluations on all relevant dimensions are combined to create a broad outline of the person's biological and psychological problems, as well as of any socio-cultural factors that might contribute to them. As shown in Table 15.2, major mental disorders, such as schizophrenia or major depressive disorder, are recorded on Axis I. Personality disorders, mental retardation, and other lifelong conditions that tend not to change much over time are noted on Axis II. Any medical conditions that might be important in understanding the person's cognitive, emotional, or behavioral problems are listed on Axis III. On Axis IV the diagnostician notes any psychosocial and environmental factors that are important for understanding the person's psychological problems. These factors include, for example, the loss of a loved one, physical or sexual abuse, discrimination, unemployment, poverty, homelessness, inadequate health care, or conflict with religious or cultural traditions. Finally, a rating (from 100 down to 1) of the person's current level of psychological, social, and occupational functioning appears on Axis V. Here is a sample *DSM-IV* diagnosis for a person who received labels on all five axes:

- Axis I* Major depressive disorder, single episode; alcohol abuse.
- Axis II* Dependent personality disorder.
- Axis III* Alcoholic cirrhosis of the liver.
- Axis IV* Problems with primary support group (death of spouse).
- Axis V* Global assessment of functioning: 50

TABLE 15.2 The *Diagnostic and Statistical Manual of Mental Disorders (DSM)* of the American Psychiatric Association

Axis I of the fourth edition (*DSM-IV*) lists the major categories of mental disorders.

Personality disorders and mental retardation are listed on Axis II.

Axis I (Clinical Syndromes)

1. **Disorders usually first diagnosed in infancy, childhood, or adolescence.** Problems such as hyperactivity, childhood fears, conduct disorders, frequent bed-wetting or soiling, and other problems in normal social and behavioral development. Autistic disorder (severe impairment in social, behavioral, and language development), as well as learning disorders.
2. **Delirium, dementia, and amnestic and other cognitive disorders.** Problems caused by physical deterioration of the brain due to aging, disease, drugs or other chemicals, or other possible unknown causes. These problems can appear as an inability to “think straight” (delirium) or as loss of memory and other intellectual functions (dementia).
3. **Substance-related disorders.** Psychological, behavioral, physical, social, or legal problems caused by dependence on, or abuse of, a variety of chemical substances, including alcohol, heroin, cocaine, amphetamines, hallucinogens, marijuana, and tobacco.
4. **Schizophrenia and other psychotic disorders.** Severe conditions characterized by abnormalities in thinking, perception, emotion, movement, and motivation that greatly interfere with daily functioning. Problems involving false beliefs (delusions).
5. **Mood disorders (also called affective disorders).** Severe disturbances of mood, especially depression, overexcitement (mania), or alternating episodes of each extreme (as in bipolar disorder).
6. **Anxiety disorders.** Specific fears (phobias); panic attacks; generalized feelings of dread; rituals of thought and action (obsessive-compulsive disorder) aimed at controlling anxiety; and problems caused by traumatic events, such as rape or military combat (see the chapter on health, stress, and coping for more on posttraumatic stress disorder).
7. **Somatoform disorders.** Physical symptoms, such as paralysis and blindness, that have no physical cause. Unusual preoccupation with physical health or with nonexistent physical problems (hypochondriasis, somatization disorder, pain disorder).
8. **Factitious disorders.** False mental disorders, which are intentionally produced to satisfy some psychological need.
9. **Dissociative disorders.** Psychologically caused problems of consciousness and self-identification—e.g., loss of memory (amnesia) or the development of more than one identity (multiple personality).
10. **Sexual and gender identity disorders.** Problems of (a) finding sexual arousal through unusual objects or situations (like shoes or exposing oneself), (b) unsatisfactory sexual activity (sexual dysfunction; see the chapter on motivation and emotion), or (c) identifying with the opposite gender.
11. **Eating disorders.** Problems associated with eating too little (anorexia nervosa) or binge eating followed by self-induced vomiting (bulimia nervosa). (See the chapter on motivation and emotion.)
12. **Sleep disorders.** Severe problems involving the sleep-wake cycle, especially an inability to sleep well at night or to stay awake during the day. (See the chapter on consciousness.)
13. **Impulse control disorders.** Compulsive gambling, stealing, or fire setting.
14. **Adjustment disorders.** Failure to adjust to, or deal well with, such stressors as divorce, financial problems, family discord, or other unhappy life events.

Axis II (Personality Disorders and Mental Retardation)

1. **Personality disorders.** Diagnostic labels given to individuals who may or may not receive an Axis I diagnosis but who show lifelong behavior patterns that are unsatisfactory to them or that disturb other people. These patterns may involve unusual suspiciousness, unusual ways of thinking, self-centeredness, shyness, overdependency, excessive concern with neatness and detail, or overemotionality, among others.
2. **Mental retardation.** As described in the chapter on cognitive abilities, the label of mental retardation is applied to individuals whose measured IQ is less than about 70 *and* who fail to display the skills of daily living, communication, and other tasks expected of people their age.

Notice that the terms *neurosis* and *psychosis* are not included as they once were in *DSM*. They were dropped because they are too vague, but some mental health professionals still sometimes use them as shorthand descriptions. *Neurosis* refers to conditions in which some form of anxiety is the major characteristic. *Psychosis* refers to conditions involving severe thought disorders that leave people “out of touch with reality” or unable to function on a daily basis. The disorders once gathered under these headings now appear in various Axis I categories in *DSM-IV*.

Further changes will undoubtedly appear in *DSM-V*, a new edition of *DSM* that is currently under development. For example, because it is common for certain kinds of disorders, such as anxiety and depression, to appear together, *DSM-V* diagnoses may include some labels that designate “mixed” disorders (Barlow & Campbell, 2000). Or there may be a mood-anxiety category that contains three subcategories: distress disorders (e.g., depression, generalized anxiety disorder, posttraumatic stress disorder), bipolar disorders (e.g., bipolar I and bipolar II disorders), and fear disorders (e.g., panic disorder, phobias) (Watson, 2005). Another proposal is to organize *DSM-V* around symptom clusters or symptom dimensions rather than around specific diagnostic categories (Vollenbergh et al., 2001; Widiger & Simonsen, 2005; Widiger & Trull, 2007; Zachar & Kendler, 2007). The idea behind this *dimensional approach* would be to create a set of symptom “building blocks” that could be combined in many different ways so as to better describe the precise contours of each person’s problems. Ratings of the severity of symptoms in each dimension would paint an even more detailed and meaningful picture of the problems a person is experiencing, a picture that would be of more use to clinicians (Krueger & Markon, 2006; Samuel & Widiger, 2006). Still other proposals for *DSM-V* include basing diagnoses on the results of brain imaging and analysis of people’s genetic characteristics (Beutler & Malik, 2002; Bracha, 2006; Helzer & Hudziak, 2002; Maj et al., 2002).

To broaden the diagnostic process even further, some researchers have suggested that mental health professionals should consider not just people’s weaknesses and problems, but also their character strengths, virtues, prosocial values, and other psychological resources upon which they can potentially build during treatment. For example, each problem-oriented *DSM* diagnosis could be supplemented by a list of the strengths (such as resilience, courage, kindness, and tolerance) that contribute to the level of functioning rating that is noted on Axis V. Some researchers have even offered comprehensive lists of human strengths and values from which diagnosticians can choose (Park, Peterson, & Seligman, 2004; Peterson, 2006). From the perspective of *positive psychology*, then, diagnosis via the *DSM* alone is seen as valuable, but incomplete. It not only tends to ignore people’s strengths and values, but it also fails to recognize that people who *lack* certain character strengths and prosocial values can experience or cause a significant amount of discomfort and social impairment, even if they don’t meet the “official” criteria for mental disorder.

● Evaluating the Diagnostic System

Many possible changes are on the horizon, but how good is the diagnostic system now in use? One way to evaluate *DSM-IV* is to consider *interrater reliability*, the degree to which different mental health professionals give the same person the same diagnostic label. Some studies indicate that interrater agreement is as high as 83 percent for schizophrenia and mood disorders. Agreement on many other Axis I categories, such as anxiety, mood disorders, and schizophrenia is also high (e.g., Brown et al., 2001; Jakobsen et al., 2005; Nathan & Langenbucher, 1999; Simpson et al., 2002). Still other categories, such as somatoform disorders and Axis II personality disorders, remain more difficult to diagnose reliably (Mayou et al., 2005; Shedler & Westen, 2004; Westen, Shedler, & Bradley, 2006; Zanarini et al., 2000). The reliability of a diagnosis depends partly on the extent to which clinicians all use similar assessment methods. For example, interrater agreement appears highest overall when diagnosis is based on structured or semistructured interviews that systematically address various areas of functioning and provide uniform guidelines for interpretation of the answers that people give (Rogers, 2003; Widiger & Sanderson, 1995).

Do diagnostic labels give accurate information that guides correct inferences about people? This *validity* question is difficult to answer because it is hard to find a fully acceptable standard for accuracy. Should a diagnosis be evaluated by comparing it with judgments of experts or with neurological measurements? Should it be evaluated by how well it predicts the diagnosed person’s behavior? Despite having no single standard available, there is evidence to support the validity of most *DSM* criteria (e.g.,

Deep-Soboslay et al., 2006; Keenan & Wakschlag, 2004; Langenbucher & Nathan, 2006; Simon & von Korff, 2006). As with reliability, though, validity is stronger for some diagnoses (e.g., schizophrenia, depression) than for others (e.g., ADHD, somatoform disorders). Validity is likely to improve further as diagnostic labels—and the diagnostic system—are refined in *DSM-V* to reflect what researchers are learning about the characteristics, causes, courses, and cultural factors involved in various disorders.

Still, the diagnostic system is far from perfect (Beutler & Malik, 2002; Kendell & Jablensky, 2003; Krueger & Markon, 2006; Nestadt et al., 2005; Widiger & Sankis, 2000). First, as already mentioned, people's problems often do not fit neatly into a single category; mixed (or “comorbid”) disorders are common. Second, the same symptom (such as sleeplessness) may appear as part of more than one disorder. Third, *DSM-IV* specifies that, in order to be given a particular diagnosis, a person must display a certain number of symptoms at a certain level of severity for a certain period of time. If these criteria are met, a person is said to “have” a certain disorder. But in setting these criteria, the authors of *DSM-IV* had to identify some rather arbitrary boundaries between “having” a disorder and “not having” it. These sharp boundaries fail to capture the varying levels of distress that different people might be experiencing. Further, diagnostic criteria often specify that there be “clinically significant impairment,” but they provide few if any guidelines for what that phrase means. When mental health professionals must decide for themselves whether a particular person's symptoms are severe enough to warrant a particular diagnosis, personal bias can creep into the system (Kim & Ahn, 2002; Widiger & Clark, 2000). All of these factors can lead to misdiagnosis in some cases. Concern over this possibility is especially relevant as the nations of North America and Western Europe become increasingly multicultural. The current *DSM* disorder categories sometimes fail to take into account the ways that different cultures influence the experience and expression of distress. Diagnosticians in these countries are encountering more and more people whose cultural backgrounds they may not fully understand and whose behavior they may misunderstand.

Some people whose behavior differs enough from cultural norms to cause annoyance feel that society should tolerate their “neurodiversity” instead of giving them a diagnostic label (Harmon, 2004). In the same vein, Thomas Szasz (pronounced “zaws”) and other critics of the medical model (e.g., Caplan, 1995; Kutchins & Kirk, 1997; Peterson, 2003; Snyder & Lopez, 2006; Szasz, 2003; Wampold, Ahn, & Coleman, 2001) argue that labeling people instead of describing them is dehumanizing because it ignores features that make each person unique. Calling people “schizophrenics” or “alcoholics,” Szasz says, may actually encourage the behaviors associated with these labels and undermine the confidence of clients (and therapists) about the chances of improvement.

In summary, the current system for diagnosing psychological disorders has not satisfied everyone, and it is unlikely that any system ever will. No shorthand diagnostic label can fully describe a person's problems or predict exactly how that person will behave. All that can be reasonably expected of a diagnostic system is that it is based on the latest research on psychopathology and that it provides informative, general descriptions of the types of problems displayed by people who have been placed in various categories (First et al., 2004).

THINKING CRITICALLY

Is Psychological Diagnosis Biased?

Some researchers and clinicians worry that problems with the reliability and validity of the diagnostic system are due partly to bias in its construction and use. They point out, for example, that if the diagnostic criteria for various disorders are based on research that focused on one culture, one gender, one ethnic group, or one age group, those criteria might not apply to other groups. Moreover, because

diagnosticians, like other people, hold expectations and make assumptions about males versus females and about individuals from differing cultures or ethnic groups, those cognitive biases could color their judgments. This “prejudging” process could lead to the application of diagnostic criteria in ways that are slightly, but significantly, different from one case to the next (Bjorklund, 2006; Garb, 1997; Hartung & Widiger, 1998; Poland & Caplan, 2004). For example, one recent study found that clinicians reading identical case reports were more likely to label patients as schizophrenic if they thought the patients were male (Hoye et al., 2006).

■ What am I being asked to believe or accept?

Here, we focus on ethnicity as a possible source of bias in diagnosing psychopathology. It is of special interest because there is evidence that, like social class and gender, ethnicity is an important sociocultural factor in the development of mental disorder. So the assertion to be considered is that clinicians in the United States base their diagnoses partly on clients’ ethnic background and, more specifically, that there is bias in diagnosing African Americans.

■ What evidence is available to support the assertion?

Several facts suggest the possibility of ethnic bias in psychological diagnosis. For one thing, African Americans receive the diagnosis of schizophrenia more frequently than European Americans do (Barnes, 2004; Kilbourne et al., 2004; Minsky et al., 2003). In fact, one study found that certain kinds of odd symptoms tend to be diagnosed as a mood disorder in European Americans but as schizophrenia in African Americans (Neighbors et al., 2003). Further, relative to their presence in the general population, African Americans are overrepresented in public mental hospitals, where the most serious forms of disorder are seen, and underrepresented in private hospitals and outpatient clinics, where less severe problems are treated (Barnes, 2004; Snowden & Cheung, 1990; U.S. Surgeon General, 1999). African Americans are also more likely than European Americans to be discharged from mental hospitals without a definitive diagnosis, suggesting that clinicians have more difficulty in diagnosing their disorders (Sohler & Bromet, 2003). Other research suggests that emergency room physicians are less likely to recognize psychiatric disorders in African American patients than in patients from other groups (Kunen et al., 2005).

There is also evidence that African Americans and members of other ethnic minority groups are underrepresented in research on mental disorders. One review found that minority participants were included in less than 30 percent of the research published in five leading clinical psychology journals over a seventeen-year period (Iwamasa, Sorocco, & Koonce, 2002). If such underrepresentation leaves clinicians less sensitive to the operation of sociocultural factors in certain groups, the quality of their diagnoses could be affected. For example, a European American diagnostician might interpret an African American patient’s suspiciousness as evidence of paranoid thinking, when it might actually reflect the patient’s history of unpleasant experiences with white authority figures (Whaley, 2001).

■ Are there alternative ways of interpreting the evidence?

Differences among ethnic groups in diagnosis or treatment do not automatically indicate bias based on ethnicity. Perhaps there are real differences in psychological functioning across different ethnic groups. If, relative to other groups, African Americans are exposed to more risk factors for disorder, such as poverty, violence, or other major stressors, they could be more vulnerable to more serious forms of mental disorder (Plant & Sachs-Ericsson, 2004; Turner & Lloyd, 2004). And poverty, not diagnostic bias, could be responsible for the fact that African Americans more often seek help at less expensive public hospitals than at more expensive private ones. Indeed African Americans are more likely than European Americans to bring mental health problems to hospital emergency rooms rather

than to family physicians or other mental health service providers. So perhaps African Americans are less likely to come to the attention of mental health professionals until their disorders have become more severe (Nelson, 2006). Finally, there is no guarantee that diagnostic criteria would be significantly different, or that clinicians would do better at diagnosis, if more African Americans had been included in psychopathology research samples.

■ What additional evidence would help to evaluate the alternatives?

So do African Americans actually display more signs of schizophrenia, or do diagnosticians just perceive them as more disordered? One way of approaching this question is to conduct experiments in which diagnosticians assign labels to clients on the basis of case histories, test scores, and the like. In some studies, the cases are selected so that pairs of clients show about the same degree of disorder, but one member of the pair is identified as European American and the other as African American. In other studies, the same case materials, identified as representing either African American or European American patients, are presented to different diagnosticians. Bias in diagnosis would be suggested if, for example, patients identified as African American were seen as more seriously disordered than others.

The results of such studies are mixed. Most have found little or no ethnic bias (e.g., Angold et al., 2002; Garb, 1997; Kales, 2005a, 2005b; Littlewood, 1992), but because the diagnosticians could have been aware of the purpose of the research, they might have gone out of their way to be unbiased (Abreu, 1999). Some evidence of diagnostic bias against African Americans *has* been found when clinicians were unaware of the purpose of the research (e.g., Baskin, Bluestone, & Nelson, 1981; Jones, 1982).

Bias has also appeared in studies aimed at identifying the factors influencing clinicians' diagnostic judgments following extensive interviews with patients. One study conducted in a hospital setting found that in arriving at their diagnoses, psychiatrists were more likely to attribute hallucinations and paranoid thinking to African American patients than to patients who were not African American. Symptoms of mood disorders were more likely to be attributed to those who were not African American (Trierweiler et al., 2000). As noted earlier, these differences could reflect differences in the rate of disorder in different populations, but when people were interviewed in their own homes as part of large-scale mental health surveys, the diagnosis of schizophrenia was given only slightly more often to African Americans than to European Americans (Robins & Regier, 1991; Snowden & Cheung, 1990). In other words, ethnic bias is suggested, at least for some diagnoses, for patients who are evaluated in mental hospitals (Trierweiler et al., 2000, 2005).

■ What conclusions are most reasonable?

Just as *DSM-IV* is imperfect, so are those who use it. As described in the chapters on cognition and language and on social cognition, biases and stereotypes affect human thinking to some extent in virtually every social situation. It should not be surprising, then, that they operate in diagnosis as well. But diagnostic bias does not necessarily reflect deliberate discrimination. At least one study has shown that, like the processes of prejudice discussed in the chapter on social cognition, diagnostic bias based on ethnicity can operate unconsciously, without the diagnostician's awareness (Abreu, 1999). So no matter how precisely researchers specify the criteria for assigning diagnostic labels, cognitive biases and stereotypes are likely to threaten the objectivity of the diagnostic process (Funtowicz & Widiger, 1999; Poland & Caplan, 2004; Trierweiler et al., 2000).

But a blanket conclusion that the entire diagnostic system is biased against African Americans would be far too general, especially because there is evidence that, given the same symptom information, clinicians are just as likely to assign certain diagnoses, such as depression, to African Americans as to European Americans (Kales et al., 2005a, 2005b). Another study found that African American youngsters

were *less* likely than European American adolescents to receive conduct disorder diagnoses (Pottick et al., 2007). It is probably more accurate to say that there may be a small amount of bias in the way diagnosticians interpret the symptoms of schizophrenia in African Americans and European Americans.

To minimize such bias, Hope Landrine (1991) suggests that diagnosticians focus more intently than ever on the fact that their concepts of “normality” and “abnormality” are affected by sociocultural values that they may not share with a given client (see Kales et al., 2006; Trierweiler et al., 2005). And Steven Lopez (1989) argues that diagnosticians must become more aware that the cognitive shortcuts and biases that affect everyone else’s thinking and decision making can impair their own clinical judgments. In fact, studies of memory, problem solving, decision making, social attributions, and other aspects of culture and cognition may turn out to hold the key to reducing whatever bias may exist in the diagnosis of psychological disorders. Meanwhile, perhaps the best way to counteract clinicians’ cognitive shortcomings is to teach them to base their diagnoses solely on published diagnostic criteria, standardized interview formats, and statistically validated decision rules (aided, perhaps, by specialized computer programs) rather than relying on their potentially biased clinical impressions (Akin & Turner, 2006; Bernstein, Kramer, & Phares, 2008). ■

We don’t have the space to cover all the *DSM-IV* categories, so we will sample several of the most prevalent and socially significant ones. As you read, try not to catch “medical student’s disease.” Just as medical students often think they have the symptoms of every illness they read about, some psychology students worry that their behavior (or that of a relative or friend) signals a mental disorder. Remember that everyone has problems sometimes. Before deciding that you or someone you know needs psychological help, consider whether the content, context, and functional impairment associated with the behavior would qualify it as abnormal according to the criteria of the practical approach.

Anxiety Disorders

If you have ever been tense before an exam, a date, or a job interview, you have some idea of what anxiety feels like. Increased heart rate, sweating, rapid breathing, a dry mouth, and a sense of dread are common features of anxiety. Brief episodes of moderate anxiety are a normal part of life for most people. But when anxiety is so intense and long-lasting that it impairs a person’s daily functioning, it is called an **anxiety disorder**.

Types of Anxiety Disorders

Here we discuss four types of anxiety disorders: *phobia*, *generalized anxiety disorder*, *panic disorder*, and *obsessive-compulsive disorder*. Another type, called posttraumatic stress disorder, is described in the chapter on health, stress, and coping. Together, these are the most common psychological disorders in North America; about 29 percent of the U.S. population will have an anxiety disorder at some point in their lives (Kessler, Berglund, et al., 2005).

- **anxiety disorder** A condition in which intense feelings of apprehension are long-standing and disruptive.
- **phobia** An anxiety disorder involving strong, irrational fear of an object or situation that does not objectively justify such a reaction.
- **specific phobia** An anxiety disorder involving fear and avoidance of heights, animals, and other specific stimuli and situations.

● **Phobia** An intense, irrational fear of an object or situation that is not likely to be dangerous is called a **phobia**. People who experience phobias usually realize that their fears are groundless, but that’s not enough to make the anxiety go away. The continuing discomfort and avoidance of the object or event may greatly interfere with daily life. Thousands of phobias have been described; Table 15.3 lists just a few.

DSM-IV classifies phobias into specific, social, and agoraphobia subtypes. **Specific phobias** include fear and avoidance of heights, blood, animals, automobile

TABLE 15.3 Some Phobias

Phobia is the Greek word for “morbid fear,” after the Greek god Phobos. Phobias are usually named by attaching the word *phobia* to the Greek word for the feared object or situation.

| Name | Feared Stimulus | Name | Feared Stimulus |
|----------------|-------------------|---------------|-----------------|
| Acrophobia | Heights | Aerophobia | Flying |
| Claustrophobia | Enclosed places | Entomophobia | Insects |
| Hematophobia | Blood | Gamophobia | Marriage |
| Gephyrophobia | Crossing a bridge | Ophidiphobia | Snakes |
| Kenophobia | Empty rooms | Xenophobia | Strangers |
| Cynophobia | Dogs | Melissophobia | Bees |

or air travel, and other specific stimuli and situations. In the United States and other developed nations, they are the most prevalent of the anxiety disorders, affecting approximately 9 percent of adults and children (Kessler, Chiu, et al., 2005; National Institute of Mental Health, 2006; U.S. Surgeon General, 1999). Here is an example:

Mr. L. was a fifty-year-old office worker who became terrified whenever he had to drive over a bridge. For years, he avoided bridges by taking round-about ways to and from work, and he refused to be a passenger in anyone else’s car, just in case they might use a bridge. Even this very inconvenient adjustment failed when Mr. L. was transferred to a position requiring frequent automobile trips, many of which were over bridges. He refused the transfer and lost his job.

Social phobias involve anxiety about being criticized by others or acting in a way that is embarrassing or humiliating. The anxiety is so intense and persistent that it impairs the person’s normal functioning. Common social phobias are fear of public speaking or performance (“stage fright”), fear of eating in front of others, and fear of using public restrooms (Kleinknecht, 2000; Noyes & Hoehn-Saric, 2006).

It’s a Long Way Down Almost everyone is afraid of something, but about 9 percent of U.S. adults suffer from a specific phobia, in which fear interferes significantly with daily life. For example, people with acrophobia (fear of heights) would not do well in a job that requires being in this high position.

Anxiety and Depression People who experience anxiety disorders—particularly panic disorder, generalized anxiety disorder, or posttraumatic stress disorder—are likely to display some other mental disorder as well, most often depression (Kaufman & Charney, 2000; Roy-Byrne et al., 2000). Accordingly, the next edition of the *DSM* may include a new category, called *mixed anxiety-depression disorder*, to identify people whose symptoms of anxiety and depression combine to impair their daily functioning.

Generalized social phobia is a more severe form in which fear occurs in virtually all social situations (Mineka & Zinbarg, 2006; Williams et al., 2005). Sociocultural factors can alter the nature of social phobias. For example, in Japan, where cultural training emphasizes group-oriented values and goals, a common social phobia is *tai-jin kyofu sho*, the fear of embarrassing those around you (Kleinknecht, 1994).

Agoraphobia is a strong fear of being away from a safe place, such as home; of being away from a familiar person, such as a spouse or close friend; or of being in a place (such as a crowded theater or mall) that might be difficult to leave or where help may be unavailable. These fears can cause serious problems. People who suffer from agoraphobia typically avoid social situations and refuse to shop, drive, or use public transportation. They may be unable to work and can easily become isolated. In severe cases, agoraphobia can make leaving home such a frightening prospect that people become housebound, unwilling to even try going out alone. Most individuals who display agoraphobia have a history of panic attacks, which we describe later. Their intense fear of public places occurs partly because they don't want to risk triggering an attack by going to places in which they had a previous attack or where they feel an attack would be dangerous or embarrassing (Kessler, Chiu, et al., 2006).

Like other phobias in Western cultures, agoraphobia is more often reported by women. However, in other cultures, such as India, where being a housebound woman is considered less unusual than in the United States, those diagnosed as agoraphobic tend to be male (Raguram & Bhide, 1985). Although agoraphobia occurs at only about one tenth the rate of specific phobias (about 0.8 percent for agoraphobia versus 9 percent for specific phobias in any given year), it is the phobia that most often leads people to seek treatment, mainly because it interferes so severely with everyday life (National Institute of Mental Health, 2006; U.S. Surgeon General, 1999).

● **Generalized Anxiety Disorder** Excessive and long-lasting anxiety that is not focused on any particular object or situation marks **generalized anxiety disorder (GAD)**. Because the problem occurs in almost all situations and because the person cannot pinpoint its source, this type of anxiety is sometimes called *free-floating anxiety*. For weeks at a time, the person feels anxious and worried, sure that some disaster is about to happen. The person becomes jumpy and irritable; sound-sleep is impossible. Fatigue, inability to concentrate, and physiological signs of anxiety are also common. Generalized anxiety disorder affects about 3.1 percent of the U.S. population in any given year and about 5 percent of the population at some point in their lives (Kessler, Berglund, et al., 2005; U.S. Surgeon General, 1999). This disorder tends to appear somewhat later in life than most of the other anxiety disorders (the median age of onset is thirty-one years old for GAD compared with the teens or early twenties for phobias). Generalized anxiety disorder is more common in women, often accompanying other problems such as depression or substance abuse (Wittchen & Hoyer, 2001).

● **Panic Disorder** For some people, anxiety takes the form of **panic disorder**. Like the man described in Table 15.1, people suffering from panic disorder experience recurrent, terrifying *panic attacks* that seem to come without warning or obvious cause. These attacks are marked by intense heart palpitations, pressure or pain in the chest, dizziness or unsteadiness, sweating, and feeling faint. Often, victims believe they are having a heart attack. They may worry constantly about suffering future panic episodes and thus restrict their activities to avoid possible embarrassment. As noted earlier, fear of experiencing panic attacks while alone or away from home can lead to agoraphobia; indeed, it does so in about one-third of people with panic disorder (Carter & Barlow, 1995; National Institute of Mental Health, 2006; Robins & Regier, 1991). Panic disorder can continue for years, with periods of improvement followed by recurrence (Ehlers, 1995). As many as 30 percent of the people in the United States have experienced at least one panic attack within the previous year (Ehlers, 1995), but only about 2 to 3 percent of the adult population

- **social phobia** An anxiety disorder involving strong, irrational fears relating to social situations.
- **agoraphobia** An anxiety disorder involving strong fear of being alone or away from the security of home.
- **generalized anxiety disorder (GAD)** A condition that involves relatively mild but long-lasting anxiety that is not focused on any particular object or situation.
- **panic disorder** An anxiety disorder involving sudden panic attacks.

A Cleaning Compulsion Obsessive-compulsive disorder is diagnosed when a culturally expected degree of cleanliness becomes an obsessive preoccupation with germs and a disruptive compulsion to clean things. Though learning and stress appear to play the major role in shaping and triggering this and other anxiety disorders, biological factors, including genetically inherited characteristics and deficiencies in certain neurotransmitters in the brain, may result in an oversensitive nervous system and a predisposition toward anxiety.

develops full-blown panic disorder in any given year (American Psychiatric Association, 2000; Kessler, Berglund, et al., 2005; Kessler, Chiu, et al., 2006). Here is one example:

Geri, a thirty-two-year-old nurse, had her first panic attack while driving on a freeway. Afterward, she would not drive on freeways. Her next attack occurred while with a patient and a doctor in a small examining room. A sense of impending doom flooded over her, and she burst out of the office and into the parking lot, where she felt immediate relief. From then on, fear of another attack made it impossible for her to tolerate any close quarters, including crowded shopping malls. She eventually quit her job because of terror of the examining rooms.

● **Obsessive-Compulsive Disorder** Anxiety is also at the root of **obsessive-compulsive disorder (OCD)**, which affects about 1 percent of the population in any given year in the United States and elsewhere (Crino, Slade, & Andrews, 2005; Kessler, Chiu, et al., 2005; National Institute of Mental Health, 2006). Like Mark, whose story opened this chapter, people displaying obsessive-compulsive disorder are plagued by persistent, upsetting, and unwanted thoughts—called *obsessions*—that often center on the possibility of infection, contamination, or doing harm to themselves or others. They do not actually carry out harmful acts, but the obsessive thoughts motivate ritualistic, repetitive behaviors—called *compulsions*—that are performed in an effort to avoid some dreaded outcome or to reduce feelings of anxiety associated with the obsessions (Noyes & Hoehn-Saric, 2006). For example, Mark engaged in incessant, ritualized cleaning to protect himself from infection. Other common compulsions include rituals such as checking locks; repeating words, images, or numbers; counting things; or arranging objects “just so.” Obsessions and compulsions are much more intense than the familiar experience of having a repetitive thought or tune “in the back of your mind” or rechecking that a door is locked. In obsessive-compulsive disorder, the obsessions and compulsions are intense, disturbing, and often strange intrusions that can severely impair daily activities. (*DSM-IV* defines compulsions as occupying more than one hour a day.) Many people who display this disorder recognize that their thoughts and actions are irrational, but they still experience severe agitation and anxiety if they try to interrupt their obsessions or give up their compulsive behaviors.

● Causes of Anxiety Disorders

As with all the forms of psychopathology we will consider, the exact causes of anxiety disorders are a matter of some debate. However, there is good evidence that biological, psychological, and social factors all contribute. Biological predispositions, distortions in thinking, and certain learning experiences appear to be particularly important (U.S. Surgeon General, 1999; Williams et al., 2005). The exact nature and combination of causal factors varies from one anxiety disorder to the next. For example, the brain regions involved in panic disorder are not identical to those involved in obsessive-compulsive disorder, and the learning experiences contributing to specific phobia may differ from those contributing to agoraphobia.

● **Biological Factors** Most anxiety disorders, including panic disorder, obsessive-compulsive disorder, and generalized social phobia, appear to run in families (Bolton et al., 2006; Grabe et al., 2006; Stewart et al., 2007). This tendency may be partly due to environmental factors that affect members of the same family, but it also suggests that people may inherit a predisposition to develop anxiety disorders (e.g., Fyer et al., 2006). Genetic influences on these disorders are suggested by research showing that if one identical twin has an anxiety disorder, the other is more likely also to have an anxiety disorder than is the case in nonidentical twin pairs (Bolton et al., 2006; Kendler, Jacobson, et al., 2002). Data from twin, family, and

● **obsessive-compulsive disorder (OCD)**
An anxiety disorder involving repetitive thoughts and urges to perform certain rituals.

other studies suggest, for example, that genetic influences play a relatively strong role in panic disorder and generalized anxiety disorder, particularly when there is early onset of symptoms (Bolton et al., 2006; Hettrema, Neale, & Kendler, 2001; Neumeister et al., 2004). Some evidence suggests that genetic factors appear to influence social phobia more strongly in males than in females (Kendler, Jacobson, et al., 2002), but overall the genetic and environmental risk factors for anxiety disorders are similar in men and women (Hettrema et al., 2005).

Some inherited predispositions may be rather specific. For instance, one study has found that identical twins were more likely than other siblings to share phobias about small animals and social situations but not about heights or enclosed spaces (Skre et al., 2000). Other research suggests that there may be a link between obsessive-compulsive disorder and a specific gene known as SLC1A1 (Leckman & Kim, 2006). It will take much more research, however, to determine the degree to which various anxiety disorders are influenced by specific genetic factors or more general ones. For example, people who display anxiety disorders may have inherited an autonomic nervous system that is oversensitive to stress and easily conditioned, thus predisposing them to react with intense anxiety to a wide range of situations (Ahmad et al., 2002; Bracha, 2006; Miller et al., 2005; Zinbarg & Barlow, 1996). A predisposition for developing anxiety disorders may also stem from abnormalities in the brain's neurotransmitter activity. Excessive activity of norepinephrine circuits in certain parts of the brain has been linked with panic disorder, and dysregulation of serotonin has been associated with obsessive-compulsive disorder and social phobia (Lanzenberger et al., 2007). Supporting this view is evidence that medications that affect these neurotransmitters are often effective in the treatment of OCD and other anxiety disorders (Bartz & Hollander, 2006).

● **Psychological Factors** Although biological predispositions may set the stage for anxiety disorders, most researchers agree that environmental stressors and psychological factors, including cognitive processes and learning, are crucial to the development of most anxiety disorders (Mineka & Zinbarg, 2006; Moses & Barlow, 2006; Schmidt et al., 2000; Stein, Chavira, & Jang, 2001). To see the effects of environmental stressors, one need only look at the dramatic rise in cases of post-traumatic stress disorder following military combat, natural disasters, or terrorist attacks (Galea et al., 2002; Hoven et al., 2005). The impact of learning can be seen in families in which parents don't socialize much, tend to be suspicious of others, and constantly exaggerate life's everyday dangers. These parents might unwittingly promote social anxiety in their children—especially children born with a tendency toward shyness—by influencing them to interpret social situations as threatening. Abuse or other traumatic childhood experiences also increase the risk of developing an anxiety disorder, particularly panic disorder (Safren et al., 2002).

People suffering from an anxiety disorder often exaggerate the dangers in their environment, thereby creating an unrealistic expectation that bad events are going to happen (Wenzel et al., 2006; Wilson et al., 2006). This expectation leads them to be constantly on the lookout for negative events (Foa et al., 1996; Leahy et al., 2005; Wells & Matthews, 2006). Further, because they tend to underestimate their capacity to control threatening events, they are likely to experience anxiety and desperation if and when feared events do occur. Their lack of perceived control, in turn, can lead these people to avoid, or overreact to, threatening situations (Wells & Matthews, 2006; White et al., 2006). As an example, consider the development of a panic attack. Unexplained symptoms of physical arousal may set the stage for a panic attack, but it is the person's sensitivity to and cognitive interpretation of those symptoms that can determine whether or not the attack actually develops (Lim & Kim, 2005; Schmidt, Lerew, & Jackson, 1999). In fact, panic attacks are less likely in panic-disorder patients who believe they can control the source of their discomfort (Rapee et al., 1992; White et al., 2006). In short, a number of dysfunctional beliefs and cognitive distortions are associated with the development of anxiety disorders.

LINKAGES

Anxiety Disorders and Learning

 LINKAGES (a link to Learning, p. 204)

The learning principles discussed in the chapter on learning also play an important role in anxiety disorders. For example, upsetting thoughts—about money or illness, for example—often create anxiety and worry, especially when people are already under stress or feel incapable of dealing with their problems. As the thoughts become more persistent, anxiety increases. If doing something such as, say, cleaning the kitchen temporarily relieves the anxiety, that behavior may be strengthened through the process of negative reinforcement discussed in the chapter on learning. But cleaning can't eliminate the obsessive thoughts, so they return, and the actions become compulsive, endlessly repeated rituals that keep the person trapped in a vicious circle of anxiety. To social-cognitive theorists, then, obsessive-compulsive disorder is a pattern that is sparked by distressing thoughts and maintained by operant conditioning (Abramowitz et al., 2006).

Phobias, too, may be partly based on learning, especially on the principles of classical conditioning and observational learning described in the learning chapter. The feared object becomes an aversive conditioned stimulus after being associated with a traumatic event that acts as an unconditioned stimulus (Öst, 1992). Fear of dogs, for example, may result from a dog attack. But fear can also be learned merely by seeing or hearing about other people's bad experiences. These fears can even be learned by watching TV or movies (Cook & Mineka, 1990). Perhaps you know someone who became reluctant to take a shower after seeing the horrific shower-room murder scene in Alfred Hitchcock's film *Psycho* or one of its many remakes. Once phobias are learned, avoiding the feared object or situation prevents the person from finding out that there is nothing to fear. This cycle of avoidance helps explain why many phobias do not simply extinguish, or disappear, on their own.

Why are phobias about snakes and spiders so common, even though people are seldom harmed by them? And why are there so few cases of electrical-shock phobia, even though lots of people receive accidental electrical shocks? As discussed in the

Learning by Watching Many phobias, including those involving needles, blood, and medical-related situations, are acquired vicariously—by what we see and hear. In fact, fear developed through observational learning can be as strong as fear developed through direct experience. Fearlessness can also be learned vicariously. By simply watching the boy in the dental chair as he learns to relax with his dentist, the other youngster is less likely to be distressed when it is his turn.

chapter on learning, the answer may be that we are *biologically prepared* to learn associations between certain stimuli and certain responses. These stimuli and responses, then, would be especially easy to link through conditioning (Hamm, Vaitl, & Lang, 1989). Specifically, we may be biologically prepared to learn to fear and to avoid stimuli that had the potential to harm our evolutionary ancestors (Skre et al., 2000; Staddon & Ettinger, 1989).

The notion that people are biologically prepared to learn certain phobias is supported by laboratory evidence. For example, a group of Swedish psychologists attempted to condition people to fear certain stimuli by associating those stimuli with electrical shocks (Öhman, Dimberg, & Öst, 1985). The research participants developed approximately equal conditioned anxiety reactions to photos of houses, human faces, and snakes. Later, however, when they were tested without shock, their fear reaction to snakes remained long after their reaction to houses and faces had faded. A series of investigations with animals has also supported preparedness theory (Cook & Mineka, 1990). If a monkey sees another monkey behaving fearfully in the presence of a snake, it quickly develops a strong and persistent fear of snakes. However, if the snake is entwined in flowers, the observer monkeys come to fear only the snake, not the flowers. So the fear conditioning appears to be selective, focusing only on potentially dangerous creatures such as snakes or crocodiles (Zinbarg & Mineka, 1991), not on harmless objects.

Learning is obviously important in the development of fear, but learning principles alone cannot explain why exposure to certain stimuli creates anxiety disorders in some people and not in others (Field, 2006). Why is it, for example, that some survivors of the terrorist attacks of 9/11 developed phobias or posttraumatic stress disorder and others did not? As suggested by the diathesis-stress approach, and as discussed in the chapter on health, stress, and coping, the impact of people's experiences is heightened or dampened by other factors, such as their genetic and biological vulnerability to stress, their previous experiences with frightening events, their expectations and other cognitive habits, and the social support and other conditions that follow the trauma (Armfield, 2006; Mineka & Zinbarg, 2006). In short, learning—including the learning that supports the development of anxiety disorders—occurs more quickly among those who are biologically and psychologically prepared for it. ■

TRY THIS  **Biological Preparedness** Being predisposed to learn to fear snakes and other potentially dangerous stimuli makes evolutionary sense. Humans and other animals who rapidly learn a fear response to objects or situations that they see causing fright in their parents or peers are more likely to survive to reproduce, thus passing on their genes to the next generation. Make a list of the things that you might be especially afraid of. How did these fears develop? And how many of them appear to have “survival value”?

Somatoform Disorders

A young athlete began to suffer fainting spells that prevented her from competing in track and field events, but doctors could find nothing physically wrong. After a program of stress management, however, her symptoms disappeared, and she was able to rejoin her team (Lively, 2001). Sometimes people show symptoms of a *somatic*, or bodily, disorder, even though it has no physical cause. Because these conditions reflect psychological problems that take somatic form, they are called **somatoform disorders**. The classic example is **conversion disorder**, a condition in which people appear to be, but are not, blind, deaf, paralyzed, or insensitive to pain in various parts of the body. (An earlier term for this disorder was *hysteria*.) Conversion disorders are rare, accounting for only about 2 percent of diagnoses (American Psychiatric Association, 1994, 2000). Although they can occur at any point in life, they usually appear in adolescence or early adulthood.

Conversion disorders differ from true physical disabilities in several ways (Allin, Streeruwitz, & Curtis, 2005). First, they tend to appear when a person is under severe stress. Second, they often help reduce that stress by allowing the person to avoid unpleasant or threatening situations. Third, the person may show remarkably little concern about what is apparently a rather serious problem. Finally, the symptoms may be neurologically impossible or improbable, as Figure 15.2 illustrates. One university student, for example, experienced visual impairment that began each Sunday evening and became total blindness by Monday morning. Her vision would begin to return on Friday evenings and was fully restored in time for weekend football games and other social activities. She expressed no particular concern over her condition (Holmes, 1991).

Can people who display a conversion disorder actually see and hear and move, even though they act as if they cannot? Observations and experiments suggest that they can. Supposedly paralyzed people have been seen to sleep-walk, and supposedly blind or deaf people make use of sights and sounds to guide their behavior (e.g., Blake, 1998; Grosz & Zimmerman, 1970). But this does not mean that they are *malinger*ing, or faking. In fact, conversion disorder is diagnosed only when the symptoms are *not* being faked. Rather than destroying sensory or motor ability, the conversion process may prevent the person from being aware of information that the brain is still processing (Ballmaier & Schmidt, 2005; Harvey, Stanton, & David, 2006).

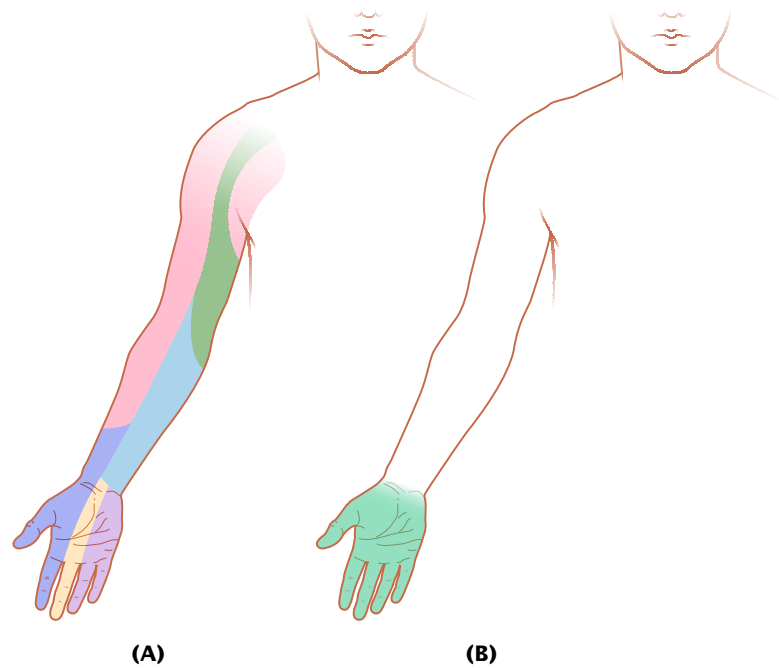

Another somatoform disorder is **hypochondriasis** (pronounced “hye-poh-kon-DRY-a-sis”), a strong, unjustified fear that one has cancer, heart disease, AIDS, or other serious physical problems. The fear prompts frequent visits to physicians and reports of numerous symptoms. Their preoccupation with illness often leads hypochondriacs to become experts on their most feared diseases. In some ways, hypochondriasis is like an anxiety disorder in that it involves health concerns and includes elements of phobia, panic, and obsessive-compulsiveness. However, whereas a person suffering from anxiety disorder might have an irrational fear of getting a serious illness, the person diagnosed with hypochondriasis is excessively concerned about already *having* the illness and is much more likely to seek unnecessary medical treatments (Hiller et al., 2006; Neziroglu, McKay, & Yaryura-Tobias, 2000). A related condition, called **somatization disorder**, is characterized by dramatic, but vague, reports about a multitude of physical problems rather than any specific illness. **Pain disorder** is marked by complaints of severe, often constant pain (typically in the neck, chest, or back) with no physical cause.

Some cases of somatoform disorder may be related to childhood experiences in which a person learns that symptoms of physical illness bring special attention, care, and privileges (Abramowitz & Braddock, 2006; Barsky et al., 1994). Others, including conversion disorder, may be triggered by severe stressors (Ballmaier & Schmidt, 2005; Ovsiew, 2006; Spiegel, 1994). Cognitive factors also come into play. When given information about their health, people with hypochondriasis are

- **somatoform disorders** Psychological problems in which there are symptoms of a physical disorder without a physical cause.
- **conversion disorder** A somatoform disorder in which a person displays blindness, deafness, or other symptoms of sensory or motor failure without a physical cause.
- **hypochondriasis** A somatoform disorder involving strong, unjustified fear of having physical illness.
- **somatization disorder** A somatoform disorder in which there are numerous physical complaints without verifiable physical illness.
- **pain disorder** A somatoform disorder marked by complaints of severe pain with no physical cause.

FIGURE 15.2**Glove Anesthesia**

In “glove anesthesia,” a form of conversion disorder, lack of feeling stops abruptly at the wrist, as in Part B. But as shown in Part A, the nerves of the hand and arm blend, so if they were actually impaired, part of the arm would also lose sensitivity. Other neurologically impossible symptoms of conversion disorder include sleepwalking at night on legs that are “paralyzed” during the day.

strongly biased to focus on threat-confirming information but to ignore reassuring information (Smeets, de Jong, & Mayer, 2000).

Based on such findings, many researchers have adopted a diathesis-stress approach to explaining somatoform disorders. The results of their work suggest that certain people may have biological and psychological traits that make them especially vulnerable to somatoform disorders, particularly when combined with a history of physical illness. Among these traits are self-consciousness and oversensitivity to physical sensations. If such people experience a number of long-lasting stressors, intense emotional conflicts, or severe traumas, they are more likely than others to display physical symptoms in association with emotional arousal (Abramowitz & Braddock, 2006; Siti, 2004).

Sociocultural factors may shape the nature of some somatoform disorders. In many Asian, Latin American, and African cultures, it is not unusual for people to experience severe physical symptoms in association with psychological or interpersonal conflicts (Brislin, 1993; recall our earlier examples of *ataque de nervios* and *koro*). However, the overall *rate* of somatoform disorders appears to be about the same across cultures (Becker, 2004; Kohrt et al., 2005).

Dissociative Disorders

If you have ever spent many hours driving on a boring highway, you may have suddenly realized that you had little or no recollection of what happened during the previous half-hour. This common experience does not signal a mental disorder, but when disruptions in a person’s memory, consciousness, or identity are more intense and long-lasting, they are known as **dissociative disorders**. These disruptions can come on gradually, but they usually occur suddenly and last from a few hours to many years.

Consider the case of John, a thirty-year-old computer manufacturing executive:

John was a meek person who was dependent on his wife for companionship and emotional support. It came as a jolt when she announced that she was leaving him to live with his younger brother. John did not go to work the

- **dissociative disorders** Rare conditions that involve sudden and usually temporary disruptions in a person’s memory, consciousness, or identity.

A Famous Case of Dissociative Identity Disorder In this scene from the film *Sybil*, Sally Field portrays a woman diagnosed with dissociative identity disorder, previously known as multiple personality disorder. *Sybil* appeared to have as many as seventeen distinct personalities. The causes of such dramatic cases, and the reasons behind their increasing prevalence in recent years, is a matter of intense debate.

next day. In fact, nothing was heard from him for two weeks until he was arrested for public drunkenness and assault in a city more than three hundred miles from his home. During those two weeks, John lived under another name at a cheap hotel and worked selling tickets at a pornographic movie theater. When he was interviewed, John did not know his real name or his home address, could not explain how he had reached his present location, and could not remember much about the previous two weeks.

John's case illustrates the dissociative disorder known as **dissociative fugue** (pronounced "fewg"), which is characterized by a sudden loss of personal memory and the adoption of a new identity in a new locale. Another dissociative disorder, **dissociative amnesia**, also involves sudden memory loss. As in fugue, all personal identifying information may be forgotten, but the person does not leave home or create a new identity. These rare conditions attract intense publicity because they are so dramatic. As with other forms of disorder, explanations for dissociative disorder symptoms can vary from culture to culture. For instance, some dissociative-disorder patients in China, Malaysia, India, and Africa report being possessed by spirits or one of their religion's gods (Ng, 2000; van Duiji, Cardena, & de Jong, 2005).

The most famous dissociative disorder is **dissociative identity disorder (DID)**, formerly known as—and still commonly called—*multiple personality disorder (MPD)*. A person diagnosed with DID appears to have more than one identity, each of which speaks, acts, and writes in a different way. Each personality seems to have its own memories, wishes, and (often conflicting) impulses. Here is a case example:

Mary, a pleasant and introverted thirty-five-year-old social worker, was referred to a psychiatrist for hypnotic treatment of chronic pain. At an early interview she mentioned the odd fact that though she had no memory of using her car after coming home from work, she often found that it had been driven fifty to one hundred miles overnight. It turned out that she also had no memory of large parts of her childhood. Mary rapidly learned self-hypnosis for pain control, but during one hypnotic session, she suddenly began speaking in a hostile manner. She told the doctor her name was Marian, and that it was "she" who had been taking long evening drives. She also called Mary "pathetic" for "wasting time" trying to please other people. Eventually, six other identities emerged, some of whom told of having experienced parental abuse in childhood. (Spitzer et al., 1994)

For about a decade after 1970, there was a minor "epidemic" of DID as well as an increase in the number of alternate personalities per case (some patients reported over twenty of them). This upsurge in DID may have occurred because clinicians were looking for it more carefully or because the conditions leading to it became more prevalent, but it may have also been influenced by movies such as *Sybil* and by tell-all books written by people who had been diagnosed with DID (Kihlstrom, 2005). These media influences might have increased the status of DID as a socio-culturally approved method of expressing distress (Hacking, 1995; Spanos, 1994). Such concerns were partly responsible for the change in designation from *multiple personality disorder* to *dissociative identity disorder*. The authors of *DSM-IV* wanted to downplay the notion that people harbor multiple personalities that can easily be "contacted" through hypnosis or related techniques. The new name was chosen to suggest, instead, that dissociation, or separation, between one's memories and other aspects of identity can be so dramatic that people experiencing it may come to believe that they have more than one personality (Gleaves, May, & Cardena, 2001; Spiegel, 1994).

How do dissociative disorders develop? Psychodynamic theorists see massive repression of unwanted impulses or memories as the basis for creating a "new person" who acts out otherwise unacceptable impulses or recalls otherwise unbearable memories (Ross, 1997). Social-cognitive theorists focus on the fact that everyone is

- **dissociative fugue** A dissociative disorder involving sudden loss of memory and the assumption of a new identity in a new locale.
- **dissociative amnesia** A dissociative disorder marked by a sudden loss of memory.
- **dissociative identity disorder (DID)** A dissociative disorder in which a person reports having more than one identity.

capable of behaving in different ways, depending on circumstances (e.g., rowdy in a bar, quiet in a museum); but in rare cases, they say, this variation can become so extreme that an individual feels—and is perceived by others as being—a “different person.” Further, dissociative symptoms may be strengthened by reward as people find that a sudden memory loss or shift in behavior allows them to escape stressful situations, responsibilities, or punishment for misbehavior (Lilienfeld & Lynn, 2003; Lilienfeld et al., 1999). The difficulty in evaluating these hypotheses had once been attributed to the rarity of dissociative disorders, but the availability of more cases, especially cases of DID, has only added to the causal controversy.

Research available so far on dissociative disorders supports four conclusions. First, memory loss and other forms of dissociations are genuine phenomena and as seen in dissociative fugue, they can sometimes become extreme. Second, many people displaying DID have experienced events they would like to forget or avoid. The majority (some clinicians believe all) have suffered severe, unavoidable, persistent abuse in childhood (Foote et al., 2006; Kihlstrom, 2005; Ross et al., 1991). Third, like Mary, most of these people appear to be skilled at self-hypnosis, through which they can induce a trance-like state. Fourth, most found that they could escape the trauma of abuse, at least temporarily, by creating “new personalities” to deal with stress (Spiegel, 1994). However, not all abused children display DID, and there is evidence that DID can indeed be triggered by media stories or by suggestions made to clients by their therapists (Spanos, 1996).

This evidence has led some skeptics to question the very existence of multiple personalities (Acocella, 1998; Merckelbach, Devilly, & Rassin, 2002). They point to research showing, for example, that people who display DID may be more aware than they think they are of the memories and actions of each apparent identity (Allen, 2002; Allen & Iacono, 2001). Research on the existence and effects of repressed memories (discussed in the memory chapter) is sure to have an impact on our understanding of, and the controversy over, the causes of DID. (“In Review: Anxiety, Somatoform, and Dissociative Disorders” presents a summary of our discussion of these disorders.)

The debate and skepticism about dissociative identity disorder—including whether it is caused partly by therapists’ expectations—is not confined to professional journals. This drawing appeared in *The New Yorker* magazine.

“Would it be possible to speak with the personality that pays the bills?”

in review Anxiety, Somatoform, and Dissociative Disorders

| Disorder | Subtypes | Major Symptoms |
|------------------------|--|---|
| Anxiety disorders | Phobias | Intense, irrational fear of objectively nondangerous situations or things, leading to disruptions of behavior |
| | Generalized anxiety disorder | Excessive anxiety not focused on a specific situation or object; free-floating anxiety |
| | Panic disorder | Repeated attacks of intense fear involving physical symptoms such as faintness, dizziness, and nausea |
| | Obsessive-compulsive disorder | Persistent ideas or worries accompanied by ritualistic behaviors performed to neutralize anxiety-driven thoughts |
| Somatoform disorders | Conversion disorder | A loss of physical ability (e.g., sight, hearing) that is related to psychological factors |
| | Hypochondriasis | Preoccupation with, or belief that one has, a serious illness in the absence of any physical evidence |
| | Somatization disorder | Wide variety of somatic complaints that occur over several years and are not the result of a known physical disorder |
| | Pain disorder | Preoccupation with pain in the absence of physical reasons for the pain |
| Dissociative disorders | Dissociative amnesia/fugue | Sudden loss of memory, which may result in relocation and the assumption of a new identity |
| | Dissociative identity disorder (multiple personality disorder) | Appearance within the same person of two or more distinct identities, each with a unique way of thinking and behaving |

Mood Disorders

Everyone's mood, or *affect*, tends to rise and fall from time to time. However, when people experience extremes of mood—wild elation or deep depression—for long periods, when they shift from one extreme to another, and especially when their moods are not consistent with the events around them, they are said to show a **mood disorder** (also known as an *affective disorder*). We will describe two main types: depressive disorders and bipolar disorders.

● Depressive Disorders

Depression can range from occasional, normal “down” periods to episodes severe enough to require hospitalization. A person suffering **major depressive disorder** feels sad and overwhelmed, typically losing interest in activities and relationships and taking pleasure in nothing (Getzfeld, 2006; Sloan, Strauss, & Wisner, 2001). Despite the person's best efforts, everything from conversation to bathing is an unbearable, exhausting effort. Changes in eating habits resulting in weight loss or weight gain often accompany major depressive disorder, as does sleep disturbance or, less often, excessive sleeping. Problems in working, concentrating, making decisions, and thinking clearly are also common. More often than not, there are also symptoms of an accompanying anxiety disorder (Zimmerman, McDermet, & Mattia, 2000). In extreme cases, depressed people may express false beliefs, or **delusions**—worrying, for example, that the government is planning to punish them. Major depressive disorder may come on suddenly or gradually. It may consist of a single episode or, more

- **mood disorder** Conditions in which a person experiences extreme moods, such as depression or mania.
- **major depressive disorder** A mood disorder in which a person feels sad and hopeless for weeks or months.
- **delusions** False beliefs, such as those experienced by people suffering from schizophrenia or extreme depression.

commonly, repeated depressive periods. These episodes can last for weeks or months; the average length of the first one is four to nine months (Durand & Barlow, 2006). Exaggerated feelings of inadequacy, worthlessness, hopelessness, or guilt are common in major depressive disorder. Here is a case example:

Mr. J. was a fifty-one-year-old industrial engineer. . . . Since the death of his wife five years earlier, he had been suffering from continuing episodes of depression marked by extreme social withdrawal and occasional thoughts of suicide. . . . He drank and, when thoroughly intoxicated, would plead to his deceased wife for forgiveness. He lost all capacity for joy. . . . Once a gourmet, he now had no interest in food and good wine . . . and could barely manage to engage in small talk. As might be expected, his work record deteriorated markedly. Appointments were missed and projects haphazardly started and left unfinished. (Davison & Neale, 1990, p. 221)

Depression is not always so extreme. In a less severe pattern of depression, called **dysthymic disorder**, the person experiences the sad mood, lack of interest, and loss of pleasure associated with major depression, but less intensely and for a longer period. (The duration must be at least two years to qualify as dysthymic disorder.) Mental and behavioral disruption are also less severe; people exhibiting dysthymic disorder rarely require hospitalization.

Major depressive disorder occurs sometime in the lives of about 17 percent of people in North America and Europe (Hasin et al., 2005; Kessler et al., 1994, 2003; U.S. Surgeon General, 1999); in any given year, about 9.5 percent of these populations are experiencing the disorder (Kessler et al., 1994, 2003; U.S. Surgeon General, 1999). Unfortunately, it is becoming more common, both in the United States and elsewhere. The World Health Organization estimates that if current trends continue, depression will become the second-leading cause of disability and premature death in developed economies (World Health Organization Mental Health Survey Consortium, 2004). However, the incidence of the disorder varies considerably across cultures and subcultures. For example, depression occurs at much higher rates in urban Ireland than in urban Spain (Judd et al., 2002), though it is not always clear whether such differences reflect real differences in rates of depression or differences in the application of diagnostic criteria (Judd et al., 2002). There are gender differences in some cultures, too. In the United States and other Western countries, females are two to three times more likely than males to experience major depressive disorder; 10 to 25 percent of women and 5 to 12 percent of men will display this disorder during their lifetimes (American Psychiatric Association, 2000; Weissman et al., 1993). This difference is smaller in the less economically developed countries of the Middle East, Africa, and Asia (Ayuso-Mateos et al., 2001; Culbertson, 1997; World Health Organization, 2003). Depression can occur at any age, but two peaks of prevalence appear across the life span. The first occurs in late adolescence or young adulthood, and the second during old age (Cross-National Collaborative Group, 2002; Durand & Barlow, 2006; Fassler & Dumas, 1997; Sowdon, 2001).

Depression is often found in combination with other psychological disorders and medical conditions; it is especially likely to be diagnosed along with posttraumatic stress disorder, obsessive-compulsive disorder, and other anxiety disorders, as well as with substance use disorders, physical disabilities, and recovery from heart attack (Mitra et al., 2005; O'Brien, 2006). As mentioned earlier, some researchers believe that the overlap between anxiety and depression is significant enough to warrant combining them into a single category in the next edition of the *DSM* (Moses & Barlow, 2006).

● **Suicide and Depression** Suicide is associated with a variety of psychological disorders, but it is most closely tied to depression and other mood disorders (Balázs et al., 2006). Some form of depression has been implicated in 40 to 70 percent of suicides (Angst, Angst, & Stassen, 1999; Oquendo & Mann, 2001). In fact, thinking about suicide is a symptom of depressive disorders. Hopelessness about the future—another

- **dysthymic disorder** A mood disorder involving a pattern of comparatively mild depression that lasts for at least two years.

depressive symptom—and a desire to seek instant escape from problems are also related to suicide attempts (Beck et al., 1990; Brown et al., 2000).

About 31,000 people in the United States commit suicide each year, or about 86 persons per day, and ten to twenty times that many people attempt it (Centers for Disease Control and Prevention, 2004). This puts the U.S. suicide rate at about 10 per 100,000 individuals, making suicide the eleventh-leading cause of death. Worldwide, the suicide rate is as high as 25 per 100,000 in some northern and eastern European countries and Japan (Lamar, 2000; World Health Organization, 2003) and as low as 6 per 100,000 in countries with stronger religious prohibitions against suicide, such as Greece, Italy, Ireland, and the nations of the Middle East.

Suicide rates also differ considerably depending on sociocultural factors such as age, gender, and ethnicity (Centers for Disease Control and Prevention, 2002b, 2002c; Oquendo et al., 2001). In the United States, suicide is most common among people over sixty-five years old, especially men. The suicide rate for men who are eighty-five or older is 55 per 100,000; for women in this age group, it is only 4 per 100,000 (Centers for Disease Control and Prevention, 2004). However, since 1950 suicide among those aged fifteen to twenty-four has tripled. And though the rate has begun to level off in the last decade (Centers for Disease Control and Prevention, 2006), suicide is still the third-leading cause of death, after accidents and homicides, among people in this age group (Centers for Disease Control and Prevention, 2002b, 2006). Suicide is the second-leading cause of death among college students. About 10,000 try to kill themselves each year, and about 1,000 succeed. These figures are much higher than for eighteen- to twenty-four-year-olds in general, but much lower than for the elderly (U.S. Surgeon General, 1999). Women attempt suicide three times as often as men, but men are four times as likely to actually kill themselves (Centers for Disease Control and Prevention, 2006). The gender difference is even greater among people who have been diagnosed with depression. In this group, the male suicide rate of 65 per 100,000 is ten times higher than the rate for women (Blair-West et al., 1999; Centers for Disease Control and Prevention, 1999b).

Suicide rates also differ across ethnic groups (Centers for Disease Control and Prevention, 2002c; Oquendo et al., 2001; see Figure 15.3). Among males in the United States, for example, the overall rate for American Indians is 19.1 per 100,000, compared with 19.4 for European Americans, 9.7 for Asian Americans, 10.7 for Hispanic Americans, and 10.4 for African Americans. The same pattern of ethnic differences appears among women, though the actual rates are much lower (Centers for Disease Control and Prevention, 2002c).

FIGURE 15.3

Suicide Rates in Various Ethnic Groups

The suicide rates among ethnic groups in the United States vary widely. For example, the rate among American Indians is almost twice that of African Americans. In 2002, more teenagers and young adults died from suicide than from cancer, heart disease, AIDS, birth defects, stroke, pneumonia and influenza, and chronic lung disease *combined* (Centers for Disease Control and Prevention, 2002c, 2004).

Predicting who will commit suicide is difficult. For one thing, suicidal thoughts are quite common—about 3 percent of all adults and as many as 10 percent of college students report having had such thoughts in the previous year (Brenner, Hassan, & Barrios, 1999; Kessler, Berglund, Borges, et al., 2005). Still, the results of hundreds of research studies provide some predictive guidelines, and new instruments are being developed to make prediction even more accurate (Smyth & MacLachlan, 2005). In the United States, at least, suicide is most likely among European American males, especially those older than forty-five, single or divorced, and living alone. The risk of suicide is also heightened among people diagnosed with a mood disorder, anxiety disorder, or schizophrenia (Boardman & Healy, 2001; Khan et al., 2002; Rihmer, 2001). Among the elderly, suicide is most common in males who suffer depression over health problems (e.g., Brown, Bongar, & Cleary, 2004). The risk is higher, too, in people who have made a specific plan, given away possessions, and are impulsive (Centers for Disease Control and Prevention, 2004). A previous suicide attempt may not always be a good predictor of eventual suicide, because such attempts may have been help-seeking gestures, not failed efforts to die (McIntosh, 2003; Nock & Kessler, 2006). In fact, although about 10 percent of unsuccessful attempters try again and succeed, most people who commit suicide had made no prior attempts (Clark & Fawcett, 1992).

It is often said that people who talk about suicide will never try it. This is a myth. On the contrary, those who say they are thinking of suicide are much more likely than other people to attempt suicide. In fact, according to Edwin Schneidman (1987), 80 percent of suicides are preceded by some kind of warning, whether direct (“I think I’m going to kill myself”) or vague (“Sometimes I wonder if life is worth living”). Although not everyone who threatens suicide follows through, if you suspect that someone you know is thinking about suicide, encourage the person to contact a mental health professional or a crisis hotline. If the danger is immediate, make the contact yourself, and ask for advice about what to do. Many suicide attempts—including those triggered by other suicides in the same town or school—can be prevented by social support and other forms of help for people at high risk (Centers for Disease Control and Prevention, 2004; Mann et al., 2005). For more information, visit suicide-related web sites, such as that of the American Association of Suicidology (www.suicidology.org).

● Bipolar Disorders

The alternating appearance of two emotional extremes, or poles, characterizes *bipolar I disorder*. We have already described one emotional pole: depression. The other is **mania**, which is an extremely agitated, usually elated, emotional state. People in a manic state tend to be utterly optimistic, boundlessly energetic, certain of having extraordinary powers and abilities, and bursting with all sorts of ideas. They become irritated with anyone who tries to reason with them or “slow them down.” During manic episodes individuals may make impulsive and unwise decisions, including spending their life savings on foolish schemes.

In **bipolar I disorder**, manic episodes may alternate with periods of deep depression. Sometimes, periods of relatively normal mood separate these extremes (Tohen et al., 2003). This pattern has also been called *manic depression*. Compared with major depressive disorder, bipolar I disorder is rare. It occurs in only about 1 percent of adults, and it affects men and women about equally. Another 1 percent of adults display *bipolar II disorder*, in which major depressive episodes alternate with episodes known as *hypomania*, which are less severe than the manic phases seen in bipolar I disorder (Merikangas et al., 2007). Both versions can severely disrupt a person’s ability to work or maintain social relationships (Kessler, Berglund, Demler, et al., 2005; National Institute of Mental Health, 2006).

Somewhat more common is *cyclothymic disorder*, the bipolar equivalent of dysthymia. Cyclothymic disorder involves episodes of depression and mania, but the

- **mania** An elated, very active emotional state.
- **bipolar I disorder** A mood disorder in which a person alternates between deep depression and mania.

in review Mood Disorders

| Type | Typical Symptoms | Related Features |
|---------------------------|---|---|
| Major depressive disorder | Deep sadness, feelings of worthlessness, changes in eating and sleeping habits, loss of interest and pleasure | Lasts weeks or months; may occur in repeating episodes; severe cases may include delusions; danger of suicide |
| Dysthymic disorder | Similar to major depressive disorder, but less severe and longer lasting | Hospitalization usually not necessary |
| Bipolar I disorder | Alternating extremes of mood, from deep depression to mania, and back | Manic episodes include impulsivity, unrealistic optimism, high energy, severe agitation |
| Cyclothymic disorder | Similar to bipolar disorder, but less severe | Hospitalization usually not necessary |

intensity of both moods is less severe than in bipolar I disorder. As with depression, bipolar disorders are often accompanied by anxiety disorders (Freeman, Freeman, & McElroy, 2002). (“In Review: Mood Disorders” summarizes the main types of mood disorders.)

● Causes of Mood Disorders

Research on the causes of mood disorders has focused on biological, psychological, and sociocultural risk factors. The more of these risk factors people have, the more likely they are to experience a mood disorder.

 LINKAGES (a link to Biological Aspects of Psychology, p. 81)

● **Biological Factors** The role of genetics in mood disorders, especially in bipolar disorders, is suggested by twin studies and family studies (Cho et al., 2005; Hayden & Nurnberger, 2006; Kendler et al., 2006). For example, bipolar disorder is much more likely to be seen in both members of genetically identical twin pairs than in fraternal, or nonidentical, twins (Bowman & Nurnberger, 1993; McGuffin et al., 2003). Family studies also show that those who are closely related to people with a bipolar disorder are more likely than others to develop that disorder themselves (Althoff et al., 2005; Blackwood, Visscher, & Muir, 2001). Major depressive disorder is also more likely to be shared among family members, and especially by identical twins (Detera-Wadleigh & McMahon, 2004; Levinson, 2006). This genetic influence is especially strong in female twins (Bierut et al., 1999). Findings such as these suggest that genetic influences tend to be stronger for mood disorders, and especially for bipolar I disorder, than for most other disorders. Researchers are making progress at identifying regions on various chromosomes that appear related to the genetic transmission of vulnerability to bipolar disorder and other affective disorders (e.g., Greenwood et al., 2006; Levinson et al., 2007). These include genes on chromosome 13 that are involved in the operation of the neurotransmitter serotonin (Detera-Wadleigh & McMahon, 2004; Hariri et al., 2005; Jacobs et al., 2006; Wilhelm et al., 2006).

Other biological factors that may contribute to mood disorders include malfunctions in regions of the brain devoted to mood, imbalances in the brain's neurotransmitter systems, malfunctioning of the endocrine system, disruption of biological rhythms, and underdevelopment in the frontal lobes, hippocampus, or other brain areas (Jans et al., 2007; Milak et al., 2005; Shankman et al., 2007;

Staley et al., 2006; Strakowski, DelBello, & Adler, 2005). All of these conditions may themselves be influenced by genetics. The brain regions involved in mood are many, including the prefrontal cortex, the hippocampus, the amygdala, and other components of the limbic system (Blumberg et al., 2003; MacQueen et al., 2003). There are so many of these regions, in fact, and so many different pathways through which their activity can be disrupted, that different mood disorders might reflect problems in different brain regions (Davidson et al., 2002; Elliott et al., 2002). Malfunctions in some of the same regions are also involved in the symptoms of anxiety disorders, which may help account for the fact that mood and anxiety disorders often appear together (Middeldorp et al., 2005).

As for the role of neurotransmitters, norepinephrine, serotonin, and dopamine were implicated in mood disorders decades ago, when scientists discovered that drugs capable of altering these brain chemicals also relieved depression. Early research suggested that depression was triggered by too little of these neurotransmitters, whereas unusually high levels caused mania. However, the neurochemical causes now appear far more complex. For example, mood disorders may result in part from changes in the sensitivity of the neuronal receptors at which these chemicals have their effects in the brain. The precise nature of these neurotransmitter-receptor mechanisms, and just how they affect mood, is not yet fully understood.

Mood disorders have also been related to malfunctions in the endocrine system, especially the hypothalamic-pituitary-adrenocortical system (HPA). As described in the chapter on health, stress, and coping this system is involved in the body's responses to stress. Research shows, for example, that as many as 70 percent of depressed people secrete abnormally high levels of the stress hormone cortisol (Dinan, 2001; Posener et al., 2000).

The cycles of mood swings seen in bipolar disorders and in recurring episodes of major depressive disorder suggest that mood disorders may be related to stressful triggering events (Hammen, 2005; Keller & Nesse, 2006; Miklowitz & Alloy, 1999). They may also be related to disturbances in the body's biological clock, which is described in the chapter on consciousness. This second possibility seems especially likely in the 15 percent of depressed people who consistently experience a calendar-linked pattern of depressive episodes known as *seasonal affective disorder* (SAD). During months of shorter daylight, these people slip into severe depression, accompanied by irritability and excessive sleeping (Durand & Barlow, 2006). Their depression tends to lift as daylight hours lengthen (Faedda et al., 1993). Disruption of biological rhythms is also suggested by the fact that many depressed people tend to have trouble sleeping—perhaps partly because during the day their biological clocks are telling them it is the middle of the night. Resetting the biological clock through methods such as sleep deprivation or light stimulation has relieved depression in many cases (Golden et al., 2005; Lewy et al., 2006).

Treating SAD Seasonal affective disorder (SAD) can often be relieved by exposure to full-spectrum light for as little as a couple of hours a day (Terman & Terman, 2005).

● **Psychological and Social Factors** Researchers have come to recognize that whatever biological causes are involved in mood disorders, their effects are always combined with those of psychological and social causes. As mentioned earlier, the very nature of depressive symptoms can depend on the culture in which a person lives. Biopsychosocial explanations of mood disorders also emphasize the impact of anxiety, negative thinking, personality traits, family interactions, and the other psychological and emotional responses triggered by trauma, losses, and other stressful events (Kendler, Hettema, et al., 2003; Kendler, Kuhn, & Prescott, 2004; Rice et al., 2006; Steunenbergh et al., 2006). For example, the higher incidence of depression among females—and especially among poor, ethnic minority, single mothers—has been attributed to several factors. Women have greater exposure than men to certain adverse experiences during childhood (e.g., sexual abuse) and adulthood (e.g., domestic violence, poverty). When these risk factors combine with depressive ways of thinking and loss of social support, depression becomes more likely (Miranda & Green, 1999; Nolen-Hoeksema, 2006). Environmental stressors

affect men, too, which may be one reason why gender differences in depression are smaller in countries in which men and women face equally stressful lives (Bierut et al., 1999; Maier et al., 1999).

A variety of social-cognitive theories suggest that the way people think about their stressors can increase or decrease the likelihood of mood disorders. One of these theories stemmed from the research on *learned helplessness* described in the chapter on learning. Just as animals become inactive and appear depressed when they have no control over negative events (El Yacoubi et al., 2003), humans may experience depression as a result of feeling incapable of controlling their lives, especially the stressors confronting them (Klein & Seligman, 1976; Seligman, 1991). But most of us have limited control, so why aren't we all depressed? The ways in which people learn to think about events in their lives may hold the key. For example, Aaron Beck's (1967, 1976) cognitive theory of depression suggests that depressed people develop mental habits of (1) blaming themselves when things go wrong; (2) focusing on and exaggerating the negative side of events; and (3) jumping to overly generalized, pessimistic conclusions. Such cognitive habits, says Beck, are errors that lead to depressing thoughts and other symptoms of depression (Beck & Beck, 1995; Evans et al., 2005). Depressed people, in fact, do think about significant negative events in ways that are likely to increase or prolong their depression (Gotlib & Hammen, 1992; Gotlib et al., 2004; Strunk, Lopez, & DeRubeis, 2006).

Social-cognitive theories of depression are somewhat consistent with the psychodynamically oriented *object relations* approach discussed in the chapter on personality. Both views suggest that negative patterns of thinking can be acquired through maladaptive experiences in childhood. For example, research indicates that children whose early relationships with parents or other primary caregivers were characterized by deprivation or abuse are especially likely to develop depression in later life (Gotlib & Hammen, 1992). It may be that close, protective, predictable, and responsive early relationships are necessary if children are to form healthy views of themselves, positive expectations about others, and a sense of control over the environment (Bowlby, 1980; Ivanova & Israel, 2005; Main, 1996).

Severe, long-lasting depression is especially common among people who see their lack of control or other problems as caused by a permanent, generalized lack of personal competence rather than by a temporary condition or an external cause (Seligman et al., 1988). This *negative attributional style* is seen by some researchers as a partly inherited trait that leaves people prone to depression because they attribute negative events to their own characteristics and believe they will never be capable of doing better (Alloy, Abramson, & Francis, 1999; Hankin, Fraley, & Abela, 2005; Hunt & Forand, 2005). Are depressed people's unusually negative beliefs about themselves actually helping to cause their depression, or are they merely symptoms of it? A number of studies have assessed the attributional styles of large samples of nondepressed people and then kept in touch with them to see if, in the face of equivalent stressors, individuals with negative self-beliefs are more likely to become depressed. These longitudinal studies suggest that a negative attributional style is, in fact, a risk factor for depression, not just a result of being depressed (Evans et al., 2005; Garber, Keiley, & Martin, 2002; Gibb et al., 2004; Satterfield, Folkman, & Acree, 2002). In one study, for example, adolescents who held strong negative self-beliefs were more likely than other youngsters to develop depression when faced with stress later in life (Lewinsohn, Joiner, & Rohde, 2001).

Social-cognitive theorists also suggest that whether depression continues or worsens depends in part on how people respond once they start to feel depressed. Those who ruminate, or continuously dwell, on negative events, on why they occur, and even on the feelings of depression are likely to feel more and more depressed (Just & Alloy, 1997; Rimes & Watkins, 2005). According to Susan Nolen-Hoeksema (1990, 2001), this *ruminative style* is especially common in women and may help explain gender differences in the frequency of depression. When men start to feel sad, she says, they tend to use a *distracting style*. That is, they engage

in activity that distracts them from their concerns and helps bring them out of their depressed mood (Hankin & Abramson, 2001; Just & Alloy, 1997; Nolen-Hoeksema, Morrow, & Fredrickson, 1993).

Notice that social-cognitive explanations of depression are consistent with the diathesis-stress approach to disorder. These explanations suggest that certain cognitive styles constitute a predisposition (or diathesis) that makes a person vulnerable to depression. The actual occurrence of depression is then made more likely by stressors. In fact, most episodes of major depressive disorder are preceded by the onset of major stressors, such as the loss of a loved one. As suggested in the chapter on health, stress, and coping, the depressing effects of these stressors are likely to be magnified in people who lack social support, who have inadequate coping skills, and who must face other stressful conditions such as poverty (e.g., Stice, Ragan, & Randall, 2004).

Given the number and complexity of biological, psychological, social, and situational factors potentially involved in causing mood disorders, the biopsychosocial model and the diathesis-stress approach appear to be especially appropriate guides to future research (Kendler, Gardner, & Prescott, 2006). Studies based on these guides are already bearing fruit. One study looked at the role of genetics and stressful events in shaping mood disorders in a large group of female twin pairs. Both factors were associated with major depression. Specifically, the women at highest genetic risk were also the most likely to become depressed following a significant stressor (Kendler, Thornton, & Gardner, 2000, 2001; Kendler et al., 2005). Another study found that people with a particular version of a single gene were more likely than others to experience depressive symptoms in relation to stressful events (Caspi et al., 2003). On the basis of studies like these, Kenneth Kendler and his colleagues (Kendler, Gardner, & Prescott, 2002) identified specific sets of risk factors for depression in women that appear at five developmental stages, including childhood, early adolescence, late adolescence, adulthood, and in the year preceding the diagnosis of depression. They recently identified a slightly different model of risk factors for men (Kendler, Gardner, & Prescott, 2006).

In the final analysis, it may turn out that each subtype in the spectrum of mood disorders is caused by a unique combination of factors. The challenge for researchers is to identify these subtypes and map out their causal ingredients.

Schizophrenia

Here is part of a letter that arrived in the mail several years ago:

Dear Sirs:

Pertaining to our continuing failure to prosecute violations of minor's rights to sovereign equality which are occurring in gestations being compromised by the ingestion of controlled substances, . . . the skewing of androgyny which continues in female juveniles even after separation from their mother's has occurred, and as a means of promulflagitating my paying Governor Hickel of Alaska for my employees to have personal services endorsements and controlled substance endorsements, . . . the Iraqi oil being released by the United Nations being identified as Kurdistanian oil, and the July, 1991 issue of the Siberian Review spells President Eltsin's name without a letter y.

The disorganization and strange content of this letter suggest that its writer suffers from **schizophrenia** (pronounced "skit-so-FREE-nee-uh"), a pattern of extremely disturbed thinking, emotion, perception, and behavior that seriously impairs the ability to communicate and relate to others and disrupts most other aspects of daily functioning (Freedman, 2003). Schizophrenia is one of the most severe and disabling of all mental disorders. Its core symptoms are seen virtually everywhere in the world, occurring in

- **schizophrenia** A severe and disabling pattern of disturbed thinking, emotion, perception, and behavior.

1 to 2 percent of the population (American Psychiatric Association, 1994, 2000; Ho, Black, & Andreasen, 2003; National Institute of Mental Health, 2006). In the United States, it appears about equally in various ethnic groups, but like most disorders, it tends to be diagnosed more frequently in economically disadvantaged populations. Schizophrenia is seen about equally in men and women, although in women it generally appears later in life, tends to be less severe, and responds better to treatment (Aleman, Kahn, & Selten, 2003; American Psychiatric Association, 2000; Häfner, 2003; U.S. Surgeon General, 1999).

Schizophrenia tends to develop in adolescence or early adulthood. About 75 percent of the time, its onset is gradual, with the earliest signs appearing as much as five years before the first major schizophrenic episode. In other cases, the onset is more rapid. About 40 percent of people with schizophrenia improve with treatment and are able to function reasonably well. The rest show continuous or intermittent symptoms that permanently disrupt their functioning (an der Heiden & Haefner, 2000; Hegarty et al., 1994). Those who also have a drug abuse problem are at increased risk for becoming homeless. It has been estimated that 10 to 13 percent of homeless individuals in the United States suffer from schizophrenia (Fischer & Breakey, 1991; Olfson et al., 1999; Timms, 2005).

One of the best predictors of the course of schizophrenia is *premorbid adjustment*, which is the level of functioning a person had achieved before schizophrenic symptoms first appeared. Improvement is more likely in those who had reached higher levels of education and occupation and who had established supportive relationships with family and friends (Keshavan, et al., 2005; Rabinowitz et al., 2002).

 LINKAGES (a link to Cognition and Language, p. 282)

● Symptoms of Schizophrenia

People displaying schizophrenia have problems in how they think and what they think. The nineteenth-century psychiatrist Eugen Bleuler (pronounced “bloy-ler”) coined the word *schizophrenia*, or “split mind,” to refer to the oddities of schizophrenic thinking. However, schizophrenia does not mean “split personality,” as in dissociative identity disorder (multiple personality disorder). It refers instead to a splitting of normally integrated mental processes, such as thoughts and feelings. For instance, some schizophrenics may giggle while claiming to feel sad.

Schizophrenic thought and language are often disorganized. *Neologisms* (“new words” that have meaning only to the person speaking them) are common. The appearance of “promulflagitating” in the preceding letter is one example. That letter also illustrates *loose associations*, the tendency for one thought to be logically unconnected, or only slightly related, to the next. Sometimes the associations are based on double meanings or on the way words sound (*clang associations*). For example, “My true family name is Abel or A Bell. We descended from the clan of Abel, who originated the bell of rights, which we now call the bill of rights.” In the most severe cases, a jumble of words known as *word salad* reflects utterly chaotic thoughts: “Upon the advisability of held keeping, environment of the seabeach gathering, to the forest stream, reinstatement to be placed, poling the paddleboat, of the swamp morass, to the forest compensation of the dunce” (Lehman, 1967, p. 627).

The *content* of schizophrenic thinking is also disturbed. Often it includes a bewildering assortment of delusions, or false beliefs. These delusions tend to fall into three general categories (Kimhy et al., 2005). *Delusions of influence* focus on the belief that one’s body, thinking, or behavior are being controlled by external forces. Patients with these delusions might claim that the CIA has implanted a control device in their brains (delusions of control). They might believe that other people’s thoughts are appearing in their mind (thought insertion) or that they can broadcast their thoughts to others (thought broadcasting). *Self-significant delusions* involve exaggerated beliefs about oneself. People with these delusions may believe, for example, that certain TV commercials contain coded messages about their innermost secrets, that they are truly an emperor, the pope, or even God (delusions of

FIGURE 15.4**Brain Activity During Hallucinations**

These are brain images of a twenty-three-year-old schizophrenia patient who was hallucinating rolling, disembodied heads that spoke to him. PET scans revealed heightened activity in visual and auditory (language) *association* cortex, rather than in the *primary* cortex regions for these senses. The posterior cingulate cortex (part of the limbic system) was also activated; it is known to be affected by drugs that produce hallucinations (Silbersweig et al., 1995).

grandeur), or that they are guilty of some terrible sin. People displaying *delusions of persecution* believe that others are out to harass or harm them. They may claim, for example, that they are always being followed, that space aliens are trying to steal their internal organs or that they are the targets of an assassin. Such delusions tend to be deeply entrenched and resistant to change, no matter how strong the evidence against them (Woodward et al., 2006).

People with schizophrenia often report that they cannot focus their attention. They may feel overwhelmed as they try to attend to everything at once. Various perceptual disorders may also appear. The person may feel detached from the world and see other people as flat cutouts. The body may feel like a machine, or parts of it may seem to be dead or rotting. **Hallucinations**, or false perceptions, are common, often taking the form of voices. These voices may sound like an overheard conversation, or they may tell the person to do or not to do things. They may also comment on, narrate, or (most often) harshly criticize the person's actions or characteristics. Hallucinations can also create sights, smells, tastes, and touch sensations even when no external stimuli are present. As shown in Figure 15.4, the brain areas activated during hallucinations are related to those that respond to real sights and sounds (Shergill et al., 2000). The emotional expressiveness of people with schizophrenia is often muted, but when they do show emotion, it is frequently exaggerated or inappropriate. They may cry for no apparent reason or fly into a rage in response to a simple question.

Some schizophrenia patients are extremely agitated, constantly moving their limbs, making facial grimaces, or pacing the floor in highly ritualistic sequences. Others become so withdrawn that they move very little. Lack of motivation and poor social skills, deteriorating personal hygiene, and an inability to function in everyday situations are other common characteristics of schizophrenia.

- **hallucinations** A symptom of disorder in which people perceive voices or other stimuli when there are no stimuli present.

TABLE 15.4 Subtypes of Schizophrenia

Mental health professionals still use these *DSM-IV* subtypes when diagnosing schizophrenia, but many researchers now tend to categorize patients in terms of whether positive or negative symptoms of schizophrenia predominate in a given case (Villalta-Gil et al., 2006).

| Type | Frequency | Prominent Features |
|--------------------------------|---|--|
| Paranoid schizophrenia | 40 percent of schizophrenics; usually appears after age 25–30 | Delusions of grandeur or persecution; anger; anxiety; argumentativeness; extreme jealousy; onset often sudden; signs of impairment may be subtle. |
| Disorganized schizophrenia | 5 percent of all schizophrenics; high prevalence in homeless population | Delusions; hallucinations; incoherent speech; facial grimaces; inappropriate laughter/giggling; neglected personal hygiene; loss of bladder/bowel control. |
| Catatonic schizophrenia | 8 percent of all schizophrenics | Disordered movement, alternating between immobility (stupor) and wild excitement. In stupor, the person does not speak or attend to communication; also, the body is rigid or can be posed in virtually any posture (a condition called <i>waxy flexibility</i>). |
| Undifferentiated schizophrenia | 40 percent of all schizophrenics | Patterns of disordered behavior, thought, and emotion that do not fall easily into any other subtype. |
| Residual schizophrenia | Varies | Applies to people who have had prior episodes of schizophrenia but are not currently displaying symptoms. |

● Categorizing Schizophrenia

DSM-IV lists five major subtypes of schizophrenia: paranoid, disorganized, catatonic, undifferentiated, and residual (see Table 15.4). These subtype labels convey a certain amount of useful information, but they don't always provide an accurate picture of patients' behavior, because some symptoms appear in more than one subtype. Further, people originally diagnosed in one subtype might later display characteristics of another subtype. Finally, the *DSM-IV* subtypes may not be linked very closely to the various biological conditions thought to underlie schizophrenia (Barch, 2006; Fenton & McGlashan, 1991; Jablensky, 2006).

Accordingly, many researchers now categorize schizophrenia in ways that focus more precisely on the kinds of symptoms that patients display. One method of categorizing schizophrenia highlights the positive or negative aspects of symptoms. Disorganized thoughts, delusions, and hallucinations are sometimes called **positive symptoms** of schizophrenia, because they appear as undesirable *additions* to a person's mental life (Andreasen et al., 1995; Iancu et al., 2005; Racenstein et al., 2002). In contrast, the absence of pleasure and motivation, lack of emotional reactivity, social withdrawal, reduced speech, and other deficits seen in schizophrenia are sometimes called **negative symptoms**, because they appear to *subtract* elements from normal mental life (Nicholson & Neufeld, 1993). Describing patients in terms of positive and negative symptoms does not require that they be placed in one category or the other. In fact, many patients exhibit both positive and negative symptoms. However, it is important to know whether negative or positive symptoms predominate, because when symptoms are mainly negative, schizophrenia is usually more severe and less responsive to treatment (Milev et al., 2005; Prikryl et al., 2006). In these cases, patients typically experience long-term disability. Such

- **positive symptoms** Schizophrenic symptoms such as disorganized thoughts, hallucinations, and delusions.
- **negative symptoms** Schizophrenic symptoms such as absence of pleasure, lack of speech, and flat affect.

Catatonic Stupor The symptoms of schizophrenia often occur in characteristic patterns. This woman's lack of motivation and other negative symptoms of schizophrenia are severe enough that she appears to be in a catatonic stupor. Such patients may become rigid or, as in this case, show a waxy flexibility that allows them to be "posed" in virtually any position. Diagnosticians using the traditional subtype system would probably label her as displaying catatonic schizophrenia.

disability has also been associated with positive symptoms if they are severe (e.g., Fenton & McGlashan, 1994; Racenstein et al., 2002).

Another way of categorizing schizophrenia symptoms focuses on whether they are *psychotic* (hallucinations, delusions), *disorganized* (incoherent speech, chaotic behavior, inappropriate affect), or *negative* (e.g., lack of speech or motivation). Other researchers have suggested categorizing schizophrenia symptoms as positive, negative, or depressive (Haefner & Maurer, 2000). The fact that, like positive and negative symptoms, these dimensions of schizophrenia are to some extent independent from one another suggests to some researchers that each symptom cluster or dimension may ultimately be traceable to different causes. For this reason, schizophrenia is often referred to as the *schizophrenia spectrum*, implying that each cluster may develop differently and require different treatments (Tsuang, Stone, & Faraone, 2000).

● Causes of Schizophrenia

The search for the causes of schizophrenia has been more intense than for any other psychological disorder. The findings so far confirm one thing: As with other disorders, there are biological, psychological, and social factors at work in causing or worsening all forms of schizophrenia (Sullivan, Kendler, & Neale, 2003).

● **Biological Factors** Research in behavioral genetics shows that schizophrenia runs in families (Asarnow et al., 2001; Dubertret et al., 2004). One family study found, for instance, that 16 percent of the children of schizophrenic mothers—compared with 2 percent of those of nonschizophrenic mothers—developed schizophrenia themselves over a twenty-five-year period (Parnas et al., 1993). Even if they are adopted by nonschizophrenic families, the children of schizophrenic parents are ten times more likely to develop schizophrenia than adopted children whose biological parents are not schizophrenic (Kety et al., 1994; Tienari et al., 2003). Still, it is unlikely that a single gene transmits schizophrenia (Chumakov et al., 2002; Plomin & McGuffin, 2003). For example, among identical-twin pairs in which one member displays schizophrenia, 40 percent of the other members will, too; but 60 percent will not (McGue, 1992).

It is more likely that some people inherit a predisposition, or diathesis, for schizophrenia that involves several genes, and researchers are currently focusing on some likely candidates, including genes known as *5-HT-sub(5A) receptor gene*, *DTNBP1*, *RGS4*, and *a-7 neuronal nicotinic receptor subunit (CHRNA7)*. These genetic factors appear to combine with other genetic and nongenetic factors to cause the disorder (DeRosse et al., 2006; Fan et al., 2006; Law, Cotton, & Berger, 2006; Levitt et al., 2006; Vazza et al., 2007).

The search for biological causes of schizophrenia also focuses on a number of abnormalities in the structure, functioning, and chemistry of the brain that tend to appear in people with schizophrenia (e.g., Andrews et al., 2006; Neves-Pereira et al., 2005; Tamminga & Holcomb, 2005). Numerous brain imaging studies have shown that, compared with other mental patients, many schizophrenia patients have less tissue in thalamic regions, prefrontal cortex, and some subcortical areas (Behrendt, 2006; Conklin & Iacono, 2002; Csernansky et al., 2004; Ettinger et al., 2007; Highley et al., 2003; Selemon et al., 2003). As shown in Figure 15.5, shrinkage of tissue in these regions leads to corresponding enlargement of the brain's fluid-filled spaces, called *ventricles*. The brain areas in which anatomical abnormalities have been found are active in emotional expression, thinking, and information processing—functions that are disordered in schizophrenia (Conklin & Iacono, 2002; Csernansky et al., 2004; Highley et al., 2003; Pol et al., 2002; Selemon et al., 2003; Velakoulis et al., 2006). Enlarged ventricles and reduced prefrontal cortex are more often found in patients whose schizophrenic symptoms are predominantly negative (Sigmundsson et al., 2001). Continued tissue loss has

FIGURE 15.5**Brain Abnormalities in Schizophrenia**

Here is a magnetic resonance imaging (MRI) comparison of the brains of identical twins. The schizophrenic twin, on the right, has greatly enlarged ventricles (see arrows) and correspondingly less brain tissue, including in the hippocampal area, a region involved in memory and emotion. The same results appeared in fourteen other identical-twin pairs. By contrast, no significant differences appeared between members of a seven-pair control group of normal identical twins (Suddath et al., 1990). These results support the idea that brain abnormalities are associated with schizophrenia and, because identical twins have the same genes, that such abnormalities may stem from nongenetic factors (Baare et al., 2001).

been associated with worsening of negative symptoms (Ho et al., 2003; Mathalon et al., 2001). Patients with mainly positive symptoms tend to have essentially normal-looking brains (Andreasen, 1997).

Hundreds of studies of brain functioning in people diagnosed with schizophrenia provide general support for the idea that their impairments in information processing and other cognitive abilities are related to structural abnormalities (Gur et al., 2000; Jeon & Polich, 2003; Lee, Williams, et al., 2003; Niznikiewicz et al., 1997). For example, patients with predominantly negative symptoms are especially likely to display cognitive deficits associated with prefrontal-cortex problems (Wible et al., 2001). This research is providing important clues (Barch, 2006), but it will take even more research to determine the extent to which, or exactly how, specific structural abnormalities are related to the cognitive problems seen in various forms of schizophrenia.

Researchers are also investigating the possibility that abnormalities in brain chemistry—especially in neurotransmitter systems that use dopamine—play a role in causing or intensifying schizophrenic symptoms (Seeman et al., 2005). Because drugs that block the brain's dopamine receptors often reduce hallucinations, delusions, disordered thinking, and other positive symptoms of schizophrenia, some investigators speculate that schizophrenia results from excess dopamine. However, the relationship between dopamine and schizophrenia is quite complex (Carlsson & Lecrubier, 2004). For example, it may be that changes in the ratio of dopamine to other neurochemicals, particularly in the region of the thalamus, are involved in the difficulties experienced by people with schizophrenia in distinguishing genuine sights and sounds from those produced by neural “noise” within the brain (Buchsbaum et al., 2006; Winterer, 2006).

Some researchers are seeking to integrate genetic, neurological, and environmental explanations of schizophrenia by looking for *neurodevelopmental abnormalities* (Meyer et al., 2005; Rapoport et al., 2005). Perhaps, they say, some forms of schizophrenia arise from disruptions in brain development during the period from before birth through childhood, when the brain is growing and its various functions are maturing. Studies have shown, for instance, that prenatal exposure to physical traumas, influenza, or other viral infections is associated with increased risk for developing schizophrenia (AbdelMalik et al., 2003; Brown et al., 2005; Subotnik et al., 2006). Similarly, low birthweight children are more likely to have the brain abnormalities described earlier. These abnormalities are especially likely in children of schizophrenic parents (Cannon et al., 1993; Lawrie

et al., 2001). Even parental age may make a difference. Children whose fathers were older than forty-five at the time the children were conceived appear to be at elevated risk for developing schizophrenia, possibly because of a sperm cell mutation (Dalman & Allebeck, 2002). These neurodevelopmental factors may help explain why children of schizophrenic parents tend to show the kinds of subtle cognitive and intellectual problems associated with brain abnormalities (Ashe, Berry, & Boulton, 2001; Cannon et al., 1994; McGlashan & Hoffman, 2000; Neumann et al., 1995).

The expression of a genetically transmitted predisposition for brain abnormality may be enhanced by environmental factors such as maternal drug use during pregnancy, oxygen deprivation or other complications during birth, childhood malnutrition, and the like (Sørensen et al., 2003). For example, as mentioned earlier, smaller-than-normal prefrontal lobes and other brain structures appear to constitute an inherited predisposition for schizophrenia. However, reduced brain growth alone is not sufficient to cause the disorder. When only one member of an identical twin pair has schizophrenia, both tend to have unusually small brains, but the schizophrenic twin's brain in each pair is the smaller of the two (Baare et al., 2001). This finding suggests that some environmental influence caused degeneration in an already underdeveloped brain, making it even more prone to function abnormally.

● **Psychological and Sociocultural Factors** Psychological processes and sociocultural influences can contribute to the appearance of schizophrenia and influence its course (Jenkins & Barrett, 2003; Kealy, 2005; Pitschel-Walz et al., 2001). These factors include maladaptive learning experiences, dysfunctional cognitive habits, and stressful family communication patterns (Cantor-Graae & Selten, 2005; Wicks et al., 2005). For example, criticism by family members—sometimes called *expressed emotion*—is associated with more severe symptoms (Nomura et al., 2005). And schizophrenia patients living with relatives who are critical, unsupportive, or emotionally overinvolved are especially likely to relapse following improvement (Hooley, 2004). Family members' negative attitudes may be a source of stress that increases the chances that disruptive or odd behaviors will persist or worsen. Keep in mind, though, that the strange and often disturbing behavior of a family member with schizophrenia can place tremendous strain on the rest of the family, making it harder for them to remain helpful and supportive (Kymalainen et al.,

in review Schizophrenia

Aspect

Key Features

Common Symptoms

Disorders of thought

Disturbed content, including delusions; disorganization, including loose associations, neologisms, and word salad

Disorders of perception

Disorders of emotion

Flat affect; inappropriate tears, laughter, or anger

Possible Causes

Biological

Genetics; abnormalities in brain structure; abnormalities in dopamine systems; neurodevelopmental problems

Psychological

Learned maladaptive behavior; disturbed patterns of family communication

FIGURE 15.6

The Vulnerability Theory of Schizophrenia

According to this theory, a person can cross the threshold into schizophrenia as a result of many combinations of predisposition and stress. A strong predisposition for schizophrenia and little environmental stress (point D), a weak predisposition and a lot of stress (point C), or any other sufficiently potent combination can lead to the disorder. Points A and B represent combinations of vulnerability and stress that would not lead to schizophrenia.

2006; Rosenfarb, Bellack, & Aziz, 2006). In any case, patients who are helped to cope with potentially damaging family influences tend to have better long-term outcomes (Bustillo et al., 2001; Velligan et al., 2000).

● **Vulnerability Theory** All the causal theories of schizophrenia we have discussed are consistent with the diathesis-stress approach, which assumes that various forms of stress can activate a person's predisposition for disorder. ("In Review: Schizophrenia" summarizes these theories, as well as the symptoms of schizophrenia.) The diathesis-stress approach is embodied in the *vulnerability theory* of schizophrenia (Cornblatt & Erlenmeyer-Kimling, 1985). This theory suggests that (1) vulnerability to schizophrenia is mainly biological; (2) different people have differing degrees of vulnerability; (3) vulnerability is influenced partly by genetic influences on development and partly by neurodevelopmental abnormalities associated with environmental risk and (4) psychological components—such as exposure to poor parenting or high-stress families, having inadequate coping skills, and the like—may help determine whether schizophrenia actually appears and may also influence the course of the disorder (Walker & Diforio, 1998; Wearden et al., 2000).

Many different blends of vulnerability and stress can lead to schizophrenia, as Figure 15.6 illustrates. People whose genetic characteristics or developmental influences leave them vulnerable to develop schizophrenia may be especially likely to do so if they are later exposed to learning experiences, family conflicts, and other stressors that trigger and maintain schizophrenic patterns of thought and action. Those same experiences and stressors would not be expected to lead to schizophrenia in people who are less vulnerable to developing the disorder. In other words, schizophrenia is a highly complex disorder—probably a spectrum of related disorders (Kirkpatrick et al., 2001; Lenzenweger, McLachlan, & Rubin, 2007)—whose origins lie in many biological, psychological, and social domains, some of which are yet to be discovered.

Personality Disorders

Personality disorders are long-standing, inflexible ways of behaving that are not so much severe mental disorders as dysfunctional styles of living (Clarkin, 2006). These disorders affect all areas of functioning and, beginning in childhood or adolescence, create problems for those who display them and for others (Millon & Davis, 1996). Some psychologists view personality disorders as interpersonal strategies (Kiesler, 1996) or as the extreme, rigid, and maladaptive expressions of personality traits (Widiger, 1997). The ten personality disorders listed on Axis II of *DSM-IV* are grouped into three clusters that share certain features (see Table 15.5).

The *odd-eccentric* cluster—referred to as *cluster A*—includes paranoid, schizoid, and schizotypal personality disorders. People diagnosed as having schizotypal personality disorder, for example, display some of the peculiarities seen in schizophrenia but are not disturbed enough to be labeled as schizophrenic. Rather than hallucinating, these people may report “illusions” of sights or sounds. They may also exhibit “magical thinking,” including odd superstitions or beliefs (such as that they have extrasensory perception or that salt under the mattress will prevent insomnia).

The *dramatic-erratic* cluster—called *cluster B*—includes the histrionic, narcissistic, borderline, and antisocial personality disorders. The main characteristics of narcissistic personality disorder, for example, are an exaggerated sense of self-importance, extreme sensitivity to criticism, a constant need for attention, and a tendency to arrogantly overestimate personal abilities and achievements. People displaying this disorder feel entitled to special treatment by others but are markedly lacking in empathy for others.

- **personality disorders** Long-standing, inflexible ways of behaving that create a variety of problems.

TABLE 15.5 Personality Disorders

Here are brief descriptions of the ten personality disorders listed on Axis II of *DSM-IV*.

| Type | Typical Features |
|----------------------|--|
| Paranoid | Suspiciousness and distrust of others, all of whom are assumed to be hostile. |
| Schizoid | Detachment from social relationships; restricted range of emotion. |
| Schizotypal | Detachment from, and great discomfort in, social relationships; odd perceptions, thoughts, beliefs, and behaviors. |
| Dependent | Helplessness; excessive need to be taken care of; submissive and clinging behavior; difficulty in making decisions. |
| Obsessive-compulsive | Preoccupation with orderliness, perfection, and control. |
| Avoidant | Inhibition in social situations; feelings of inadequacy; oversensitivity to criticism. |
| Histrionic | Excessive emotionality and preoccupation with being the center of attention; emotional shallowness; overly dramatic behavior. |
| Narcissistic | Exaggerated ideas of self-importance and achievements; preoccupation with fantasies of success; arrogance. |
| Borderline | Lack of stability in interpersonal relationships, self-image, and emotion; impulsivity; angry outbursts; intense fear of abandonment; recurring suicidal gestures. |
| Antisocial | Shameless disregard for, and violation of, other people's rights. |

The *anxious-fearful* cluster—*cluster C*—includes dependent, obsessive-compulsive, and avoidant personality disorders. Avoidant personality disorder, for example, is similar to social phobia in the sense that persons labeled with this disorder tend to be “loners” with a long-standing pattern of avoiding social situations and of being particularly sensitive to criticism or rejection. They want to be with others but are too inhibited.

Personality disorder diagnoses are among the most controversial. The controversy arises partly because persons with these diagnoses sometimes produce more distress in others than in themselves, so the role of social and moral judgment in deciding who is disordered comes into play (Clark, 2006). In addition, the overlap among symptoms of some of the personality disorders makes diagnosis difficult. Studies that use symptom checklists or other behavioral measures, as well as those that use molecular genetic data, generally identify either three or four clusters, not always what would be expected according to *DSM-IV* (Fossati et al., 2006; Livesley, 2005). Some critics have suggested that there is gender bias in the application of diagnoses—pointing to the fact that women are labeled as borderline much more often than men, while men are labeled as antisocial more often than women (Bjorklund, 2006; Boggs et al., 2005). Even the stability of personality disorders over the lifetime has been questioned (Durbin & Klein, 2006). Some aspects of personality disorders diagnoses may be revised in *DSM-V*, but as yet there is no strong consensus about what changes should be made.

From the perspective of public welfare and safety, the most serious, costly, and intensively studied personality disorder is **antisocial personality disorder** (e.g., Scott et al., 2001). It is marked by a long-term pattern of irresponsible, impulsive, unscrupulous, even criminal behavior beginning in childhood or early adolescence. In

- **antisocial personality disorder**
A personality disorder involving impulsive, selfish, unscrupulous, even criminal behavior.

A Classic Case of Antisocial Personality Disorder

Alfred Jack Oakley meets women through personal ads, claiming to be a millionaire movie producer, pilot, and novelist. In reality, he is a penniless con artist who uses smooth talk and charm to gain the women's trust so he can steal from them. In January 2000, after being convicted of stealing a Florida woman's Mercedes, Oakley complimented the prosecutor's skills and the jury's wisdom and claimed to feel remorseful. The judge appeared to see through this ploy ("I don't believe there is a sincere word that ever comes out of your mouth"), but it was still effective enough to get him probation instead of jail time!

the 1800s, this pattern was called *moral insanity*, because the people displaying it appear to have no morals or common decency. The terms *sociopath* or *psychopath* are sometimes still used. All these labels share a common foundation of referring to social norm violation and deception (Warren & South, 2006), but the current "antisocial personality" label more accurately portrays people displaying the disorder as troublesome and sometimes dangerous, but not "insane" by the legal standards we will discuss shortly. About 3 percent of men and about 1 percent of women in the United States fall into this diagnostic category (American Psychiatric Association, 1994, 2000).

At their least troublesome, people exhibiting antisocial personality disorder are a nuisance. They are charming, intelligent "fast talkers" who borrow money and fail to return it. They are arrogant and self-centered manipulators who con people into doing things for them, usually by lying and taking advantage of people's decency and trust. A hallmark of people with antisocial personality disorder is a lack of anxiety, remorse, or guilt, whether they have wrecked a borrowed car or killed an innocent person (Gray et al., 2003; Hare, 1993). Fortunately, these individuals tend to become less active and dangerous after the age of forty or so (Stoff, Breiling, & Maser, 1997).

Perhaps you are wondering whether terrorists and suicide bombers should be classified as antisocial personalities—after all, they exhibit violent and disruptive behavior in the extreme. Some terrorists do exhibit the characteristics of antisocial personality disorder, but many do not (Martens, 2004). Acts of terrorism might better be explained from the perspective of social and political psychology—terrorists are persons spurred to take extreme destructive measures by political and religious ideologies during intense group conflict. In short, the psychology of group conflict and war might better explain the terrorism of today, just as it might have explained the terrifying behavior of Japanese kamikaze pilots during World War II.

As for the causes of antisocial personality disorder, theories abound. Some studies suggest a genetic predisposition (Slutske et al., 2001). Genes appear implicated in nearly all disorders; however, the available evidence suggests that the genetic contribution to antisocial behaviors that begin in adolescence or adulthood is modest at best. In contrast, forms of antisocial activity that appear in early childhood appear to have a stronger genetic component (Arseneault et al., 2003). Genes may influence brain development; reduced brain size and reductions in the hippocampal regions are associated with antisocial personality (Barkataki et al., 2006; van Goozen et al., 2007). Genes may also contribute to chronic underarousal of both the autonomic and central nervous systems (Dolan & Park, 2002; Lindberg et al., 2005). This underarousal may render people less sensitive to punishment and more likely to seek exciting stimulation than is normally the case (Herpertz et al., 2001; Stoff et al. 1997).

Other evidence suggests more specific information-processing defects. For example, people diagnosed with antisocial personality disorder perform less well than others do on neuropsychological tests of the ability to make plans (Dolan & Park, 2002). There seem to be specific problems, too, in the processing of fear-related information among people whose symptoms of antisocial personality disorder include extreme emotional detachment (Levenston et al., 2000; Patrick, Bradley, & Lang, 1993). In one study, film clips of delinquent acts were shown to young men with antisocial personality and to non-APD males. The APD males reported lower levels of guilt and fear and higher levels of excitement and happiness while watching (Cimbara & McIntosh, 2003). This diminished responsiveness may be partly explained by a finding that, compared to those without APD, antisocial adolescents have more difficulty simply remembering emotional material (Dolan & Fullam, 2006). Deficits in the ability to encode, recall, and respond to emotional material might help explain the apparent "fearlessness" (and foolishness) of some of their behavior.

Broken homes, rejection by parents, poor discipline, lack of good parental models, lack of attachment to early caregivers, impulsivity, conflict-filled childhoods, and poverty have all been suggested as psychological and social factors contributing

to the development of antisocial personality disorder (Lahey et al., 1995; Lyman & Gudonis, 2005; Tremblay et al., 1994). The biopsychosocial model suggests that antisocial personality disorder results when these psychosocial and environmental conditions interact with genetic predispositions to low arousal and the sensation seeking and impulsivity associated with it (Gray et al., 2003; Rutter, 1997). Environmental and/or genetic factors can suppress the development of antisocial personality disorder, too. In one study, for example, boys whose environments heightened their risk of antisocial behavior were less likely to display such behavior if they had inherited a particular gene (Caspi et al., 2002). Research suggests that identification of antisocial personalities prior to the development of their more treatment-resistant traits may offer the best hope for dealing with this disorder (Crawford, Cohen, & Brooks, 2001; Lynam, 1996; Stoff et al., 1997).

FOCUS ON RESEARCH METHODS

Exploring Links Between Child Abuse and Antisocial Personality Disorder

One of the most prominent environmental factors associated with the more violent forms of antisocial personality disorder is the experience of abuse in childhood (MacMillan et al., 2001). However, most of the studies that have found a relationship between childhood abuse and antisocial personality disorder were based on potentially biased reports (Monane, Leichter, & Lewis, 1984; Rosenbaum & Bennett, 1986). People with antisocial personalities—especially those with criminal records—are likely to make up stories of abuse in order to shift blame for their behavior onto others. Even if these people's reports were accurate, however, most of the studies lacked a control group of people from similar backgrounds who were not antisocial. Because of this research design flaw, it is virtually impossible to separate the effects of reported child abuse from the effects of poverty or other factors that might also have contributed to the development of antisocial personality disorder.

■ What was the researcher's question?

Can childhood abuse cause antisocial personality disorder? To help answer this question and to correct some of the flaws in earlier studies, Cathy Widom (1989) used a prospective research design, first finding cases of childhood abuse and then looking for the effects of that abuse on adult behavior.

■ How did the researcher answer the question?

Widom began by identifying 416 adults whose backgrounds included official records of having been physically or sexually abused before the age of eleven. She then explored the stories of these people's lives, as told in police and school records, as well as in two-hour diagnostic interviews. To reduce experimenter bias and distorted reporting, Widom ensured that the interviewers were unaware of the purpose of the study and that the respondents were told only that the researchers wanted to learn about people who had grown up in a midwestern U.S. metropolitan area in the late 1960s and early 1970s. Widom also selected a comparison group of 283 people who had no history of abuse but who were similar to the abused sample in terms of age, gender, ethnicity, hospital of birth, schools attended, and area of residence. Her goal was to obtain a nonabused control group that had been exposed to approximately the same environmental risk factors and socioeconomic conditions as the abused children.

■ What did the researcher find?

First, Widom (1989) tested the hypothesis that exposure to abuse in childhood is associated with criminality and/or violence in later life. She found that 26 percent of the abused youngsters went on to commit juvenile crimes, 29 percent were arrested as

adults, and 11 percent committed violent crimes. These percentages were significantly higher than the figures for the nonabused group. The association between criminality and abuse was stronger for males than for females and stronger for African Americans than for European Americans. And overall, victims of physical abuse were more likely to commit violent crimes as adults than were victims of sexual abuse.

Next, Widom tested the hypothesis that childhood abuse is associated with the development of antisocial personality disorder (Luntz & Widom, 1994). She found that the abused group exhibited a significantly higher rate of antisocial personality disorder (13.5 percent) than did the comparison group (7.1 percent). The apparent role of abuse in antisocial personality disorder was particularly pronounced in men, and it remained strong even when other factors—such as age, ethnicity, and socioeconomic status—were accounted for in the statistical analyses. It is interesting to note that one other factor—failure to graduate from high school—was also strongly associated with the appearance of antisocial personality disorder, whether or not childhood abuse had occurred.

■ What do the results mean?

Widom's research supported earlier studies in finding an association between childhood abuse and criminality, violence, and antisocial personality disorder. Further, although her study did not permit a firm conclusion that abuse alone causes antisocial personality disorder, the data from its prospective design added strength to the argument that abuse may be an important causal factor (Widom, 2000). This interpretation is supported by the results of research by other investigators (Jaffee et al., 2004). Finally, Widom's work offers yet another reason—as if more reasons were needed—why it is so important to prevent the physical and sexual abuse of children. The long-term consequences of such abuse can be tragic not only for its immediate victims but also for those victimized by the violence, criminal actions, and antisocial behavior perpetrated by some abused children as they grow up (Weiler & Widom, 1996).

■ What do we still need to know?

Widom's results suggest that one or more of the factors leading teenagers to drop out (or be thrown out) of high school might help create antisocial personality disorder even in children who were not abused. Some of her more recent work suggests, too, that exposure to poverty and other stressors can be as important as abuse in promoting antisocial personality disorder (Horwitz et al., 2001). Further research is needed to discover whether antisocial personality disorder stems from abuse itself, from one of the factors accompanying it, or from some other specific combination of known and still-unknown risk factors. The importance of combined and interacting risk factors is suggested by the fact that abuse is often part of a larger pool of experiences, such as exposure to deviant models, social rejection, poor supervision, and the like.

In fact, another of Widom's more recent studies (Horwitz et al., 2001) supported the conclusion that childhood abuse increases the likelihood of encountering later stressful life events and that it is some of these events that lead to an increase risk of antisocial personality disorder. In other words, childhood abuse might create general vulnerability for a variety of psychological disorders and life stressors, but the chain of events that promote the development of any particular disorder, such as antisocial personality disorder, are not yet fully understood.

We need to know more, too, about why such a small percentage of the abused children in Widom's sample displayed violence, criminal behavior, and antisocial personality disorder. What genetic characteristics or environmental experiences serve to protect children from at least some of the devastating effects of abuse (Rind & Tromovitch, 1997; Rind, Tromovitch, & Bauserman, 1998)? As described in the chapter on human development, some clues have already been found (Caspi et al., 2002; Wills et al., 2001), but a better understanding of these protective elements is needed if there are to be effective programs for the prevention of antisocial personality disorder. ■

A Sampling of Other Psychological Disorders

The disorders described so far represent some of the most prevalent and socially disruptive psychological problems encountered in cultures around the world. Several others are mentioned in other chapters. For example, mental retardation is covered in the chapter on cognitive abilities; sexual dysfunctions are mentioned in the chapter on motivation and emotion; posttraumatic stress disorder is described in the chapter on health, stress, and coping; and sleep disorders are discussed in the chapter on consciousness. Here, we consider two other significant psychological problems: disorders of childhood and substance-related disorders.

● Psychological Disorders of Childhood

The physical, cognitive, emotional, and social changes seen in childhood—and the stress associated with them—can create or worsen psychological disorders in children. Stress can do the same in adults, but childhood disorders are not just miniature versions of adult psychopathology. Because children's development is still incomplete and because their capacity to cope with stress is limited, children are often vulnerable to special types of disorders. Two broad categories encompass the majority of childhood behavior problems: externalizing disorders and internalizing disorders (Lahey et al., 2004; Nigg, 2000).

The *externalizing*, or *undercontrolled*, category includes behaviors that are particularly disturbing to people in the child's environment. Lack of control shows up as *conduct disorders* in about 9.5 percent of children and adolescents, mostly boys, and appears most frequently at around 11 or 12 years of age (Nock et al., 2006). Conduct disorders are characterized by a relatively stable pattern of aggression, disobedience, destructiveness, and other problematic behaviors (Kalb & Loeber, 2003). Often these behaviors involve criminal activity, and they may signal the development of antisocial personality disorder (Loeber & Stouthamer-Loeber, 1998; Lyman & Gudonis, 2005).

There may be a genetic predisposition toward externalizing disorders, including conduct disorders (Gelhorn et al., 2005; Hicks et al., 2004). For example, many children who display conduct disorder have parents who display antisocial personality disorder. Further, externalizing disorders are especially likely to appear in children with temperamentally high activity levels (Mesman & Koot, 2000). There is no doubt, however, that environmental and parenting factors also help to shape these children's behavior, and that these factors interact with genetic factors (Hanish et al., 2005; Laird et al., 2001; Leve, Kim, & Pears, 2005; Scourfield et al., 2004).

Another kind of externalizing problem, *attention deficit hyperactivity disorder (ADHD)*, is seen in 3 to 7 percent of children, mostly boys. A diagnosis of ADHD is given to children who are impulsive and unable to concentrate on an activity as well as other children their age can (Nigg, 2001). *DSM-IV* lists three subtypes of this disorder: primarily inattentive, primarily impulsive, and combined inattention and impulsivity. As the name implies, many of these children are *hyperactive*. That is, they have great difficulty sitting still or otherwise controlling their physical activity. Their impulsiveness and lack of self-control contribute to significant impairments in learning and to an astonishing ability to annoy and exhaust those around them (Henker & Whalen, 1989). The day-to-day behavior problems of children diagnosed with ADHD are reflected in poor performance on certain clinical tests of attention, memory, decision making, and other information-processing tasks. As a result, ADHD is being increasingly viewed as a neurological condition rather than just "bad" behavior (Ollendick & Prinz, 2002; Sergeant, Geurts, & Oosterlaan, 2002).

TRY THIS  **Active or Hyperactive?** Normal behavior for children in one culture might be considered hyperactive in other cultures. Do people in the *same* culture disagree on what is hyperactive? To find out, ask two or three friends to join you in observing a group of children at a playground, a schoolyard, a park, or some other public place. Ask your friends to privately identify which children they would label as “hyperactive,” and then count how many of their choices agree with yours and with each other’s.

Inheritance of a genetic risk factor has been proposed as a likely cause of ADHD, with many studies focusing on genes that regulate dopamine, a neurotransmitter important in the functioning of the attention system (Levy, Hay, & Bennett, 2006; Waldman & Gizer, 2006). But other factors, including brain damage, poisoning from lead or other household substances, and low birth weight, may play a causal role, too (Daly et al., 1999; Linnert et al., 2003; Mick et al., 2002; Spencer, 2002). In some cases, problems in parenting may increase the risk for this disorder (Clarke et al., 2002). Exactly how all these factors might combine is still not clear. Also uncertain is exactly what constitutes hyperactivity. Cultural standards about acceptable activity levels in children vary, so a “hyperactive” child in one culture might be considered merely “active” in another. In fact, when mental health professionals from four cultures used the same rating scales to judge the presence and severity of hyperactivity in a videotaped sample of children’s behavior, the Chinese and Indonesians rated the children as significantly more hyperactive than did their American and Japanese colleagues (Mann et al., 1992; see also Jacobson, 2002). Such findings remind us again that socio-cultural factors can be important determinants of what is acceptable, and thus what is abnormal, in various parts of the world.

A second group of child behavior problems falls into the *internalizing*, or *over-controlled*, category. Children in this category experience distress, especially depression and anxiety, and may be socially withdrawn. Those displaying *separation anxiety disorder*, for example, constantly worry that they will be lost, kidnapped, or injured or that some harm may come to a parent (usually the mother). The child clings desperately to the parent and becomes upset or sick at the prospect of any separation. Refusal to go to school (sometimes called “school phobia”) is often the result. Children whose temperaments are shy or withdrawn are at a higher risk for internalizing disorders, but they are also associated with environmental factors, including being rejected by peers and (especially for girls) being raised by a single parent (Mesman & Koot, 2000; Prinstein & La Greca, 2002).

A few childhood disorders, such as *pervasive developmental disorders*, do not fall into either the externalizing or internalizing category. Children diagnosed with these disorders show severe problems in communication and impaired social relationships. They also often display repetitive, stereotyped behaviors and unusual preoccupations and interests (American Psychiatric Association, 2000; Filipek et al., 1999). The disorders in this group, also known as *autistic spectrum disorders*, share many of these core symptoms, although the severity of those symptoms may vary (Çeponien et al., 2003; Constantino & Todd, 2003). Estimates of the prevalence of autistic spectrum disorders range from 10 to 20 children per 10,000 births (Bryson & Smith, 1998; Filipek et al., 1999) to as high as 62 per 10,000 (Chakrabarti & Fombonne, 2001). About half of these children suffer *autistic disorder*, which can be the most severe of the group. The earliest signs of autistic disorder usually appear within the first thirty months after birth, as these babies show little or no evidence of forming an attachment to their caregivers. Language development is seriously disrupted in most of these children; half of them never learn to speak at all. They have great difficulty engaging in tasks that require shared attention, and they often focus on nonsocial aspects of human interaction such as clothing rather than on social aspects such as eye contact, facial expression, and tone of voice (Klin et al., 2002). Those who display high-functioning autism or a less severe autistic spectrum disorder called *Asperger’s disorder* have impaired relationships, engage in repetitive behaviors, and may memorize arcane facts or activities (such as sports scores or ZIP codes), but they show few severe cognitive deficits and are able to function adaptively and, in some cases, independently as adults (e.g., Grandin, 1996).

Possible biological roots of autistic disorder include genetic factors (Freitag, 2007; Gupta & State, 2007; Veenstra-VanderWeele & Cook, 2004) or neurodevelopmental abnormalities affecting language and communication (Akshoomoff, 2005; Belmonte et al., 2004; Courchesne et al., 2001). Researchers have recently focused

on specific kinds of neurons that serve to relate observed actions of others (e.g., smiling) with regions in one's own brain where that same action would be initiated. These "mirror neurons" apparently allow us to have an idea of what is going on in other peoples' minds. The functioning of such neurons appears disturbed in persons with autism, partly explaining why these individuals seem to operate with little appreciation for what others might be thinking or feeling (Williams et al., 2006). Researchers today have rejected the once-popular hypothesis that autistic disorder is caused by cold and unresponsive parents.

Disorders of childhood differ from adult disorders not only because the patterns of behavior are distinct but also because their early onset disrupts development. To take one example, children whose separation anxiety causes spotty school attendance may not only fall behind academically but also fail to form the relationships with other children that promote normal social development. Some children never make up for this deficit. They may drop out of school and risk a life of poverty, crime, and violence. Moreover, children are dependent on others to obtain help for their psychological problems, and all too often those problems may go unrecognized or untreated. For some, the long-term result may be adult forms of mental disorder.

● Substance-Related Disorders

Childhood disorders, especially externalizing disorders, often lead to *substance-related disorders* in adolescence and adulthood. *DSM-IV* defines substance-related disorders as the use of psychoactive drugs for months or years in ways that harm the user or others. These disorders create major political, economic, social, and health problems worldwide. The substances involved most often are alcohol and other depressants (such as barbiturates), opiates (such as heroin), stimulants (such as cocaine or amphetamines), and hallucinogens (such as LSD).

As mentioned in the chapter on consciousness, one effect of using some substances (including alcohol, heroin, and amphetamines) is **addiction**, a physical need for the substance. *DSM-IV* calls addiction *physiological dependence*. Usually, addiction is evident when the person begins to need more and more of a substance to achieve the desired state. This condition is called building a *tolerance*. When addicted people stop using the substance, they experience painful, often terrifying, and potentially dangerous *withdrawal symptoms* as the body tries to readjust to a substance-free state. People can also display *psychological dependence*, sometimes called *behavioral dependence*. In such cases, a drug has become their primary source of reward, and their lives essentially revolve around getting and using it. People who are psychologically dependent on a drug often display problems that are at least as serious as, and sometimes more difficult to treat than, those of people who are physiologically addicted.

Even when use of a drug does not create psychological or physiological dependence, some people may use it in a way that is harmful to themselves or others. For example, they may rely on the drug to bolster self-confidence or to avoid depression, anger, fear, or other unpleasant feelings. However, the drug effects these people seek may also impair their ability to hold a job, care for their children, or drive safely. This pattern of behavior, defined in *DSM-IV* as *substance abuse*, creates significant social, legal, and interpersonal problems.

In short, substance-related disorders can be extremely serious, even when they do not involve addiction. The chapter on consciousness includes a discussion of how consciousness can be affected by a wide range of psychoactive drugs. Here we focus more specifically on problems associated with the use of alcohol, heroin, and cocaine.

● **Alcohol Use Disorders** According to a large national survey, in 2001–2002 the twelve-month prevalence of alcohol abuse, as defined in *DSM-IV*, was 4.65 percent of adults (Grant et al., 2004). *Alcohol abuse* is characterized by a pattern of continuous or intermittent drinking that may lead to *alcohol dependence*,

● **addiction** Development of a physical need for a psychoactive drug.

an addiction that almost always causes severe social, physical, and other problems (U.S. Department of Health and Human Services Office of Applied Studies, 2003). Males outnumber females in this category by about three to one, although the problem is on the rise among women and among teenagers of both genders. Abuse is greater among European Americans and American Indians than among African Americans and Hispanics; it is lowest among Asians (Chassin, Pitts, & Prost, 2002; Grant et al., 2004). Binge drinking, which peaks in late adolescence and early adulthood, can have serious consequences, including impaired academic performance and injury or death from driving while intoxicated. Prolonged overuse of alcohol can result in life-threatening liver damage, reduced cognitive abilities, vitamin deficiencies that can lead to an irreversible brain disorder called *Korsakoff's psychosis* (severe memory loss), and a host of other physical ailments. Many of these adverse effects appear to be due to the fact that excessive alcohol consumption causes deterioration in several brain areas (Hommer et al., 2001; Pfefferbaum et al., 2001).

Alcohol dependence or abuse, commonly referred to as **alcoholism**, has been implicated in half of all the traffic fatalities, homicides, and suicides that occur each year (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2001). Alcoholism also has a stronger association to rape, child abuse, and many other forms of violence than other drugs do (Martin, Maxwell, et al., 2004). It contributes to elevated rates of hospitalization and absenteeism from work, resulting in total costs to society of over \$180 billion each year in the United States alone (NIAAA, 2001). It is estimated that about half of U.S. adults have a close relative who is an active or recovering alcoholic and that about 25 percent of children are exposed to adults who display alcohol abuse or dependence (NIAAA, 2001). Children growing up in families in which one or both parents abuse alcohol are at increased risk for developing a host of mental disorders, including substance-abuse disorders (Hoffmann & Cerbone, 2002). And, as described in the chapter on human development, children of mothers who abused alcohol during pregnancy may be born with fetal alcohol syndrome.

The biopsychosocial model suggests that alcohol use disorders stem from a combination of genetic characteristics (including inherited aspects of temperament such as impulsivity and emotionality) and what people learn in their social and cultural environment (Kendler, Jacobson, et al., 2003; Petry, 2001; Wall et al., 2001). For example, the children of alcoholics are more likely than others to become alcoholics themselves; and if the children are identical twins, both are at increased risk for alcoholism, even when raised apart (Kendler et al., 1992; McGue, 1999; Slutske et al., 1998). These findings could be explained by genetics, by learning (modeling), or by both. Now that the human genome has been decoded, researchers are focusing on specific chromosomes and gene complexes as likely candidates for alcohol vulnerability. However, the genetics of addiction is complex, and there are likely multiple pathways to alcoholism (Crabbe, 2002; Higuchi, Matsushita, & Kashima, 2006). As with other disorders, alcoholism probably arises as many genes interact with one another and with environmental events, including parental influences (Duncan et al., 2006; Kaufman et al., 2007). For example, one study of the sons of identical twins found that they were at elevated risk for alcoholism if their own father was an alcoholic, but not if the father's identical twin was alcoholic (Jacob et al., 2003). Something in these boys' nonalcoholic family environment had apparently moderated whatever genetic tendency toward alcoholism they might have inherited.

Expectations, such as that alcohol will create good feelings and helps to cope with stressors, play an important role in the development of alcohol use disorders. Shaped by experience and by exposure to others who drink, the network of memories to which alcohol is associated influence the amount one drinks (Reich & Goldman, 2005). If drinking becomes a person's main stress-coping strategy, alcohol use can become abuse and often addiction (NIAAA, 2001; see Table 15.6). The stress-reduction theory of alcoholism has been supported by studies showing that alcohol can reduce animals' learned fear of a particular location and that animals in a stressful conflict situation will choose to drink alcohol if it is available. The stress-

- **alcoholism** A pattern of drinking that may lead to addiction and almost always causes severe social, physical, and other problems.

TABLE 15.6 Social Drinking Versus Alcoholism

| Social drinking differs markedly from alcoholism, but it is all too easy for people to drift from social to alcoholic drinking patterns. Alcoholism can include heavy drinking on a daily basis, on weekends only, or in isolated binges lasting weeks or months (NIAAA, 2000). | Social Drinkers | Alcoholics |
|---|---|--|
| | Sip drinks. | Gulp drinks. |
| | Usually drink in moderation and can control the amount consumed. | Drink increasing quantities (develop tolerance); sometimes drink until blacking out; may not recall events that occur while drinking. |
| | Usually drink to enhance the pleasure of social situations. | Drink for the chemical effect, often to relieve tension or face problems; often drink alone, including in the morning to reduce hangover or to face the day. |
| | Do not usually think about or talk about drinking in nondrinking situations | Become preoccupied with getting their next drink, often sneaking drinks during working hours or at home. |
| Do not experience physical, social, or occupational problems caused by drinking. | Suffer physical disorders, damaged social relationships, and impaired capacity to work because of drinking. | |

reducing effects of alcohol have also been shown in humans, though not consistently (Armeli et al., 2003; Cooper et al., 1992). The emotion-regulating effects of alcohol may be more significant in young women who engage in occasional binge drinking than in boys who started drinking early in life and continue to drink heavily (Chassin et al., 2002; Timko et al., 2005).

The importance of social and cultural learning is further suggested by evidence that alcoholism is more common among ethnic and cultural groups (such as the Irish and English) in which frequent drinking tends to be socially reinforced than among groups (such as Jews, Italians, and Chinese) in which all but moderate drinking tends to be discouraged (see Gray & Nye, 2001; Wilson et al., 1996). Moreover, variations in social support for drinking can result in differing consumption patterns within a cultural group. For example, one study found significantly more drinking among Japanese men living in Japan (where social norms for males' drinking are quite permissive) compared with those living in Hawaii or California, where excessive drinking is less strongly supported (Kitano et al., 1992). Learning would also help explain why rates of alcoholism are higher than average among bartenders, cocktail servers, and others who work where alcohol is available and drinking is socially reinforced or even expected (Fillmore & Caetano, 1980). (Of course, it is also possible that attraction to alcohol led some of these people into such jobs in the first place.)

● **Heroin and Cocaine Dependence** Like alcoholics, heroin and cocaine addicts suffer many serious physical problems, both as a result of the drugs themselves and of the poor eating and other unhealthy habits associated with drug use. The risk of death from an overdose, contaminated drugs, or AIDS (contracted through blood in shared needles), as well as from suicide, is also always present. Dependence on these drugs tends to be more prevalent among males, especially young males (Compton et al., 2007; Warner et al., 1995).

Continued use or overdoses of cocaine can cause problems ranging from nausea and hyperactivity to paranoid thinking, sudden depressive “crashes,” and even death. Cocaine use has been on the decline since 1985, but it is still a serious problem. Surveys indicate that 7.7 percent of high school seniors in the United States have used cocaine at some time in their lives, and millions more teens and adults still use it on occasion (Johnston et al., 2004). The widespread availability of crack, a

powerful and relatively cheap form of cocaine, has made it one of the most dangerous and addicting of all drugs. Pregnant women who use cocaine are much more likely than nonusers to lose their babies through spontaneous abortion, placental detachment, early fetal death, or stillbirth.

Addiction to substances such as heroin and cocaine is largely a biological process brought about by the physiological effects of the drugs (Phillips et al., 2003). Explaining why people start using them is more complicated. Beyond the obvious and immediate pleasure that these drugs provide, the causes of initial drug abuse are less well established than the reasons for alcohol abuse. One line of theorizing suggests that a complex genetic predisposition toward behavioral dysregulation or compulsion leads some people to abuse many kinds of drugs (Crabbe, 2002; Kreek et al., 2005; NIAAA, 2001). A study supporting this possibility found a link between alcoholism in biological parents and drug abuse in adopted-away sons (Cadoret et al., 1995). The same study also found a link between antisocial personality traits in biological parents and antisocial acts—including drug abuse—in the sons they had put up for adoption.

A number of psychological and environmental factors have been proposed as promoting initial drug use (Alessi et al., 2002; Brems & Namyniuk, 2002; Hoffmann & Cerbone, 2002). These include peer pressure, thrill seeking, seeing parents using drugs, being abused in childhood, efforts to cope with stressors or to ease anxiety or depression, and associating drug use with pleasant experiences (Baker et al., 2004; Dube et al., 2003; Putnam, 2003). Research has not yet established why continued drug use occurs in some people and not in others, but again, it is likely that a biological predisposition sets the stage on which specific psychological processes and stressors play out their roles in specific social and cultural contexts (Kendler, Jacobson, et al., 2003).

Mental Illness and the Law

Cheryl was barely twenty when she married Glen, a graduate student in biology. They moved into a large apartment complex near the university and within three years had two sons. Cheryl's friends had always been impressed by the attention and affection she showered on her boys; she seemed to be the ideal mother. She and Glen had serious marital problems, however, and she felt trapped and unhappy. One day Glen came home to find that Cheryl had stabbed both children to death. At her murder trial, she was found not guilty by reason of insanity and was placed in a mental institution.

This verdict reflects U.S. laws and rules that protect people with severe psychological disorders when they are accused of crimes (Cassel & Bernstein, 2007). Similar laws and rules are in effect in many other countries as well. The protection takes two forms.

First, under certain conditions, people designated as mentally ill may be protected from prosecution. If, at the time of their trial, individuals accused of a crime are unable to understand the proceedings and charges against them or to assist in their own defense, they are declared to be *mentally incompetent to stand trial*. In such cases, defendants are sent to a mental institution until they are judged to have become mentally competent. If still not competent after a court-specified period—two years, in most cases—a defendant may be ruled permanently ineligible for trial and either committed in civil court to a mental institution or released. Release is rare, however, because competency to stand trial requires only minimal mental abilities. If drugs can produce even temporary mental competence, the defendant will usually go to trial (Nietzel, 1999).

Second, mentally ill defendants may be protected from punishment. In most U.S. states, they may be judged *not guilty by reason of insanity* if, at the time of the crime, mental illness prevented them from (1) understanding what they were doing, (2) knowing that what they were doing was wrong, or (3) resisting the impulse to

Assessment of Mental Competence

Andrea Yates admitted to drowning her five children in the bathtub of her Houston, Texas, home in 2001. She had twice tried to kill herself in previous years, and she was reportedly depressed at the time of the murders. Accordingly, she pleaded not guilty by reason of insanity. The court's first step in deciding her fate was to confine her in a mental institution for assessment of her mental competency to stand trial. Following testimony of psychologists who examined her, she was found competent, tried, and sentenced to life in prison. Her conviction was overturned on appeal, though, and at a second trial in 2006, she was found not guilty by reason of insanity and committed to a mental hospital.

do wrong. The first two of these criteria—understanding the nature or wrongfulness of an act—are “cognitive” criteria known as the M’Naughton rule. This rule stems from an 1843 case in England in which a man named Daniel M’Naughton, upon hearing “instructions from God,” tried to kill British prime minister Robert Peel. He was found not guilty by reason of insanity and put into a mental institution for life. The third criterion, which is based on a defendant’s emotional state during a crime, is known as the irresistible-impulse test. All three criteria were combined in a rule proposed by the American Law Institute (ALI) in 1962 and now followed by about one-third of the U.S. states: “A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality (wrongfulness) of his conduct or to conform his conduct to the requirements of law” (ALI, 1962, p. 66).

In 1984, after John Hinckley, Jr., was found not guilty by reason of insanity under the ALI rule for his attempted assassination of President Ronald Reagan, the U.S. Congress passed the Insanity Defense Reform Act, which eliminated the irresistible-impulse criterion from the definition of insanity in federal cases. About 75 percent of the U.S. states have passed similar or related reform laws (Giorgi-Guarnieri et al., 2002). As a result, about half the states employ some version of the narrower M’Naughton rule (American Psychiatric Association, 2003). These laws highlight the fact that *insanity* is a legal term, not a psychiatric diagnosis; it does not appear in *DSM-IV* (Cassel & Bernstein, 2007). When defendants plead insanity, judges and juries must decide whether or not these people understood what they were doing or had control over their actions. Defendants who are judged not guilty by reason of insanity and who still display a psychological disorder are usually required to receive treatment, typically through commitment to a hospital, until judged to be cured or no longer dangerous.

Insanity rules have been faulted on several grounds. Some critics argue that everyone, even those who meet legal criteria for insanity, should be held responsible for their actions and punished for their crimes. Others point out significant problems in the implementation of insanity rules. For one thing, different experts often give conflicting, highly technical testimony about a defendant’s sanity at the time of

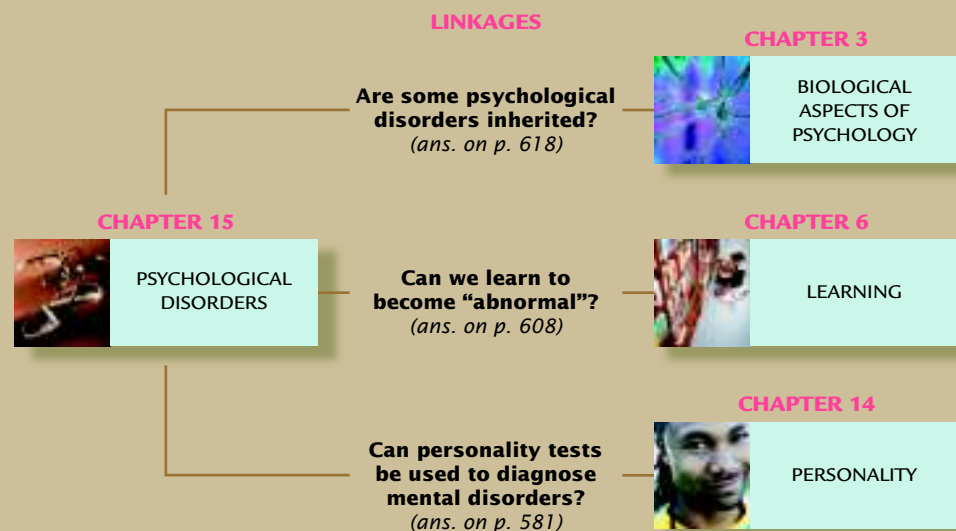

a crime. (In the case mentioned at the beginning of this section, one expert said Cheryl was sane; another concluded she was insane.) Jurors are then left in the difficult position of deciding which expert to believe and what to make of the experts' diagnostic judgments. Their task is complicated by the fact that people suffering from mental disorders—even those as severe as schizophrenia—are still capable of some rational decision making and of controlling some aspects of their behavior (Grisso & Appelbaum, 1995; Matthews, 2004). Concern over such problems has led four U.S. states—Montana, Idaho, Utah, and Kansas—to abolish the insanity defense. Other states have tried less extreme reforms. In thirteen states, it is now possible for juries to find defendants *guilty but mentally ill*. These defendants still serve a sentence, and although they are supposed to receive treatment while confined, they seldom do (Cassel & Bernstein, 2007). A second reform already noted is that federal courts no longer use the irresistible-impulse criterion in defining insanity. Third, federal courts and some state courts now require defendants to prove that they were insane at the time of their crime, rather than requiring the prosecution to prove that the defendants were sane.

Does the insanity defense allow lots of criminals to “get away with murder”? No. Although certain high-profile cases might suggest otherwise, the insanity plea is used in fewer than 1 of every 200 felony cases in the United States—usually when the defendant displays severe psychological disorder—and this plea is successful in only 2 of every 1,000 attempts (American Psychiatric Association, 2003; Silver, Cirincione, & Steadman, 1994). Further, the few defendants found not guilty by reason of insanity are usually hospitalized for two to nine times as long as they would have spent in prison had they been convicted (Silver, 1995; Steadman, 1993). For example, John Hinckley, Jr., has been in St. Elizabeth's Hospital in Washington, D.C., since 1982, and despite his annual efforts to be released and court approval for some visits with his parents outside the hospital, he is unlikely to be freed anytime soon.

In summary, legislators, victims' rights groups, civil liberties advocates, and ordinary citizens are constantly seeking the proper balance between protecting the rights of defendants and protecting society from dangerous criminals. In doing so, the sociocultural values that shape views about what is abnormal also influence judgments about the extent to which abnormality should relieve people of responsibility for criminal behavior.

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of the role of learning principles in the development of phobias illustrates just one way in which the topic of this chapter, psychological disorders, is linked to the subfield of learning (which is the focus of the chapter by that name). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

SUMMARY

Psychopathology involves patterns of thinking, feeling, and behaving that cause personal distress or that significantly impair a person's social or occupational functioning.

Defining Psychological Disorders

Some disorders show similarity across cultures, but the definition of abnormality is largely determined by social and cultural factors.

What Is Abnormal? The criteria for judging abnormality include statistical infrequency (a comparison with what most people do), norm violation, and personal suffering. Each of these criteria is flawed to some extent.

Behavior in Context: A Practical Approach The practical approach to defining abnormality, which considers the content, context, and consequences of behavior, emphasizes the question of whether individuals show *impaired functioning* in fulfilling the roles appropriate for particular people in particular settings, cultures, and historical eras.

Explaining Psychological Disorders

Abnormal behavior has been attributed, at one time or another, to many different factors, including the action of supernatural forces.

The Biopsychosocial Model In today's *biopsychosocial model*, mental disorders are attributed to the combination and interaction of biological, psychological, and sociocultural factors. Biological factors are emphasized by the medical, or *neurobiological model*, which sees psychological disorders as reflecting disturbances in the anatomy and chemistry of the brain and in other biological processes. The causal factors emphasized by the *psychological model* of mental disorders include unconscious conflicts, disruptions in attachment, learning, or maladaptive cognitive schemas. The *sociocultural model* focuses on factors that help define abnormality and influence the form that disorders take in different parts of the world.

Diathesis-Stress as an Integrative Explanation No single aspect of the biopsychosocial model can adequately explain all psychological disorders. The *diathesis-stress approach* takes into account all the causal factors in that model by suggesting that biological, psychological, and sociocultural characteristics create predispositions for disorder and that the symptoms of a disorder appear only in the face of sufficient amounts of stress.

Classifying Psychological Disorders

There seems to be a set of behavior patterns that roughly defines abnormality in most cultures. Classifying these patterns helps to identify the features, causes, and most effective methods of treating various psychological disorders.

A Classification System: DSM-IV The dominant system for classifying abnormal behavior in North America is the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* and its most recent text revision (*DSM-IV-TR*). It includes more than three hundred specific categories of mental disorders. As with medical illnesses, categories for psychological disorders are periodically revised as research accumulates.

Evaluating the Diagnostic System Research on the reliability and validity of *DSM-IV* shows that it is a useful, but imperfect, classification system.

Anxiety Disorders

Long-standing and disruptive patterns of anxiety characterize *anxiety disorders*.

Types of Anxiety Disorders The most prevalent type of anxiety disorder is *phobia*, which includes *specific phobias*, *social phobias*, and *agoraphobia*. Other anxiety disorders are *generalized anxiety disorder*, which involves nonspecific anxiety; *panic disorder*, which brings unpredictable attacks of intense anxiety; and *obsessive-compulsive disorder (OCD)*, in which uncontrollable repetitive thoughts and ritualistic actions occur.

Causes of Anxiety Disorders The most influential explanations of anxiety disorders suggest that they may develop through the combination of a biological predisposition for strong anxiety reactions and the impact of fear-enhancing thought patterns and learned anxiety responses.

Somatoform Disorders

Somatoform disorders, including *conversion disorder*, involve physical problems that have no apparent physical cause. Other examples are *hypochondriasis*, an unjustified concern about being ill; *somatization disorder*, in which the person complains of numerous, unconfirmed physical complaints; and *pain disorder*, in which pain is felt in the absence of a known physical cause.

Dissociative Disorders

Dissociative disorders involve rare conditions such as *dissociative fugue*, *dissociative amnesia*, and *dissociative identity disorder*, or *DID* (multiple personality disorder), in which a person suffers memory loss or develops two or more identities.

Mood Disorders

Mood disorders, also known as affective disorders, involve extreme moods of long duration that may be inconsistent with events.

Depressive Disorders *Major depressive disorder* is marked by feelings of inadequacy, worthlessness, and guilt; in extreme cases, delusions may also occur. *Dysthymic disorder* includes

similar but less severe symptoms persisting for a long period. Suicide is often related to these disorders.

Bipolar Disorders Alternating periods of depression and *mania* characterize bipolar I disorder, which is also known as *manic depression*. *Cyclothymic disorder*, an alternating pattern of less extreme mood swings, is more common.

Causes of Mood Disorders Mood disorders have been attributed to biological causes such as genetics—which underlie disruptions in neurotransmitter and endocrine systems—and irregularities in biological rhythms. Both loss of significant sources of reward and maladaptive patterns of thinking are among the psychological causes proposed. A predisposition toward some of these disorders appears to be inherited, although their appearance may be determined by a diathesis-stress process.

Schizophrenia

Schizophrenia is perhaps the most severe and puzzling disorder of all.

Symptoms of Schizophrenia Among the symptoms of schizophrenia are problems in thinking, perception (often including *hallucinations*), attention, emotion, movement, motivation, and daily functioning.

Categorizing Schizophrenia Although *DSM-IV* lists five major subtypes of schizophrenia (paranoid, disorganized, catatonic, undifferentiated, and residual), many researchers today favor viewing it as a spectrum disorder involving displays of *positive symptoms* (such as hallucinations and disorganized thoughts) and *negative symptoms* (such as lack of speech and restricted emotional expression). Each category of symptoms may be traceable to different causes. Predominantly negative symptoms tend to be associated with more severe disorder and less successful treatment outcomes.

Causes of Schizophrenia Genetic factors, neurotransmitter problems, abnormalities in brain structure and functioning, and neurodevelopmental abnormalities are biological factors implicated in schizophrenia. Psychological explanations have focused on maladaptive learning experiences and disturbed family interactions. The diathesis-stress approach, often described in terms

of the vulnerability model, remains a promising framework for research into the multiple causes of schizophrenia.

Personality Disorders

Personality disorders are long-term patterns of maladaptive behavior that may be disturbing to the person displaying them and/or to others. Examples include schizotypal, avoidant, narcissistic, and *antisocial personality disorders*.

A Sampling of Other Psychological Disorders

Psychological Disorders of Childhood Childhood disorders can be categorized as externalizing disorders (such as conduct disorders or attention deficit hyperactivity disorder) and internalizing disorders (in which children show overcontrol and experience distress, as in separation anxiety disorder). Pervasive developmental disorders do not fall into either category and include the autistic spectrum disorders. In autistic disorder, which can be the most severe of these, children show no interest in, or attachment to, others.

Substance-Related Disorders *Substance-related disorders* involving alcohol and other drugs affect millions of people. *Addiction* to, psychological dependence on, or abuse of these substances contributes to disastrous personal and social problems, including physical illnesses, accidents, and crime. Genetic factors may create a predisposition for *alcoholism*, but learning, cultural traditions, and other psychosocial processes are also important. In the case of dependence on heroin and cocaine, stress reduction, imitation, thrill seeking, and parental modeling have been proposed as important causal factors, along with genetics. The exact causes of initial use of these drugs, however, are not fully understood.

Mental Illness and the Law

Current rules protect people accused of crimes from prosecution or punishment if they are mentally incompetent at the time of their trials or if they were legally insane at the time of their crimes. Difficulty in establishing the mental state of defendants and other knotty problems have created dissatisfaction with those rules and prompted a number of reforms, including the “guilty but mentally ill” verdict.

Treatment of Psychological Disorders

16

Many movies and television dramas include scenes in a psychotherapist's office, but even the best of them tell only part of the story of how psychological disorders can be treated. In this chapter we describe a wide range of treatment options, from "talking therapy" to drugs. We also summarize the results of research on the effectiveness of treatment and on efforts to prevent psychological disorders. Here's how we have organized the material:

SUMMARY

In the chapter on psychological disorders, we described José, an electronics technician who was forced to take medical leave from his job because of repeated panic attacks (see Table 15.1). After four months of diagnostic testing turned up no physical problems, José's physician suggested that he see a psychologist. José resisted at first, insisting that his condition was not "just in his head," but he eventually began psychological treatment. Within a few months, his panic attacks had stopped, and José had returned to all his old activities. After the psychologist helped him reconsider his workload, José decided to retire from his job in order to pursue more satisfying work at his home-based computer business.

José's case is by no means unique. During any given year in the United States alone, about 15 percent of adults and about 21 percent of children are receiving some form of treatment for a psychological disorder (Kancelbaum, Singer, & Wong, 2004; Kessler, Demler, et al., 2005; Wang, Lane, et al., 2005). The cost of treating these disorders is just one part of their economic impact—which amounts to a staggering \$150 billion per year, including disability payments and lost productivity. Fortunately, the cost of treatment is more than made up for by the savings it creates. Compared with untreated patients, those who receive treatment for psychological disorders typically need fewer mental and physical health services later on (American Psychological Association, 2002c; Chiles, Lambert, & Hatch, 1999; Schoenbaum, Sherbourne, & Wells, 2005).

The most common targets of treatment are problems involving anxiety, mood, impulse control, substance abuse, or some combination of these (Kessler, Demler, et al., 2005). Many people also seek treatment for problems that are not officially diagnosed as disorders, such as relationship conflicts or difficulties associated with grief, divorce, retirement, or other life transitions.

In this chapter, we describe a variety of treatment methods, most of which are based on the theories of stress and coping, personality, and psychological disorders reviewed in the chapters on those topics. First we examine the basic features common to all forms of treatment. Then we discuss approaches that rely on **psychotherapy**, the treatment of psychological disorders through psychological methods, such as talking about problems and exploring new ways of thinking and acting. These methods are based on psychodynamic, humanistic, or social-cognitive (behavioral) theories of disorder and treatment. We then consider biological approaches to treatment, which consist of prescription drugs and other physical therapies.

Although we discuss different psychotherapy methods in separate sections, keep in mind that the majority of mental health professionals see themselves as *eclectic* or *integrative* therapists. In other words, they might lean toward one set of methods, but when working with particular clients or particular problems, they employ other methods as well (Hayes & Harris, 2000; Magnavita, 2006; Slife & Reber, 2001).

Basic Features of Treatment

All treatments for psychological disorders share certain basic features. These common features include a *client* or patient, a *therapist* who is accepted as being capable of helping the client, and the establishment of a *special relationship* between the client and therapist. In addition, all forms of treatment are based on some *theory* about the causes of the client's problems. That theory may presume causes ranging

Medieval Treatment Methods

Methods used to treat psychological disorders have always been related to the presumed causes of those disorders. In medieval times, when demonic possession was widely blamed for abnormal behavior, physician-priests tried to make the victim's body an uncomfortable place for evil spirits. Here, we see a depiction of demons fleeing as an afflicted person's head is placed in an oven.

from magic spells to infections and everything in between (Frank & Frank, 1991). The theory, in turn, leads to procedures for dealing with the client's problems. So traditional healers combat supernatural forces with ceremonies and prayers, medical doctors treat chemical imbalances with drugs, and psychologists focus on altering psychological processes through psychotherapy.

People receiving treatment for psychological disorders can be inpatients or outpatients. *Inpatients* are treated in a hospital or other residential institution. They are voluntarily or involuntarily committed to these institutions because their problems are severe enough to create a threat to their own well-being or the safety of others. Depending on their level of functioning, inpatients may stay in the hospital for a few days or weeks or—in rare cases—several years. Their treatment almost always includes psychoactive drugs. *Outpatients* receive psychotherapy and/or drugs while living in the community. Compared with inpatients, outpatients tend to have fewer and less severe symptoms of disorder and to function better in social and occupational situations (Mendlowicz et al., 1998; Sanguineti et al., 1996; White & Litovitz, 1998).

Those who provide psychological treatment are a diverse group (Robiner, 2006). **Psychiatrists** are medical doctors who have completed specialty training in the treatment of psychological disorders. Like other physicians, they are authorized to prescribe drugs for the relief of psychological problems. **Psychologists** who offer psychotherapy have usually completed a doctoral degree in clinical or counseling psychology, often followed by additional specialized training. Except in New Mexico and Louisiana, psychologists are not authorized to prescribe drugs, though this privilege may eventually be granted to specially trained psychologists elsewhere (Heiby, DeLeon, & Anderson, 2004). Other treatment providers include *clinical social workers*, *marriage and family therapists*, and *licensed professional counselors*, all of whom typically hold a master's degree in their respective professions and provide therapy in a variety of settings, such as hospitals, clinics, and private practice. *Psychiatric nurses*, *substance abuse counselors*, members of the clergy working as *pastoral counselors*, and a host of paraprofessionals also provide therapy services, often as part of a hospital or outpatient treatment team (Bernstein, Kramer, & Phares, 2008).

The general goal of treatment is to help troubled people change their thinking, feelings, and behavior in ways that relieve discomfort, promote happiness, and improve their overall functioning as parents, students, workers, and the like. To

- **psychotherapy** The treatment of psychological disorders through talking and other psychological methods.
- **psychiatrists** Medical doctors who have completed special training in the treatment of psychological disorders.
- **psychologists** Among therapists, those whose education includes completion of a master's or (usually) a doctoral degree in clinical or counseling psychology, often followed by additional specialty training.

Group Therapy for War Veterans

Some psychotherapy occurs in one-to-one office sessions, but some treatment is conducted with couples, families, and groups in hospitals, community health centers, and facilities for former mental hospital residents. Therapy is also offered in prisons, at military bases, in drug and alcoholism treatment centers, and in many other places.

reach this goal, some therapists try to help clients gain insight into the hidden causes of problems. Others seek to promote growth through more genuine self-expression, and still others help clients learn and practice new ways of thinking and acting. The particular methods used in each case—whether some form of psychotherapy, a drug treatment, or both—depend on the problems, preferences, and financial circumstances of the client; the time available for treatment; and the therapist’s theoretical leanings, methodological preferences, and professional qualifications. Later, we will discuss drugs and other biological treatments; here, we consider several forms of psychotherapy, each of which is based on a different theoretical explanation of mental disorder.

Psychodynamic Psychotherapy

The field of formal psychotherapy began in the late 1800s when, as described in the chapter on personality, Sigmund Freud established the psychodynamic approach to understanding psychological disorders. Central to his approach, and to modern revisions of it, is the assumption that personality and behavior reflect the efforts of the ego to referee conflicts, usually unconscious, among various components of the personality.

Freud’s method of treatment, **psychoanalysis**, was aimed at understanding these unconscious conflicts and how they affect the client, but most other forms of psychotherapy also incorporate some of his ideas. These include (1) a one-to-one treatment approach; (2) searching for relationships between an individual’s life history and current problems; (3) emphasizing the role of thoughts, emotions, and motivations; and (4) focusing on the client-therapist relationship. We will describe Freud’s original methods first and then consider some more recent treatments that are rooted in his psychodynamic approach.

● Classical Psychoanalysis

Classical psychoanalysis developed mainly out of Freud’s medical practice. He was puzzled by patients who suffered from “hysterical” ailments—blindness, paralysis, or other symptoms that had no apparent physical cause (see our discussion of *conversion*

- **psychoanalysis** A method of psychotherapy that seeks to help clients gain insight by recognizing and understanding unconscious thoughts and emotions.

Freud's Consulting Room During psychoanalytic sessions, Freud's patients lay on this couch, free-associating or describing dreams and everyday events, while he sat in the chair behind them (this famous couch is now at The Freud Museum in London, which you can visit online at <http://www.freud.org.uk/>). According to Freud, even apparently trivial behavior may carry messages from the unconscious. Forgetting a dream or missing a therapy appointment might reflect a client's unconscious resistance to treatment. Even accidents may be meaningful. The waiter who spills hot soup on an elderly male customer might be seen as acting out unconscious aggressive impulses against a father figure.

disorders in the chapter on psychological disorders). Inspired by his colleague Josef Breuer's dramatic success in using hypnosis to treat hysterical symptoms in a patient known as "Anna O." (Breuer & Freud, 1895/1974), Freud tried similar methods with other hysteria patients but found them to be only partially and temporarily successful. Eventually, Freud merely asked patients to lie on a couch and report whatever thoughts, memories, or images came to mind, a process Freud called *free association*.

The results of this "talking cure" were surprising. Freud was struck by how many of his patients reported childhood memories of sexual abuse, usually by a parent or other close relative (Esterson, 2001). Freud wondered whether child abuse was rampant in Vienna, whether he was seeing a biased sample of patients, or whether his patients' memories were being distorted in some way. He eventually concluded that his patients' memories of abuse probably reflected unconscious childhood wishes and fantasies, not reality. He also believed that hysterical symptoms stem from unconscious conflicts over those wishes and fantasies.

As a result, Freud's psychoanalysis came to focus on exploring the unconscious and the conflicts raging within it. Classical psychoanalytic treatment aims first to help troubled people gain *insight* into their problems by recognizing unconscious thoughts and emotions. Then they are encouraged to discover, or *work through*, the many ways in which those unconscious elements continue to motivate maladaptive thinking and behavior in everyday life. The treatment may require as many as three to five sessions per week, usually over several years. Generally, the psychoanalyst is compassionate but emotionally neutral as the patient slowly develops an understanding of how past conflicts determine current problems (Gabbard, 2004).

To gain glimpses of the unconscious—and of the sexual and aggressive impulses he believed reside there—Freud looked for meaning in his patients' free associations, their dreams, their everyday behaviors, and their relationship with him. He believed that hidden beneath the obvious or *manifest content* of dreams is *latent content* that reflects the wishes, impulses, and fantasies that the dreamer's defense mechanisms keep out of consciousness during waking hours. He focused also on what have become known as "Freudian slips" of the tongue and other seemingly insignificant, but potentially meaningful, behaviors. So if a patient mistakenly used the name of a former girlfriend while talking about his wife, Freud might wonder if the patient unconsciously regrets his marriage. Similarly, when patients expressed dependency, hostility, or even love toward him, Freud saw it as an unconscious process in which childhood feelings and conflicts about parents and other significant people were being transferred to the therapist. Analysis of this *transference*, this "new edition" of the patient's childhood conflicts and current

Analysis of the transference in this therapy relationship would be quite a challenge! This parody of psychoanalysis illustrates the point that therapists focus not only on their client's feelings toward them but also on their feelings toward clients—called *countertransference*. For example, if transference leads a client to treat the therapist as a mother, the therapist might, because of countertransference, unintentionally begin treating the client as her child.

"What do you think I think about what you think I think you've been thinking about?"

problems, became another important psychoanalytic method (Gabbard, 2004). Freud believed that focusing on the transference allows patients to see how old conflicts haunt their lives and helps them to resolve these conflicts (Arlow, 1995).

● Contemporary Variations on Psychoanalysis

Classical psychoanalysis is still practiced, but not as much as it was several decades ago (Gabbard, 2004; Horgan, 1996). The decline is due to many factors, including disenchantment with Freud's personality theory; the expense of classical psychoanalysis; its limited usefulness with children; and the availability of many alternative forms of treatment, including variations on classical psychoanalysis (e.g., Roseborough, 2006; Russ, 2006; Stricker, 2006).

Some of these variations were developed by the neo-Freudian theorists discussed in the chapter on personality. As noted there, those theorists tended to place less emphasis than Freud did on the past and on unconscious impulses stemming from the id. They also tended to stress the role of social relationships in clients' problems and how the power of the ego can be harnessed to solve those problems (Gray, 2005). *Ego analysis* (Hartmann, 1958; Klein, 1960) and *individual analysis* (Adler, 1927/1963) were among the first treatments to be based on neo-Freudian theories. Some were designed for treating children (Freud, 1946; Klein, 1960). More recent variations on psychoanalysis alter the format of treatment so that it is less intense, less expensive, and more appropriate for a broader range of clients (Hoyt, 1995; Messer & Kaplan, 2004). Some of these variants have come to be known as *short-term psychodynamic therapy* because they aim to provide benefits in far less time than is required in classical psychoanalysis (Levenson, 2003; Rawson, 2006). However, virtually all modern psychodynamic therapies still focus attention on

Play Therapy Modern versions of psychoanalytic treatment include fantasy play and other techniques that make the approach more useful with children. A child's behavior and comments while playing with puppets representing family members, for example, are seen as a form of free association that the therapist hopes will reveal important unconscious material, such as fear of abandonment (Carlson, Watts, & Maniaci, 2006).

unconscious as well as conscious aspects of mental life, on the impact of internal conflicts, and on transference analysis as a key element in treatment (Levy et al., 2006; Luborsky & Luborsky, 2006; Vanheule et al., 2006).

In a particularly popular short-term psychodynamic approach known as *object relations therapy*, the powerful need for human contact and support takes center stage. Object relations therapists believe that most of the problems that bring clients to treatment ultimately stem from their relationships with others, especially their mothers or other early caregivers. (The term *object* usually refers to a person who has emotional significance for the client.) Psychotherapists who adopt an object relations perspective take a much more active role in therapy sessions than classical analysts do—particularly by directing the client's attention to evidence of certain conflicts, rather than waiting for free association or other more subtle methods to reveal these conflicts. Object relations therapists work to develop a nurturing relationship with their clients, providing a “second chance” for them to receive the support that might have been lacking in infancy and to counteract some of the consequences of maladaptive early attachment patterns (Kahn & Rachman, 2000; Wallerstein, 2002). For example, object relations therapists take pains to show that they will not abandon their clients, as might have happened to these people in the past. *Interpersonal therapy*, too, is rooted partly in neo-Freudian theory (Sullivan, 1954), but it focuses on helping clients explore and overcome the problematic effects of interpersonal events that occur *after* early childhood—events such as the loss of a loved one, conflicts with a parent or a spouse, job loss, or social isolation (Mufson, Polack, & Moreau, 2004; Stuart & Robertson, 2003).

In another version of psychodynamic treatment, the therapist looks for a “core conflict” that appears repeatedly across a variety of relationships, including in the therapy relationship (Luborsky & Luborsky, 2006). In one case, for example, “Katie” reported recurring dreams about breaking glass and accidentally cutting her therapist (Vaughan, 1998). She also recalled two childhood incidents in which she broke glassware after wandering away from her mother; in one incident, her mother cut herself while cleaning up the glass. Katie's therapist suggested that these dreams and memories indicated a core conflict about wanting to be independent of her mother, yet also close to her. Addressing this conflict during therapy helped Katie to realize that professional success did not require her to reject or hurt the people she cared about.

With their focus on interpersonal relationships rather than instincts, their emphasis on clients' potential for self-directed problem solving, and the reassurance and emotional support they provide, contemporary variants on classical psychoanalysis have helped the psychodynamic approach retain its influence among mental health professionals (Stiles et al., 2006; Westen & Gabbard, 1999).

Humanistic Psychotherapy

Whereas some therapists revised Freud's ideas, others developed radical new therapies based on the humanistic approach to personality, which we describe in the personality chapter. *Humanistic psychologists*, sometimes called *phenomenologists*, see people as capable of consciously controlling their own actions and taking responsibility for their own decisions. Most humanistic therapists believe that human behavior is motivated not by sexual or aggressive impulses but rather by an innate drive toward personal growth and improvement that is guided from moment to moment by the way people perceive their world. Disordered behavior, they say, reflects a blockage of natural growth brought on by distorted perceptions or lack of awareness of feelings. Accordingly, humanistic therapy operates on the following assumptions:

1. Treatment is an encounter between equals, not a cure provided by an expert. It is a way to help clients restart their natural growth and to feel and behave more in line with that growth.
2. Clients will improve on their own, given the right conditions. These ideal conditions promote clients' awareness, acceptance, and emotional expression. So, like psychodynamic therapy, humanistic therapy promotes insight, but it is insight into current feelings and perceptions, not into unconscious childhood conflicts.
3. Ideal conditions in therapy can best be established through a relationship in which clients feel fully accepted and supported as human beings, no matter how problematic or undesirable their behavior may be. It is the client's experience of this relationship that brings beneficial changes. (As noted earlier, this assumption is also important in object relations therapy.)
4. Clients must remain responsible for choosing how they will think and behave.

Of the many humanistically oriented treatments in use today, the most influential are client-centered therapy, developed by Carl Rogers (1951), and Gestalt therapy, developed by Frederick and Laura Perls.

- **client-centered therapy (person-centered therapy)** A therapy that allows the client to decide what to talk about, without direction, judgment, or interpretation from the therapist.
- **unconditional positive regard (acceptance)** A therapist attitude that conveys a caring for, and acceptance of, the client as a valued person.
- **empathy** The therapist's attempt to appreciate and understand how the world looks from the client's point of view.
- **reflection** An active listening method in which a therapist conveys empathy by paraphrasing clients' statements and noting accompanying feelings.

● Client-Centered Therapy

Carl Rogers was trained in psychodynamic therapy methods during the 1930s, but he soon began to question their value. He especially disliked being a detached expert observer whose task was to "figure out" the client. Convinced that a less formal approach would be more effective for the client and more comfortable for the therapist, Rogers allowed his clients to decide what to talk about and when, without direction, judgment, or interpretation by the therapist (Raskin & Rogers, 2001). This approach, now called **client-centered therapy** or **person-centered therapy**, relies on the creation of a relationship that reflects three intertwined attitudes of the therapist: unconditional positive regard, empathy, and congruence.

● **Unconditional Positive Regard** The attitude Rogers called **unconditional positive regard**, also known as **acceptance**, is expressed by treating the client as a valued person, no matter what. Rogers believed that experiencing unconditional

acceptance by the therapist helps clients to overcome the sense that their value as a person depends on being successful, intelligent, attractive, or meeting the other *conditions of worth* described in the personality chapter. Acceptance is communicated through the therapist's willingness to listen to the client without interrupting and without making judgments or expressing opinions. The therapist doesn't have to approve of everything the client says but must accept each statement as reflecting the client's view of the world. Client-centered therapists also avoid giving advice, because acceptance includes trusting clients to solve their own problems. They don't want their advice to convey the unspoken suggestion that clients are incompetent and dependent on the therapist's help.

● **Empathy** Client-centered therapists also try to appreciate the client's point of view. This goes far beyond saying "I know what you mean." It involves an effort to see the world as each client sees it, and not to look at clients from the outside. In other words, client-centered therapists work at developing **empathy**, an emotional understanding of what the client might be thinking and feeling. They convey empathy by showing that they are *actively listening* to the client. Like other skillful interviewers, they make eye contact with the client, nod in recognition as the client speaks, and give other signs of careful attention. They also use **reflection**, a paraphrased summary of the client's words that emphasizes the feelings and meanings that appear to accompany them. Reflection confirms the communication, shows that the therapist is interested, and helps the client to perceive and focus on the thoughts and feelings being expressed. Here is an example:

CLIENT: This has been such a bad day. I've felt ready to cry any minute, and I'm not even sure what's wrong!

THERAPIST: You really do feel so bad. The tears just seem to well up inside, and I wonder if it's a little scary to not even know why you feel this way.

Notice that in rephrasing the client's statements, the therapist reflected back not only the obvious feelings of sadness but also the fear in the client's voice. Most clients respond to empathic reflection by elaborating on their feelings. In this example, the client went on to say, "It *is* scary, because I don't like to feel in the dark about myself. I have always prided myself on being in control." Clients do this, said Rogers, simply because the therapist expresses the desire to listen and understand

A Client-Centered Therapy Group
Carl Rogers (shown here in shirtsleeves) believed that, as successful treatment progresses, clients become more self-confident, more aware of their feelings, more accepting of themselves, more comfortable and genuine with other people, more reliant on self-evaluation than on the judgments of others, and more effective and relaxed.

Existential Therapy Rogers's and Perls's methods of treatment represent two prominent examples of humanistic therapies, but there are others, too. For example, Rollo May (1969; May, Angel, & Ellenberger, 1958), Viktor Frankl (1963), and Irwin Yalom (1980) developed therapies based on existential philosophy, which highlights such uniquely human concerns as our freedom to choose our actions, being responsible for those actions, feeling alone in the world, trying to find meaning and purpose in our lives, and confronting the prospect of death (Yalom, 2002). *Existential therapy* is designed to help people accept and deal with these concerns head-on rather than to continue ignoring or avoiding them. Because people can feel lost, alone, and unsure of life's meaning without displaying serious behavior problems, existential therapists see their approach as applicable to anyone, whether or not they are officially diagnosed with some form of mental disorder.

without asking disruptive questions. Empathic listening tends to be so effective in promoting self-understanding and awareness that it is used across a wide range of therapies (Corsini & Wedding, 2001; Miller & Rollnick, 2002). Even outside the realm of therapy, people who are thought of as easy to talk to are usually “good listeners” who reflect back the important messages they hear from others.

● **Congruence** Rogerian therapists also try to convey **congruence** (sometimes called *genuineness*) by acting in ways that are consistent with their feelings during therapy. For example, if they are confused by what a client has said, they would say so rather than trying to pretend that they always understand everything. When the therapist's acceptance and empathy are genuine, the client is able to see that relationships can be built on openness and honesty. Ideally, this experience will help the client become more congruent in other relationships.

Here is an excerpt that illustrates the three therapist attitudes we have described.

CLIENT: . . . I cannot be the kind of person I want to be. I guess maybe I haven't the guts or the strength to kill myself, and if someone else would relieve me of the responsibility or I would be in an accident I, I . . . just don't want to live.

THERAPIST: At the present time things look so bad that you can't see much point in living. [Note the empathic reflection and the attitude of acceptance.]

CLIENT: Yes. I wish I'd never started this therapy. I was happy when I was living in my dream world. There I could be the kind of person I wanted to be. But now there is such a wide, wide gap between my ideal and what I am. . . . [Notice that the client responds to reflection by giving more information.]

THERAPIST: It's really a tough struggle digging into this like you are, and at times the shelter of your dream world looks more attractive and comfortable. [Note the use of empathic reflection.]

CLIENT: My dream world or suicide. . . . So I don't see why I should waste your time—coming in twice a week—I'm not worth it—what do you think?

THERAPIST: It's up to you. . . . It isn't wasting my time. I'd be glad to see you whenever you come but it's how you feel about it. . . . [Note the congruence in stating an honest desire to see the client and the acceptance in trusting her capacity and responsibility for choice.]

CLIENT: You're not going to suggest that I come in oftener? You're not alarmed and think I ought to come in every day until I get out of this?

THERAPIST: I believe you are able to make your own decision. I'll see you whenever you want to come. [Note again the attitude of acceptance.]

CLIENT: (With a note of awe in her voice) I don't believe you are alarmed about—I see—I may be afraid of myself but you aren't afraid for me. [Here the client experiences the therapist's confidence in her; in the end, the client chose not to commit suicide.] (adapted from Rogers, 1951, p. 49)

● Gestalt Therapy

Another form of humanistic treatment was developed by Frederick S. (Fritz) Perls, along with his wife, Laura. A European psychoanalyst, Perls was greatly influenced by research in *Gestalt psychology*. (As described in the chapter on perception, Gestalt psychologists emphasized the idea that people actively organize their perceptions of the world.) He believed that (1) people create their own versions of reality and

● **congruence** A consistency between the way therapists feel and the way they act toward clients.

(2) people's natural psychological growth continues only as long as they perceive, remain aware of, and act on their true feelings. Growth stops and symptoms appear, said Perls, when people are not aware of all aspects of themselves (Perls, 1969; Perls, Hefferline, & Goodman, 1951).

Fritz and Laura Perls based Gestalt therapy on these beliefs. Like client-centered therapy, **Gestalt therapy** seeks to create conditions in which clients can become more unified, self-aware, and self-accepting—and thus ready to grow again. However, Gestalt therapists use more direct and dramatic methods than do Rogerians. Often working in group settings, Gestalt therapists prod clients to become aware of feelings and impulses that they have disowned and to discard feelings, ideas, and values that are not really their own. For example, the therapist or other group members might point out inconsistencies between what clients say and how they behave. Gestalt therapists pay particular attention to clients' gestures and other kinds of “body language” that appear to conflict with what the clients are saying (Kepner, 2001). They may also ask clients to engage in imaginary dialogues, or “conversations,” with other people, with parts of their own personalities, and even with objects (Elliott, Watson, & Goldman, 2004a, 2004b). Like a shy person who can be socially outgoing only while masked at a costume party, clients often find that these dialogues help to get them in touch with, and express, their feelings (Paivio & Greenberg, 1995; Woldt & Toman, 2005).

In recent years, client-centered and other forms of humanistic therapy have declined in popularity (Norcross, Hedges, & Castle, 2002), but Carl Rogers's contributions to psychotherapy remain significant. In particular, his emphasis on the importance of the therapeutic relationship in bringing about change has been adopted by many other treatment approaches (Kirschenbaum & Jourdan, 2005).

Behavior Therapy

Psychodynamic and humanistic approaches to therapy assume that if clients gain insight or self-awareness about underlying problems, the symptoms created by those problems will disappear. Behavior therapists emphasize a different kind of client insight, namely that most psychological problems are *learned behaviors* that can be changed by taking action to learn new ones, not by searching for underlying causes (Martin & Pear, 2002; Miltenberger, 2003).

For example, consider again José, the electronics technician whose panic attacks are described in the chapter on psychological disorders. Some of these attacks had occurred while he was scuba diving, so he began making excuses when friends invited him to go on diving trips. Avoiding diving situations eased his anxiety temporarily but it did nothing to solve the problem. Could José reduce his fear without first discovering its “underlying meaning”? *Behavior therapy* would offer just such an alternative by first identifying the signals, rewards and punishments, and other learning-based factors that maintain José's fear and then helping him to develop new responses in feared situations.

These goals are based on both the *behavioral approach* to psychology and the *social-cognitive approach* to personality and disorder. As described in the chapters on introducing psychology, on personality, and on psychological disorders, these approaches emphasize the role of learning in the development of personality, as well as in most psychological disorders. Accordingly, behaviorists tend to see those disorders as examples of the maladaptive thoughts and actions that a client has learned. For instance, behavior therapists believe that fear of leaving home (*agoraphobia*) develops through classically conditioned associations between being away from home and having panic attacks. The problem is maintained in part through operant conditioning: Staying home and making excuses for doing so are rewarded by reduced anxiety. Therapists adopting a behavioral approach argue that if learning experiences can create problems, they can also help to alleviate problems.

- **Gestalt therapy** An active treatment designed to help clients get in touch with genuine feelings and disown foreign ones.

So even if the experiences that led to today's problems began in the client's childhood, behavior therapy seeks to solve those problems by creating beneficial new experiences using the principles discussed in the chapter on learning.

Inspired by John B. Watson, Ivan P. Pavlov, B. F. Skinner, and others who studied learning during the 1920s and 1930s, researchers in the late 1950s and early 1960s began to systematically apply the principles of classical conditioning, operant conditioning, and observational learning to alter disordered human behavior (Ullmann & Krasner, 1965). By 1970, behavioral treatment had become a popular alternative to psychodynamic and humanistic methods (Craighead, Craighead, & Ilardi, 1995).

The most notable features of behavioral treatment include the following:

1. Development of a productive therapist-client relationship. As in other therapies, this relationship enhances clients' confidence that change is possible and makes it easier for them to speak openly and to cooperate in treatment (Creed & Kendall, 2005; Lejuez et al., 2005).
2. A careful listing of the behaviors and thoughts to be changed (Umbreit et al., 2006). This assessment—and the establishment of specific treatment goals—often replaces the formal diagnosis used in some other therapy approaches. So instead of treating “depression” or “obsessive-compulsive disorder,” behavior therapists work to change the specific thoughts, behaviors, and emotional reactions that cause people to receive these diagnostic labels.
3. A therapist who acts as a kind of teacher/assistant by providing learning-based treatments, giving “homework” assignments, and helping the client make specific plans for dealing with problems, rather than just talking about them (Shelton & Levy, 1981).
4. Continuous monitoring and evaluation of treatment, along with constant adjustments to any procedures that are not effective (Farmer & Nelson-Gary, 2005). Because ineffective procedures are soon altered or abandoned, behavioral treatment tends to be one of the briefer forms of therapy.

Behavioral treatment can take many forms. By tradition, those that rely mainly on classical conditioning principles are usually referred to as **behavior therapy**. Those that focus on operant conditioning methods are usually called **behavior modification**. And behavioral treatment that focuses on changing thoughts as well as overt behaviors is called **cognitive-behavior therapy**. These methods, especially cognitive-behavior therapy, are among the most important and influential approaches to psychological treatment available today (Durlak, 2006).

- **behavior therapy** Treatments that use classical conditioning principles to change behavior.
- **behavior modification** Treatments that use operant conditioning methods to change behavior.
- **cognitive-behavior therapy** Learning-based treatment methods that help clients change the way they think, as well as the way they behave.
- **systematic desensitization** A behavioral treatment for anxiety in which clients visualize a graduated series of anxiety-provoking stimuli while remaining relaxed.
- **flooding** An exposure technique for reducing anxiety that involves keeping a person in a feared, but harmless, situation.
- **exposure techniques** Behavior therapy methods in which clients remain in the presence of strong anxiety-provoking stimuli until the intensity of their emotional reactions decrease.

● Techniques for Modifying Behavior

Among the most important behavior therapy methods are systematic desensitization, exposure techniques, modeling, positive reinforcement, extinction, punishment, and aversion conditioning.

● **Systematic Desensitization** Joseph Wolpe (1958) developed one of the first behavioral methods for helping clients overcome phobias and other forms of anxiety. Called **systematic desensitization**, it is a method in which the client visualizes a series of anxiety-provoking stimuli while remaining relaxed. Wolpe believed that this process gradually weakens the learned association between anxiety and the feared object, until the fear disappears.

Wolpe first helped his clients learn to relax, often using the *progressive relaxation training* procedures described in the chapter on health, stress, and coping. Then, while relaxed, the clients would be asked to imagine an item from a *desensitization hierarchy*, a sequence of increasingly fear-provoking situations (see Table 16.1). The clients would imagine one hierarchy item at a time, moving to a more difficult scene only after tolerating the previous one without distress. Wolpe found that once clients

TABLE 16.1 A Desensitization Hierarchy

Desensitization hierarchies are lists of increasingly fear-provoking situations that clients visualize while using relaxation methods to remain calm. Here are a few items from the beginning and the end of a hierarchy that was used to help a client overcome fear of flying.

1. You are reading a newspaper and notice an ad for an airline.
2. You are watching a television program that shows a group of people boarding a plane.
3. Your boss tells you that you need to take a business trip by air.
4. You are in your bedroom packing your suitcase for your trip.
- .
- .
- .
12. Your plane begins to move as you hear the flight attendant say, "Be sure your seat belt is securely fastened."
13. You look at the runway as the plane is readied for takeoff.
14. You look out the window as the plane rolls down the runway.
15. You look out the window as the plane leaves the ground.

could calmly imagine being in feared situations, they were better able to deal with them in reality later on.

Wolpe's original treatment package is not used as much as it once was (McGlynn, Smitherman, & Gothard, 2004), partly because of research indicating that desensitization is especially effective if it slowly and carefully presents clients with real (rather than imagined) hierarchy items (Bouton, 2000, 2002; Choy, Fyer, & Lipsitz, 2007; Marks, 2002; Tryon, 2005). This *in vivo*, or "real life," desensitization was once difficult to arrange or control, especially in cases involving fear of flying, heights, or highway driving, for example. However, *virtual reality graded exposure* now makes it possible for clients to "experience" extremely vivid and precisely graduated versions of feared situations without actually being exposed to them. In one study, clients who feared heights wore a head-mounted virtual reality helmet that gave them the impression of standing on bridges of gradually increasing heights, on outdoor balconies at higher and higher floors, and in a glass elevator as it slowly rose forty-nine stories (Rothbaum et al., 1995). The same technology has been used successfully in the treatment of many other anxiety disorders, ranging from fear of spiders or air travel to social phobia and posttraumatic stress disorder (Anderson, Rothbaum, & Hodges, 2003; Glantz, Rizzo, & Graap, 2003; Maltby, Kirsch, & Mayers, 2002; Rothbaum, 2006; Wiederhold & Wiederhold, 2005).

Exactly why systematic desensitization works is not clear. Traditionally, clinicians believed that change occurs because of basic learning processes—either through classical conditioning of a new, calmer response to the fear-provoking stimulus or through extinction, as the object or situation that had been a conditioned fear stimulus repeatedly occurs without being paired with pain or any other aversive unconditioned stimulus (Hermans et al., 2006; McNeil & Zvolensky, 2000). More recent explanations emphasize that desensitization also modifies clients' cognitive processes, including their expectation that they can deal calmly and successfully with previously feared situations (McNeil & Zvolensky, 2000).

Virtual Desensitization This client fears heights. He is wearing a virtual reality display that creates the visual experience of being in a glass elevator which, under the therapist's careful control, seems to gradually rise higher and higher. After learning to tolerate these realistic images without anxiety, clients are better able to fearlessly face the situations they once avoided.

● **Exposure Techniques** Extinction is also the basis of **flooding**, an anxiety-reduction treatment that keeps people in a feared but harmless situation and prevents them from engaging in their normally rewarding pattern of escape (O'Donohue, Hayes, & Fisher, 2003). Because they continuously expose clients to feared stimuli, flooding and other similar methods are called **exposure techniques**. The clients are flooded with fear at first, but after an extended period of exposure to the feared

Treating Fear Through Flooding

Flooding is designed to extinguish anxiety by allowing it to occur without the harmful consequences the person dreads. This man's fear of flying is obvious here, on takeoff, but it is likely to diminish during and after an uneventful flight. Like other behavioral treatments, flooding is based on the idea that phobias and other psychological disorders are learned and can thus be "unlearned." Some therapists prefer more gradual exposure methods similar to those of *in vivo* desensitization, which start with situations that are lower on the client's fear hierarchy.

stimulus (a frog, say) without experiencing pain, injury, or any other dreaded result, the association between the feared stimulus and the fear response gradually weakens, and the conditioned fear response is extinguished (Basoglu, Livanou, & Salcioglu, 2003; McNally, 2007). In one study, twenty clients who feared needles were exposed for two hours to the sight and feel of needles, including mild finger pricks, harmless injections, and blood samplings (Öst, Hellström, & Kåver, 1992). Afterward, all but one of these clients were able to have a blood sample drawn without experiencing significant anxiety.

Although often highly effective, flooding is equivalent to immediately exposing a fearful client to the most distressing item on a desensitization hierarchy. Therefore, some therapists and clients prefer more gradual exposure methods, especially when a client's fear is not focused on a specific stimulus (Hecker & Thorpe, 1992). In dealing with agoraphobia, for instance, the therapist might provide gradual exposure by escorting the client away from home for increasing periods and eventually venturing into shopping malls and other previously avoided places (Barlow, Raffa, & Cohen, 2002; Craske et al., 2003). Clients can also practice gradual exposure methods on their own. They might be instructed, for example, to spend a little more time each day looking at photos of some feared animal or to spend some time alone in a dental chair or waiting room. In one study, clients suffering from various phobias made as much progress after six hours of instruction in gradual self-exposure methods and daily "homework" exercises as did those who received an additional nine hours of therapist-aided gradual exposure (Al-Kubaisy et al., 1992). Effective self-treatment using gradual exposure has also been reported in cases of panic disorder (Hecker et al., 1996) and obsessive-compulsive disorder (Fritzler, Hecker, & Losee, 1997).

● **Modeling** Behavior therapists sometimes help clients to develop more desirable behaviors by demonstrating those behaviors. In **modeling** treatments, the client watches the therapist or other people perform desired behaviors, thus learning skills vicariously, or second-hand, without going through a lengthy shaping process (Bidwell & Rehfeldt, 2004). In fear treatment, for example, modeling can teach the client how to respond fearlessly while vicariously extinguishing conditioned fear responses. One therapist showed a twenty-four-year-old student with a severe spider phobia how to kill spiders with a fly swatter and had her practice this skill at home with rubber spiders (MacDonald & Bernstein, 1974). The combination of live modeling with gradual practice is called *participant modeling*, and it is one of the most powerful treatments for fear (Bandura, Blanchard, & Ritter, 1969; Faust, Olson, & Rodriguez, 1991; see Figure 16.1).

Modeling is also a major part of *social skills training* and *assertiveness training*, which teach clients how to interact with people more comfortably and effectively. The goals of **social skills training** range from helping socially phobic singles make conversation on dates to rebuilding the abilities of mental patients so they can interact more normally with people outside the hospital (Al-Kubaisy & Jassim, 2003; McQuaid et al., 2000; Spence, Donovan, & Brechman-Toussaint, 2000; Trower, 1995). In **assertiveness training**, the therapist helps clients learn to be more direct and expressive in social situations. So instead of sheepishly agreeing to be seated at a badly located restaurant table, clients learn to be comfortable making "I-statements," such as "I would rather sit over there, by the window." Notice that *assertiveness* does not mean aggressiveness; instead it involves clearly and directly expressing both positive and negative feelings and standing up for one's own rights while respecting the rights of others (Alberti & Emmons, 1986; Paterson, 2000). Assertiveness training is often conducted in groups and involves both modeling and role playing of specific situations (Spence, 2003). For example, group assertiveness training has helped wheelchair-bound adults more comfortably handle the socially awkward situations in which they sometimes find themselves (Gleuckauf & Quittner, 1992; Weston & Went, 1999).

- **modeling** Demonstrating desirable behaviors as a way of teaching them to clients.
- **assertiveness training and social skills training** Methods for teaching clients how to interact with others more comfortably and effectively.

FIGURE 16.1

Participant Modeling

In this study, participant modeling was compared with systematic desensitization, symbolic modeling (watching filmed models), and no treatment (control). Notice that, compared with no treatment, all three methods helped snake-phobic clients approach live snakes, but participant modeling was clearly the best. Ninety-two percent of the participants in that group were virtually free of any fear. The value of participant modeling has been repeatedly confirmed (e.g., Öst, Salkovskis, & Hellström, 1991).

- **positive reinforcement** A therapy method that uses rewards to strengthen desirable behaviors.
- **token economy** A system for improving the behavior of institutionalized clients in which desirable behaviors are rewarded with tokens that can be exchanged for desired items or activities.
- **extinction** The gradual disappearance of a conditioned response or operant behavior through nonreinforcement.
- **punishment** A therapy method that weakens undesirable behavior by following it with an unpleasant stimulus.
- **aversion conditioning** A method that uses classical conditioning to create a negative response to a particular stimulus.

● **Positive Reinforcement** Behavior therapists also use systematic **positive reinforcement** to change problematic behaviors and to teach new skills in cases ranging from childhood tantrums and juvenile delinquency to schizophrenia and substance abuse (e.g., Lussier et al., 2006). Using operant conditioning principles, they set up *contingencies*, or rules, that specify the behaviors to be strengthened through reinforcement. In one study, language-impaired autistic children were given grapes, popcorn, or other items they liked in return for saying “please,” “thank you,” and “you’re welcome” while exchanging crayons and blocks with a therapist. The therapist first modeled the behavior by saying the appropriate words. The children almost immediately began to utter the phrases themselves and were reinforced for doing so. The effects of positive reinforcement generalized to situations involving other toys, and, as indicated in Figure 16.2, the new skills were still evident at a follow-up session six months later (Matson et al., 1990).

When working with severely retarded or disturbed clients in institutions, behavior therapists sometimes establish a **token economy**, a system in which desirable behaviors are positively reinforced with coin-like tokens or points that can be exchanged later for snacks, access to television, or other rewards (Ayllon, 1999; LePage et al., 2003; Paul & Lentz, 1977; Seeger, 2003). The goal is to shape behavior patterns that will persist outside the institution.

● **Extinction, Punishment, and Aversion Conditioning** Just as reinforcement can make desirable behaviors more likely, other behavioral techniques can make undesirable behaviors less likely. One operant conditioning method, for example, promotes the **extinction** of undesirable behaviors by removing the reinforcers that normally follow those behaviors. So a person who gets satisfying attention by disrupting a classroom, damaging property, or violating hospital rules might be placed in a quiet, boring “time out” room for a few minutes in order to interrupt reinforcement for this misbehavior (e.g., Kee, Hill, & Weist, 1999; Reitman & Drabman, 1999). When such behavior no longer “pays off,” people usually stop performing it, though the process of change can be slow. Still, extinction-based programs are often chosen when dealing with children and retarded or seriously disturbed adults because they provide a gentle way to eliminate undesirable behaviors (Ducharme & Van Houten, 1994).

Sometimes, though, the only way to eliminate a dangerous or disruptive behavior is through **punishment**, an operant conditioning technique in which undesirable behavior is followed by an unpleasant but harmless stimulus, such as a shouted “No!” or a mild electrical shock. However, before behavior therapists use punishment with the institutionalized clients, other impaired adults, or children for whom it might be appropriate and beneficial, they must consider certain ethical and legal questions: Would the client’s life be in danger without treatment? Have all other methods failed? Has an ethics committee reviewed and approved the procedures? And has the client or a close relative formally agreed to the treatment? (Kazdin, 1994a). When the answer to these questions is yes, punishment can be an effective, sometimes lifesaving, treatment—as in the case illustrated in Figure 6.11 in the chapter on learning. And even then, punishment is best used only long enough to eliminate undesirable behavior and in combination with other behavioral methods designed to reinforce more appropriate behavior (Hanley et al., 2005).

When unwanted behaviors—such as using addictive drugs, gambling, or engaging in certain sexual offenses—have become deeply habitual and immediately rewarding, not even punishment may be effective in eliminating them. In such cases, behavior therapists may try to make these behaviors less attractive, thus making it easier for clients to give them up. Methods for reducing the appeal of certain stimuli are known as **aversion therapy**. The name reflects the fact that these methods rely on a classical conditioning principle called **aversion conditioning** to associate nausea, painful electrical shock, or some other unpleasant stimulus with the actions, thoughts, or situations the client wants to stop or avoid (e.g., Bordnick et al., 2004).

FIGURE 16.2**Positive Reinforcement for an Autistic Child**

During each pretreatment baseline period, an autistic child rarely said “please,” “thank you,” or “you’re welcome,” but these statements began to occur once they were modeled, then reinforced. Did modeling and reinforcement actually cause the change? Probably, because each type of response did not start to increase until the therapist began demonstrating it.

Because aversion therapy is unpleasant and uncomfortable, because it may not work with all clients (Flor et al., 2002), and because its effects are often temporary, behavior therapists use this method relatively rarely, only when it is the best treatment choice, and only long enough to allow the client to learn a more desirable alternative behavior.

● Cognitive-Behavior Therapy

Like psychodynamic and humanistic therapists, behavior therapists recognize that depression, anxiety, and many other behavior disorders can stem from how clients think about themselves and the world. And like other therapists, behavior therapists also try to change their clients' troublesome ways of thinking. However, the methods used by behavior therapists—known collectively as *cognitive-behavior therapy*—rely on learning principles to help clients change the way they think (e.g., Dobson, 2003; O'Donohue et al., 2003). Suppose, for example, that a client suffers intense anxiety in social situations, despite having excellent social skills. In a case such as this, social skills training would be unnecessary. Instead, the behavior therapist would use cognitive-behavioral methods designed to help the client identify the recurring thoughts (such as “I shouldn't draw attention to myself”) that get in the way of self-expression and create discomfort. Once these cognitive obstacles are brought to light, the therapist models—and encourages the client to develop and practice—new and more adaptive ways of thinking. As these new cognitive skills are learned, it becomes easier and more rewarding for clients to let these new thoughts guide their behavior (Meichenbaum, 1995).

● **rational-emotive behavior therapy (REBT)** A treatment designed to identify and change self-defeating thoughts that lead to anxiety and other symptoms of disorder.

● **Rational-Emotive Behavior Therapy** One prominent form of cognitive-behavior therapy is **rational-emotive behavior therapy (REBT)**. Developed by Albert Ellis (1962, 1993, 1995, 2004a, 2004b), REBT is based on the notion that anxiety, guilt, depression, and other psychological problems are caused by how people think

Albert Ellis Rational-emotive behavior therapy (REBT) focuses on altering the self-defeating thoughts that Ellis believed underlie people's behavior disorders. Ellis argued, for example, that students do not get upset because they fail a test but because they have learned to believe that failure is a disaster that indicates they are worthless. Many of Ellis's ideas have been incorporated into various forms of cognitive-behavior therapy, and they helped Ellis himself to deal rationally with the health problems he encountered near the end of his life (Ellis, 1997).

about events, not by the events themselves. Ellis's therapy aims first at identifying self-defeating beliefs, usually in the form of *shoulds* or *musts*, such as "I should be loved or approved by everyone" or "I must be perfect in order to be worthwhile." After the client learns to recognize thoughts like these and to see how they can cause problems, the therapist uses modeling, encouragement, and logic to help the client replace them with thoughts that are more realistic. The client is then given "homework" assignments to try out these new ways of thinking in everyday situations. Here is part of an REBT session with a woman who suffered from panic attacks. She has just said that it would be "terrible" if she had an attack in a restaurant and that people "should be able to handle themselves!"

THERAPIST: . . . The reality is that . . . "shoulds" and "musts" are the rules that other people hand down to us, and we grow up accepting them as if they are the absolute truth, which they most assuredly aren't.

CLIENT: You mean it is perfectly okay to, you know, pass out in a restaurant?

THERAPIST: Sure!

CLIENT: But . . . I know I wouldn't like it to happen.

THERAPIST: I can certainly understand that. It would be unpleasant, awkward, inconvenient. But it is illogical to think that it would be terrible, or . . . that it somehow bears on your worth as a person.

CLIENT: What do you mean?

THERAPIST: Well, suppose one of your friends calls you up and invites you back to that restaurant. If you start telling yourself, "I might panic and pass out and people might make fun of me and that would be terrible," . . . you might find you are dreading going to the restaurant, and you probably won't enjoy the meal very much.

CLIENT: Well, that is what usually happens.

THERAPIST: But it doesn't have to be that way. . . . The way you feel, your reaction . . . depends on what you choose to believe or think, or say to yourself. (Masters et al., 1987)

Cognitive-behavior therapists use many techniques related to REBT to help clients learn to think and act in more adaptive ways. Behavioral techniques aimed at replacing upsetting thoughts with alternative thinking patterns are called *cognitive restructuring* (Lazarus, 1971). Using these techniques, clients develop calming thoughts that they can use as part of *self-instruction* during exams, tense discussions, and other anxiety-provoking situations. The calming thoughts might be something like "OK, you can handle this if you just focus on the task and don't worry about being perfect" (Meichenbaum, 1977). Sometimes, the methods are expanded into *stress inoculation training*, in which clients imagine being in a stressful situation, then practice newly learned cognitive skills to remain calm (Meichenbaum, 1995). In one study of stress inoculation training, first-year law students tried out calming new thoughts during role-playing exercises that exposed them to stressful classroom-style questioning, hostile feedback, and a competitive learning atmosphere. Following training, these students showed reductions in troublesome responses to stressors as well as improved academic performance (Sheehy & Horan, 2004).

● **Beck's Cognitive Therapy** Behavior therapists seek a different kind of cognitive restructuring by using Aaron Beck's **cognitive therapy** (Beck, 1976, 1995, 2005). Beck's treatment approach is based on the idea that certain psychological disorders—especially those involving depression and anxiety—can be traced to errors in logic, or what he calls *cognitive distortions*. Common cognitive distortions include *catastrophizing* (e.g., "If I fail my driver's test the first time, I'll never pass it and that'll be the end of my social life"), *all-or-none thinking* (e.g., "Everyone ignores me"),

● **cognitive therapy** A treatment in which the therapist helps clients to notice and change negative thoughts associated with anxiety and depression.

TABLE 16.2 Some Examples of Negative Thinking

TRY THIS  Here are just a few examples of the kinds of thoughts that cognitive-behavior therapists see as underlying anxiety, depression, and other behavior problems. After reading this list, try writing an alternative thought that clients could use to replace each of these ingrained cognitive habits. Then jot down a “homework assignment” that you would recommend to help clients challenge each maladaptive statement, and thus develop new ways of thinking about themselves.

“I shouldn’t draw attention to myself.”
 “I will never be any good at this.”
 “It will be so awful if I don’t know the answer.”
 “Everyone is smarter than I am.”
 “Nobody likes me.”
 “I should be able to do this job perfectly.”
 “What if I panic?”
 “I’ll never be happy.”
 “I should have accomplished more by this point in my life.”

and *personalization* (e.g., “I know those people are laughing at *me*”). Beck points out that these learned cognitive distortions occur so quickly and automatically that the client never stops to consider that they might not be true.

Cognitive therapy is an active, structured, problem-solving approach in which the therapist first helps clients to identify the distorted thoughts and beliefs that precede anxiety, depression, eating disorders, and other psychological problems (Beck & Rector, 2005; Drinkwater & Stewart, 2002; Hendricks & Thompson, 2005; Pardini & Lochman, 2003; see Table 16.2). Then, much as in the five-step critical thinking system illustrated throughout this book, those thoughts and beliefs are treated as hypotheses to be scientifically tested rather than as assertions to be uncritically accepted (Hatcher, Brown, & Gariglietti, 2001). Accordingly, therapist and client take the role of “investigators” who develop ways to test beliefs such as “I’m no good around the house.” They might decide on tasks that the client will attempt as “homework”—such as cleaning out the basement, cooking a meal, paying bills, or cutting the grass. Success at accomplishing even one of these tasks provides concrete evidence to challenge a false belief that has supported depression, thus helping to reduce it. As therapy progresses, clients become more skilled at recognizing, and then correcting, the cognitive distortions related to their problems.

As mentioned in the chapter on psychological disorders, however, the cognitive roots of depression, anxiety, and some other disorders may involve more than specific thoughts and beliefs about certain situations (Beck, 2002). They may be associated with a more general cognitive style that leads people to expect the worst and to consider any negative events to be confirmation that they are completely and permanently incompetent or unlovable (Peterson, 1995; Peterson & Seligman, 1984). Accordingly, cognitive-behavior therapists help depressed clients, for example, to develop more optimistic ways of thinking and to reduce their tendency to blame themselves for negative outcomes (Persons, Davidson, & Tompkins, 2001). In some cases, cognitive restructuring is combined with practice at using logical thinking, anxiety management techniques, and skill training—all designed to help clients experience success and develop confidence in situations in which they had previously expected to fail (Beck & Beck, 1995). Some cognitive therapists have also encouraged clients to use traditional Eastern practices such as meditation (see the chapter on consciousness) to help monitor problematic thoughts. This combined approach is called *mindfulness-based cognitive therapy* (Ma & Teasdale, 2004; Segal, Williams, & Teasdale, 2001). Research in the field of positive psychology suggests, too, that the effects of cognitive behavior therapy may be enhanced through exercises designed to promote positive emotions—such as identifying and using personal strengths, and making a list of three things that have gone well each day (Seligman, Berkowitz, et al., 2005; Seligman, Rashid, & Parks, 2006).

Group, Family, and Couples Therapy

The psychodynamic, humanistic, and behavioral treatments we have described are often conducted with individuals, but they can also be adapted for use with groups of clients or with family units (Petrocelli, 2002; Thorngren & Kleist, 2002).

● Group Therapy

Group therapy refers to the treatment of several unrelated clients under the guidance of a therapist who encourages helpful interactions among group members. Many groups are organized around a particular problem (such as alcoholism) or a particular type of client (such as adolescents). In most cases, six to twelve clients meet with their therapist at least once a week for about two hours. All group members agree to hold confidential everything that occurs during these sessions.

Group therapy offers several features not found in individual treatment (Marmarosh, Holtz, & Schottenbauer, 2005; Yalom, 1995). First, group therapy allows the therapist to see clients interacting with one another, which can be helpful in identifying problems in clients' interpersonal styles. Second, clients discover that they are not alone as they listen to others and realize that many people struggle with difficulties similar to theirs. This realization tends to lift each client's expectations for improvement, a factor important in all forms of treatment. Third, group members can boost one another's self-confidence and self-acceptance as they come to trust and value one another. Fourth, clients learn from one another by sharing ideas for solving problems and giving one another honest feedback about how each member "comes across" to others. Fifth, perhaps through mutual modeling, the group experience makes clients more willing to share their feelings and more sensitive to other people's needs and messages. Finally, group therapy allows clients to try out new skills—such as assertiveness—in a safe and supportive environment.

Some of the advantages of group therapy are also put to use in *self-help organizations*. Self-help groups, such as Alcoholics Anonymous (AA), are made up of people who share some problematic experience and meet to help one another. There are

A Circle of Friends This meeting of Overeaters Anonymous is but one example of the self-help movement in North America, a growing network of inexpensive mental health and anti-addiction services offered by volunteer helpers, including friends and relatives of troubled people. A recent edition of one small-town Florida newspaper listed 104 local self-help groups focused on problems ranging from alcohol abuse to weight control. The services provided by these nonprofessional groups make up about 20 percent of the total mental health and anti-addiction services offered in the United States (Borkman, 1997; Regier et al., 1993; Swindle et al., 2000).

self-help groups for a wide range of problems, including alcohol and drug addiction, childhood sexual abuse, cancer, overeating, overspending, bereavement, compulsive gambling, and schizophrenia, among many others (e.g., Humphreys, 2004; Kurtz, 2004). The worldwide self-help movement has grown dramatically in recent decades, partly because many troubled people prefer to seek help from friends, teachers, or other “unofficial” helpers before turning to mental health practitioners (Swindle et al., 2000). Dozens of self-help organizations operate through hundreds of thousands of local chapters, enrolling 10 million to 15 million participants in the United States and about half a million in Canada (Barlow et al., 2000; Norcross et al., 2000; Swindle et al., 2000).

Lack of reliable data makes it difficult to assess the value of many self-help groups, but available information suggests that active members may experience moderate improvement in their lives (Kelly, 2003; Mains & Scogin, 2003; Masudomi et al., 2004; Moos et al., 2001). Some professional therapists view these groups with suspicion; others encourage clients to participate in them as part of their treatment or as a first step toward more formal treatment (Haaga, 2000; Salzer, Rappaport, & Segre, 1999), especially in cases of eating disorders, alcoholism, and other substance-related problems (Dunne & Fitzpatrick, 1999; Guimon, 2004; Scheidinger, 2004).

● Family and Couples Therapy

As its name implies, **family therapy** involves treatment of two or more individuals from the same family system, one of whom—often a troubled child or adolescent—is the initially identified client. The term *family system* highlights the idea that the problems displayed by one family member usually reflect problems in the functioning of the entire family (Cox & Paley, 2003; Pilling et al., 2002; Williams, 2005).

Whether family therapy is based on psychodynamic, humanistic, or cognitive-behavioral approaches, the family itself becomes the client, and treatment involves as many members as possible (Novick & Novick, 2005). In fact, the goal of family therapy is not just to ease the identified client’s problems but also to create greater harmony and balance within the family by helping each member understand the family’s interaction patterns (Blow & Timm, 2002). As with group therapy, the family format gives the therapist a chance to see how the initially identified client interacts with others, thus providing a basis for discussion of topics that are important in the operation of the family system.

Family therapists who emphasize psychodynamic theory point out that if the parents in a family have not worked out conflicts with their own parents, these conflicts will surface in relation to their spouses and children (Scharff & Scharff, 2003). Accordingly, these family therapy sessions might focus on the parents’ problems with their own parents and, when possible, include members of the older generation. A related approach, called *structural family therapy*, concentrates on family communication patterns. It focuses on changing the rigid patterns and rituals that create *alliances* (such as mother and child against father), because these alliances maintain conflicts and prevent healthy communication within the family. Structural family therapists argue that when dysfunctional communication patterns are eliminated, problematic interactions will decrease because family members no longer need them in order to survive in the family system (McLendon, McLendon, & Petr, 2005).

Behavior therapists often use family therapy sessions as meetings at which family members can discuss and agree on behavioral “contracts” (e.g., Hayes et al., 2000). Based on operant conditioning principles, these contracts establish rules and reinforcement contingencies that help parents encourage their children’s desirable behaviors (while discouraging undesirable ones) and help spouses become more supportive of each other (O’Farrell, 1995; Sanders & Dadds, 1993).

Therapists of many theoretical persuasions also offer **couples therapy**, in which communication between partners is the main focus of treatment (Christensen et al., 2004; Gurman & Jacobson, 2002). Discussion in couples therapy sessions is usually

- **family therapy** Treatment of two or more individuals from the same family.
- **couples therapy** A form of therapy focusing on improving communication between partners.

TABLE 16.3 Some “Rules for Talking” in Couples Therapy

TRY THIS Many forms of couples therapy help partners improve communication by establishing rules such as these. Think about your own experience in relationships or your observations of couples as they interact, and then write down some rules you would add to this list. Why do you think it would be important for couples to follow the rules on your list?

1. Always begin with something positive when stating a problem.
2. Use specific behaviors rather than derogatory labels or overgeneralizations to describe what is bothersome about the other person.
3. Make connections between those specific behaviors and feelings that arise in response to them (e.g., “It makes me sad when you . . .”).
4. Admit your own role in the development of the problem.
5. Be brief; don’t lecture or harangue.
6. Maintain a focus on the present or the future; don’t review all previous examples of the problem or ask “why” questions, such as “Why do you always . . .?”
7. Talk about observable events; don’t make inferences about them (e.g., say, “I get angry when you interrupt me” rather than “Stop trying to make me feel stupid”).
8. Paraphrase what your partner has said, and check out your own perceptions of what was said before responding. (Note that this suggestion is based on the same principle as Rogers’s empathic listening.)

aimed at identifying and improving the problematic interactions that are interfering with a couple’s happiness and intimacy. In behavioral marital therapy, for example, couples learn to abide by certain “rules for talking,” such as those listed in Table 16.3 (Shadish & Baldwin, 2005). Another version of couples therapy focuses on strengthening the bond between partners by teaching them how to deal with their unsolvable problems and recover from their fights by expressing at least five times as many positive statements as negative ones (Gottman, Driver, & Tabares, 2002).

Some therapists even offer programs designed to *prevent* marital problems in couples whose interactions suggest that they are at high risk for developing discord (Gottman, Gottman, & Declaire, 2006; Jacobson et al., 2000; Laurenceau et al., 2004). “In Review: Approaches to Psychological Treatment” summarizes key features of the main approaches to treatment that we have discussed so far.

Fortunately, most couples are not this far out of touch, but couples therapy aims to identify the communication problems that do exist in the relationship and to help the partners speak to each other more directly and listen to each other more carefully.

in review Approaches to Psychological Treatment

| Dimension | Classical Psychoanalytic | Contemporary Psychodynamic | Humanistic | Behavioral/Cognitive-Behavioral |
|---------------------------|--|---|---|--|
| Nature of the human being | Driven by sexual and aggressive urges | Driven by the need for human relationships | Has free will, choice, and capacity for self-actualization | Is a product of social learning and conditioning; behaves on the basis of past experience |
| Therapist's role | Neutral; helps client explore meaning of free associations and other material from the unconscious | Active; develops relationship with client as a model for other relationships | Facilitates client's growth; some therapists are active, some are nondirective | Teacher/trainer who helps client replace undesirable thoughts and behaviors; active, action oriented |
| Focus | Emphasizes unresolved unconscious conflicts from the distant past | Understanding the past, but focusing on current relationships | Here and now; focus on immediate experience | Current behavior and thoughts; may not need to know original causes to create change |
| Goals | Psychosexual maturity through insight; strengthening of ego functions | Correction of effects of failures of early attachment; development of satisfying intimate relationships | Expanded awareness; fulfillment of potential; self-acceptance | Changes in thinking and behaving in particular classes of situations; better self-management |
| Typical methods | Free association; dream analysis; analysis of transference | Analysis of interpersonal relationships, including the client-therapist relationship | Reflection-oriented interviews designed to convey unconditional positive regard, empathy, and congruence; exercises to promote self-awareness | Systematic desensitization, social skills training, positive reinforcement, extinction, aversion conditioning, punishment, and cognitive restructuring |

Evaluating Psychotherapy

 LINKAGES (a link to *Introducing Psychology*, p. 10)

Most psychotherapists and their clients believe in psychotherapy's effectiveness (*Consumer Reports*, 1995), but confirming this belief with experimental research has proved to be challenging and controversial (Beutler, 2002; Dawes, 1994; Laurenceau, Hayes, & Feldman, 2007; Norcross, Beutler, & Levant, 2005; Seligman, 1996; Weisz, Weersing, & Henggeler, 2005; Westen, Novotny, & Thompson-Brenner, 2004).

The value of psychotherapy was first widely questioned in 1952, when British psychologist Hans Eysenck reviewed studies in which thousands of clients had received either traditional psychodynamic therapy, various other therapies, or no treatment. To the surprise and dismay of many therapists, Eysenck (1952) concluded that the percentage of clients who improved following any kind of psychotherapy was actually lower than that of people who received no treatment.

Critics argued that in drawing his conclusions, Eysenck had ignored studies that supported the value of psychotherapy and that he had misinterpreted his data (Bergin, 1971; de Charms, Levy, & Wertheimer, 1954; Luborsky, 1972). They pointed out, for example, that untreated clients might have been less disturbed than those in treatment. Further, they said, untreated clients might have received informal treatment from their medical doctors. Finally, the physicians who judged untreated clients'

progress might have used less demanding criteria than the psychotherapists who rated their own clients. In fact, when some of these critics conducted their own counts of successes and failures, they concluded that psychotherapy tends to be more helpful than no treatment (Bergin, 1971).

Debate over Eysenck's findings—and the contradictory reports that followed them—highlighted several factors that make it so hard to answer the apparently simple question: Does psychotherapy work? For one thing, there is the problem of how to measure improvement in psychotherapy. Should it be measured with psychological tests, behavioral observations, interviews, or a combination of all three? And what kinds of tests should be used? Where should clients be observed (and by whom)? Should equal weight be given to interviews with clients, friends, relatives, therapists, and teachers? The fact that these various measures don't always tell the same story about improvement makes it that much more difficult for researchers to compare or combine the results of different studies and draw conclusions about the overall effectiveness of treatment (De Los Reyes & Kazdin, 2006; Krause, 2005; Sass, Twohig, & Davies, 2004).

The question of effectiveness is further complicated by the broad range of clients, therapists, and treatments involved in psychotherapy. Clients differ not only in terms of their problems but also in terms of their motivation to solve them and in the amount of stress and social support present in their environments. Therapists differ, too, not only in skill, experience, and personality but also in which of the hundreds of available treatment procedures they might select (Feltham, 2000; Wampold, 2005), and how long treatment lasts (Barkham et al., 2006). Further, differences in the nature and quality of the client-therapist relationship from one case to another can significantly alter the course of treatment, the clients' faith in the procedures, and their willingness to cooperate (Lambert & Barley, 2001; Zuroff & Blatt, 2006). Because clients' responses to psychotherapy can be influenced by all these factors, results from any particular treatment evaluation study might not tell us much about how well different therapists, using different methods, would do with other kinds of clients and problems (Kazdin, 1994b; Roth & Fonagy, 2005). Consider the example of a study in which “kindly college professors” were found to be as effective as experienced psychotherapists in helping people solve their problems (Strupp & Hadley, 1979). This result would appear relevant to the question of psychotherapy's effectiveness, but a careful reading of the study shows that the clients were college students with minor problems, not severe psychological disorders. Further, the fact that these students already had a relationship with their professors might have given the professors an edge over unfamiliar therapists (Chambless & Hollon, 1998). So the outcome of this study probably does not apply to the outcome of professional psychotherapy in general.

THINKING CRITICALLY

Are All Forms of Therapy Equally Effective?

LINKAGES (a link to Personality, p. 584)

In short, the general question of whether psychotherapy “works” is difficult or impossible to answer scientifically in a way that applies to all therapies for all disorders (Roth & Fonagy, 2005). However, the findings of several research reviews (Anderson & Lambert, 1995; Galatzer-Levy et al., 2000; Leichsenring, Rabung, & Leibling, 2004; Shadish et al., 2000; Smith, Glass, & Miller, 1980; Weisz & Jensen, 1999) have reinforced therapists' beliefs that psychotherapy does work (see Figure 16.3). In fact, most therapists believe that the theoretical approach and treatment methods they use are superior to those of other therapists (e.g., Giles, 1990; Mandelid, 2003). They can't all be right, of course, so what is going on?

FIGURE 16.3**An Analysis of Psychotherapy Effects**

These curves show the results of one large-scale analysis of the effects of psychotherapy. Notice that on average, people who received therapy for their problems were better off than 80 percent of troubled people who did not. The overall effectiveness of psychotherapy has also been confirmed in a more recent analysis of ninety treatment outcome studies (Shadish et al., 2000).

■ What am I being asked to believe or accept?

Some researchers argue that the success of psychotherapy doesn't have much to do with theories about the causes of psychopathology, or even with the specific treatment methods that are used in treatment. All approaches, they say, are equally effective. This has been called the "Dodo Bird Verdict," after the *Alice in Wonderland* character who, when called upon to judge a race, answered, "Everybody has won and all must have prizes" (Duncan, 2002; Luborsky, Singer, & Luborsky, 1975).

■ What evidence is available to support the assertion?

Some evidence does suggest that there are no significant differences in the overall effectiveness of psychodynamic, humanistic, and behavioral therapies. Statistical methods, called *meta-analysis*, that combine the results of a large number of therapy studies have shown that the three treatment approaches are associated with about the same degree of success overall (Lambert & Bergin, 1994; Luborsky et al., 2002; Luborsky, Rosenthal, & Diguier, 2003; Shadish et al., 2000; Smith et al., 1980; Wampold et al., 1997; Weisz, McCarty, & Valeri, 2006).

■ Are there alternative ways of interpreting the evidence?

It is possible, however, that evidence for the Dodo Bird Verdict is based on statistical methods that tend to make all treatments look equally effective, even if they are not. For example, a meta-analysis that averages the results of many studies might miss important differences in the impact of particular treatments for particular problems. To understand how this might happen, suppose that Therapy A works better than Therapy B in treating anxiety but that Therapy B works better than Therapy A in cases of depression. If you combined the results of treatment studies with both kinds of clients, the average effects of each therapy would be about the same, making it appear that the two treatments are about equally effective.

Differences in the effects of specific treatment procedures might also be overshadowed by the beneficial *common factors* shared by almost all forms of therapy—such as the support of the therapist, the hope and expectancy for improvement that therapy creates, and the trust that develops between client and therapist (Greenberg, Constantino, & Bruce, 2006; Kazantzis, Lampropoulos, & Deane, 2005; Vocisano et al., 2004). Therapists whose personal characteristics can motivate clients to change might promote that change no matter what specific therapeutic methods they use (Elkin, 1999; Hubble, Duncan, & Miller, 1999).

■ What additional evidence would help to evaluate the alternatives?

Debate is likely to continue over the question of whether, on average, all forms of psychotherapy are equally effective. But many researchers believe that this is the wrong question to ask. In their view, it is pointless to compare the effects of psychodynamic,

humanistic, and behavioral methods in general. It is more important, they say, to address what Gordon Paul called the “ultimate question” about psychotherapy: “What treatment, by whom, is most effective for this individual with that specific problem, under what set of circumstances?” (Paul, 1969, p. 44).

■ What conclusions are most reasonable?

Statistical analyses show that various treatment approaches appear to be about equally effective overall. But this does not mean that every specific psychotherapy method works in the same way or that every psychotherapy experience will be equally beneficial. Clients entering therapy must realize that the success of their treatment can still be affected by how severe their problems are, the quality of the relationship they form with a therapist, and the appropriateness of the therapy methods chosen for their problems. ■

Like those seeking treatment, many clinical psychologists, too, are eager for more specific scientific evidence about the effectiveness of particular therapies for particular kinds of clients and disorders. These empirically oriented clinicians are concerned that all too often, a therapist’s choice of therapy methods depends more heavily on personal preferences or current trends than on scientific evidence of effectiveness (Lynn, Lilienfeld, & Lohr, 2003; Nathan, Stuart, & Dolan, 2000; Norcross et al., 2005; Tavis, 2003). They believe that advocates of any treatment—whether it is object relations therapy or systematic desensitization—must demonstrate that its benefits are the result of the treatment itself and not just of the passage of time, the effects of repeatedly measuring progress, the client’s motivation and personal characteristics, or other confounding factors. A movement toward this same kind of *evidence-based practice* has also appeared in the medical and dental professions (Borry, Schotsmans, & Dierickx, 2006; Niederman & Richards, 2005).

Empirically oriented psychologists also want to see evidence that the benefits of treatment are *clinically significant*. To be clinically significant, therapeutic changes must be not only measurable but also substantial enough to make treated clients’ feelings and actions similar to those of people who have not experienced these clients’ disorders (Kendall & Sheldrick, 2000). For example, a reduction in treated clients’ scores on an anxiety test might be *statistically significant*, but if those clients do not now feel and act more like people without an anxiety disorder, the change is probably not clinically significant (see Figure 16.4). The need to demonstrate the clinical significance of treatment effects has become clearer than ever as increasingly cost-conscious clients—and their health insurance companies—decide whether, and how much, to pay for various psychotherapy services (Levant, 2005; Makeover, 2004; Nelson & Steele, 2006).

FIGURE 16.4

Clinical Significance

Evaluations of psychological treatments must consider the clinical, as well as statistical, significance of observed changes. Here, the shaded area shows the range of deviant behaviors per minute displayed at home by normal boys. The solid line shows the average rate of deviant behaviors for boys in an operant conditioning treatment for severe behavior problems. The improvement following reinforcement of appropriate behavior was not only statistically significant (compared with the pretreatment baseline) but also clinically significant, inasmuch as the once-deviant behavior came to resemble that of normal boys.

By scientific tradition, the ideal way to evaluate treatment effects is through experiments in which clients are randomly assigned to various treatments or control conditions and their progress is objectively measured over time.

FOCUS ON RESEARCH METHODS

Which Therapies Work Best for Which Problems?

 LINKAGES (a link to Research in Psychology, p. 40)

To help clinicians select treatment methods on the basis of that kind of empirical evidence, the American Psychological Association's Division of Clinical Psychology created a task force on effective psychotherapies (Task Force on Promotion and Dissemination of Psychological Procedures, 1995), now called the Committee on Science and Practice (Sanderson, 2003).

■ What was the researchers' question?

The question addressed by this task force was: Which therapies have proven themselves most effective in treating various kinds of psychological disorders?

■ How did the researchers answer the question?

Working with other empirically oriented clinical psychologists, members of this task force examined the outcomes of thousands of experiments that evaluated psychotherapy methods used to treat mental disorder, marital distress, and health-related behavior problems in adults, children, and adolescents (Baucom et al., 1998; Chambless & Ollendick, 2001; Compas et al., 1998; DeRubeis & Crits-Christoph, 1998; Foley, 2004; Kazdin & Weisz, 1998; Kendall & Chambless, 1998; Norcross, 2002).

■ What did the researchers find?

The task force found that a number of treatments—known as **empirically supported therapies**, or **ESTs**—have been validated by controlled experimental research (Chambless & Ollendick, 2001; DeRubeis & Crits-Christoph, 1998; Kendall & Chambless, 1998; Norcross, 2001, 2002). Table 16.4 contains some examples of these therapies. Notice that the treatments identified as effective for particular problems in adult clients are mainly behavioral, cognitive, and cognitive-behavioral methods but that certain psychodynamic therapies (e.g., interpersonal therapy and brief dynamic therapy) also made the list (Chambless & Ollendick, 2001; Svartberg, Stiles, & Seltzer, 2004).

■ What do the results mean?

The authors of the report on ESTs, as well as those who support their efforts, claim that by relying on analysis of experimental research, they have accomplished a scientific evaluation of various treatments and generated a list of methods from which clinicians and consumers can choose with confidence when dealing with specific disorders (e.g., Hunsley & Rumstein-McKean, 1999; Kendall & Chambless, 1998). Therapists are even being urged to follow the *treatment manuals* that were used in successful research studies to help them deliver empirically supported therapies exactly as they were intended (Addis, 1997; Wade, Treat, & Stuart, 1998).

However, not everyone agrees with the conclusions or recommendations of the APA task force (Norcross et al., 2005; Westen & Bradley, 2005; Westen et al., 2004). Critics note, first, that treatment methods are not necessarily discredited just because they are not on the latest list of ESTs. Some of these treatments might not yet have been studied or validated according to the efficacy criteria selected by the task force (Lantz, 2004; Westen & Morrison, 2001). These critics also have doubts about the value of some of those criteria. They point to research showing that had the task force used different outcome criteria, it might have reached different—and perhaps less

- **empirically supported therapies (ESTs)**
Treatments whose effects have been validated by controlled experimental research.

TABLE 16.4 Some Empirically Supported Therapies

Treatments listed as “efficacious and specific” (pronounced “effeh-KAY-shus”) were shown to be superior to no treatment or to some alternative treatment in at least two experiments in which clients were randomly assigned to various treatment conditions. These experiments are called randomized clinical trials, or RCTs. Also included in this category are treatments supported by scientific outcome measures from a large number of carefully conducted case studies. Treatments listed as “probably efficacious” are supported by at least one RCT

or by a smaller number of rigorously evaluated case studies. Those listed as “possibly efficacious” are supported by a mixture of data, generally from single-case studies or other nonexperimental studies (Chambless & Ollendick, 2001). More information about these ESTs is available at http://www.apa.org/divisions/div12/rev_est/. Other reviews of empirical research are aimed at identifying potentially harmful therapies (Lilienfeld, 2007).

| Problem | Efficacious and Specific | Probably Efficacious | Possibly Efficacious |
|-------------------------------|---|--|--|

optimistic—conclusions about the value of some empirically supported treatments (Bradley, Heim, & Westen, 2005; Thompson-Brenner, Glass, & Westen, 2003). There is concern, too, about the wisdom of categorizing treatments as either “supported” or “unsupported.” These simple either-or judgments seem reassuring, but may fail to give a complete picture of the impact of various treatments on various clients with various problems (Krause & Lutz, 2006; Westen & Bradley, 2005). Critics argue further that

the list of ESTs is based on research that may not be relevant to clinicians working in the real world of clinical practice. They note that experimental studies of psychotherapy have focused mainly on relatively brief treatments for highly specific disorders, even though most clients' problems tend to be far more complex (Westen & Bradley, 2005). These studies focus, too, on the therapeutic procedures used rather than on the characteristics and interactions of therapists and clients (Cornelius-White, 2002; Garfield, 1998; Hilliard, Henry, & Strupp, 2000; Westen et al., 2004). This emphasis on procedure is a problem, critics say, because the outcome of therapy in these experiments might have been strongly affected by client-therapist factors, such as whether the random pairing of clients and therapists resulted in a match or a mismatch on certain personal characteristics. In real clinical situations, clients and therapists are not paired up at random (Goldfried & Davila, 2005; Hill, 2005; Hohman & Shear, 2002). Finally, because therapists participating in experimental research were required to follow standard treatment manuals, they were not free to adapt treatment methods, as they normally would, to the needs of particular clients (Garfield, 1998). Perhaps, say critics, when there is less experimental control over the treatment situation, all therapies really are about equally effective, as suggested by the statistical analyses of outcome research we mentioned earlier (Shadish et al., 2000; Smith et al., 1980).

In short, critics reject the EST list as a useful guide. In fact, some see it as an incomplete and ultimately misleading document (Westen & Bradley, 2005). They also worry that widespread use of treatment manuals would make psychotherapy mechanical and less effective and would discourage therapists' from developing new treatment methods (Addis & Krasnow, 2000; Beutler, 2000; Garfield, 1998).

■ What do we still need to know?

The efforts of the APA task force represent an important step in responding to Paul's (1969) "ultimate question" about psychotherapy: "What treatment, by whom, is most effective for this individual with that specific problem, under what set of circumstances?" We still have a long way to go, but empirically oriented clinical psychologists are determined to find scientific answers to this question. As suggested by critics of the EST list, the challenge now is to combine research on EST methods with research on the common factors they share and to create a picture of psychotherapy effectiveness that is based on both sets of data (Messer, 2004; Westen & Bradley, 2005). So researchers are focusing not only on the long-term efficacy of psychotherapy—in naturalistic as well as laboratory settings—but also on the role of the therapeutic relationship in promoting that efficacy (Morrison, Bradley, & Westen, 2003; Nathan, Stuart, & Dolan, 2000; Wampold, Lichtenberg, & Waehler, 2002; Westen & Morrison, 2001). Ideally, their work will speed the development of evidence-based practice in psychology (Levant, 2005; Messer, 2004), in which therapists are guided by research that is clinically relevant as well as empirically supported (Arkowitz & Lilienfeld, 2006). ■

Choosing a Therapist

We have seen that the Dodo Bird Verdict is probably incorrect, and it is certainly incomplete. Although different treatments can be equally effective in addressing some disorders, empirical research shows that for other disorders certain therapies tend to be more effective than others. For example, when differences show up in comparative studies of adult psychotherapy, they reveal a small to moderate advantage for behavioral and cognitive-behavioral methods, especially in the treatment of phobias and certain other anxiety disorders (Barrowclough et al., 2001; Butler et al., 2006; DeRubeis & Crits-Christoph, 1998; Eddy et al., 2004; Hollon, Stewart, & Strunk, 2006; Schnurr et al., 2007; Lambert & Bergin, 1994; Weisz et al., 1995), as well as bulimia nervosa, an eating disorder (Hendricks & Thompson, 2005; Wilson, 1997). The same tends to be true for child and adolescent clients (Epstein et al., 1994; Weiss & Weisz, 1995; Weisz et al., 1995).

This research provides valuable guidelines for matching treatments to disorders, but it doesn't guarantee success. The outcome of any given case will also be affected by client characteristics, therapist characteristics, and the quality of the relationship that develops between them (e.g., Hill, 2005; Sherer & Schreiber, 2005). Indeed, the client-therapist relationship plays a consistent role in the success of all forms of treatment (Constantino et al., 2005; Horvath, 2005; Karver et al., 2006; Uwe, 2005; Zuroff & Blatt, 2006). Certain people seem to be particularly effective in forming productive human relationships. Even without formal training, these people can sometimes be as helpful as professional therapists because of personal qualities that are inspiring, healing, and soothing to others (Stein & Lambert, 1995). Their presence in self-help groups may well underlie some of the success of those groups and, among professionals, may help account for the success of many kinds of formal therapy.

Before choosing a therapist and treatment approach, then, clients should keep Paul's "ultimate question" in mind. They should carefully consider (1) what treatment approach, methods, and goals they find most comfortable and appealing; (2) information about the therapist's "track record" of clinically significant success with a particular method for treating problems similar to those they face; and (3) the likelihood of forming a productive relationship with the therapist. This last consideration assumes special importance when client and therapist do not share similar cultural backgrounds.

● Cultural Factors in Psychotherapy

Imagine that after moving to an unfamiliar country to pursue your education or career, you become severely depressed. A friend there refers you to a therapist who specializes in depression. At your first session the therapist stares at you intently, touches your head for a moment, and says, "You have taken in a spirit from the river, and it is trying to get out. I will help." The therapist then begins chanting softly and appears to go into a trance. What would you think? Would you return for a second visit? If you are like most people raised in a Western culture, you probably wouldn't continue treatment, because this therapist may not share your beliefs and expectations about what is wrong with you and what should be done about it.

Similar sociocultural clashes can also occur within a particular country if clients bring to therapy a cultural or subcultural world view that is not shared by their therapist (Seeley, 2006). Suppose, for example, that a therapist suggests that a client's panic attacks are a reaction to stress, but the client is sure that they come as punishment for having offended a dead ancestor. That client may not easily accept a treatment based on the principles of stress management. Similarly, a therapist who believes that people should confront and overcome life's problems might run into trouble when treating clients whose cultural or religious training encourages calmly accepting these problems (Sundberg & Sue, 1989). In such cases, the result may be much like two people singing a duet using the same music but different lyrics (Martinez et al., 2005).

In the United States, cultural clashes may be partly to blame for the underuse of, or withdrawal from, mental health services by recent immigrants, as well as by African Americans, Asian Americans, Hispanic Americans, American Indians, and members of other minority populations (Duran et al., 2005; Gone, 2004; Neighbors et al., 2007; Sanders-Thompson et al., 2004; Wang, Lane, et al., 2005). In other words, cultural differences, including religious differences and differences in sexual orientation, can create enough miscommunication or mistrust to threaten the quality of the client-therapist relationship (Jones, Botsko, & Gorman, 2003; Wintersteen, Mensinger, & Diamond, 2005). Accordingly, major efforts are under way to ensure that cultural differences between clients and therapists do not interfere with the delivery of treatment to anyone who wants or needs it. Virtually every mental health training program in North America is seeking to recruit more

students from traditionally underserved minority groups to eventually make it easier to match clients with therapists from similar cultural backgrounds (e.g., Kersting, 2004; Rogers & Molina, 2006).

In the meantime, many minority clients are likely to encounter a therapist from a differing background, so researchers have also examined the value of matching therapeutic techniques with clients' culturally based expectations and preferences (Jones et al., 2003; Li & Kim, 2004; Muñoz & Mendelson, 2005). For example, many clients from collectivist cultures—in which the emphasis is on meeting the expectations of family and friends rather than satisfying personal desires—might expect to receive instructions from a therapist about how to overcome problems. How would such clients respond to a therapist whose client-centered treatment emphasizes more individualist goals, such as being independent and taking responsibility for the direction of change? David Sue and his students have investigated the hypothesis that the collectivist values of Asian cultures would lead Asians and Asian Americans to prefer a directive, problem-solving approach over nondirective, client-centered methods. Sue (1992) found that a preference for directive treatment was highest among foreign-born Asians compared with American-born Asians and European Americans. There are still individual differences, however, so two people from the same culture may react quite differently to a treatment that group research suggests should be ideal for both of them. In Sue's (1992) study, for example, more than a third of the foreign-born Asians preferred the nondirective approach, and 28 percent of the European Americans preferred the directive approach.

Today, psychotherapists are more sensitive than ever to the cultural values of particular groups and to the difficulties that can impair intercultural communication (Ali, Liu, & Humedian, 2004; Hays & Iwamasa, 2006; Hwang, 2006; Martinez et al., 2005). Some U.S. states now require clinical and counseling psychologists to complete courses or gain supervised experience focused on the role of cultural factors in therapy before being licensed. This training helps clinicians appreciate, for example, that it is considered impolite in some cultures to make eye contact with a stranger. Having that information makes it easier for them to recognize that clients from those cultures are not necessarily depressed, lacking in self-esteem, or inappropriately submissive just

Preparing for Therapy Special pretreatment orientation programs may be offered to clients who, because of sociocultural factors, are unfamiliar with the rules and procedures of psychotherapy. These programs provide a preview of what psychotherapy is, how it can help, and what the client is expected to do to make it more effective (Reis & Brown, 2006).

because they look at the floor during an interview. Graduate students are receiving similar training and practical experience as part of their course work in clinical or counseling psychology (Kersting, 2004; Smith, Constantine, et al., 2006).

There is no guarantee that cultural sensitivity training will improve treatment results (Ramirez et al., 1996; Shin et al., 2005), but there is some evidence that it can help (e.g., Constantine, 2002; Razali, Aminah, & Umeed, 2002). Although it is unrealistic to expect all therapists to be equally effective with clients of every ethnic or religious background, cultural sensitivity training offers a way to improve their *cultural competence*, an extension of Carl Rogers's concept of empathy. When therapists appreciate the client's view of the world, it is easier for them to set goals that are in harmony with that view (Dyche & Zayas, 2001; Pedersen & Draguns, 2002; Stuart, 2004). Minimizing the chances of cultural misunderstanding and miscommunication is one of the many ethical obligations that therapists assume whenever they work with a client. Let's consider some others.

● Rules and Rights in the Therapeutic Relationship

Treatment can be an intensely emotional experience, and the relationship established with a therapist can profoundly affect a client's life. Professional ethics and common sense require the therapist to ensure that this relationship does not harm the client. For example, the American Psychological Association's *Ethical Principles of Psychologists and Code of Conduct* forbids a sexual relationship between therapist and client—during treatment and for at least two years afterward—because of the severe harm it can cause the client (American Psychological Association, 2002b; Behnke, 2004).

These same ethical standards require therapists, with a few exceptions, to keep strictly confidential everything a client says in therapy. Confidentiality is one of the most important features of a successful therapeutic relationship, because it allows the client to discuss unpleasant or embarrassing feelings, behaviors, or events without fear that the therapist might disclose this information to others. Professionals sometimes consult with one another about their clients, but they do not identify clients by name, and they do not reveal information to outsiders (even to members of the client's family) without the client's consent. The APA's code of ethics also includes standards for protecting confidentiality for the growing number of clients who seek psychological services via *telehealth* or *e-health* channels, which include telephone, videophone, e-mail, or other Internet links (APA, 2002b; Barnett & Scheetz, 2003; Christensen, Griffiths, & Jorm, 2004; Mohr, Hart, et al., 2005; Ruskin et al., 2004). One of these standards, for example, requires therapists to inform clients that others might be able to gain access to their e-mail messages and that no formal client-therapist relationship exists in e-mail exchanges.

Professional rules about confidentiality are backed up in most U.S. states by laws recognizing that information revealed in therapy—like information given to a priest, a lawyer, or a physician—is privileged communication. In 1996, a U.S. Supreme Court ruling also established psychotherapist-client privilege in the federal courts (DeBell & Jones, 1997; Knapp & VandeCreek, 1997). This means that by asserting *privilege*, a therapist can refuse, even in court, to answer questions about a client or to provide personal notes or tape recordings from therapy sessions (Kaplan, 2005). The law may require a therapist to violate confidentiality only under special circumstances, including those in which: (1) a client is so severely disturbed or suicidal that hospitalization is needed, (2) a client uses his or her mental condition and history of therapy as part of his or her defense in a civil or criminal trial, (3) the therapist must defend against a client's charge of malpractice, (4) a client reveals information about sexual or physical abuse of a child, and (5) the therapist believes a client may commit a violent act against a specific person.

This last condition poses a dilemma: Suppose a client says, "Someday I'm going to kill that brother of mine!" Should the therapist consider this a serious threat and

Rights of the Mentally Ill In 1996, after years of odd behavior—including vague threats against government officials and claims that the government was spying on him through TV satellite dishes—Russell Eugene Weston, Jr., was diagnosed with paranoid schizophrenia. He was hospitalized for seven weeks but had to be released when doctors determined that he was not a threat to himself or others as long as he took his prescribed medication. He failed to do so, however, and in July of 1998, Weston killed two police officers during an armed rampage at the U.S. Capitol Building. Cases such as his are frustrating to mental health professionals whose decisions about hospitalization must balance the rights of mental patients against those of the public.

warn the brother? In most cases, there is no real danger, but there have been tragic exceptions. For example, Prosenjit Poddar, a graduate student receiving therapy at the University of California at Berkeley in 1969, revealed his intention to kill Tatiana Tarasoff, a young woman whom he had dated the previous year but who later rejected him. The therapist took the threat seriously, consulted his supervisor, and asked the campus police to take Mr. Poddar to a hospital. They did not do so, however, and neither Ms. Tarasoff nor her parents were warned about the possible danger (Ewing & McCann, 2006). After dropping out of therapy, the client killed Tarasoff, whose parents later sued the university, the campus police, and the therapist. They won their case, thus setting an important precedent (Yufik, 2005). Several U.S. states now have laws that make a therapist liable for failing to take steps to protect those who are threatened with violence by the therapist's clients (Bersoff, 1999). Other states allow therapists more discretion in warning or protecting potential victims (Stromberg, Schneider, & Joondeph, 1993).

In the United States, people are protected from being casually committed to mental hospitals (Johnson, 2004). Federal court decisions have given clients threatened with commitment the right to have written notice; an opportunity to prepare a defense with the help of an attorney; a court hearing, with a jury if desired; and the right to take the Fifth Amendment to avoid self-incrimination. Furthermore, before people can be forcibly committed, the state must provide “clear and convincing” evidence that they are not only mentally ill but also gravely disabled or an “imminent danger” to themselves or others. Most states now require a periodic review of every committed person's records to determine whether release is appropriate.

While hospitalized, patients have the right to receive treatment, but they also have the right to refuse certain forms of treatment (Stromberg et al., 1988). These rules are designed to protect hospitalized mental patients from abuse, neglect, or exploitation, but they can also create difficulties and dangers. Consider Russell Eugene Weston, Jr., a former mental patient who was hospitalized after being charged with the murders of two police officers in 1998. Facing a possible death penalty but judged mentally incompetent to stand trial, he asserted his right to refuse drug treatment that would make him competent. After a long legal battle, Weston was forced to take medication. Prosecutors successfully argued that the right to refuse treatment does not extend to hospitalized patients who pose a danger to themselves or others (Manahan, 2004).

Hospitalized patients who do not pose these dangers—including those whose dangerous impulses are being suppressed by drug treatment—have the right to be subjected to minimal restriction of their freedom (Bell, 2005). Accordingly, they are released from mental hospitals, usually with a supply of medication that they are to take on their own. Unfortunately, not all these patients follow doctors' orders. Like Weston, Andrew Goldstein was not considered dangerous as long as he took his antipsychotic medication, but after being released from a New York City mental hospital in December 1998, he stopped doing so. About two weeks later, Goldstein pushed Kendra Webdale to her death under the wheels of a subway train (Perlin, 2003). Cases such as these put the staff at mental health facilities in a bind—they worry about being sued if they keep patients unnecessarily confined *or* if someone is harmed by a patient they have released too soon. In an effort to strike a balance between the rights of mental patients and those of the public, several states now have laws requiring outpatient treatment for people who are dangerous when not medicated. The New York Statute is known as Kendra's Law (Appelbaum, 2005).

Biological Treatments

Drugs that can ease the symptoms of psychological disorders are the latest and most effective in a long line of biological treatments based on the idea that psychological problems have physical causes. Hippocrates, a physician of ancient Greece, was

Hospital Restraints Here are examples of the chains, straitjackets, belts, and covered bathtubs that were used to restrain disruptive patients in North American and European mental hospitals in the 1800s and well into the 1900s. These devices were gentle compared with some of the methods endorsed in the late 1700s by Benjamin Rush. Known as the “father of American psychiatry,” Rush advocated curing patients by frightening or disorienting them—for example, by placing them in a coffinlike box, which was then briefly immersed in water.

among the first to propose this idea, and the treatments he prescribed included rest, special diets, laxatives, and abstinence from alcohol or sex. In the mental hospitals of Europe and North America during the sixteenth through eighteenth centuries, treatment of psychological disorders was based in part on Hippocrates’ methods and consisted mainly of physical restraints, laxative purges, draining of “excess” blood, and induced vomiting. Cold baths, hunger, and other physical discomforts were also used in efforts to shock patients back to normality (Jones, 1923). Even as recently as the mid-1900s, physicians treated most forms of psychological disorder by means of brain surgery or electric shock.

● Psychosurgery

Psychosurgery involves the destruction of brain tissue for the purpose of treating mental disorder. Among the first to try these procedures was a Portuguese neurosurgeon named António Egas Moniz. In 1935 he developed a technique, called *prefrontal lobotomy*, in which small holes are drilled in the forward portion of the skull and a sharp instrument is inserted and moved from side to side to cut connections between the prefrontal cortex and the rest of the brain (Freeman & Watts, 1942; Moniz, 1948). The theory was that emotional reactions in disturbed people become exaggerated due to neural processes in the frontal lobes and that the lobotomy disrupts these processes. During the 1940s and 1950s, psychosurgery became almost routine in the treatment of schizophrenia, depression, anxiety, aggressiveness, and obsessive-compulsive disorder (Valenstein, 1980). Unfortunately, brain surgery is risky, and sometimes fatal; its benefits are uncertain; and its side effects and complications, including epilepsy, are irreversible (Balon, 2004; Martin et al., 2001; Rueck, Andreewitch, & Flyckt, 2003). Today, psychosurgery is performed only in rare cases in which all else has failed, and—guided by brain imaging techniques—it focuses on much smaller brain areas than those involved in lobotomies (Anderson & Booker, 2006; Dougherty et al., 2002; Feldman & Goodrich, 2001).

● Electroconvulsive Therapy

In the 1930s, a Hungarian physician named Ladislaus Von Meduna used a drug to induce convulsions in schizophrenics. He believed—incorrectly—that because schizophrenia and epilepsy rarely occur in the same person, epileptic-like seizures might

- **psychosurgery** Surgical procedures that destroy tissue in small regions of the brain in an effort to treat psychological disorders.

Electroconvulsive Therapy Estimates of the number of people receiving ECT each year in the United States range from 30,000 to over 100,000 (Hermann et al., 1995; Mathew, Amiel, & Sackeim, 2005). A survey in the United Kingdom suggests that about 12,000 patients a year are receiving ECT (U.K. Statistical Bulletin, 1999). Because of its dramatic and potentially dangerous nature, the use of ECT remains controversial (Breggin, 1997). Critics want it outlawed, but proponents say the benefits of ECT for certain patients outweigh its potential costs.

combat schizophrenia. In 1938, Italian physicians Ugo Cerletti and Lucio Bini created seizures by passing an electric current through schizophrenics' brains. During the next twenty years or so, this procedure, called **electroconvulsive therapy (ECT)**, became a routine treatment for schizophrenia, depression, and sometimes mania. Although many patients improved, they often relapsed. The benefits of ECT also had to be weighed against side effects such as memory loss, confusion, speech disorders, and in some cases, death due to cardiac arrest (Lickey & Gordon, 1991; Shiwach, Reid, & Carmody, 2001). To make ECT safer, patients are now given an anesthetic so that they are unconscious before the shock is delivered, along with a muscle relaxant to prevent bone fractures during convulsions. Also, the shock now lasts only about half a second and is usually delivered to only one side of the brain (Sackeim et al., 2000). Finally, in contrast to the dozens of treatments administered decades ago, patients now receive only about six to twelve shocks, one approximately every two days (Fink, 1999).

The use of ECT has declined since the 1950s, but it is still performed more frequently in the United States than coronary bypass operations, appendectomies, and tonsillectomies (Mathew, Amiel, & Sackeim, 2005). It is administered mainly to patients suffering severe depression (and occasionally to manic patients) who do not respond to drug treatments (Daly et al., 2001; de Macedo-Soares et al., 2005; Rasmussen, 2003). ECT can be effective in some of these cases—especially when followed up with medication—and it does not appear to cause brain damage, even when administered repeatedly (e.g., Angheliescu et al., 2001; Dwork et al., 2004; Kellner et al., 2005, 2006; Sackeim et al., 2001). No one knows for sure how and why ECT works (Greenberg & Kellner, 2005; Rudorfer, Henry, & Sackeim, 1997), but the fact that it helps some patients has led ECT researchers to seek even safer methods of inducing seizures. Among the techniques being investigated are *magnetic seizure therapy (MST)*, which creates seizures with timed pulses of magnetic energy (Lisanby, 2004), and a related, but less intense procedure called *repetitive transcranial magnetic stimulation (rTMS)* (Couturier, 2005; Schutter, 2005). *Deep brain stimulation (DBS)* does not cause seizures, but requires the placement of electrodes in the brain to provide continuous pulses of electricity to particular target area. Some researchers suggest that DBS may be of value in severe cases of depression and obsessive-compulsive disorder that are unresponsive to any other treatments (Hardesty & Sackeim, 2007).

● Psychoactive Drugs

The use of psychosurgery and ECT declined after the 1950s, not only because of their complications and general distastefulness but also because *psychoactive drugs* had begun to emerge as more convenient and effective treatment alternatives. These drugs are now the most common biological treatment for all forms of psychological disorder. In the chapters on biological aspects of psychology and on consciousness, we discuss how psychoactive drugs affect neurotransmitter systems and consciousness. Here, we describe how drugs are used to combat schizophrenia, depression, mania, and anxiety.

● **Neuroleptics** One group of drugs, called **neuroleptics** or *antipsychotics*, dramatically reduces the intensity of psychotic symptoms such as hallucinations, delusions, paranoid suspiciousness, disordered thinking, and confused speech in many mental patients, especially those with schizophrenia. The most widely used antipsychotic drugs are the *phenothiazines* (pronounced “fee-noh-THIGH-uh-zeens”), of which the first, *chlorpromazine* (marketed as *Thorazine* in the United States and as *Largactil* in Canada and the United Kingdom), has been especially popular. Another neuroleptic, *haloperidol* (*Haldol*), is about as effective as the phenothiazines, but it creates less sedation (Julien, 2005). Patients who do not respond to one type of neuroleptic may respond to the other (Davis, Chen, & Glick, 2003). Between 60 and 70 percent of patients receiving these drugs show improvement, though fewer than 30 percent respond well enough to live successfully on their own (Freedman, 2003).

Neuroleptics also have side effects ranging from dry mouth and dizziness to symptoms similar to those of Parkinson’s disease, including muscle rigidity, restlessness, tremors, and slowed movement. Some of these side effects can be treated with medication, but at least 25 percent of patients who take chlorpromazine or haloperidol for several years develop an irreversible movement disorder called *tardive dyskinesia* (*TD*), which causes uncontrollable, repetitive actions, often including twitching of the face and flailing of the arms and legs, and thrusting of the tongue (Miller, McEvoy, et al., 2005).

Among a newer generation of antipsychotic drugs (also called *atypical neuroleptics*) is *clozapine* (*Clozaril*), which has effects like those of the phenothiazines but is less likely to cause movement disorders (Louzá & Bassit, 2005; Rochon et al., 2005). Although no more effective overall than the phenothiazines, clozapine has helped many patients who did not respond to the phenothiazines or haloperidol (Green & Patel, 1996; Rabinowitz et al., 2001). Unfortunately, taking clozapine carries a slight risk of developing a fatal blood disease called *agranulocytosis* (Ginsberg, 2006). Weekly blood tests to detect early signs of this disease greatly increase the cost of using this drug.

Several other atypical neuroleptics have been introduced lately, including *risperidone* (*Risperdal*), *olanzapine* (*Zyprexa*), *quetiapine* (*Seroquel*), *ziprasidone* (*Geodon*), and most recently, *aripiprazole* (*Abilify*). These medications are expensive, but they have fewer side effects than clozapine, and they do not cause agranulocytosis (Correll, Leucht, & Kane, 2004). Like clozapine, they also appear to reduce the “negative” symptoms of schizophrenia, such as lack of emotion, social withdrawal, and reduced speech (e.g., Fleischhacker & Widschwendter, 2006; Kapur, Sridhar & Remington, 2004; Potkin et al., 2003). There is some doubt, though, as to whether these newest atypical neuroleptics are significantly more effective than older drugs (Matza, Baker, & Revicki, 2005), partly because 60 to 80 percent of patients may stop taking them due to weight gain, nervous tics, and other bothersome side effects (Lieberman et al., 2005; Swartz et al., 2007).

- **electroconvulsive therapy (ECT)** Brief electrical shock administered to the brain, usually to reduce depression that does not respond to drug treatments.
- **neuroleptics** Drugs that alleviate the symptoms of severe disorders such as schizophrenia.
- **antidepressants** Drugs that relieve depression.

● **Antidepressants** Soon after antipsychotic drugs appeared, they were joined by **antidepressants**, a class of drugs that is now the most widely prescribed treatment for depression (National Institute for Clinical Excellence, 2004; Olfson et al., 2002).

Although these drugs have almost immediate effects on neurotransmitters (usually increasing the availability of serotonin or norepinephrine in the brain), their effects on depressive symptoms do not appear for a week or two and maximum effects may take even longer (Quitkin et al., 2003; Taylor et al., 2006). The fact that these drugs affect specific neurotransmitters is consistent with some theories about the biology of depression discussed in the chapter on psychological disorders, although the time lag suggests that the effects occur through a long-term compensatory process in the nervous system.

There are several classes of antidepressant drugs. The *monoamine oxidase inhibitors (MAOIs)* are used to treat many cases of depression, especially clients who also experience anxiety and panic (Julien, 2005). The *tricyclic antidepressants (TCAs)* are another popular class of antidepressants. The TCAs have been prescribed more frequently than MAOI drugs because they seem to work somewhat better and have fewer side effects. However, overdoses of TCAs can be fatal, as can taking TCAs and drinking alcohol at the same time (Nutt, 2005a). Still, if side effects are controlled, tricyclics can be effective in treating depression and can also reduce the severity of panic attacks in some cases of panic disorder.

Today, the most popular medications for depression are those that affect the neurotransmitter *serotonin*. The most prominent drug in this group is *fluoxetine (Prozac)*, which after its introduction in 1986, quickly became the most widely used antidepressant in the United States (Brambilla et al., 2005). Its popularity is due to the fact that it is as effective as older antidepressants and, in most cases, has milder side effects—mainly weight gain, sexual dysfunction, and gastrointestinal problems (Nutt, 2005a; Patten et al., 2005). An improved version of Prozac, containing a purer active ingredient called *R-fluoxetine*, has now been developed (Norman & Olver, 2004). Other, even newer antidepressants, including *venlafaxine (Effexor)*, *nefazodone (Serzone)*, *bupropion (Wellbutrin)*, *escitalopram (Lexapro)*, and *duloxetine (Cymbalta)*, are also now on the market (Brambilla et al., 2005; Hirschfeld & Vornik, 2004; Zimmerman, Posternak, et al., 2005).

About 50 to 60 percent of patients who take antidepressant drugs experience improved mood, greater physical activity, increased appetite, and better sleep (Hollon, Thase, & Markowitz, 2002). This degree of improvement is seen in only 10 to 20 percent of the most severe cases of psychotic depression, however (Agency for Healthcare Research and Quality, 1999; U.S. Surgeon General, 1999). It has long been assumed that these results were due to the drugs' active ingredients, but there is now some doubt about this assumption. An analysis of clinical trial data submitted to the U.S. Food and Drug Administration by the makers of six widely prescribed antidepressant drugs showed that in 57 percent of the trials, antidepressant drugs did only a little better than placebo medication ("sugar pills") at relieving depression (Kirsch et al., 2002). Defenders of antidepressant medications argue that even relatively small effects are better than none (e.g., Thase, 2002), whereas critics contend that those effects are too small to matter (e.g., Moncrieff & Kirsch, 2005; Wampold et al., 2005).

A Natural Cure? An herbal remedy from the plant called *Saint John's wort* has become a popular nonprescription treatment for depression. One of its active ingredients, *hypericin*, is thought to affect serotonin much as Prozac does. Double-blind, placebo-controlled studies have shown Saint John's wort to be as effective as Prozac for depression (e.g., Hammerness, Basch, & Ulbricht, 2003; Hypericum Depression Trial Study Group, 2002; Szegedi et al., 2005). The design of some of these studies has been questioned, however (e.g., Spira, 2001), so final conclusions about the safety and effectiveness of Saint John's wort must await the results of further research.

● **Lithium and Anticonvulsants** In 1949, J. F. Cade discovered that a mineral salt of the element *lithium*, when taken regularly, could prevent the mania associated with bipolar disorders in some patients (Schou, 2001). In fact, for 30 to 50 percent of patients with bipolar disorder, lithium is effective in preventing both manic and depressive episodes, thereby earning its label as a *mood stabilizer* (Baldessarini & Tondo, 2000; Geddes et al., 2004; Manji, Bowden, & Belmaker, 2000). Without lithium, the typical bipolar patient has a manic episode about every fourteen months and a depressive episode about every seventeen months (Lickey & Gordon, 1991). With lithium, attacks of mania occur as rarely as every nine years (Bowden, 2000; Geddes et al., 2004). The lithium dosage must be exact and carefully controlled, however, because taking too much can cause nausea, vomiting, tremor, fatigue, slurred speech, and, if the overdose is severe, coma or death

(Johnson, 2002). Further, lithium is not useful for treating a manic episode in progress because, as in the case of antidepressants, it takes a week or two of regular use before its effects are seen. So, as with the antidepressants, lithium's effects probably occur through some form of long-term adaptation as the nervous system adjusts to the presence of the drug. Combining lithium with other mood-stabilizing drugs, such as carbamazepine, has shown enhanced benefits but also more adverse side effects (Baethge et al., 2005).

In recent years, anticonvulsant drugs such as *divalproex* and *lamotrigine* (*Epival/Depakote*; *Lamictal*) have been used as an alternative to lithium in treating mania (e.g., Daban et al., 2006; Delbello et al., 2006). Compared with lithium, these drugs cause fewer side effects, are less dangerous at higher doses, and are easier to regulate (Bowden, 2000, 2003; Hirschfeld et al., 1999). However, their long-term benefits in reducing mania and the risk of suicide are not as well established, so lithium is still considered the treatment of choice against which other drugs are measured (Calabrese et al., 2005; Capriani et al., 2005; McAllister-Williams, 2006).

● **Anxiolytics** During the 1950s, a new class of drugs called *tranquilizers* was shown to reduce mental and physical tension and other symptoms of anxiety. The first of these drugs, called *meprobamate* (*Miltown* or *Equanil*), acts somewhat like barbiturates, meaning that overdoses can be fatal (Allen, Greenblatt, & Noel, 1977). Newer tranquilizers, known as *benzodiazepines*—such as *chlordiazepoxide* (*Librium*) and *diazepam* (*Valium*)—do not pose this danger and have become the worldwide drug treatment of choice for anxiety (Stevens & Pollack, 2005). Today, these and other anti-anxiety drugs, now called **anxiolytics** (pronounced “ang-zee-oh-LIT-iks”), continue to be the most widely prescribed of all legal drugs (Stevens & Pollack, 2005).

Anxiolytics have an immediate calming effect and are quite useful in reducing anxiety, including in cases of generalized anxiety disorder and posttraumatic stress disorder. One of the newest of the benzodiazepines, *alprazolam* (*Xanax*), has also become especially popular for the treatment of panic disorder and agoraphobia (Verster & Volkerts, 2004). Another benzodiazepine, *clonazepam* (*Klonopin*), is also being used, alone or in combination with other anxiolytics, in the treatment of anxiety ranging from phobias to panic disorder. But benzodiazepines can have bothersome side effects such as sleepiness, lightheadedness, and impaired psychomotor and mental functioning. Combining these drugs with alcohol can have fatal consequences, and continued use can lead to tolerance and physical dependence (Chouinard, 2004). Furthermore, after heavy or long-term use, attempts to stop taking benzodiazepines, particularly if the change is sudden, can result in severe withdrawal symptoms, including seizures and a return of anxiety more intense than the patient had originally experienced (Lemoine et al., 2006; Rickels et al., 1993).

An anxiolytic called *bupirone* (*BuSpar*) provides an alternative anxiety treatment that eliminates some of these problems, but it acts more slowly. As with the antidepressants, bupirone's effects do not occur for days or weeks after treatment begins. As a result, many patients stop taking it because they think it has no effect other than dizziness, headache, and nervousness (Stahl, 2002; Wagner et al., 2003). Yet bupirone can ultimately equal benzodiazepines in reducing generalized anxiety (Gorman, 2003; Rickels & Rynn, 2002). Further, it does not seem to promote dependence, has fewer side effects than the benzodiazepines, and does not interact dangerously with alcohol.

Because depression often accompanies anxiety, antidepressant drugs such as fluoxetine (Prozac), paroxetine (Paxil), clomipramine (Anafranil), fluvoxamine (Luvox), and sertraline (Zoloft) are also used in treating anxiety-related problems such as panic disorder, social phobia, obsessive-compulsive disorder, and posttraumatic stress disorder (e.g., Gorman, 2003; Julien, 2005; Nutt, 2005b; Rickels et al., 2003). Table 16.5 lists the effects and side effects of the psychoactive drugs we have described.

TABLE 16.5 A Sampling of Psychoactive Drugs Used for Treating Psychological Disorders

Psychoactive drugs have been successful in dramatically reducing the symptoms of many psychological disorders. Critics point out that drugs can have troublesome side effects, however, and they may create dependence, especially after years of use (e.g., Breggin, 1997). They note, too, that drugs

do not “cure” mental disorders (National Institute of Mental Health, 1995), that their effects are not always strong (Kirsch et al., 2002), and that temporary symptom relief may make some patients less likely to seek a permanent solution to their psychological problems.

For Schizophrenia: Neuroleptics (Antipsychotics)

| Chemical Name | Trade Name | Effects and Side Effects |
|----------------|------------|--|
| Chlorpromazine | Thorazine | Reduce hallucinations, delusions, incoherence, jumbled thought processes; cause movement-disorder side effects, including tardive dyskinesia |
| Haloperidol | Haldol | |
| Clozapine | Clozaril | Reduces psychotic symptoms; causes no movement disorders, but raises risk of serious blood disease |
| Risperidone | Risperdal | Reduces positive and negative psychotic symptoms without risk of blood disease |
| Ziprasidone | Geodon | Reduces positive and negative psychotic symptoms without causing weight gain |
| Aripiprazole | Abilify | Reduces positive and negative psychotic symptoms without weight gain and with few side effects |

For Mood Disorders: Antidepressants and Mood Elevators

Tricyclics

| | | |
|---------------|----------------|---|
| Imipramine | Tofranil | Act as antidepressants, but also have antipanic action; cause sleepiness and other moderate side effects; potentially dangerous if taken with alcohol |
| Amitriptyline | Elavil, Amitid | |

Other Antidepressants

| | | |
|--------------|-----------|---|
| Fluoxetine | Prozac | Have antidepressant, antipanic, and anti-obsessive action |
| Clomipramine | Anafranil | |
| Fluvoxamine | Luvox | |
| Sertraline | Zoloft | |
| Escitalopram | Lexapro | |

Other Drugs

| | | |
|-------------------|----------------------|--|
| Lithium carbonate | Carbolith, Lithizine | Calms mania; reduces mood swings of bipolar disorder; overdose harmful, potentially deadly |
| Divalproex | Depakote | Is effective against mania, with fewer side effects |
| Lamotrigine | Lamictal | Is effective in delaying relapse in bipolar disorder; most benefits associated with depression |

For Anxiety Disorders: Anxiolytics

Benzodiazepines

| | | |
|------------------|----------|---|
| Chlordiazepoxide | Librium | Act as potent anxiolytics for generalized anxiety, panic, stress; extended use may cause physical dependence and withdrawal syndrome if abruptly discontinued |
| Diazepam | Valium | |
| Alprazolam | Xanax | Also has antidepressant effects; often used in agoraphobia (has high dependence potential) |
| Clonazepam | Klonopin | Often used in combination with other anxiolytics for panic disorder |

Other Anti-anxiety Agents

| | | |
|-----------|--------|---|
| Buspirone | BuSpar | Has slow-acting anti-anxiety action; no known dependence problems |
|-----------|--------|---|

in review Biological Treatments for Psychological Disorders

| Method | Typical Disorders Treated | Possible Side Effects | Mechanism of Action |
|---------------------------------|--|---|---|
| Electroconvulsive therapy (ECT) | Severe depression | Temporary confusion, memory loss | Uncertain |
| Psychosurgery | Schizophrenia, severe depression, obsessive-compulsive disorder | Listlessness, overemotionality, epilepsy | Uncertain |
| Psychoactive drugs | Anxiety disorders, depression, obsessive-compulsive disorder, mania, schizophrenia | Variable, depending on drug used: movement disorders, physical dependence | Alteration of neurotransmitter systems in the brain |

● **Human Diversity and Drug Treatment** Drug treatments are designed to benefit everyone in the same way (“In Review: Biological Treatments for Psychological Disorders” summarizes our discussion of drugs and other biological treatments), but it turns out that the same psychoactive drug dose can have significantly different effects in people from various ethnic groups and in men versus women (e.g., Esel et al., 2005; Seeman, 2004). For example, compared with Asians, Caucasians must take significantly higher doses of the benzodiazepines, haloperidol, clozapine, lithium, and possibly the tricyclic antidepressants in order to obtain equally beneficial effects (Lin & Poland, 1995; Matsuda et al., 1996). In addition, African Americans may show a faster response to tricyclic antidepressants than European Americans and may respond to lower doses of lithium (Strickland et al., 1991). There is also some evidence that compared with European Americans or African Americans, Hispanic Americans require lower doses of antipsychotic drugs to get the same benefits (Ruiz et al., 1999). Some of these ethnic differences are thought to be related to genetically regulated differences in drug metabolism, whereas others may be due to dietary practices.

Males and females may respond in about the same way to tricyclic antidepressants (Wohlfarth et al., 2004), but women may maintain higher blood levels of these and other therapeutic psychoactive drugs and may show better response to neuroleptics (Hildebrandt et al., 2003; Salokangas, 2004). They also may be more vulnerable to adverse effects such as tardive dyskinesia (Yonkers et al., 1992). These gender differences in drug response appear less related to estrogen than to other hormonal or body-composition differences between men and women, such as the ratio of body fat to muscle (Salokangas, 2004). Continued research on these and other dimensions of human diversity will undoubtedly lead to more effective and safer drug treatments (Thompson & Pollack, 2001).

● Evaluating Psychoactive Drug Treatments

Despite the widespread success of psychoactive drugs in the treatment of psychological disorders, critics point out several problems with them. First, even if a disorder has physical components, drugs may mask the problem without curing it. This masking effect is desirable in treating otherwise incurable physical conditions such as diabetes, but it may divert attention from potentially effective nondrug approaches to psychological problems. So although anti-anxiety drugs may be an aid to psychotherapy, these drugs alone cannot teach people to cope with the source of their anxiety. Critics are concerned that psychiatrists, and especially general practitioners, rely too heavily on anxiolytics and other drugs to solve patients’ psychological problems (Glenmullen, 2000). The antidepressant Prozac, for instance, is being widely prescribed—overprescribed, critics say—for problems ranging from hypersensitivity

There is widespread concern that psychiatrists, and especially general practitioners, rely too heavily on drugs to deal with psychological problems, including those of adolescents and children (Olfson et al., 2006; Zuvekas, Vitiello, & Nordquist, 2006). This trend appears due in part to drug ads that fuel consumer demand, but drugs are not always the answer. In one case, medication failed to stop a paranoid schizophrenia patient from repeatedly running away from a mental hospital, but allowing him to use a telephone at a nearby shopping mall eliminated the problem. A psychologist discovered that the man had been afraid to use “bugged” hospital phones and kept escaping to call his mother (Rabasca, 1999).

“I medicate first and ask questions later.”

to criticism and fear of rejection to low self-esteem and premenstrual problems. Second, abuse of some drugs (such as the anti-anxiety benzodiazepines) can result in physical or psychological dependence. Third, drug side effects can range from minor problems, such as the thirst and dry mouth caused by some antidepressants, to movement disorders such as tardive dyskinesia caused by certain neuroleptics. The most serious of these side effects are relatively rare, but some are irreversible, and it is impossible to predict in advance who will develop them. Although a clear causal link has not been confirmed (Gibbons et al., 2005; Simon et al., 2006), recent research has led the U.S. National Institute of Mental Health (NIMH) and regulatory agencies in Canada and Britain to issue warnings about the danger of suicidal behavior in children and adolescents who are given Prozac and similar antidepressant drugs (Bridge et al., 2007; Gualtieri & Johnson, 2006; Hammad, Laughren, & Racosin, 2006; Martinez et al., 2005; NIMH, 2004; Olfson, Marcus, & Shaffer, 2006; Whittington, Kendall, & Pilling, 2005). Warnings have also been issued about the elevated risk of death in elderly patients who are taking antipsychotic medications (U.S. Food and Drug Administration, 2005; Wang, Schneeweiss, et al., 2005). There is concern, too, about whether psychoactive drugs are as effective as they appear to be, especially in research sponsored by the drug companies that make them (Chan et al., 2004; Heres et al., 2006; Melander et al., 2003; Moncrieff & Kirsch, 2005).

● Drugs and Psychotherapy

With these issues in mind, many clinicians and clients wonder which is better, drugs or psychotherapy. Can they be effectively combined? A considerable amount of research is being conducted to address these questions.

Although occasionally a study does show that one approach or the other is more effective, there is no clear consensus. Overall, neither form of therapy is clearly superior for treating problems such as anxiety disorders and major depressive disorder (Smits, O’Cleirigh, & Otto, 2006; Thase et al., 2007). For example, large-scale studies of treatment for severe depression found that behavior therapy, cognitive-behavior therapy, and interpersonal psychotherapy can be as effective as an antidepressant drug (Butler et al., 2006; DeRubeis et al., 2005; Dimidjian et al., 2006; Hollon et al.,

2002; March et al., 2004; Nemeroff et al., 2003; Spanier et al., 1996). Cognitive-behavior therapy has also equaled drug effects in the treatment of phobias (Clark et al., 2003; Davidson et al., 2004; Otto et al., 2000; Thom, Sartory, & Jöhren, 2000), panic disorder (Klosko et al., 1990; Mitte, 2005a), generalized anxiety disorder (Gould et al., 1997; Mitte, 2005b), and obsessive-compulsive disorder (Abramowitz, 1997; Kozak, Liebowitz, & Foa, 2000). Further, the dropout rate from psychotherapy may be lower than from drug therapies (Casacalenda, Perry, & Loper, 2002; Hollon et al., 2005; Mitte, 2005b), and the benefits of many kinds of psychotherapy may last longer than those of drug therapies (e.g., Bockting et al., 2005; Hollon et al., 2002, 2006; Segal, Gemar, & Williams, 2000; Thom et al., 2000), thus making psychotherapy more cost-effective than medication in the long run (Barrett, Byford, & Knapp, 2005).

What about combining drugs and psychotherapy? Recent research suggests that doing so can sometimes be helpful (Hofmann et al., 2006; Miklowitz et al., 2007; Winston, Been, & Serby, 2005). Combined treatment is recommended in cases of bipolar disorder (Otto, Smits, & Reese, 2005) and produces slightly better results than either psychotherapy or drugs alone in people suffering from severe, long-term depression (Friedman et al., 2004; Hegerl, Plattner, & Moller, 2004). The combination of drugs and psychotherapy also has been shown to be more effective than either method alone in treating attention deficit hyperactivity disorder, obsessive-compulsive disorder, alcoholism, stammering, compulsive sexual behavior, and panic disorder (Barlow et al., 2000; Engeland, 1993; Keller et al., 2000; March et al., 2004; Roy-Byrne et al., 2005). The combined approach may be especially useful for clients who are initially too distressed to cooperate in psychotherapy. A related approach, already shown successful with clients who had been taking drugs for panic disorder and depression, is to use psychotherapy to prevent relapse and make further progress as drug treatment is discontinued (e.g., Lam et al., 2003). Preliminary evidence also suggests that a drug called D-cycloserine might be helpful in preventing the reappearance of fears being extinguished through exposure techniques or other forms of behavior therapy (Choy et al., 2007; Davis et al., 2005, 2006; Hofmann et al., 2006; Ressler et al., 2004).

However, many other studies have found little advantage in combining drugs and psychotherapy (e.g., Davidson et al., 2004; Elkin, 1994; Nemeroff et al., 2003; Spiegel & Bruce, 1997). One research team compared the effects of gradual in vivo exposure and an anti-anxiety drug (Xanax) in the treatment of agoraphobia. Clients receiving gradual exposure alone showed better short- and long-term benefits than those getting either the drug alone or a combination of the drug and gradual exposure (Echeburua et al., 1993).

Perhaps the most conservative strategy for treating most cases of anxiety and depression is to begin with cognitive or interpersonal psychotherapy (which have no major negative side effects) and then to add or switch to drug treatment if psychotherapy alone is ineffective (Jacobs et al., 2004; Schatzberg et al., 2005). Often, clients who do not respond to one method will be helped by the other (e.g., Heldt et al., 2006). Someday, research may offer better guidelines as to which clients should be treated with psychotherapy alone, medication alone, a combination of the two (Hollon et al., 2005).

LINKAGES

Biological Aspects of Psychology and the Treatment of Psychological Disorders

 LINKAGES (a link to Biological Aspects of Psychology, p. 64)

As described in the chapter on biological aspects of psychology, human feelings, thoughts, and actions—whether normal or abnormal—are ultimately the result of biological processes, especially those involving neurotransmitters and their

receptors in the brain. Because different neurotransmitters are especially prominent in particular brain regions or circuits, altering the functioning of particular neurotransmitter systems has relatively specific psychological and behavioral effects.

Let's consider some of the ways in which therapeutic psychoactive drugs affect neurotransmitters and their receptors. Some therapeutic drugs cause neurons to fire, whereas others reduce or inhibit such firing. For example, benzodiazepines (e.g., Valium and Xanax) exert their anti-anxiety effects by helping the inhibitory neurotransmitter GABA bind to receptors and thus suppress neuron firing. This increased inhibitory effect acts as a sort of braking system that slows the activity of GABA-sensitive neurons involved in the experience of anxiety. However, benzodiazepines also slow the action of all neural systems that use GABA, including those associated with motor activity and mental processing, which are spread throughout the brain. The result is the decreased motor coordination and clouded thinking that appear as benzodiazepines' side effects. Research suggests that it might soon be possible to develop drugs that will bind only to certain kinds of GABA receptors and thus greatly reduce these side effects (Gorman, 2005).

Other therapeutic drugs are receptor *antagonists* (see Figure 9.11 in the chapter on consciousness), acting to block the receptor site normally used by a particular neurotransmitter. The phenothiazines, for example, exert their antipsychotic effects by blocking receptors for dopamine, a neurotransmitter that is important for movement, as described in the chapter on biological aspects of psychology. Blocking dopamine seems to normalize the jumbled thinking of many schizophrenia patients, but it can also create severe disorders—including tardive dyskinesia—in the movement systems that are also controlled by dopamine.

Finally, some psychoactive drugs exert their therapeutic influence by increasing the amount of a neurotransmitter available to act on receptors. This effect usually occurs because the drug slows a process called *reuptake*, by which the neurotransmitter would normally return to the brain cell from which it was released. The tricyclic antidepressants, for example, operate by slowing the reuptake of norepinephrine. Prozac, Anafranil, and some other antidepressants are called *selective serotonin reuptake inhibitors (SSRIs)* because they slow the reuptake of serotonin. Others, such as Effexor, slow the reuptake of both serotonin and norepinephrine. These effects are consistent with biological theories suggesting that some cases of depression are traceable to faulty norepinephrine or serotonin systems. ■

Community Psychology: From Treatment to Prevention

It has long been argued that even if psychologists knew exactly how to treat every psychological problem, there would never be enough mental health professionals to help everyone who needs it (Albee, 1968). This view fostered the rise of **community psychology**, an approach whose goals are to treat people in their local communities and to work for social changes (such as lower unemployment) that may help prevent psychological disorders (Nelson & Prilleltensky, 2004).

One aspect of community psychology, the *community mental health movement*, arose during the 1960s amid growing concern that patients were not improving after years of confinement in mental hospitals. The plan was that these patients would be released from their hospitals and would receive newly available antipsychotic drugs and other mental health services in newly funded community mental health centers. This *deinstitutionalization* process did spare patients the boredom and isolation of the hospital environment, but the mental health services available in the community never matched the need for them (Leff, 2006). Some former

- **community psychology** A movement to minimize or prevent psychological disorders through changes in social systems and through community mental health programs.

Community Mental Health Efforts

Professional and nonprofessional staff members of community mental health centers provide traditional therapy and mental health education, along with walk-in facilities and hotlines for people who are suicidal or in crises because of rape or domestic violence. They also offer day treatment to former mental patients, many of whom are homeless.

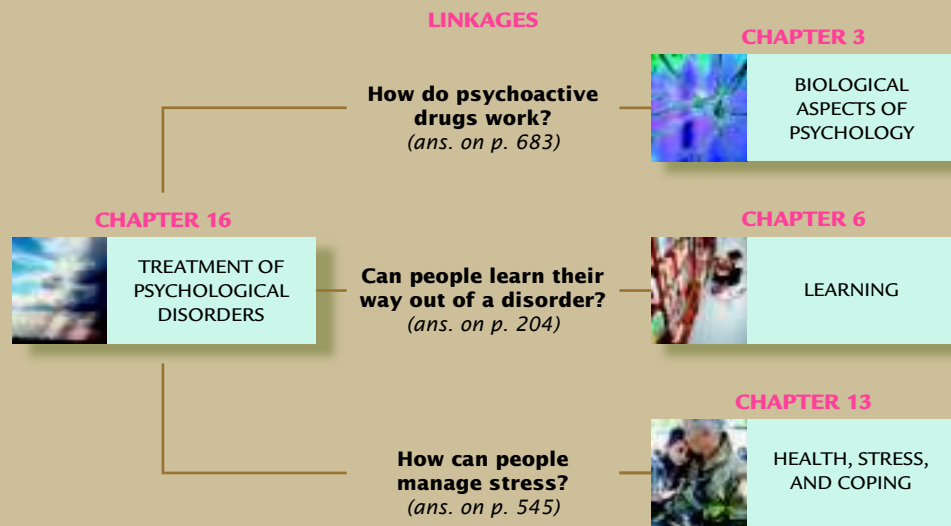

hospital patients and many people whose disorders might once have sent them to mental hospitals are now living in halfway houses and other community-based facilities where they receive *psychosocial rehabilitation*. These community support services are not deigned to “cure” severe disorders, but to help troubled people to cope with their problems and develop the social and occupational skills necessary for semi-independent living (Coldwell & Bender, 2007; Cook et al., 2005). All too many others with severe psychological disorders do not receive or fail to respond to rehabilitation, and are to be found enduring the dangers of urban homelessness or of confinement in jails and prisons (Teplin et al., 2005; U.S. Department of Health and Human Services, 2001b; World Health Organization World Mental Health Survey Consortium, 2004).

Community psychology also attempts to prevent psychological disorders by addressing poverty, substandard housing, and other stressful social problems that may underlie some disorders (Tucker & Herman, 2002; Weissberg, Kumpfer, & Seligman, 2003; Xue et al., 2005). Researchers in the field of positive psychology applaud this approach, suggesting that the development of many disorders could be further minimized by teaching skills that promote mental well-being and by offering programs designed to help young people build the character strengths they need to be resilient in the face of stress (Keyes, 2007; Seligman et al., 2005; Wallace & Shapiro, 2006). Another dimension of community psychology involves detecting psychological problems in their earliest stages and keeping them from becoming worse. Examples include programs for the prevention of depression and suicide (Gillham et al., 2007; Horowitz & Garber, 2006; Lynch et al., 2005; Spence, Sheffield, & Donovan, 2005); programs such as Project Head Start that help preschoolers whose backgrounds put them at risk for school failure and delinquency (Foster et al., 2006; Reid, Webster-Stratton, & Baydar, 2004; Shaw, Dishion, et al., 2006); and efforts to identify children who are at risk for disorders due to aggressiveness, parental divorce, or being rejected or victimized at school (e.g., Frey et al., 2005; Lochman & Wells, 2004; Martinez & Forgatch, 2001). Still other interventions aim to head off anxiety disorders or schizophrenia in children and adults (McGorry et al., 2002; Rapee et al., 2005), to prevent child abuse and other domestic violence (Duggan et al., 2004; Whitaker et al., 2006), and to promote health consciousness in ethnic minority communities (Borg, 2002).

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of treating psychological disorders through the use of psychoactive drugs illustrates just one way in which the topic of this chapter, the treatment of psychological disorders, is linked to the subfield of biological psychology (see the chapter on biological aspects of psychology). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

SUMMARY

Psychotherapy for psychological disorders is usually based on psychodynamic, humanistic, or social-cognitive (behavioral) theories of personality and behavior disorder. Most therapists combine features of these theories in an eclectic approach. The biological approach is reflected in the use of drugs and other physical treatment methods.

Basic Features of Treatment

All forms of treatment for psychological disorders include a client; a therapist; an underlying theory of behavior disorder; a set of treatment procedures suggested by the underlying theory; and the development of a special relationship between the client and therapist, which may make it easier for improvement to occur. Therapy may be offered to inpatients and outpatients in many different settings by *psychologists*, *psychiatrists*, and other mental health professionals. The goal of treatment is to help people change their thinking, feelings, and behavior so that they will be happier and function better. This goal may be pursued by promoting insight into hidden causes of behavior problems, by fostering personal growth through genuine self-expression, or by helping clients learn new ways of thinking and acting.

Psychodynamic Psychotherapy

Psychodynamic psychotherapy, which began with Sigmund Freud's methods of *psychoanalysis*, seeks to help clients gain insight into unconscious conflicts and impulses and then to explore how those factors have created disorders.

Classical Psychoanalysis Exploration of the unconscious is aided by the use of free association, dream interpretation, and analysis of transference.

Contemporary Variations on Psychoanalysis Some variations on psychoanalysis focus less on the id, the unconscious,

and the past and more on helping clients harness the ego to solve problems in the present. Other forms of psychodynamic treatment retain most of Freud's principles but use a more flexible format. Object relations therapy, for example, examines the effects of early relationships with caregivers and how those relationships affect current ones.

Humanistic Psychotherapy

Humanistic (or phenomenological) psychotherapy helps clients to become more aware of discrepancies between their feelings and their behavior. According to the humanistic approach, these discrepancies are at the root of behavior disorders and can be resolved by the client once they are brought to light in the context of a genuine, trusting relationship with the therapist.

Client-Centered Therapy Therapists using Carl Rogers's *client-centered therapy*, also known as *person-centered therapy*, help mainly by adopting attitudes toward the client that express *unconditional positive regard (acceptance)*, *empathy*, and *congruence*. These attitudes create a nonjudgmental atmosphere that facilitates the client's honesty with the therapist, with himself or herself, and with others. One way of creating this atmosphere is through *reflection*.

Gestalt Therapy Therapists employing the *Gestalt therapy* of Fritz and Laura Perls use more active techniques than do Rogerian therapists, often confronting and challenging clients.

Behavior Therapy

Behavior therapy, *behavior modification*, and *cognitive-behavior therapy* use learning principles to reduce clients' undesirable patterns of thought and behavior and to strengthen more desirable alternatives.

Techniques for Modifying Behavior Common behavioral treatments include *systematic desensitization*, *flooding* and other *exposure techniques*, *modeling*, *social skills training*, and *assertiveness training*. Behavior therapists also use *positive reinforcement* (sometimes in a *token economy*), *extinction*, *punishment*, and *aversion conditioning* to make desirable behaviors more likely or problematic behaviors less likely.

Cognitive-Behavior Therapy Many behavior therapists employ cognitive-behavior therapy to help clients change the way they think, as well as the way they behave. Among the specific cognitive-behavior therapy methods are *rational-emotive behavior therapy (REBT)*, cognitive restructuring, stress inoculation training, and *cognitive therapy*.

Group, Family, and Couples Therapy

Therapists of all theoretical persuasions may offer therapy to several clients at once. Clients' interactions with one another can enhance the effects of treatment.

Group Therapy *Group therapy* may involve a variety of people and problems, or it may focus on particular types of clients and problems. The group format is also adopted in many self-help organizations, such as Alcoholics Anonymous.

Family and Couples Therapy *Family therapy* involves treatment of two or more individuals from the same family system. In *couples therapy*, the clients are spouses or other intimate partners. In both formats, treatment usually focuses on improving communication and other interactions among the people involved.

Evaluating Psychotherapy

There is some disagreement about exactly how to measure improvement following psychotherapy and how best to ensure that observed improvement was actually due to the treatment itself and not to some other factor. Meta-analyses have found that clients who receive psychotherapy are better off than most people who receive no treatment but that no single approach is uniformly better than all others for all clients and problems. Still, some methods appear effective enough in the treatment of particular disorders to have been listed by an American Psychological Association task force as *empirically supported therapies (ESTs)*.

Choosing a Therapist

Research is needed to discover which combinations of therapists, clients, and treatments are ideally suited to alleviating particular psychological problems. Several factors, including personal preferences, must be considered when choosing a treatment approach and a therapist.

Cultural Factors in Psychotherapy The effects of cultural differences in values and goals between therapist and client have attracted increasing attention. Efforts are under way to minimize the problems that these differences can create.

Rules and Rights in the Therapeutic Relationship

Whatever the specific form of treatment, the client's rights include the right to confidentiality; the right to receive or, sometimes, to refuse treatment; and the right to protection from unnecessary confinement.

Biological Treatments

Biological treatment methods seek to relieve psychological disorders by physical rather than psychological means.

Psychosurgery *Psychosurgery* procedures once involved mainly prefrontal lobotomy; when used today, usually as a last resort, they focus on more limited areas of the brain.

Electroconvulsive Therapy In *electroconvulsive therapy (ECT)*, an electric current is passed through the patient's brain, usually in an effort to relieve severe depression.

Psychoactive Drugs Today the most prominent form of biological treatment is the prescription of psychoactive drugs, including drugs that are used to treat schizophrenia (the *neuroleptics*, or antipsychotics), mood disorders (*antidepressants*, *lithium*, and *anticonvulsants*), and anxiety disorders (*anxiolytics*). There appear to be significant differences among members of various ethnic groups and between men and women in the dosages of psychoactive drugs necessary to produce clinical effects.

Evaluating Psychoactive Drug Treatments Psychoactive drugs have proven impressively effective in many cases, but critics point out a number of undesirable side effects associated with these drugs, the risks of abuse, and the dangers of over-reliance on chemical approaches to human problems that might have other solutions.

Drugs and Psychotherapy So far, neither psychotherapy nor drug treatment has been found clearly superior overall for treating problems such as anxiety or depression. Combining drugs and psychotherapy may help in some cases, but their joint effect may not be any greater than the effect of either one alone.

Community Psychology: From Treatment to Prevention

The realization that there will never be enough therapists to treat everyone who needs help prompted the development of *community psychology*. Community mental health programs and efforts to prevent mental disorders are the two main elements of community psychology.

Social Cognition

Your view of yourself, and what you think about others, play major roles in shaping your behavior every day. In this chapter, we explore the ways in which perception, learning, emotion, and other factors affect how people think about themselves and others. We'll consider topics such as how we form first impressions, how we develop attitudes—including prejudiced attitudes—and why we may like (or love) one person and dislike another. We have organized the material as follows:

Social Influences on the Self 689

Social Comparison

FOCUS ON RESEARCH METHODS: *Self-Esteem and the Ultimate Terror*

Social Identity Theory

Self-Schemas

Social Perception 693

The Role of Schemas

SUMMARY

The death toll in the September 11, 2001, terrorist attacks on the United States exceeded 3,000, the largest number of people to die violently on American soil in a single day since 1862, during the U.S. Civil War. Almost all of the questions that can be asked

about these attacks, and about terrorism in general, relate to human behavior. For example, what could lead people to kill themselves, along with thousands of innocent people, in the name of political or religious beliefs? Why did hundreds of New York City firefighters, police officers, emergency medical workers, and others enter the World Trade Center's burning towers to save the lives of others while risking, and some ultimately losing, their own? Why did some of the people who were fleeing the damaged buildings return to their offices after hearing an announcement telling them to do so? Is there any reason to hope that someday the hatred and distrust that brought about this disaster can be reduced or eliminated?

We may never have final answers to such questions, but some partial answers may come from **social psychology**, the scientific study of how people's thoughts and feelings influence their behavior toward others and how the behavior of others influences people's own thoughts, feelings, and behavior. In this chapter we focus on **social cognition**, the mental processes associated with the ways in which people perceive and react to other individuals and groups (Wyer, 2004). Specifically, we will examine how people think about themselves and others, how they form and change attitudes, why and how they use stereotypes to judge other people (sometimes in unfair and biased ways), and why they like and dislike other people. In the companion chapter on *social influence*, we describe how social factors affect individuals, helping to shape behaviors that range from despicable acts of aggression to inspiring acts of heroism and self-sacrifice.

Social Influences on the Self

In the chapters on human development and personality, we describe how each individual develops within a cultural context and the ways in which collectivist and individualist cultures emphasize different core values and encourage contrasting definitions of the self. In this section we highlight the processes through which people in each culture help to shape two important components of the self. The first is our **self-concept**, the beliefs we hold about who we are and what characteristics we have. The second is our **self-esteem**, the evaluations we make about how worthy we are as human beings (Crocker & Park, 2004).

- **social psychology** The study of how people's thoughts, feelings, and behavior influence, and are influenced by, the behavior of others.
- **social cognition** Mental processes associated with people's perceptions of, and reactions to, other people.
- **self-concept** The way one thinks of oneself.
- **self-esteem** The evaluations people make about how worthy they are as human beings.
- **temporal comparison** Using one's previous performance or characteristics as a basis for judging oneself in the present.

Social Comparison

People spend a lot of time thinking about themselves, trying to evaluate their own perceptions, opinions, values, abilities, and the like (Mussweiler, 2003). Decades ago, Leon Festinger (1954) pointed out that self-evaluation involves two types of questions: those that can be answered by taking objective measurements and those that cannot. So you can determine your height or weight by measuring it, but how do you answer questions about your cognitive ability, social skills, athletic talent, or the quality of your relationships? Here, there are no yardsticks to act as objective measurement criteria. In these cases, we make one of two types of comparisons. If we use a **temporal comparison**, we consider the way we are now in relation to how

The Muhammad Ali Effect When former world heavyweight boxing champion Muhammad Ali was once asked why he did so poorly on an intelligence test, he replied, “I only said I was the greatest, not the smartest.” Research in the United States and in Holland suggests that most people, like Ali, consider it more important to be moral and honest than to be smart. They also believe that they are more honest than other people. This helps to maintain self-esteem (Van Lange & Sedikides, 1998).

we were in the past (Zagefka & Brown, 2005). Using a **social comparison**, we evaluate ourselves in relation to others. So if you use others as a basis for evaluating how intelligent, athletic, interesting, or attractive you are, you are using social comparison (Buunk et al., 2005).

Who serves as your basis of comparison? Festinger said that people usually look to others who are similar to themselves. If you are curious about how good a swimmer you are, you are likely to compare yourself with the people you normally compete against, not with Olympic champions. In other words, you tend to choose swimmers at your own level of experience and ability. The categories of people to which you see yourself belonging and to which you usually compare yourself are called **reference groups**.

The performance of people in a reference group can influence your self-esteem (Seta, Seta, & McElroy, 2006). For example, if being a good swimmer is very important to you, knowing that someone in your reference group swims much faster than you do can lower your self-esteem. People use a wide variety of strategies to protect or maintain their self-esteem (Leary, 2004; Pyszczynski et al., 2004). Sometimes they choose to compare themselves with those who are not as good as they are, a strategy called *downward social comparison*. They may also engage in *upward social comparison*, comparing themselves with people who do much better (Buunk et al., 2005). Both kinds of social comparisons can make people feel better about themselves. Downward social comparisons remind them that although their performance or their lives may not be ideal, things could be far worse. The comfort provided by such reminders helps explain the popularity of television talk shows whose guests are stuck in unpleasant, dysfunctional, and even bizarre family situations. But people may also feel better after comparing themselves with those who are doing much better than they are (Buunk & Oldersma, 2001). This result occurs partly because seeing people who are better off than we are can create optimism about improving our own situation (Buunk & Oldersma, 2001). We may tell ourselves “If they can do it, so can I!”

Some people use a related tactic to maintain their self-esteem through upward social comparison. Specifically, they tell themselves that a superior performer is not similar enough to be in their reference group. They may even exaggerate the ability of the other person so that their own performance doesn’t look so bad when viewed in light of such an able competitor (Mussweiler, 2003). If you can convince yourself that you lost every hole during a golf game because your opponent is almost as good as Tiger Woods, Michele Wie, or some other world-class golfer, then it is easier to believe that your performance wasn’t so terrible and that you would do just fine against someone with normal athletic skills.

An unfavorable comparison of your own status with that of others can produce **relative deprivation**—the belief that no matter how much you are getting in terms of recognition, status, money, and so forth, it is less than you deserve (Brehm, Kassin, & Fein, 2005). The concept of relative deprivation explains why an actor who receives \$5 million to star in a film feels abused if a costar is receiving \$10 million. It also explains the far more common situation in which employees become dissatisfied when they see themselves as underpaid or underappreciated in comparison to their co-workers (Tougas et al., 2005). When large groups of people experience relative deprivation, political unrest may follow. Social and political turmoil usually begins after the members of a deprived group experience some improvement in their lives and begin to compare their circumstances with those in other groups (Worchel et al., 2000). With this improvement comes higher expectations about what they deserve. When these expectations are not met, violence may follow. A feeling among citizens of poor countries that the United States enjoys and exploits its great prosperity may have played a role in creating the hatred that led to the attack on the World Trade Center, a symbol of U.S. financial strength (Plous & Zimbardo, 2004).

- **social comparison** Using other people as a basis of comparison for evaluating oneself.
- **reference groups** Categories of people to which people compare themselves.
- **relative deprivation** The belief that, in comparison to a reference group, one is getting less than is deserved.

FOCUS ON RESEARCH METHODS

Self-Esteem and the Ultimate Terror

Why is self-esteem so important to so many people? An intriguing answer to this question comes from the *terror management theory* proposed by Jeff Greenberg, Tom Pyszczynski, and Sheldon Solomon. This theory is based on the notion that humans are the only creatures capable of thinking about the future. One result of this ability is the realization that we will all eventually die, and the sense of terror it may bring. We can't change this reality, but terror management theory suggests that humans cope with anxiety about death by developing a variety of self-protective psychological strategies, including efforts to establish and maintain high self-esteem (Pyszczynski et al., 2004; Solomon, Greenberg, & Pyszczynski, 2004).

■ What was the researchers' question?

In one series of experiments, Greenberg and his colleagues (1992) asked whether high self-esteem would, in fact, serve as a buffer against anxiety—specifically, the anxiety brought on by thoughts about death and pain.

■ How did the researchers answer the question?

About 150 students at several North American universities participated in these studies, each of which followed a similar format. The first step in each experiment was to manipulate the independent variable, in this case the participants' self-esteem. To do this, the researchers gave the students feedback on a test they had taken earlier in the semester. Half the participants received esteem-building feedback, such as that their scores indicated high intelligence or a stable personality. The other half received feedback that was neutral (i.e., neither flattering nor unflattering). Next, the students' self-esteem was measured, and these measures showed that the positive feedback actually did produce higher self-esteem than the neutral feedback. In the third phase of each experiment, the researchers manipulated a second independent variable by causing some anxiety in half of the participants in each of the two feedback groups. In one study, for example, anxiety was created by showing some students a film containing pictures of dead people and discussions of death. The others saw a film that did not arouse emotion. In two other experiments, anxiety was created by leading some of the participants to believe (falsely) that they would be receiving a mild electrical shock. Afterward, the participants' anxiety was measured by their self-reports or by monitoring galvanic skin resistance (GSR), an anxiety-related measure of perspiration.

■ What did the researchers find?

Self-reports or GSR measures revealed that participants in all three experiments were significantly less upset by an anxiety-provoking experience (the death film or the threat of shock) if they had first received esteem-building feedback about their previous test performance.

■ What do the results mean?

The researchers concluded that these results offer support for terror management theory, and specifically for the notion that self-esteem is important as a buffer against anxiety and other negative feelings. The results may help explain why the maintenance of self-esteem is such a powerful human motive (Tesser, 2001). People do not like to feel anxious, and increased self-esteem reduces most people's anxiety.

■ What do we still need to know?

Additional research by Greenberg and his associates, as well as by others, has provided additional support for terror management theory. For instance, the theory

predicts that when people are sensitized to the threat of death, they will seek to protect themselves by suppressing thoughts of death and also by doing things that increase the approval and support of others in the society in which they live. Consistent with this prediction, people have been found to make larger contributions to charity after they have been made more aware of their own mortality (Jonas et al., 2002). Similarly, dramatic increases in volunteering for charity work occurred after the terrorist attacks of September 11, 2001 (Penner et al., 2005).

But which esteem-building strategies are people most likely to use, and why? Are some strategies more or less likely to be adopted at different times in a person's life or among people in certain cultures? Most of the research on terror management theory has been done in individualistic cultures such as North America, in which self-esteem is largely based on personal accomplishments. However, terror management theory has also been supported by preliminary studies in Japan, aboriginal Australia, and other collectivist cultures in which feelings of self-worth tend to be more closely tied to the performance and status of the groups to which people belong (Halloran & Kashima, 2004; Heine, Harihara, & Niiya, 2002).

Researchers also wonder whether terror management theory offers the best explanation of why high self-esteem reduces anxiety. Perhaps people value self-esteem not because it makes them less afraid of death but simply because it is a flattering indicator (a sort of “sociometer”) of their acceptance by others (Leary, 2004). According to sociometer theory, people want to have high self-esteem because it tells them that they are liked and accepted. Perhaps the goal of acceptance evolved because people who were excluded from the protective circle of their group were not likely to survive to reproduce. Compared with terror management theory, sociometer theory is certainly a simpler and more plausible explanation of the desire for high self-esteem, but is it the best explanation? Both theories make similar predictions about the effects of self-esteem on anxiety, so it will take additional research to evaluate their relative merits. ■

● Social Identity Theory

TRY
THIS

Stop reading for a moment, and fill in the blank in the following sentence: “I am a(n) _____.”

Some people complete the sentence by using characteristics such as “hard worker,” “good sport,” or some other aspect of their *personal* identity. However, many others identify themselves by using a word or phrase that reflects their nationality,

All in the Family Many people find that their place in their family is a central aspect of their social identity. For others, their role in a political, religious, cultural, or business organization might be most vital to that identity. Whatever the specifics, social identity is an important part of people's self-concept, or view of themselves.

gender, or religion (e.g., Lee & Yoo, 2004). These responses reflect **social identity**, our beliefs about the groups to which we belong. Our social identity is thus part of our self-concept (Brewer & Hewstone, 2004; Vignoles et al., 2006).

Our social, or group, identity permits us to feel part of a larger whole (Ashmore, Deaux, & McLaughlin-Volpe, 2004). Its importance is seen in the pride that people feel when a member of their family graduates from college or when a local team wins a big game. In wars between national, ethnic, or religious groups, individuals make sacrifices, and even die, for the sake of their group identity. A group identity is also one reason people donate money to the needy, support friends in a crisis, and display other helping behaviors toward those with whom they can identify. We will see later, though, that defining ourselves in terms of a group identity can create an “us-versus-them” mentality that sets the stage for prejudice, discrimination, intergroup conflict, and even terrorism (Brewer & Pierce, 2005).

● Self-Schemas

Through social comparison and the formation of a social identity, people develop **self-schemas**, which are people’s beliefs about themselves and the attributes they possess (Taylor, Peplau, & Sears, 2006). Like other schemas, self-schemas help people organize and process incoming information. For example, information that is consistent with our self-schema (something flattering, perhaps) is usually perceived faster and remembered longer than information that is inconsistent with our self-schema (Franzoi, 2003).

The beliefs contained in our self-schemas, and the importance we attach to each of them, can differ widely from one person to the next and can affect our feelings and actions. In one study, for example, women whose self-schemas included the belief that their appearance is important were found to have lower self-esteem, and to diet more, than those whose self-schemas did not emphasize appearance so much (Jung & Lee, 2006). Another study showed that when women with appearance-oriented self-schemas looked at pictures of attractive women, their self-esteem declined and their mood became more negative (Jung & Lennon, 2003). On a more positive note, women are more likely to eat healthy diets if their self-schemas include the belief that health is important to them (Kendzierski & Costello, 2004).

Self-schemas contain information not only about what we are like at the moment but also about what we could be like in the future. Recognition of this *future self* or *possible self* can be a source of motivation to try doing better at various tasks. In one study, people who were told to think of themselves as successful at work persisted longer on a difficult task than people who were told to think of themselves as failing at work (Ruvolo & Markus, 1992).

● Social Perception

- **social identity** The beliefs we hold about the groups to which we belong.
- **self-schemas** Mental representations that people form of themselves.
- **social perception** The processes through which people interpret information about others, draw inferences about them, and develop mental representations of them.

There is a story about a company president who was having lunch with a man being considered for an executive position. When the man salted his food without first tasting it, the president decided not to hire him. The reason, she explained, was that the company had no room for a person who acted before collecting all relevant information. The candidate lost his chance because of **social perception**, the process through which people interpret information about others, form impressions of them, and draw conclusions about the reasons for their behavior. In this section we examine how and why social perception influences our thoughts, feelings, and actions.

● The Role of Schemas

The perception of people follows many of the same laws that govern the perception of objects, including the Gestalt principles discussed in the chapter on perception

**FIGURE 17.1****A Schema-Plus-Correction**

People who see an object like this tend to use a preexisting mental representation (their schema of a square) and then correct or modify it in some way (here, with a notch).

(Cloutier, Mason, & Macrae, 2005). Consider Figure 17.1. Consistent with Gestalt principles, most people would describe it as “a square with a notch in one side,” not as eight straight lines. The reason is that they interpret new information using the mental representations, or *schemas*, they already have about squares. In short, they interpret this diagram as a square with a slight modification.

Schemas about people, too, can have a significant influence on our perception of them. First of all, schemas influence what we pay attention to and what we ignore. Characteristics or events that are consistent with our schema about another person usually get more attention than those that are inconsistent with that schema. As a result, we tend to process information about the other person more quickly if it confirms our beliefs about, say, that person’s gender or ethnic group than if it violates those beliefs (Smith & Queller, 2001). Second, schemas influence what we remember about others. One study demonstrated that if people thought a woman they saw in a video was a waitress, they later recalled that she had a beer with dinner and owned a TV set. If they thought she was a librarian, they remembered that she was wearing glasses and liked classical music (Cohen, 1981). Finally, schemas affect our judgment about other people’s behavior. As an example, Thomas Hill and his colleagues (1989) found that participants’ ratings of male and female friends’ sadness were influenced not only by the friends’ actual behavior but also by the participants’ general schemas about whether men or women experience more sadness.

In other words, through “top-down” processing, schemas can influence—and sometimes bias—person perception in the same way in which schemas about objects can affect object perception. And just as schemas help us read sentences in which words have missing letters, they also allow us to efficiently “fill in the blanks” about people. So we don’t usually ask our doctors or bus drivers to show us their credentials. Our schemas about these people lead us to perceive them as competent, confident, skilled, and experienced. And usually these perceptions are correct. It is only when our expectations are violated that we realize that schemas can create errors in our judgment about other people.

● First Impressions

The schemas we have about people act as lenses that shape our first impressions of them. Those impressions, in turn, influence both our perceptions of their behaviors

May I Help You? Schemas help us to quickly categorize people and respond appropriately to them, but they can also create narrow-mindedness and even prejudice. If this woman does not fulfill your schema—your mental representation—of how carpenters are supposed to look, you might be less likely to ask her advice on your home improvement project. One expert carpenter who manages the hardware department of a large home improvement store told us that most customers walk right past her in order to ask the advice of one of her less experienced male clerks.

Noticeable features or actions help shape our impressions of others. Those impressions may or may not be correct.

© Scott Adams/Dist. by United Feature Syndicate, Inc.

and our reactions to those behaviors. First impressions are formed quickly, usually change slowly, and typically have a long-lasting influence. No wonder first impressions are so important in the development of social relations. How do people form impressions of other people? And why are they so resistant to change?

TRY
THIS

● **Forming Impressions** Think about your first impression of a close friend. It probably formed rapidly, because as mentioned earlier, existing schemas create a tendency to automatically infer a great deal about a person on the basis of limited information. One study found that people could make judgments about how trustworthy and competent a person was after seeing that person's face for only a tenth of a second (Willis & Todorov, 2006). Other attributes, such as an ethnic name, might have caused you to draw inferences about your friend's religion, food preferences, or temperament. Clothing or hairstyle might have led you to make assumptions about your friend's political views or taste in music. These inferences and assumptions may or may not have been accurate. How many turned out to be true in your friend's case?

One schema has a particularly strong influence on our first impressions: We tend to assume that people we meet will have attitudes and values similar to our own (Hoyle, 1993). So all else being equal, we are inclined to like other people. However, it doesn't take much negative information to change our minds. The main reason for this is that most of us don't expect other people to act negatively toward us. When unexpectedly negative behaviors do occur, they capture our attention and lead us to believe that these behaviors reflect something negative about the other person (Taylor, Peplau, & Sears, 2006). For example, we know that there are many reasons why people might be nice to us—because they are kind, because they like our best friends, or because they want to sell us a car. But if they do something negative—such as insult us or steal our lecture notes—the most likely explanation is that they are unfriendly or have other undesirable personality traits. In other words, negative behavior carries more weight than positive behavior in shaping first impressions (Smith & Mackie, 2000).

● **Lasting Impressions** Does your friend seem the same today as when you first met? First impressions can change, but the process is usually slow. One reason is that negative first impressions may cause us to avoid certain people, thus reducing our exposure to new information that might change our view of them (Denrell, 2005). Further, most people want to keep their social environment simple and easy to understand (Kenrick, Neuberg, & Cialdini, 2005). We cling to our beliefs about the world, often using our schemas to preserve a reality that fits our expectations. Holding on to existing impressions appears to be part of this effort. If your friend has recently said or done something that violates your expectations, your view of her probably did not change much, if at all. In fact, you may have acted to preserve your impression by thinking something like, "She's just not herself today." In other words, impressions are slow to change because the meaning we give to new information about people is shaped by what we already know or believe about them (Kenrick et al., 2005).

Self-Fulfilling Prophecies in the Classroom

If teachers inadvertently spend less time helping children who impressed them as “dull,” those children may not learn as much, thus fulfilling the teachers’ expectations. If the girl in the back row has not impressed this teacher as being bright, how likely do you think it is that she will be called on?

● **Self-Fulfilling Prophecies** Another reason first impressions tend to be stable is that we often do things that cause others to confirm our impressions (Madon et al., 2004). If teachers expect particular students to do poorly in mathematics, those students may sense this expectation, exert less effort, and perform below their ability level. Similarly, if mothers expect their young children to eventually abuse alcohol, they are more likely to do so than the children of mothers who didn’t convey that expectation (Madon et al., 2006). When, without our awareness, schemas cause us to subtly lead people to behave in line with our expectations, a **self-fulfilling prophecy** is at work.

In one experiment on self-fulfilling prophecies, men and women participated in “get-acquainted” conversations over an intercom system. They could not see each other, but before the conversations took place, the men were shown photographs and told that they were pictures of their partners. Some saw a photograph of an obese woman, whereas others saw a picture of a woman of normal weight. In fact, the photographs bore no relationship to the women’s actual appearance. Judges who had not seen any of the participants listened to tapes of the conversations and rated the women’s behavior and personalities. The women who had been portrayed as normal in weight were rated as more articulate, lively, interesting, exciting, and fun to be with. Apparently, when the men thought their partners were of normal weight, they were more friendly and engaging, and this behavior drew more positive reactions from the women. In contrast, men who thought their partners were overweight behaved in ways that drew comparatively dull responses (Snyder & Haugen, 1995).

Self-fulfilling prophecies also help maintain judgments about groups. If you assume that members of a certain ethnic group are unfriendly, for example, you might be defensive or even hostile when you meet a member of that group. If the person reacts to your behavior with hostility, your prophesy would be fulfilled and you would have an even stronger impression that “all those people” are unfriendly (Ross & Jackson, 1991).

- **self-fulfilling prophecy** A process through which an initial impression of someone leads that person to behave in accordance with that impression.

● Explaining Behavior: Attribution

So far, we have considered how people form impressions about the characteristics of other people. But our perceptions of others include another key element: explanations of their behavior. People tend to form *implicit theories* about why people (including themselves) behave as they do and about what behavior to expect in the future. Psychologists use the term **attribution** to describe the process people go through to explain the causes of behavior (including their own).

As an example, suppose a classmate fails to return some borrowed notes on time. You could attribute this behavior to many causes, from an unavoidable emergency to simple selfishness. Which of these alternatives you choose is important because it will help you to *understand* your classmate's behavior, *predict* what will happen if this person asks to borrow something in the future, and decide how to *control* the situation should it arise again. Similarly, your decision to stick with a troubled relationship or end it may be influenced by whether you attribute your partner's recent indifference to stressful circumstances or to a loss of love.

People tend to attribute behavior in a particular situation to either internal causes (characteristics of the person) or external causes (characteristics of the situation). If you thought your classmate's failure to return your notes was due to lack of consideration or laziness, you would be making an *internal attribution*. If you thought that the oversight was caused by time pressure or a family crisis, you would be making an *external attribution*. And if you failed an exam, you could explain it by concluding either that you're not very smart (internal attribution) or that your job responsibilities didn't leave you enough time to study (external attribution). The attribution that you make, in turn, might determine how much you study for the next exam or even whether you decide to stay in school.

● **Sources of Attributions** Harold Kelley (1973) proposed an influential theory of how people (whom Kelley called *observers*) make attributions about the actions of other people (whom Kelley called *actors*). To illustrate this theory, suppose you are at your parents' home for the weekend. You want to invite your friend Ralph to stay for dinner, but your father says no. According to Kelley, understanding the reasons for your father's behavior requires information about three key variables: consensus, consistency, and distinctiveness (Kelley, 1973):

1. *Consensus* is the degree to which other people's behavior is similar to the actor's—in this case, your father. If everyone you know avoids Ralph, your father's behavior has a high degree of consensus, and you would attribute his reaction to an external cause (probably something about Ralph). However, if everyone except your father likes Ralph, your father's negative response would have low consensus. In that case you would probably attribute the response to something about your father, such as rudeness or having a personal dislike for Ralph.
2. *Consistency* is the degree to which the behavior is the same across time and/or situations. If your father has invited Ralph to dinner several times in the past but rejects him this time, the consistency of his behavior is low. Low consistency suggests that your father's behavior is attributable to external causes, such as conflicts at work that have left your father feeling unsociable. If your father's behavior toward Ralph is always hostile, it has high consistency. But is your father's consistent behavior attributable to an internal cause (his consistent rudeness) or to an external cause (consistent conflicts at work)? This question is difficult to answer without information about distinctiveness.
3. *Distinctiveness* concerns the extent to which the actor's response to one situation stands out from responses to similar situations. If your father is nasty to all your friends, his behavior toward Ralph has low distinctiveness. Behavior

● **attribution** The process of explaining the causes of people's behavior, including our own.

that is low in distinctiveness is usually attributable to internal causes, such as personality traits. However, if your dad gets along with everyone except Ralph, his behavior has high distinctiveness, and your attribution about the cause of his behavior is likely to shift toward a cause other than your father's personality, such as how Ralph acts.

In summary, Kelley's theory suggests that people are most likely to make internal attributions about an actor's behavior when there is low consensus, high consistency, and low distinctiveness. If you observe your boss insulting customers (a situation of low consensus, inasmuch as most people in business are polite to customers) every day (high consistency) no matter who the customers are (low distinctiveness), you would probably attribute this behavior to the boss's personality rather than to the customers' unreasonable demands or some other external cause. But if you saw the boss on just one day (low consistency) being rude (low consensus) to one particular customer (high distinctiveness), you would probably attribute the incident to the customer's behavior, an external factor.

● **Culture and Attribution** Most theories of causal attribution were developed by North American psychologists who implicitly assumed that people all over the world use the same kinds of information to make similar kinds of attributions. However, there is substantial evidence to suggest that this may not be true (Lehman, Chiu, & Schaller, 2004). For example, Joan Miller and David Bersoff (1994) found that students from the United States and students from India made very different attributions about the reasons why people would do a favor for someone who had just helped them. The Americans attributed the behavior to an external cause (feeling an obligation to repay a favor), but the Indians attributed it to an internal cause (liking to help people). Miller (1994) suggested that the differences in the two groups' responses reflected differences in their cultural experiences. The results of Miller and Bersoff's experiment highlight once again the danger of assuming that phenomena seen in European American cultures generalize to all cultures. Cross-cultural differences in attribution and other aspects of social cognition may help to explain why people in different cultures sometimes have so much difficulty in understanding one another.

Why Are They Helping? Helping occurs all around the world, but research shows that people's attributions, or explanations, about why it happens can differ from culture to culture.

Attributional Bias Men whose thinking is colored by the ultimate attribution error might assume that women who succeed at tasks associated with traditional male gender roles are just lucky, but that men succeed at those tasks because of their skill (Deaux & LaFrance, 1998). When this attributional bias is in operation, people who are perceived as belonging to an out-group, whether on the basis of their gender, age, sexual orientation, religion, ethnicity, or other characteristics, may be denied fair evaluations and equal opportunities.

● Biases in Attribution

Whatever their background, most people are usually logical in their attempts to explain behavior (Trope, Cohen, & Alfieri, 1991). However, they are also sometimes prone to *attributional biases* that can distort their views of behavior (Gilbert, 1998).

● **The Fundamental Attribution Error** North American psychologists have paid special attention to the **fundamental attribution error**, a tendency to over-attribute the behavior of others to internal factors, such as personality traits (Moskowitz, 2005). Imagine that you hear a student give an incorrect answer in class. You will probably attribute this behavior to an internal cause and assume that the person is not very smart. In doing so, however, you might be failing to consider the possible influence of various external causes, such as lack of study time.

A related form of cognitive bias is called the *ultimate attribution error*. Through this error, when members of a social or ethnic *out-group* (people we see as “different”) do something positive, we attribute their behavior to luck or some other external cause. But we attribute their negative behavior to an internal cause, such as dishonesty (Pettigrew, 1979). At the same time, when members of an *in-group* (people we see as being like ourselves) do good deeds, we attribute the behavior to integrity or other internal factors. If they do something bad, we attribute it to some external cause. Because of the ultimate attribution error, members of the out-group receive little credit for their positive actions, and members of the in-group get little blame for their negative actions. Biases such as the ultimate attribution error help maintain people’s negative views of out-groups and positive views of their own in-group (Fiske, 1998).

Like other aspects of social cognition, the fundamental attribution error may not be universal (Miyamoto & Kitayama, 2002). Researchers have found, for example, that people in collectivist cultures such as India, China, Japan, and Korea are less likely than those in the individualist cultures of North America and Europe to attribute people’s behavior to internal causes. Instead, these people tend to see behavior as due to an interaction between individual characteristics and the situations or contexts in which the person is immersed (Lehman et al., 2004).

Researchers have also pointed out that attributing behavior to internal causes may not always be an “error.” Sometimes an internal attribution may simply be the most reasonable attribution to make, given the information available (Sabini, Siepmann, & Stein, 2001). Further, David Funder (2004) has argued that, in many situations, personality characteristics and other internal factors are indeed the true causes of behavior. In other words, according to Funder, social perception is much more accurate than many psychologists have previously recognized.

● **Other Attributional Biases** The inclination toward internal attributions is much less pronounced when people explain their own behavior. Here, in fact, another bias tends to come into play: the **actor-observer bias**. Whereas people often attribute other people’s behavior to internal causes, they tend to attribute their own behavior to external factors, especially when the behavior is inappropriate or inadequate. For example, when Australian students were asked why they sometimes drive too fast, they focused on circumstances such as being late, but saw other people’s dangerous driving as a sign of aggressiveness or immaturity (Harré, Brandt, & Houkamau, 2004). Similarly, when you drive slowly, it’s because you are looking for an address, or for some other good reason, not because you’re a dimwitted loser like that jerk who crawled along in front of you yesterday.

The actor-observer bias occurs mainly because people have different kinds of information about their own behavior and about others’ behavior. When *you* are acting in a situation—giving a speech, perhaps—the information that is most available to you is likely to be external and situational, such as the temperature of the room and the size of the audience. You also have a lot of information about other external factors, such as the amount of time you had to prepare your talk or the

- **fundamental attribution error** A bias toward overattributing the behavior of others to internal causes.
- **actor-observer bias** The tendency to attribute other people’s behavior to internal causes while attributing our own behavior (especially errors and failures) to external causes.

upsetting argument that occurred this morning. If your speech is disorganized and boring, you can easily attribute it to one or all of these external causes. But when you observe someone else, the most noticeable stimulus in the situation is *that person*. You do not know what happened to the person last night or this morning, so you are likely to attribute whatever he or she does to enduring internal characteristics (Moskowitz, 2005).

Of course, people do not always attribute their own behavior to external forces. In fact, the degree to which they do so depends on whether the outcome of their behavior is positive or negative. In one study, when people were asked what they saw as the cause of their good and bad experiences when shopping online, they tended to take personal credit for positive outcomes but to blame the computer for the negative ones (Moon, 2003). In other words, these people showed a **self-serving bias**, the tendency to take personal credit for success but to blame external causes for failure. This tendency has been found in almost all cultures, but as with the fundamental attribution error, it is usually more pronounced among people from individualistic Western cultures than among those from collectivist Eastern cultures (Mezulis et al., 2004).

● The Self-Protective Functions of Social Cognition

The self-serving bias occurs partly because, as noted earlier, people are motivated to maintain their self-esteem—and ignoring negative information is one way to do so. If you just failed an exam, it is painful to admit that your grade was fair, so you might blame your performance on an unreasonably demanding instructor. Other forms of social cognition also help people think about their failures and shortcomings in ways that protect their self-esteem (Gilbert et al., 2004).

One example is *unrealistic optimism*, the tendency to believe that positive events (such as financial success or having a gifted child) are more likely to happen to yourself than to others and that negative events (such as being in an accident or having cancer) are more likely to happen to others than to yourself (Lin & Raghuram, 2005; see “In Review: Some Biases in Social Perception”).

in review Some Biases in Social Perception

| Bias | Description |
|--------------------------------|--|
| Importance of first impression | Ambiguous information is interpreted in line with a first impression, and the initial schema is recalled better and more vividly than any later correction to it. Actions based on this impression may elicit behavior that confirms it. |
| Fundamental attribution error | The tendency to attribute the behavior of others to internal factors. |
| Actor-observer bias | The tendency for actors to attribute their own behavior to external causes and for observers to attribute the behavior of others to internal factors |
| Self-serving bias | The tendency to attribute one's successes to internal factors and one's failures to external factors. |
| Unrealistic optimism | The tendency to assume that positive events are more likely, and negative events are less likely, to occur to oneself than to others. |

Unrealistic optimism is fueled, in part, by another self-protective form of social cognition called *unique invulnerability*. For example, when motorcyclists in England were asked to estimate the chances that they would be in a serious traffic accident during the next twelve months, virtually all of them said that this was far less likely to happen to them than to other motorcycle riders (Rutter, Quine, & Albery, 1998).

Remember that *unrealistic* optimism is not the same as the optimistic (but realistic) perspective on life that, as mentioned in the chapter on health, stress, and coping, is associated with good physical and mental health (Radcliffe & Klein, 2002). In fact, unrealistic optimism can have the opposite effects because it tends to persist even in the face of contradictory evidence and it can lead to potentially harmful behaviors. In one study, unrealistically optimistic smokers not only underestimated their chances of getting lung cancer but also were less likely than others to believe that smoking causes lung cancer or that quitting can lower their risk (Dillard, McCaul, & Klein, 2006). Similarly, one reason that people engage in risky sexual behaviors (e.g., unprotected sex with multiple partners) is that they estimate the risks of unsafe sex to be much lower for themselves than for other people (Taylor et al., 1992).

Like the defense mechanisms described in the personality chapter, self-protective cognitive biases can help us temporarily escape from unpleasant thoughts and feelings. But these biases also set the stage for a somewhat distorted view of reality and can create problems in the long run. For example, although unrealistic optimism may reduce anxiety and blunt the impact of stress for a while, it may also keep people from taking the rational steps necessary for long-term protection of their health, well-being, and safety (Ayanian & Cleary, 1999).

Attitudes

People's views about health or safety reflect their *attitudes*, an aspect of social cognition that social psychologists have studied longer and more intensely than any other. An **attitude** is the tendency to think, feel, or act positively or negatively toward objects in our environment (Albarracín, Johnson, & Zanna, 2005). Attitudes play an important role in guiding how we act toward other people, what political causes we support, which products we buy, and countless other daily decisions.

● The Structure of Attitudes

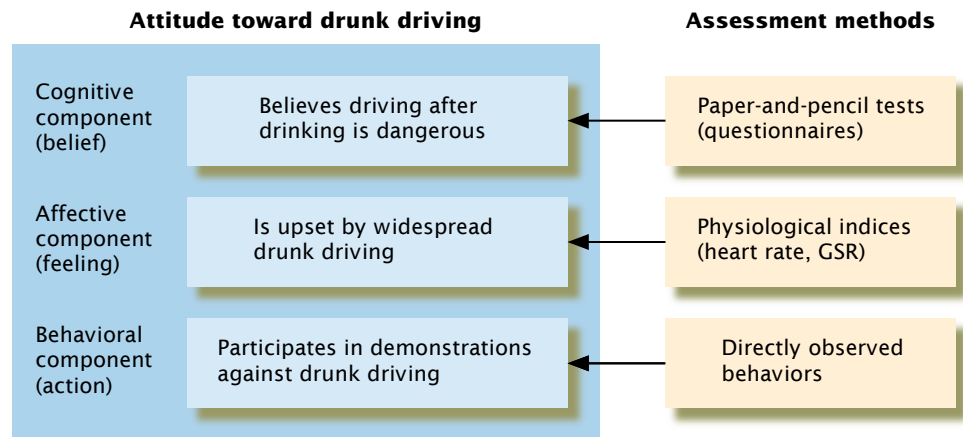

Social psychologists have long viewed attitudes as having three components (Fabrigar, MacDonald, & Wegener, 2005; see Figure 17.2). The *cognitive* component is a set of beliefs about the attitude object. The emotional, or *affective*, component includes feelings about the object. The *behavioral* component is the way people act toward the object. If these components were always in harmony, we would be able to predict people's behavior toward the homeless, for example, on the basis of the thoughts or feelings they express and vice versa. This is often not the case, however (Bohner & Schwarz, 2001). Many people's positive thoughts and supportive emotions regarding homeless people are never translated into actions aimed at helping them.

What determines whether people's behavior will be consistent with the cognitive and affective components of their attitudes? Several factors are important. For one thing, behavior is more likely to be consistent with attitude when people see the attitude as important and relevant to their lives (Kenrick et al., 2005). Second, consistency is more likely when the behavioral component of the attitude is in line with a *subjective norm*, our view of how important people in our lives want us to act. Conflict between attitudes and subjective norms may cause us to behave in

- **self-serving bias** The tendency to attribute our successes to internal characteristics while blaming our failures on external causes.
- **attitude** A predisposition toward a particular cognitive, emotional, or behavioral reaction to objects.

FIGURE 17.2**Three Components of an Attitude**

Various attitude components may or may not be consistent with one another. For example, people may think that drunken driving is wrong (cognitive component) and be upset by its tragic consequences (affective component), yet they may still get behind the wheel after drinking too much (behavioral component).

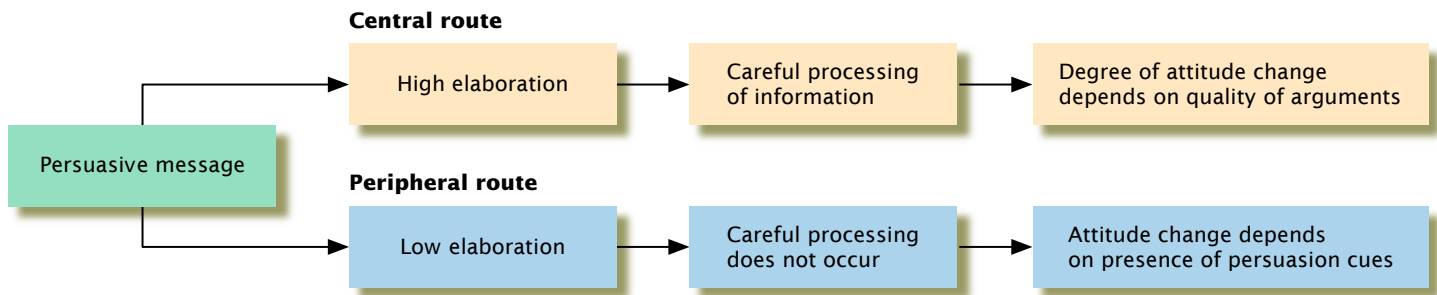

TRY THIS  **A Reminder about Poverty** Photographs such as this one are used by fund-raising organizations to remind us of the kind thoughts and charitable feelings we have toward needy people and other social causes. As a result, we may be more likely to behave in accordance with the cognitive and affective components of our attitudes and make a donation to these causes. Browse through several newspapers and popular magazines and calculate the percentage of such photos you find in ads for charitable organizations.

ways that are inconsistent with our attitudes (Ajzen & Fishbein, 2005). For example, someone who believes that the rights of gay men and lesbians should be protected might not campaign for this cause because doing so would upset family members or friends who are against it. Third, attitude-consistent behavior is more likely when people have *perceived control*, the belief that they can actually perform such behavior (Ajzen & Fishbein, 2005). The cognitive and affective components of your attitude about the homeless may be positive, but if you don't believe you can do anything about it, you are not likely to even try. Fourth, *direct experience* with the attitude object increases the likelihood of attitude-consistent behavior (Glasman & Albarracín, 2006). This is because attitudes based on direct experiences are more stable and memorable and thus more likely to come into play when the attitude object is present. Accordingly, you might be more likely to actively support, and perhaps even participate in, efforts to help the homeless if you have come to know a homeless person on your campus than if you have only read about their plight.

The importance of direct experience in creating consistency among attitude components reflects the cognitive network theories described in the chapters on learning and memory. According to these theories, attitudes are stored in long-term memory as networks of cognitions—interconnected evaluations and beliefs about attitude objects (Tourangeau, Rips, & Rasinski, 2000; see also Figure 7.10 in the memory chapter). When you encounter an attitude object, the cognitions associated with it in your cognitive network are activated. If your thoughts and feelings are well defined and come easily to mind, then your behavior is likely to be consistent with them. If not, there may be less consistency (Glasman & Albarracín, 2006).

● Forming Attitudes

People are not born with specific attitudes toward specific objects, but their attitudes about new objects begin to appear in early childhood and continue to emerge throughout life. How do attitudes form? Some of the variation we see in people's attitudes may reflect genetic influences inherited from their parents (Abrahamson, Baker, & Caspi, 2002), but what they *learn* from their parents and others appears to play the major role in attitude formation. In childhood, modeling and other forms of social learning are especially important. Children learn not only the names of objects but also what they should believe and feel about them and how they should act toward them. For example, a parent may teach a child not only that snakes are reptiles but also that they should be feared and avoided. So as children learn concepts such as "reptile" or "work," they learn attitudes about those concepts, too.

**FIGURE 17.3****The Elaboration Likelihood Model of Attitude Change**

The central route to attitude change involves carefully processing and evaluating the content of a message (high elaboration). The peripheral route involves low elaboration, or processing, of the message and relying on persuasion cues such as the attractiveness of the person making the argument (Cacioppo, Petty, & Crites, 1993).

Attitudes can also be influenced by classical and operant conditioning. In one study demonstrating this process, certain cartoon characters were associated with positive words (e.g., *excellent*) and images (e.g., an ice cream sundae), whereas others were associated with negative words and images (Olson & Fazio, 2001). Afterward, participants in this study liked the characters associated with the positive stimuli much more than those associated with the negative ones. No wonder so many advertisers present enjoyable music or attractive images in association with the products they are trying to sell (Aronson, Wilson, & Akert, 2005; Pratkanis & Aronson, 2001)! As for operant conditioning, parents, teachers, and peers actively shape children's attitudes by rewarding them for stating particular views. The *mere-exposure effect* is influential as well: All else being equal, attitudes toward an object will become more positive the more frequently people are exposed to it (Winkielman & Cacioppo, 2004). One study found that even newborns showed a preference for stories that their mother had repeatedly read aloud while they were still in the womb (Cacioppo, Berntson, & Petty, 1997). The mere-exposure effect helps explain why we sometimes come to like a song only after hearing it several times—and why we may come to like products and candidates only after being repeatedly exposed to commercials and political ads.

● Changing Attitudes

Although mere exposure can help to form new attitudes, it is not very effective at changing existing ones (Crano & Prislin, 2006). If you are already strongly against requiring motorcyclists to wear helmets, for example, that attitude is unlikely to change much no matter how often you see riders wearing their helmets. Changing attitudes usually requires more active efforts, mainly in the form of persuasive messages. The nearly \$100 billion a year spent on advertising in the United States alone provides just one example of how people are constantly trying to change our attitudes. Stop for a moment and make a list of other examples, perhaps starting with the messages of groups concerned with abortion or recycling—and don't forget your friends who want you to think the way they do.

● **Two Routes to Attitude Change** Whether a persuasive message succeeds in changing attitudes depends primarily on three factors: (1) the person communicating the message, (2) the content of the message, and (3) the audience who receives it (Johnson, Maio, & Smith-McLallen, 2005). The **elaboration likelihood model** of attitude change provides a framework for understanding when and how these factors affect attitude change. As shown in Figure 17.3, the model is based on the notion that persuasive messages can change people's attitudes through one of two main routes.

- **elaboration likelihood model** A model suggesting that attitude change can be driven by evaluation of the content of a persuasive message (central route) or by irrelevant persuasion cues (peripheral route).

**FIGURE 17.4****Personal Involvement and Routes to Attitude Change**

In the study represented here, students' reactions to messages supporting exit exams for seniors depended on whether they thought the policy would begin immediately (high involvement) or only after they had graduated (low involvement). In the low-involvement condition, students followed a peripheral route to attitude change, agreeing with messages from expert communicators regardless of how logical they were. More involved students followed a central route, changing their minds only if the message contained a strong, logical argument.

Source: Data from Petty, Cacioppo, & Goldman (1981); Petty, Cacioppo, & Schumann (1983).

- **cognitive dissonance theory** A theory asserting that attitude change is driven by efforts to reduce tension caused by inconsistencies between attitudes and behaviors.

The first is called the *peripheral route* because, when it is activated, we devote little attention to the central content of the persuasive message. Instead, we tend to be affected by the *persuasion cues* that surround it, such as the confidence, attractiveness, or other characteristics of the person delivering the message. Persuasion cues influence attitude change even though they say nothing about the logic or validity of the message content. Commercials in which movie stars or other attractive nonexperts praise pain relievers or political candidates are designed to operate via the peripheral route to attitude change.

By contrast, when the *central route* to attitude change is activated, the content of the message becomes more important than the characteristics of the communicator in determining attitude change. A person following the central route uses logical steps—such as those outlined in the Thinking Critically sections of this book—to rationally analyze the content of the persuasive message. This analysis considers the validity of the message's claims, determines whether the message leaves out important information, assesses alternative interpretations of evidence, and so on.

What determines which route people will follow? Personal involvement with the content of the message is one important factor. The elaboration likelihood model proposes that the more personally involving a topic is, the more likely it is that the central route will be activated (Fabrigar et al., 2005). Suppose, for example, that you heard someone arguing for the elimination of student loans in Chile. This message might persuade you via the peripheral route if it came from someone who looked attractive and sounded intelligent. However, you would be more likely to follow the central route if the message proposed doing away with student loans at your own school. You might be persuaded, but only if the logic of the message was undeniable (see Figure 17.4). This is why celebrity endorsements tend to be most effective when the products being advertised are relatively unimportant to the audience.

“Cognitive busyness” is another factor affecting which attitude-change route is activated. If you are busy thinking about other things while a message is being delivered, you will be unable to pay much attention to its content. In this case, activation of the peripheral route becomes more likely. Personality characteristics are also related to attitude-change processes. For example, people with a strong *need for cognition* like to engage in thoughtful mental activities and are therefore more likely to use the central route to attitude change (Suedfeld & Tetlock, 2001). In contrast, people whose discomfort with uncertainty creates a *need for closure* are more likely to use the peripheral route (Cacioppo et al., 1996).

Persuasive messages are not the only means of changing attitudes. Another approach is to get people to act in ways that are inconsistent with their current attitudes in the hope that they will adjust those attitudes to match their behavior. Often, such adjustments do occur. Cognitive dissonance theory and self-perception theory each attempt to explain why.

● **Cognitive Dissonance Theory** Leon Festinger's (1957) classic **cognitive dissonance theory** holds that people want their thoughts, beliefs, and attitudes to be consistent with one another and with their behavior. When people experience inconsistency, or *dissonance*, among these elements, they become anxious and are motivated to make them more consistent (Elliot & Devine, 1994; Olson & Stone, 2005). For example, someone who believes that “smoking is unhealthy” but must also acknowledge that “I smoke” would be motivated to reduce the resulting dissonance. Because it is often difficult to change behavior, people usually reduce cognitive dissonance by changing inconsistent attitudes. So rather than quit smoking, the smoker might decide that smoking is not so dangerous.

In one of the first studies of cognitive dissonance, Festinger and his colleague Merrill Carlsmith asked people to turn pegs in a board, a very dull task (Festinger & Carlsmith, 1959). Later, some of these people were asked to persuade a person waiting to participate in the study that the task was “exciting and fun.” Some were told

FIGURE 17.5

Cognitive Dissonance and Attitude Change

According to cognitive dissonance theory, people who were paid \$20 to say a boring task was enjoyable had clear justification for lying, so they should experience little dissonance between what they said and what they thought about the task. In fact, their attitudes toward the task did not change much. However, participants who received just \$1 had little justification to lie and reduced their dissonance mainly by displaying a more positive attitude toward the task.

that they would be paid \$1 to tell this lie; others were promised \$20. After they had talked to the waiting person, their attitudes toward the dull task were measured.

Figure 17.5 shows the surprising results. The people who were paid just \$1 to lie liked the dull task more than those who were paid \$20. Why? Festinger and Carlsmith (1959) argued that telling another person that a boring task is enjoyable will produce dissonance (between the thoughts “I think the task is boring” and “I am saying it is fun”). To reduce this dissonance, the people who were paid just \$1 adopted a favorable attitude toward the task, making their cognitions consistent: “I think the task is fun” and “I am saying it is fun.” But if a person has adequate justification for the behavior, any dissonance that exists will be reduced simply by thinking about the justification. The participants who were paid \$20 thought they had adequate justification for lying and so did not need to change their attitudes toward the task.

Hundreds of other experiments have also found that when people publicly engage in behaviors that are inconsistent with their privately held attitudes, they are likely to change their attitudes to be consistent with their behavior (Cooper, Mirabile, & Scher, 2005). These experiments have also found that behavior-attitude inconsistency will produce attitude change when (1) the inconsistency causes some distress or discomfort and (2) changing attitudes will reduce this distress or discomfort. But what causes the discomfort in the first place? There is considerable debate among attitude researchers about this question (Crano & Prislin, 2006).

Currently, the most popular of several possible answers is that discomfort results when people’s positive self-concept is threatened by the recognition that they have done something inconsistent with that self-concept. For example, if they have encouraged another person to do something that they themselves didn’t believe in or that they themselves wouldn’t do, this inconsistency makes most people feel uncomfortable, so they change their attitudes to reduce or eliminate such feelings (Stone, 2003; Stone & Cooper, 2001). If people can persuade themselves that they really believed in what they did, the perceived inconsistency disappears, and their positive self-concepts are restored. Changing one’s private attitude to match one’s public actions is one way to accomplish this self-persuasion. Claude Steele’s work on *self-affirmation* supports this explanation of why dissonance causes discomfort (e.g., Steele, Spencer, & Lynch, 1993). He has found that people will not change their attitudes after recognizing their own attitude-behavior inconsistency if they can do something else that makes them look good and feel good about themselves (e.g., showing how smart or competent they are). In other words, when people do not need to change their attitudes to reestablish a positive view of themselves, they don’t.

The circumstances that lead to cognitive dissonance may be different in the individualist cultures of Europe and North America than in collectivist cultures such as Japan and China. In individualist cultures, dissonance typically arises from behaving in a manner inconsistent with one’s own beliefs, because this behavior causes self-doubt. But in collectivist cultures, dissonance typically arises when such behavior causes the person to worry about one’s reputation with others (Kitayama et al., 2004). Cultural values also operate in shaping dissonance-reducing strategies. For example, people from individualistic cultures can reduce the unpleasant feelings that accompany dissonance by affirming their value as unique individuals, whereas people from collectivist cultures can reduce the same kind of feelings by affirming the value of the groups to which they belong (Hoshino-Browne et al., 2005).

● **Self-Perception Theory** Over the years, cognitive dissonance theory has been challenged by other explanations of why attitudes change when they are inconsistent with behavior (Dunning, 2001). The first and strongest of these challenges came from Daryl Bem’s (1967) **self-perception theory**. Unlike dissonance theory, self-perception theory does not assume that people experience discomfort when their attitudes are inconsistent with their behaviors. According to Bem, situations often arise in which people are not quite sure about their attitudes. When this happens, Bem says, people look at their own behavior under particular circumstances and then infer what their

- **self-perception theory** A theory suggesting that attitudes can change as people consider their behavior in certain situations and then infer what their attitude must be.

in review Forming and Changing Attitudes

| Type of Influence | Description |
|--|---|
| Modeling and conditioning | Attitudes are usually formed through observation of how others behave and speak about an attitude object, as well as through classical and operant conditioning. |
| Elaboration likelihood model | People change attitudes through either a central or peripheral route, depending on factors such as personal involvement, “cognitive busyness,” and personality characteristics. |
| Cognitive dissonance and self-perception | Inconsistencies between attitudes and behaviors can produce attitude change, as can reviewing one’s behavior in light of circumstances. |

attitude must be. The person says, “If I did that under those circumstances, my attitude must be this.” This process makes their attitudes consistent with their behavior, but the process is not driven by tension or discomfort.

Self-perception explanations of attitude change seem reasonable, but two kinds of evidence are inconsistent with it. First, people actually do become physiologically aroused and feel uncomfortable when they experience an inconsistency between their attitudes and behavior, and their discomfort is reduced when they change their attitudes to match their behavior (Elliot & Devine, 1994). This finding suggests that some kind of internal tension is, in fact, created by cognitive dissonance. Second, people adjust their attitudes to match their behavior even when they are unable to reflect on that behavior—a process that is crucial to self-perception theory. In one experiment, for example, researchers studied the effects of attitude-behavior inconsistencies in people suffering from anterograde amnesia, a condition described in the memory chapter that leaves its victims unable to recall what they have said or done minutes earlier. Like the participants in other attitude-change experiments, these people, too, changed their attitudes to be more consistent with their behavior (Lieberman et al., 2001).

Although these results do not support self-perception theory, they do not entirely invalidate it. It may be that self-perception theory applies best either when people have no prior attitude toward some object or when the discrepancy between their attitude and their behavior is slight. For instance, if you know you like Coca-Cola, but you also know that you just drank a Pepsi, this self-perception may drive an attitude change toward Pepsi even though you did not experience any dissonance. However, when attitudes are strong and clearly defined, and the inconsistency between attitudes and behaviors is larger and more important to a person’s self-concept, attitude change appears to occur mainly because of cognitive dissonance (Dunning, 2001). (“In Review: Forming and Changing Attitudes” summarizes some of the major processes through which attitudes are formed and changed.)

LINKAGES**Biological and Social Psychology**

Social psychologists’ research on thoughts, feelings, and behaviors was once entirely separate from research on the biological processes that underlie those thoughts, feelings, and behaviors (Cacioppo & Berntson, 2005). Social psychologists believed that it was not possible to reduce complex social psychological processes to the firing

of neurons or the secretion of hormones. For their part, biological psychologists, more commonly known as *neuroscientists*, viewed the study of social psychology as having little, if any, relevance to the understanding of behavioral genetics or the functioning of the nervous, endocrine, or immune systems. Recently, however, scientists in both subfields have begun to take a closer look at each other's research and how their subfields are related. The result has been the emergence of a new specialty called *social neuroscience* (Cacioppo & Bernston, 2005; Decety & Keenan, 2006). This new specialty focuses on the neurological aspects of social processes and is part of a more general trend toward research on the interaction of biological and social processes.

There are already many reasons to believe that this research approach will be valuable. For example, the chapter on health, stress, and coping contains numerous examples of how social stressors can have health-related biological consequences. Health psychologists have also found that the quality of a person's social relationships can affect biological processes ranging from the functioning of the immune system to the healing of wounds (Kiecolt-Glaser et al., 1998; Robles & Kiecolt-Glaser, 2003; Uchino, Cacioppo, & Kiecolt-Glaser, 1996). The social environment can affect even the way genes express themselves. In one study, for example, monkeys were selectively bred to react strongly to even mild stressors. These animals' oversensitivity appeared to be based on a specific gene, but researchers found it possible to modify the effects of this gene by changing the monkeys' social situation. When the animals were paired with a warm, nurturant foster mother, their oversensitivity diminished significantly, and it remained low even when they were later separated from her (Suomi, 1999).

Researchers are also beginning to identify the biological underpinnings of many social processes. One example can be seen in studies of how the amygdala—a brain structure that plays a significant role in emotion—is related to the stereotypes and prejudice described in the next section. Using functional magnetic resonance imaging technology, researchers found that European Americans who were prejudiced against African Americans showed significantly more amygdala activity when looking at pictures of black people than when looking at pictures of white people (Hart et al., 2000; Phelps et al., 2000). More recently, researchers have used fMRI to study people's emotional reactions to other people's distress (Lamm, Batson, & Decety, 2007). They found patterns of brain activity that were quite different depending on whether the individual experienced empathy for a distressed person or simply observed the person's distress. Studies such as this one are helping to shed light on the biological aspects of empathy, and they may eventually lead to a broader understanding of the factors influencing people's motivation to help each other (Tankersley, Stowe, & Huettel, 2007; see the chapter on social influence). Social neuroscientists have also used electroencephalography (EEG) and other techniques to record the brain activity associated with positive and negative attitudes about people and objects (e.g., Amodio et al., 2004). Their research has shown that these evaluative reactions are associated with activity in specific brain regions (Cacioppo, Crites, & Gardner, 1996).

Social neuroscience is still in its infancy; the first journal devoted to social neuroscience research only began publication in 2006 (Decety & Keenan, 2006). However, this new field already shows great promise for improving our understanding of the linkages among social, cognitive, and biological phenomena, as well as of complex social and physiological processes (Cacioppo et al., 2007). ■

LINKAGES (a link to Biological Aspects of Psychology, p. 73)

Prejudice and Stereotypes

All of the principles that underlie impression formation, attribution, and attitudes come together to create prejudice and stereotypes. **Stereotypes** are the perceptions, beliefs, and expectations a person has about members of some group. They are schemas about entire groups of people (Dion, 2003). Usually, stereotypes involve the false assumption that all members of a group share the same characteristics. The characteristics that make up the stereotype may be positive, but they are usually negative.

- **stereotypes** False assumptions that all members of some group share the same characteristics.

FIGURE 17.6

The Impact of Stereotypes on Behavior

TRY THIS When these men suddenly appeared on a video screen, participants were supposed to “shoot” them, but only if they appeared to be armed (Correll et al., 2002). Stereotypes about whether white men or black men are more likely to be armed significantly affected the errors made by participants in firing their video game “weapons.” Cover these photos with a pair of index cards; then ask a few friends to watch as you show each photo, one at a time, for just an instant, before covering it again. Then ask your friends to say whether either man appeared to be armed. Was one individual more often seen as armed? If so, which one?

The most common and powerful stereotypes focus on observable personal attributes, particularly ethnicity, gender, and age (Operario & Fiske, 2001).

The stereotypes people hold can be so ingrained that their effects on behavior can be automatic and unconscious (Banaji, Lemm, & Carpenter, 2001; Blair, Judd, & Fallman, 2004). In one study, for example, European American and African American participants played a video game in which white or black men suddenly appeared on a screen holding objects that might be weapons (Correll et al., 2002; see Figure 17.6). The participants were instructed to immediately “shoot” an armed man, but not an unarmed one. Under this time pressure, the participants’ errors were not random. If they “shot” an unarmed man, he was significantly more likely to be black than white. If they failed to “shoot” an armed man he was more likely to be white than black. These differences occurred among both European American and African American participants but were most pronounced among those who held the strongest cultural stereotypes about blacks.

Stereotyping often leads to **prejudice**, which is a positive or negative attitude toward an individual based simply on membership in some group (Dion, 2003). The literal meaning of the word *prejudice* is “prejudgment.” Many theorists believe that prejudice, like other attitudes, has cognitive, affective, and behavioral components. Stereotyped thinking is the cognitive component of prejudicial attitudes. The hatred, admiration, anger, and other feelings people have about stereotyped groups make up the affective component. The behavioral component of prejudice involves **discrimination**, which is differing treatment of individuals who belong to different groups.

● Theories of Prejudice and Stereotyping

Prejudice and stereotyping may occur for several reasons (Duckitt, 1994). Let’s consider three explanatory theories, each of which has empirical support and accounts for some, but not all, instances of stereotyping and prejudice.

● Motivational Theories For some people, prejudice against certain groups might enhance their sense of security and help them meet certain personal needs. This idea was first proposed by Theodor Adorno and his associates more than fifty years ago (Adorno et al., 1950). It has since been revised and expanded by Bob Altemeyer (2004; Altemeyer & Hunsberger, 2005). Specifically, these researchers suggest that prejudice may be especially likely among people who display a personality trait called *authoritarianism*. According to Altemeyer, authoritarianism is composed of three elements: (1) an acceptance of conventional or traditional values, (2) a willingness to unquestioningly follow the orders of authority figures, and (3) an inclination to act aggressively toward individuals or groups identified by these authority figures as threatening the values held by one’s in-group. People with an authoritarian orientation tend to view the world as a threatening place (Winter, 1996), and one way to protect themselves from perceived threats is to identify strongly with their in-group and to dislike, reject, and perhaps even punish anyone who is a member of other groups (Cottrell & Neuberg, 2005). Looking down on, and discriminating against, out-groups—such as gay men and lesbians, African Americans, or Muslims, for example—may help people with authoritarian tendencies to feel safer and feel better about themselves (Haddock & Zanna, 1998).

Another motivational explanation of prejudice employs the concept of social identity discussed earlier. Recall that whether they are authoritarian or not, most people are motivated to identify with their in-group and tend to see it as better than other groups (Brewer & Pierce, 2005). As a result, members of an in-group often see all members of out-groups as less attractive and less socially acceptable than in-group members and may thus treat them badly (Jackson, 2002). In other words, prejudice may result when people’s motivation to enhance their own self-esteem causes them to disrespect other people.

- **prejudice** A positive or negative attitude toward an entire group of people.
- **discrimination** Differential treatment of various groups; the behavioral component of prejudice.

● **Cognitive Theories** Stereotyping and prejudice may also result from the social-cognitive processes people use in dealing with the world. There are so many other people, so many situations in which one meets them, and so many possible behaviors they might perform that we cannot possibly attend to and remember them all. Therefore, we use schemas and other cognitive shortcuts to organize and make sense out of our social world (Moskowitz, 2005). These cognitive processes allow us to draw accurate and useful conclusions about other people, but sometimes they lead to inaccurate stereotypes. For example, one effective way to deal with social complexity is to group people into *social categories*. Rather than remembering every detail about everyone we have ever encountered, we tend to put other people into categories, such as doctor, senior citizen, Republican, student, Italian, and the like (Dovidio, Kawakami, & Gaertner, 2000). To further simplify perception of these categories, we tend to see their members as being quite similar to one another. In fact, members of one ethnic group may find it harder to distinguish among specific faces within other ethnic groups than within their own group (Michel et al., 2006). People also tend to assume that all members of a different group share the same beliefs and values and that those beliefs and values differ from their own (Dion, 2003). Finally, as noted in the chapter on perception, people's attention tends to be drawn to distinctive stimuli. Rude behavior by even a few members of an easily identified ethnic group may lead other people to see an *illusory correlation* between rudeness and ethnicity (Hamilton & Sherman, 1994). As a result, they may incorrectly believe that all members of that group are rude.

● **Learning Theories** Like other attitudes, prejudice can be learned. Some prejudice is learned on the basis of conflicts between members of different groups, but people also develop negative attitudes toward groups with whom they have had little or no contact. Learning theories suggest that children can pick up prejudices just by watching and listening to parents, peers, and others (Taylor et al., 2006). Movies and television may also portray ethnic or other groups in ways that teach stereotypes and prejudice (Brehm et al., 2005). One study found, for example, that local news coverage often gives the impression that African Americans are responsible for a higher percentage of crimes than is actually the case (Romer, Jamieson, & deCoteau, 1998). No wonder so many young children already know about the supposed negative characteristics of certain groups long before they ever meet members of those groups (Baron & Banaji, 2006; Quintana, 1998).

Schemas and Stereotypes The use of schemas to assign certain people to certain categories can be helpful when deciding who is a customer and who is a store employee, but it can also lead to inaccurate stereotypes. After the September 11, 2001, terrorist attacks on New York and Washington, D.C., many people began to think of all Muslims as potential terrorists and to discriminate against them. This false assumption and the problems it has created for Muslims in the United States was one of the many awful side effects of the terrorist attacks.

Fighting Ethnic Prejudice Negative attitudes about members of ethnic groups are often based on negative personal experiences or the negative experiences and attitudes people hear from others. Cooperative contact between equals can help promote mutual respect and reduce ethnic prejudice.

● Reducing Prejudice

One clear implication of the cognitive and learning theories of prejudice and stereotyping is that members of one group are often ignorant or misinformed about the characteristics of people in other groups (Dovidio, Gaertner, & Kawakami, 2003). Before 1954, for example, most black and white children in the United States knew very little about one another because they went to separate schools. Then the Supreme Court declared that segregated public schools should be prohibited. By ruling segregation to be unconstitutional, the court created a real-life test of the **contact hypothesis**, which states that stereotypes and prejudice toward a group will diminish as contact with that group increases (Pettigrew & Tropp, 2006).

Did the desegregation of U.S. schools confirm the contact hypothesis? In a few schools, integration was followed by a decrease in prejudice, but in most places either no change occurred or prejudice actually increased (Oskamp & Schultz, 1998). However, these results did not necessarily disprove the contact hypothesis. In-depth studies of schools in which desegregation was successful suggested that contact alone was not enough. Integration reduced prejudice only when certain social conditions were created (Pettigrew & Tropp, 2006). First, members of the two groups had to be of roughly equal social and economic status. Second, school authorities had to promote cooperation and interdependence between the members of different ethnic groups by having them work together on projects that required relying on one another to reach success. Third, the contact between group members had to occur on a one-on-one basis. It was only when people got to know one another as individuals that the errors contained in stereotypes became apparent. Finally, the members of each group had to be seen as typical and not unusual in any significant way. When these four conditions prevailed, the children's attitudes toward one another became more positive. The same effects have appeared in adults, and in other countries, too. In Italy, for example, people who had equal-status contact with black immigrants from North Africa displayed less prejudice against them than did Italians who had no contact with those immigrants (Kirchler & Zani, 1995).

Elliot Aronson (1997) describes a teaching strategy, called the *jigsaw technique*, that helps create the conditions that reduce prejudice. The strategy calls for children from several ethnic groups to work as a team to complete a task, such as writing a

- **contact hypothesis** The idea that stereotypes and prejudice toward a group will diminish as contact with the group increases.

report about a famous person in history. Each child learns, and provides the team with, a separate piece of information about this person, such as place of birth (Aronson, 1990). Studies show that children from various ethnic groups who are exposed to the jigsaw technique and other cooperative learning experiences show substantial reductions in prejudice toward other groups (Aronson, 1997). The success reported in these studies has greatly increased the popularity of cooperative learning exercises in classrooms in the United States. Such exercises may not eliminate all aspects of ethnic prejudice in children, but they seem to be a step in the right direction.

Can friendly, cooperative, interdependent contact reduce the more entrenched forms of prejudice seen in adults? It may. When equal-status adults work jointly toward a common goal, bias and distrust can be reduced, particularly among those in ethnic majority groups (Tropp & Pettigrew, 2005). This is especially true if they come to see themselves as members of the same group rather than as belonging to opposing groups (Dovidio et al., 2000; Fiske, 2000). The challenge to be met in creating such cooperative experiences in the real world is that the participants must be of equal status—a challenge made more difficult in many countries by the sizable status differences that still exist between ethnic groups (Kenworthy et al., 2006).

In the final analysis, contact provides only part of the solution to the problems of stereotyping, prejudice, and discrimination. To reduce ethnic prejudice, we must develop additional educational techniques that address the social cognitions and perceptions that lie at the core of bigotry and hatred toward people who are different from ourselves (Bigler & Liben, 2007; Monteith, Zuwerink, & Devine, 1994).

THINKING CRITICALLY

Is Ethnic Prejudice Too Ingrained Ever to Be Eliminated?

There is little doubt that overt forms of ethnic prejudice have decreased dramatically in the United States over the past forty to fifty years. For example, in the 1950s fewer than half of European American college students surveyed said they were willing to live in integrated neighborhoods. More recent surveys indicate that about 95 percent say they would be willing to do so. And four decades ago, fewer than 40 percent of European Americans said they would vote for an African American presidential candidate; over 95 percent now say they might do so (Dovidio & Gaertner, 1998). Despite these changes, research in social psychology suggests that more subtle aspects of prejudice and discrimination may remain as entrenched in the United States today as they were fifteen or even twenty years ago (Dovidio & Gaertner, 2000).

■ What am I being asked to believe or accept?

Even people who see themselves as unprejudiced and who disavow ethnic stereotypes and discrimination still hold negative stereotypes about ethnic out-groups and, in certain situations, will display prejudice and discrimination toward them (Dovidio, Kawakami, & Beach, 2001). Some people claim, therefore, that negative attitudes toward ethnic out-groups are so deeply ingrained in all of us that ethnic prejudice can never be eliminated.

■ What evidence is available to support the assertion?

Evidence for this assertion focuses primarily on prejudice against African Americans by European Americans. It comes, first, from studies testing the theory of *aversive racism* (Hodson, Dovidio, & Gaertner, 2004). This theory holds that even though many European Americans consider ethnic prejudice to be unacceptable, or aversive, they will still sometimes display it—especially when they can do so without admitting, even to themselves, that they are prejudiced.

LINKAGES (a link to Consciousness, p. 329)

In one test of this theory, a male experimenter telephoned male and female European Americans who were known to believe in ethnic equality. The man claimed to be a stranded motorist who was trying to call a service station from a pay phone. When told he had called the wrong number, the man replied that he was out of coins and asked the person he'd reached to call a service station for him. If people listened long enough to learn of the man's problem, they were just as likely to contact the service station whether the caller "sounded" European American or African American. However, if the caller "sounded" African American, these supposedly unprejudiced people were almost five times as likely to hang up even before the caller could ask for help (Gaertner & Dovidio, 1986). In other studies, female European American college students were asked to help another female student who was doing poorly on some task. When the student's poor performance was described as being due to the difficulty of the task, the students agreed to help, regardless of the other student's ethnicity. But if the problem was said to be due to lack of effort, help was offered much more often to European Americans than to African Americans (Frey & Gaertner, 1986; McPhail & Penner, 1995). These findings suggest that even people who do not display prejudice in most situations may do so in others.

 LINKAGES (a link to Perception, p. 157)

A second line of evidence for the entrenched nature of prejudice comes from research showing that many people hold negative stereotypes about ethnic minorities (and women) but are unaware that they do so. These negative stereotypes can also be *activated* without conscious awareness, even among people who believe they are free of prejudice (Banaji et al., 2001; Wheeler & Petty, 2001). To demonstrate these phenomena, researchers have used the priming procedures described in the chapter on consciousness to activate unconscious thoughts and feelings that can alter people's reactions to stimuli without their awareness. In one study, for example, white participants were exposed to subliminal presentations of pictures of black individuals (Chen & Bargh, 1997). The participants were not consciously aware that they had seen these pictures, but when they interacted with a black man soon afterward, those who had been primed with the pictures acted more negatively toward him and saw him as more hostile than did people who had not been primed. Priming apparently activated these participants' negative ethnic stereotypes. It is also possible to prime unconscious negative stereotypes about other groups, including women and the elderly (Glick & Fiske, 2001; Hense, Penner, & Nelson, 1995). All of these findings suggest that stereotypes are so well learned and so ingrained in people that they may be activated automatically and without conscious awareness (Dovidio et al., 2001).

■ Are there alternative ways of interpreting the evidence?

The evidence presented so far suggests that it may be impossible to eliminate ethnic prejudice, because everyone harbors unconscious negative stereotypes about various groups. But this evidence does not necessarily mean that unconscious stereotypes affect everyone in the same way. Perhaps they have a greater impact on people who are more overtly prejudiced.

■ What additional evidence would help to evaluate the alternatives?

One way to evaluate this possibility is to compare the responses of prejudiced and unprejudiced people in various experimental situations. In one mock-trial study, for example, overtly prejudiced white jurors recommended the death penalty more often for black defendants than for white defendants found guilty of the same crime. Low-prejudice white jurors showed this bias only when they believed that a black member of the jury also favored giving the death penalty (Dovidio et al., 1997). Priming studies, too, show that although negative stereotypes can be primed in both prejudiced and unprejudiced people, it is easier to do in people who openly display their ethnic bias (Dovidio et al., 2000). Furthermore, activation of these stereotypes may be less likely to affect the conscious attitudes and behavior of unprejudiced people. So when unconscious stereotypes are activated in unprejudiced people, the effects tend to appear in subtle ways, such as in facial expressions or other nonverbal behaviors (Kawakami, Dion, & Dovidio, 1998; Lepore & Brown, 1997; Vanman et al., 2004).

■ What conclusions are most reasonable?

Taken together, research evidence presents a mixed picture regarding the possibility of eliminating ethnic prejudice. True, people in the United States are not nearly as colorblind as we might hope, and ethnic prejudice may be so ingrained in some people as to be subconscious. However, research suggests that it may still be possible to eliminate even subconscious stereotypes (Kawakami, Dovidio, & van Kamp, 2005; Plant & Peruche, 2005; Wheeler & Fiske, 2005). It also appears that when unprejudiced people are made aware of their negative beliefs about some target group, they will actively work to prevent those beliefs from influencing their behavior toward members of that group (Amodio et al., 2004; Devine, Plant, & Buswell, 2000). In short, prejudice is ingrained, but it can also be reduced, and it makes sense to do everything possible to reduce it. In the United States, as in any multicultural country, survival as a civilized society requires that we all continue to fight against overt and covert forms of stereotyping, prejudice, and discrimination. This goal is more important than ever, as fear of, and the fight against, international terrorism can make it all too easy to misjudge and mistreat innocent people based on their ethnicity. ■

Interpersonal Attraction

TRY THIS  **Proximity and Liking** Research on environmental factors in attraction suggests that, barring bad first impressions, the more often we make contact with someone—as neighbors, classmates, or co-workers, for example—the more we tend to like that person. Does this principle apply in your life? To find out, think about how and where you met each of your closest friends. If you can think of cases in which proximity did not lead to liking, what do you think interfered with the formation of friendship?

Research on prejudice suggests some of the reasons why people, from childhood on, may come to dislike or even hate other people. An equally fascinating aspect of social cognition is why people like or love other people. Folklore tells us that “opposites attract,” but also that “birds of a feather flock together.” Although valid to some degree, neither of these statements is entirely accurate in all cases. We begin our coverage of interpersonal attraction by discussing the factors that lead to initial attraction. We then examine how liking sometimes develops into more intimate relationships.

● Keys to Attraction

Whether you like someone or not depends partly on situational factors and partly on personal characteristics.

● **The Environment** One of the most important determinants of attraction is simple physical proximity (Berscheid & Reis, 1998). As long as you do not initially dislike a person, your liking for that person will increase with additional contact. For example, Richard Moreland and Scott Beach (1992) varied the number of times that several experimental assistants (posing as students) attended a class. Even though none of the assistants ever spoke to anyone in the class, they were rated by the other students as more likable the more often they attended. A more recent study found that these higher ratings generalized to individuals who resembled the people who had been present (Rhodes, Halberstadt, & Brajkovich, 2001). This proximity phenomenon—another example of the mere-exposure effect mentioned earlier—helps account for the fact that next-door neighbors are usually more likely to become friends than people who live farther from one another. Chances are, most of your friends are people whom you met as neighbors, co-workers, or classmates (Liben-Nowell et al., 2005).

The circumstances under which people first meet also influence attraction. In accordance with the conditioning principles discussed in the chapter on learning, you are much more likely to be attracted to a stranger if you meet in comfortable, rather than uncomfortable, physical conditions. Similarly, if you are rewarded in the presence of a stranger, the chances that you will like that stranger are increased, even if the stranger was not the one who gave the reward. In one study, for example, an experimenter judged people’s creativity while another person watched. Compared with those

FIGURE 17.7

Attitude Similarity and Attraction

This graph shows the results of a study in which participants learned about another person's attitudes. Their liking for that person was strongly related to the proportion of the other person's attitudes that were similar to the participants' own attitudes.

Source: Adapted from Byrne & Nelson (1965).

who received a negative evaluation, participants who were evaluated positively tended to like the observer more (Griffitt & Guay, 1969). At least among strangers, then, liking can occur through associating someone with something pleasant.

● **Similarity** People also tend to like those they perceive as similar to themselves on variables such as age, religion, smoking or drinking habits, or being a “morning” or “evening” person (Buston & Emlen, 2003; Rushton & Bons, 2005). As shown in Figure 17.7, similarity in attitudes is an especially important influence on attraction. This relationship has been found among children, college students, adult workers, and senior citizens (Taylor et al., 2006).

Similarity in attitudes toward mutual acquaintances is a particularly good predictor of liking, because in general, people prefer relationships that are *balanced*. As illustrated in Figure 17.8, if Zoe likes Abigail, the relationship is balanced as long as they agree on their evaluation of a third person, Samantha, regardless of whether they like or dislike that third person. However, the relationship will be imbalanced if Zoe and Abigail disagree on their evaluation of the third person.

One reason why we like people with similar views of the world is that we expect such people to think highly of us (Condon & Crano, 1988). Like many important relationships, it's hard to say whether attraction is a cause or an effect of similarity. For example, you might like someone because his attitudes are similar to yours, but it is also possible that as a result of liking him, your attitudes will become more similar to his (Davis & Rusbult, 2001). Even if your own attitudes don't change, you may change your *perceptions* of the liked person's attitudes such that those attitudes seem more similar to yours (Brehm, 1992).

● **Physical Attractiveness** Physical characteristics are another important factor in attraction, particularly during the initial stages of a relationship (Berscheid & Reis, 1998). From preschool through adulthood, physical attractiveness is a key to popularity with members of both sexes (e.g., Langlois et al., 2000). Consistent with the **matching hypothesis** of interpersonal attraction, however, people tend to date, marry, or form other committed relationships with those who are similar to themselves in physical attractiveness (Yela & Sangrador, 2001). One possible reason for this outcome is that people tend to be most attracted to those with the greatest physical appeal, but they also want to avoid being rejected by such individuals. So it may be compromise, not preference, that leads people to pair off with those who are roughly equivalent to themselves in physical attractiveness (Carli, Ganley, & Pierce-Otay, 1991).

FIGURE 17.8

Balanced and Imbalanced Relationships

Here are some common examples of balanced and imbalanced patterns of relationships among three people. The plus and minus signs refer to liking and disliking, respectively. Balanced relationships are comfortable and harmonious. Imbalanced ones often bring conflict.

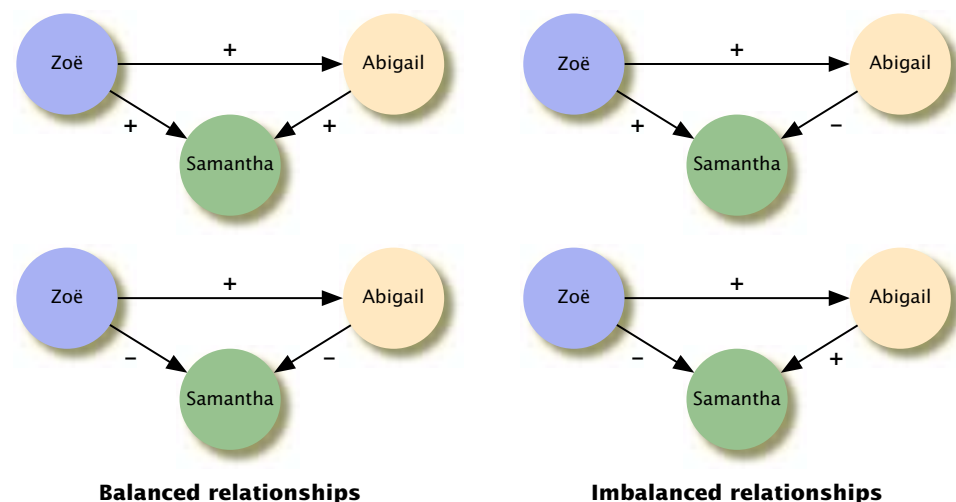

FIGURE 17.9**Sex Differences in Date and Mate Preferences**

According to evolutionary psychologists, men and women have developed different strategies for selecting sexual partners. These psychologists say that women became more selective than men because they can have relatively few children and want a partner who is able to help care for those children. Here are some data supporting this idea. When asked about the intelligence of people they would choose for one-night stands, dating, and sexual relationships, women preferred much smarter partners than men did. Only when the choices concerned steady dating and marriage did the men's preference for bright partners equal that of the women. Critics of the evolutionary approach explain such sex differences as reflecting learned social norms and expectations of how men and women should behave (Eagly & Wood, 1999; Miller, Putcha-Bhagavatula, & Pedersen, 2002).

Source: Kenrick et al. (1993).

● Intimate Relationships and Love

There is much about intimate relationships that psychologists do not—and may never—understand, but they are learning all the time. As mentioned in the chapter on motivation and emotion, evolutionary psychologists suggest that men and women employ different mating strategies and that each gender looks for different attributes in a potential mate (Buss, 2004b; Li & Kenrick, 2006). For example, in short-term relationships, at least, women may be much more selective than men about the intelligence of their partners (Buss, 2004b; see Figure 17.9).

● Intimate Relationships Eventually, people who are attracted to each other usually become *interdependent*, which means that the thoughts, emotions, and behaviors of one person affect the thoughts, emotions, and behaviors of the other (Rusbult & Van Lange, 2003). Interdependence is one of the defining characteristics of intimate relationships.

Another key component of successful intimate relationships is *commitment*, which is the extent to which each party is psychologically attached to the relationship and wants to remain in it (Amodio & Showers, 2005). People feel committed to a relationship when they are satisfied with the rewards they receive from it, when they have invested significant tangible and intangible resources in it, and when there are few attractive alternative relationships available to them (Bui, Peplau, & Hill, 1996).

● Analyzing Love Although some people think love is simply a strong form of liking, recent research suggests that romantic love and liking are quite separate emotions, at least in the sense that they activate separate areas of the brain (Aron et al., 2005; Emanuele et al., 2006). And although romantic love and sexual desire are often experienced together, they, too, seem to be separate emotions associated with different patterns of physiological arousal (Diamond, 2004). Further, most theorists agree that there are several different types of love (Brehm et al., 2005). One widely accepted view distinguishes between *passionate love* and *companionate love* (Hendrick & Hendrick, 2003). Passionate love is intense, arousing, and marked by both strong physical attraction and deep emotional attachment. Sexual feelings are strong, and thoughts of the loved one intrude on a person's awareness frequently. Companionate love is less arousing but psychologically more intimate. It is marked by mutual concern for the welfare of the other (Kim & Hatfield, 2004).

- **matching hypothesis** The notion that people are most likely to form relationships with those who are similar to themselves in physical attractiveness.

A Wedding in India Most people in Western cultures tend to marry a person whom they choose on the basis of love, sometimes without regard for differences between them in religion, ethnicity, and financial or social status. In other cultures, however, these sociocultural considerations—and even arrangements made by parents—may largely determine who marries whom. What factors do you think might have brought this couple together?

Robert Sternberg (1997a) has offered a more comprehensive analysis of love. According to his *triangular theory*, the three basic components of love are *passion*, *intimacy*, and *commitment*. Various combinations of these components result in different types of love, as illustrated in Figure 17.10. For example, Sternberg suggests that *romantic love* involves a high degree of passion and intimacy, yet lacks substantial commitment to the other person. *Companionate love* is marked by a great deal of intimacy and commitment but little passion. *Consummate love* is the most complete and satisfying. It is the most complete because it includes a high level of all three components, and it is the most satisfying because the relationship is likely to fulfill many of the needs of each partner.

Cultural factors have a strong influence on the value that people place on love. In North America and the United Kingdom, for example, the vast majority of people believe that they should love the person they marry. By contrast, in India and Pakistan, about half the people interviewed in a survey said they would marry someone they did not love if that person had other qualities that they desired (Levine et al., 1995). Many such cultural differences in the role of love in marriage are likely to continue, but some of them, such as the differences that had once existed between the United States and China, for example, seem to be disappearing (Hatfield & Rapson, 2006).

● **Strong and Weak Marriages** Long-term studies of successful and unsuccessful marriages suggest that premarital attitudes and feelings predict marital success. For example, one study found that couples who had a close, intimate relationship and similar attitudes when they were dating were more likely to still be married fifteen years later (Hill & Peplau, 1998; Neff & Karney, 2005). Also, still-married couples were more likely to have had a premarital relationship that was rewarding and balanced.

Among married couples, women—but not men—generally tend to be more satisfied with their marriage when the partners talk a lot about the relationship (Acitelli, 1992). Partners in successful marriages also tend to share each other's view of themselves and the other, even if that view is a negative one (Swann, De La Ronde, & Hixon, 1994). The perception that the relationship is fair and equitable also enhances marital satisfaction (Grote & Clark, 2001). After the birth of a first child, for example, many wives find that they have much more work than they had

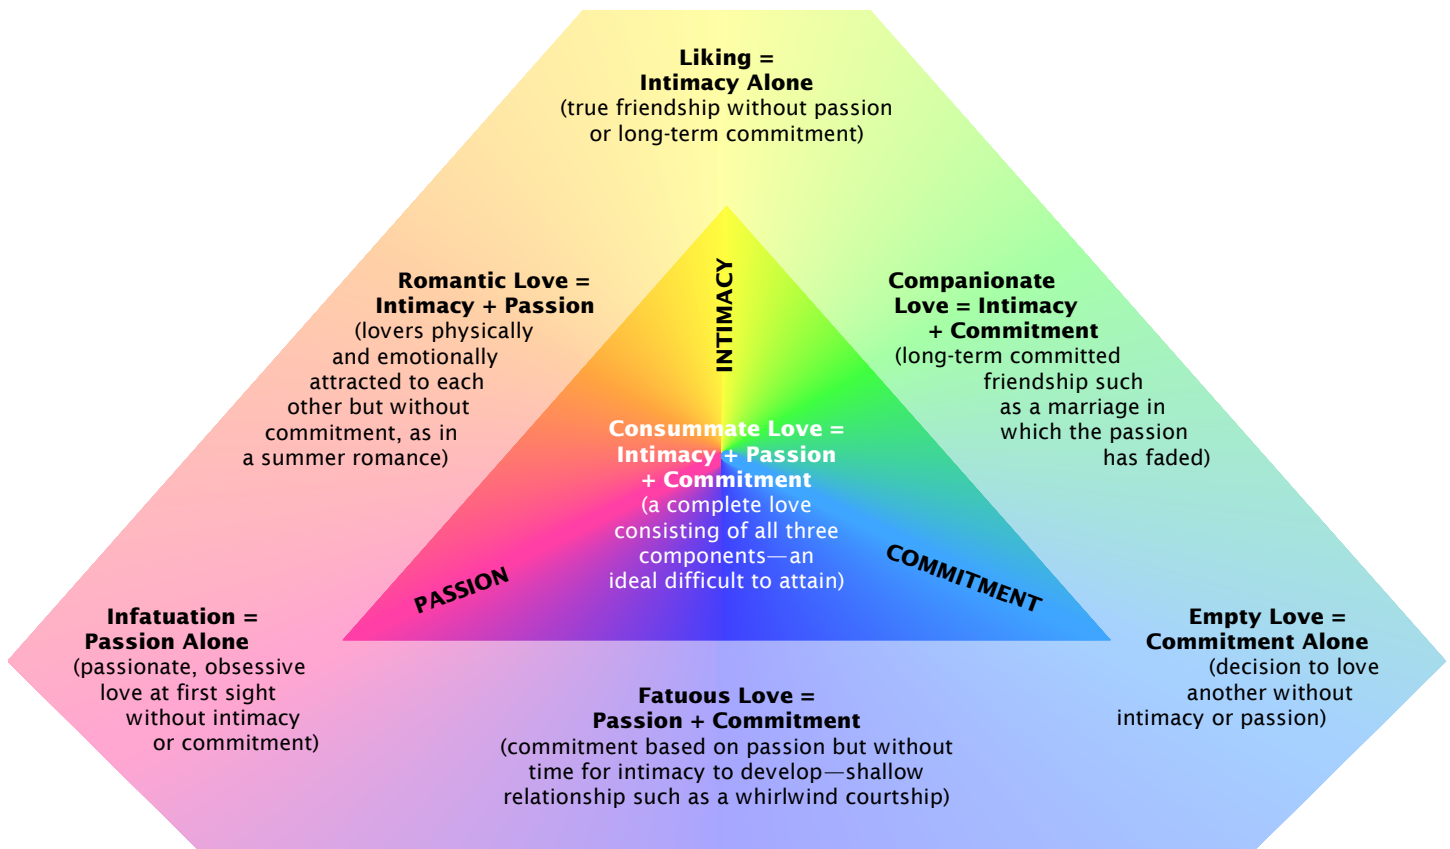

FIGURE 17.10
A Triangular Theory of Love

According to Sternberg, different types of love result when the three basic components in his triangular theory occur in different combinations. Sternberg has also explored factors associated with falling in love (Sternberg, Hojjat, & Barnes, 2001). Preliminary results suggest that people who share similar views about what a loving relationship should be like are much more likely to fall in love with each other, and remain committed to the relationship, than are people whose views on love are dissimilar.

Source: Sternberg (1988b), pp. 500, 520.

anticipated. If their husbands do not share this work to the degree they expected, wives' marital satisfaction tends to decrease (Hackel & Ruble, 1992; McNulty & Karney, 2004).

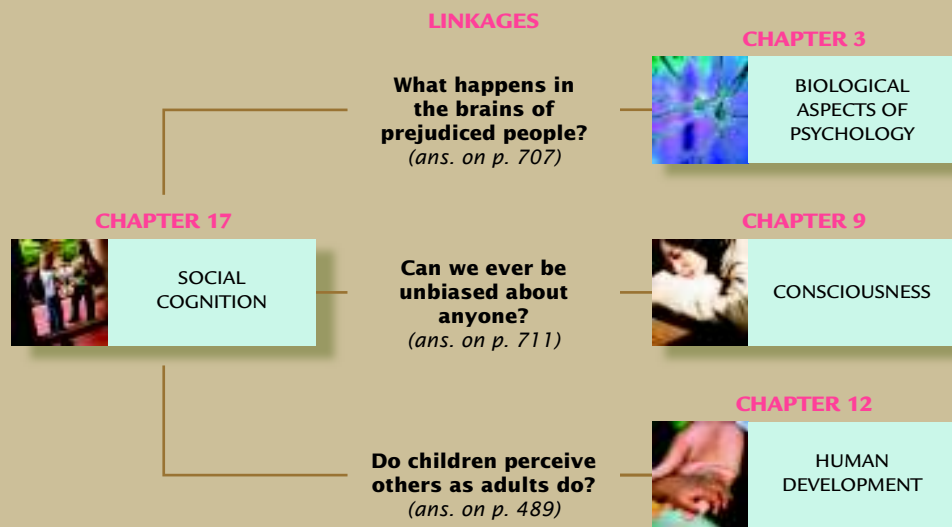

One particularly interesting line of research suggests that even brief observations of couples' interactions can predict whether those couples will divorce and when (Driver & Gottman, 2004). Among couples who divorced relatively soon after marriage, the partners tended to express both positive and negative feelings toward one another, but they were unable to control the way they expressed these feelings, especially the negative ones. Communication became increasingly hurtful and eventually broke down (Driver et al., 2003). A different picture emerged, however, in couples who divorced after many years of marriage. These people did not necessarily express negative emotions toward one another. They simply became less and less likely to communicate *any* feelings. The increasing emotional distance between the spouses created a sense of isolation that eventually led to divorce (Gottman & Levenson, 2002). These findings can help us understand why people in a long, and apparently strong, marriage might suddenly announce that they are divorcing—and why they may remain friends afterward. These people may still like each other, but no longer love each other (Gottman & Levenson, 2000; Huston et al., 2001).

TRY THIS  **Happy and Healthy** People in marriages and other long-term relationships that are satisfying tend to enjoy better physical and psychological health than those in unsatisfying relationships. In light of research described in the chapter on health, stress, and coping, make a list of reasons why this might be the case.

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's many subfields are related to one another. Our discussion of brain activity and attitudes illustrates just one way in which the topic of this chapter, social cognition, is linked to the subfield of biological psychology (see the chapter on biological aspects of psychology). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and better appreciate the big picture that is psychology.

SUMMARY

Social cognition (the mental processes through which people perceive and react to others) is one aspect of *social psychology* (the study of how people influence, and are influenced by, other people).

Social Influences on the Self

People's social and cultural environments affect their thoughts and feelings about themselves, including their *self-esteem* and their *self-concept*.

Social Comparison When people have no objective criteria by which to judge themselves, they engage in *social comparison* (using others) or *temporal comparison* (using themselves at an earlier time) as their standard. Such comparison can affect self-evaluation, or self-esteem. Categories of people that are habitually used for social comparison are known as *reference groups*. Comparison to reference groups sometimes produces *relative deprivation*, which in turn can cause personal and social turmoil.

Social Identity Theory A person's *social identity* is formed from beliefs about the groups to which the person belongs. Social identity affects the beliefs we hold about ourselves. It permits us to feel part of a larger group, engendering loyalty and sacrifice from group members but also potentially creating bias and discrimination toward people who are not members of the group.

Self-Schemas Through social comparison and the formation of social identity, people develop mental representations of their views and beliefs about themselves. These mental representations, called *self-schemas*, are part of one's self-concept. Self-schemas can affect people's emotional reactions to events.

Social Perception

Social perception concerns the processes by which people interpret information about others, form impressions of them, and draw conclusions about the reasons for their behavior.

The Role of Schemas Schemas, the mental representations about people and social situations that we carry into social interactions, affect what we pay attention to, what we remember, and how we judge people and events.

First Impressions First impressions are formed easily and quickly, in part because people apply existing schemas to their perceptions of others. First impressions change slowly because once we form an impression about another person, we try to maintain it. Schemas, however, can create *self-fulfilling prophecies*, leading people to act in ways that bring out in others behavior that is consistent with expectations.

Explaining Behavior: Attribution *Attribution* is the process of explaining the causes of people's behavior, including our own. Observers tend to attribute behavior to causes that are either internal or external to the actor. In general, they do this by looking at three aspects of the behavior: consensus, consistency, and distinctiveness. People from different cultures may sometimes reach different conclusions about the causes of an actor's behavior.

Biases in Attribution Attributions are affected by biases that systematically distort one's view of behavior. The most common attributional biases are the *fundamental attribution error* (and its cousin, the ultimate attribution error), the *actor-observer bias*, and the *self-serving bias*. Personal and cultural factors can affect the extent to which people exhibit attributional biases.

The Self-Protective Functions of Social Cognition People often protect themselves from admitting something threatening about themselves through unrealistic optimism and a feeling of unique invulnerability.

Attitudes

An *attitude* is the tendency to respond positively or negatively to a particular object. Attitudes affect a wide range of behaviors.

The Structure of Attitudes Many theorists believe that attitudes consist of cognitive (beliefs), affective (feelings), and behavioral (actions) components. However, it is often difficult to predict a specific behavior from a person's beliefs or feelings about an object. Cognitive theories propose that attitudes consist of evaluations of an object that are stored in memory. This approach suggests that the likelihood of attitude-behavior consistency depends on the accessibility of evaluations in memory, on subjective norms, on perceived control over the behavior, and on prior direct experience with the attitude object.

Forming Attitudes Attitudes can be learned through modeling, as well as through classical or operant conditioning. They are also subject to the mere-exposure effect: All else being equal, people develop greater liking for a new object the more often they are exposed to it.

Changing Attitudes The effectiveness of a persuasive message in changing attitudes is influenced by the characteristics of the person who communicates it, by its content, and by the audience receiving it. The *elaboration likelihood model* suggests that attitude change can occur through either a peripheral or a central route, depending on a person's ability and motivation to carefully consider an argument. Another approach to attitude change is to change a person's behavior in the hope that the person's attitude will be adjusted to match the behavior. *Cognitive dissonance theory* holds that if inconsistency between attitudes and behavior creates discomfort related to a person's self-concept or self-image, the person will be motivated to reduce that discomfort. *Self-perception theory* suggests that such attitude changes occur in some cases as people look to their behavior for clues about what their attitudes are.

Prejudice and Stereotypes

Stereotypes often lead to *prejudice* and *discrimination*.

Theories of Prejudice and Stereotyping Motivational theories of prejudice suggest that some people have a need to disrespect and dislike others. This need may stem from the trait of authoritarianism, as well as from a strong social identity. In either case, feeling superior to members of out-groups helps these people to feel better about themselves. As a result, in-group members tend to discriminate against members of out-groups. Cognitive theories suggest that people categorize others into groups in order to reduce social complexity. And learning theories maintain that stereotypes, prejudice, and discriminatory behaviors can be learned from parents, peers, and the media.

Reducing Prejudice The *contact hypothesis* proposes that intergroup contact can reduce prejudice and lead to more favorable attitudes toward a stereotyped group—but only if the contact occurs under specific conditions, such as when there is equal status between group members. Helping diverse people to feel as if they belong to the same group can also reduce intergroup prejudice.

Interpersonal Attraction

Keys to Attraction Interpersonal attraction is a function of many variables. Physical proximity is important because it allows people to meet. The situation in which they meet is important because positive or negative aspects of the situation tend to be associated with the other person. Characteristics of the other person are also important. Attraction tends to be greater when two people share similar attitudes and characteristics. Physical appearance plays a role in attraction. Initially, attraction is strongest to those who are most physically attractive. But for long-term relationships, the *matching hypothesis* applies: People tend to choose others whose physical attractiveness is about the same as theirs.

Intimate Relationships and Love A defining characteristic of intimate relationships is interdependence, and a key component of successful relationships is commitment. Commitment, in turn, is affected by the rewards coming from the relationship, by the resources invested in it, and by the possible alternatives open to each party. Robert Sternberg's triangular theory suggests that love is a function of three components: passion, intimacy, and commitment. Varying combinations of these three components create different types of love. Couples who have long and successful marriages are likely to perceive the relationship as fair to both parties, and they are likely to share warm and loving feelings for each other.

Social Influence

If you are like most people, there is probably at least one thing you do in private that you would never do when someone else is around. In this chapter we describe many other ways in which the presence and behavior of other people affect our own behavior, and how we, in turn, affect the behavior of others. Here's how we have organized our presentation:

SUMMARY

In the days following the September 11, 2001, attacks on the World Trade Center and the Pentagon—and also after anthrax bacteria were mailed to news organizations and the U.S. Congress—cities throughout the United States experienced a substantial

increase in false bomb threats, anthrax hoaxes, and other “copycat” crimes apparently inspired by the terrorists’ actions. Unfortunately, this phenomenon is not unusual. After the murderous rampage at Columbine High School in April of 1999, for example, a number of students at other high schools were arrested for threatening similar acts of violence against their classmates. Copycat threats were also made following the horrific massacre at Virginia Tech University in April of 2007. Well-publicized suicides, too, are often copied (Romer, Jamieson, & Jamieson, 2006). After German television reported the case of a young man who killed himself by jumping in front of a train, there was a dramatic increase in railway suicides (Schmidtke & Hafner, 1988). Even telecasts of major professional boxing matches are typically followed by a small increase in murders.

Do these correlations mean that media coverage of violence triggers copycat violence? As described in the chapter on learning, televised violence can play a causal role in aggressive behavior, but there are additional reasons to believe that when suicides and murders become media events, they stimulate people to imitate them. For one thing, many of the people who kill themselves soon after a notable suicide bear a strong similarity to the original victim (Cialdini, 2001). The copycat railway suicides in Germany, for example, were committed almost exclusively by other young German men. Further, murder victims in the days following a professional championship fight are more likely to be young white men if the losing boxer was white, and more likely to be young black men if the loser was black (Miller et al., 1991).

Copycat, or imitative, crimes illustrate the effects of **social influence**, the process whereby a person’s behavior is directly or indirectly affected by the words or actions of other people. This chapter begins with a discussion of social influence itself, after which we consider several related aspects of how we are influenced by others, including the processes of conformity, compliance, and obedience. Then we explore the causes and consequences of aggression, helping, and altruism. Finally, we examine circumstances in which people jointly influence one another’s behavior, especially circumstances in which people compete with one another for some scarce resource or work together in groups to solve some problem.

Social Influence

Copycat crimes are but one illustration of the fact that people can influence the way other people think, feel, and act, even without specifically trying to do so. There are countless others. For example, simply asking people if they have thought about buying a car in the coming year dramatically increases the chance they will actually purchase a car (Fitzsimons & Shiv, 2001). The most widespread, yet subtle, form of social influence is communicated through social norms.

Norms are learned, socially based rules that prescribe what people should or should not do in various situations (Cialdini & Goldstein, 2004). Norms are

- **social influence** The process whereby one person’s behavior is affected by the words or actions of others.
- **norms** Socially based rules that prescribe what people should or should not do in various situations.

FIGURE 18.1

Descriptive and Injunctive Norms

When both descriptive norms (a littered parking lot) and injunctive norms (a person discarding paper in the parking lot) were consistent with littering, 30 percent of the people crossing the parking lot also littered. But after seeing a person picking up a bag in the parking lot (creating an injunctive norm against littering), very few people engaged in littering, whether or not the lot was littered (Reno, Cialdini, & Kallgren, 1993). Applying these findings to combat alcohol abuse on campus, some student health campaigns now create descriptive norms for responsible drinking by citing statistics showing that most students drink in moderation (Zernike, 2000). Such campaigns might also change injunctive norms by portraying excessive drinking as socially unacceptable (Larimer et al., 2004).

Source: Adapted from Reno, Cialdini, & Kallgren (1993).

transmitted by parents, teachers, clergy, peers, and other agents of culture. Although they often cannot be verbalized, norms are so powerful that people usually follow them automatically. At movie theaters in North America and Britain, for example, norms tell us that we should get in line to buy a ticket rather than crowd around the ticket window; they also lead us to expect that others will do the same. By informing people of what is expected of them and others, norms make social situations less uncertain and more comfortable (Schultz et al., 2007).

Robert Cialdini (2001) has described social norms as either descriptive or injunctive. *Descriptive norms* indicate how most other people actually behave in a given situation. They tell us what actions are common in the situation and thereby implicitly give us permission to act in the same way. The fact that most people do not cross a street until the green light or “walk” sign appears is an example of a descriptive norm. *Injunctive norms* give more specific information about the actions that others find acceptable and those that they find unacceptable. Subtle pressure exists to behave in accordance with these norms. A sign that reads “Do not cross on red” or the person next to you saying the same thing is an example of an injunctive norm.

A study by Raymond Reno and his colleagues (Reno, Cialdini, & Kallgren, 1993) illustrates the differing effects of these two types of norms. The participants were people who walked through a parking lot just after being handed an advertising leaflet. The experimenters arranged for the participants to see another person (who was working with the experimenters) either toss a paper bag on the ground or pick one up from the ground. On half the trials of this experiment, the parking lot was littered with paper; on the other half, the lot was clean. As shown in Figure 18.1, the descriptive norm—seeing another person litter in an already messy environment—appeared to communicate that “many people do this,” and a relatively high percentage of people dropped their leaflet in the littered parking lot. By contrast, the injunctive norm—seeing someone pick up litter—appeared to communicate that even though many people litter, it’s not the right thing to do. When this norm was evident, fewer than 5 percent of the people dropped their leaflet in the littered parking lot. Later research has shown that norms are most likely to actually reduce littering when a person focuses on and believes in the relevant norm (Kallgren, Reno, & Cialdini, 2000)

One very powerful injunctive norm is *reciprocity*, the tendency to respond to others as they have acted toward you (Cialdini & Goldstein, 2004). Restaurant servers often apply this norm by leaving some candy with the bill. Customers who receive this gift tend to reciprocate by leaving a larger tip than customers who don’t get candy (Strohmetz et al., 2002). The reciprocity norm probably exists in every culture, but other norms are not universal (Miller, 2001). For instance, people around the world differ greatly in terms of the physical distance they maintain between themselves and others during conversation. People from South America usually stand much closer to one another than do people from North America. And as suggested in the chapter on psychological disorders, behavior considered normal and friendly in one culture may be seen as abnormal, and even offensive, in another.

The social influence exerted by norms creates orderly social behavior. But social norms can also lead to a breakdown in order. For example, **deindividuation** is a phenomenon in which a person becomes “submerged in a group” and loses the sense of individuality (Cialdini & Goldstein, 2004). When people experience deindividuation, they become emotionally aroused and feel intense closeness with the group. This increased awareness of group membership may create greater adherence to the group’s norms, even if those norms promote antisocial behavior. In other words, through deindividuation, people appear to become “part of the herd,” and they may perform acts that they would not do otherwise. Fans at rock concerts and athletic events have trampled one another to death in their frenzy to get the best seats.

- **deindividuation** A psychological state occurring in group members that results in loss of individuality and a tendency to do things not normally done when alone.

Clothing and Culture The social norms that guide how people dress and behave in various situations are part of the culturally determined socialization process described in the chapter on human development. The process is the same worldwide. Parents, teachers, peers, religious leaders, and others communicate their culture's social norms to children, but differences in those norms result in quite different behaviors from culture to culture.

Deindividuation Robes, hoods, and group rituals help create deindividuation in these Ku Klux Klansmen by focusing their attention on membership in their organization and on its values. The hoods also hide their identities, which reduces their sense of personal responsibility and accountability and makes it easier for them to engage in hate crimes and other cowardly acts of bigotry. Deindividuation operates in other groups, too, ranging from lynch mobs and terrorist cells to political protesters and urban rioters. In short, people who feel themselves to be anonymous members of a group may engage in antisocial acts that they might not perform on their own.

Normally mild-mannered people may find themselves throwing rocks or fire bombs at police during political protests.

The greater the sense of personal anonymity, the more influence the group appears to have (Lea, Spears, & de Groot, 2001). An analysis of newspaper accounts of lynchings in the United States over a fifty-year period showed that larger lynch mobs were more savage and vicious than smaller ones (Mullen, 1986). Deindividuation provides an example of how, given the right circumstances, quite normal people can engage in destructive, even violent, behavior.

Motivation and the Presence of Others

 LINKAGES (a link to Motivation and Emotion, p. 429)

In the chapter on motivation and emotion, we noted that social factors such as parental attitudes toward achievement often affect motivation. But a person's current motivational state is also affected by the mere presence of other people. As an illustration, consider what was probably the first experiment in social psychology, conducted by Norman Triplett in 1897.

Triplett noticed that bicycle racers tended to go faster when other racers were nearby than when they were alone. Did seeing one another remind the racers of the need to go faster to win? To test this possibility, Triplett arranged for bicyclists to complete a twenty-five-mile course under three conditions: riding alone in a race against the clock; riding with another cyclist, but not in competition; or

Social Facilitation Premier athletes like Lindsay Davenport, shown here winning the women's singles championship at Wimbledon in 2005, are able to perform at their best even though large crowds are present. In fact, the crowds probably help them do well, because the presence of others tends to increase arousal, which enhances the performance of familiar and well-learned skills, such as tennis strokes. However, arousal created by an audience tends to interfere with the performance of unfamiliar and poorly developed skills. This is one reason that professional athletes who show flawless grace in front of thousands of fans are likely to freeze up or blow their lines in front of a small production crew when trying for the first time to tape a TV ad or a public service announcement.

competing directly with another rider. The cyclists went much faster when another rider was present than when they were simply racing against time. This was true even when they were not competing against the other person. Something about the presence of the other person, not just competition, produced increased speed.

The term **social facilitation** describes circumstances in which the mere presence of other people can improve performance. This improvement does not always occur, however. The presence of other people sometimes hurts performance, a process known as **social impairment**. For decades these results seemed contradictory. Then Robert Zajonc (pronounced “ZYE-onze”) suggested that both effects could be explained by one process: arousal.

The presence of other people, said Zajonc, increases a person's general level of arousal or motivation (Zajonc, 1965). Why? One reason is that being watched by others increases our sense of being evaluated, producing worry that in turn increases emotional arousal (Penner & Craiger, 1992). Arousal increases the tendency to perform those behaviors that are most *dominant*—the ones we know best—and this tendency can either help or hinder performance. If you are performing an easy, familiar task, such as riding a bike, the increased arousal caused by the presence of others should allow you to ride even faster than normal. But if the task is hard or unfamiliar—such as trying new dance steps or playing a piano piece you just learned—the most dominant responses may be incorrect and cause your performance to suffer. In other words, the impact of other people on performance depends on whether the task is easy or difficult.

The presence of others may affect performance in other ways as well. For example, having an audience may distract us from the task at hand or cause us to focus on only one part of it, thus impairing performance (Aiello & Douthitt, 2001).

If a person is not merely in the presence of others but is actually working on a task with them, the impact of their presence changes somewhat. In these situations, people typically exert less effort than they do when performing alone, a phenomenon called **social loafing** (Karau & Williams, 1997). Whether the task is pulling on a rope, clapping as loudly as possible, or trying to solve puzzles, people tend to work harder when performing alone than with others (Baron, Kerr, & Miller, 1992; Geen, 1991). There are at least three reasons behind this social

- **social facilitation** A phenomenon in which the presence of others improves a person's performance.
- **social impairment** A reduction in performance due to the presence of other people.
- **social loafing** Exerting less effort when performing a group task than when performing the same task alone.

loafing phenomenon. First, it is usually much harder to evaluate the performance of individuals when they are working as part of a group. As a result, it is simply easier to succeed at loafing when in a group. Second, rewards may come to a group whether or not every member exerts maximum effort. Third, a group's rewards are usually divided equally among its members rather than according to individual effort (Karau & Williams, 1997).

In North American and other Western countries, social loafing can be seen in all kinds of groups, from volunteer committees to search parties. Because social loafing can reduce productivity in business situations, it is important for managers to develop ways of evaluating the efforts of every individual in a work group, not just the overall output of the team. Social loafing can also be reduced by strategies that cause people to like the group and identify with it (Karau & Williams, 1997), and by the punishment that social loafers tend to receive from other, harder-working group members (Barclay, 2006).

Social loafing is much less common in Eastern cultures, such as those of China and Japan. In fact, in collectivist cultures, working in a group usually produces *social striving*—defined as greater individual effort when working in a group (Matsumoto, 2000). This difference in the effects of group membership on individual efforts probably reflects the value that collectivist cultures place on coordinated and cooperative group activities. This orientation serves to discourage social loafing. ■

Conformity and Compliance

Suppose you are with three of your friends. One says that Franklin Roosevelt was the greatest president in the history of the United States. You think that the greatest president was Abraham Lincoln, but before you can say anything, another friend agrees that it was Roosevelt, and then the other one does as well. What would you do? Disagree with all three? Maintain your opinion but keep quiet? Change your mind?

Mass Conformity The faithful who gather at Mecca, at the Vatican, and at other holy places around the world exemplify the power of religion and other social forces to produce conformity to group norms.

FIGURE 18.2

Stimulus Lines for Conformity Studies

TRY THIS Participants in Asch's (1956) experiments saw a new set of lines like these on each trial. The middle line in Part B matches the one in Part A, but when several of Asch's assistants chose an incorrect line, so did many of the participants. Try re-creating this experiment with four friends. Secretly ask three of them to choose the line on the left when you show this drawing, then see if the fourth person conforms to the group norm. If not, do you think it was something about the person, the length of the incorrect line chosen, or both that led to nonconformity? Would conformity be more likely if the first three people were to choose the line on the right? (Read on for more about this possibility.)

Source: Asch (1955).

When people change their behavior or beliefs to match those of other members of a group, they are said to conform. **Conformity** occurs as a result of group pressure, real or imagined (Cialdini & Goldstein, 2004). You probably have experienced such group pressure when everyone around you stood to applaud a performance you thought was not that great. You might have conformed by standing as well, though no one told you to do so. The group's behavior created a silent, but influential, pressure to follow suit. **Compliance**, in contrast, occurs when people adjust their behavior because of a request. The request can be clear and *explicit*, such as when someone says, "Could you do me a favor?," or subtle and *implicit*, as when someone simply looks at you in a way that lets you know the person needs a favor.

● The Role of Norms

Conformity and compliance are usually generated by spoken or unspoken norms. In a classic experiment, Muzafer Sherif (1937) charted the formation of a group norm by taking advantage of a perceptual illusion, called the *autokinetic phenomenon*. In this illusion, a stationary point of light in a pitch dark room appears to move. Estimates of the amount of movement tend to stay the same over time—if an observer is alone. But when Sherif tested several people at once, asking each person to say aloud how far the light moved on repeated trials, their estimates tended to converge. They had established a group norm. Even more important, when the individuals from the group were later tested alone, they continued to be influenced by this norm.

In another classic experiment, Solomon Asch (1956) examined how people would respond when they faced a norm that already existed but was obviously wrong. The participants in this experiment saw a standard line like the one in Figure 18.2(A); then they saw a display like that in Figure 18.2(B). Their task was to pick out the line in the display that was the same length as the one they had first been shown.

Each participant performed this task in a small group of people who posed as fellow participants, but who were actually the experimenter's assistants. There were two conditions. In the control condition, the real participant responded first. In the experimental condition, the participant did not respond until after the assistants did. The assistants chose the correct response on six trials, but on the other twelve trials they all gave the same obviously incorrect response. So on twelve trials, each participant was confronted with a "social reality" created by a group norm that conflicted with the physical reality created by what the person could clearly see. Only 5 percent of the participants in the control condition ever made a mistake on this easy task. However, among participants who heard the assistants' responses before giving their own, about 70 percent made at least one error by conforming to the group norm. An analysis of 133 studies conducted in seventeen countries reveals that conformity in Asch-type situations has declined somewhat in the United States since the 1950s, but it still occurs. It is especially likely in collectivist cultures, in which conformity to group norms is emphasized (Cialdini et al., 2001).

Pressure for conformity can even affect reports about personal experiences. In one study that used a procedure similar to Asch's, participants were shown a number of objects. Later, the same objects were shown again, along with some new ones, and the participants were asked to say whether they had seen each object in the previous display. When tested alone, the participants' memories were quite accurate, but hearing another person's opinion about which objects had or had not been shown before strongly affected their memory of which objects they had seen (Hoffman et al., 2001).

● Why Do People Conform?

Why did so many people in Asch's experiment, and others like it, give incorrect responses when they were capable of near-perfect performance? One possibility is that they displayed public conformity, giving an answer they did not believe simply because it was the socially desirable thing to do. Another possibility is that they

- **conformity** Changing one's behavior or beliefs to match those of others, generally as a result of real or imagined, though unspoken, group pressure.
- **compliance** Adjusting one's behavior because of an explicit or implicit request.

experienced *private acceptance*: Perhaps the participants used other people's responses as legitimate evidence about reality, were convinced that their own perceptions were wrong, and actually changed their minds. Morton Deutsch and Harold Gerard (1955) reasoned that if conformity disappeared when people gave their responses without identifying themselves, then Asch's findings must reflect public conformity, not private acceptance. Actually, conformity does decrease when people respond anonymously instead of publicly, but it doesn't disappear (Deutsch & Gerard, 1955). So people sometimes say things in public that they don't believe, but hearing other people's responses also influences their private beliefs (Moscovici, 1985).

Why are group norms so powerful? Research suggests three influential factors (Cialdini & Goldstein, 2004). First, people want to be correct, and norms provide information about what is right and wrong. This factor may help explain why some extremely disturbed or distressed people consider stories about suicide to be "social proof" that self-destruction is a reasonable way out of their problems (Cialdini, 2001). Second, people want others to like them, so they may seek favor by conforming to the norms that those others have established. Third, conforming to group norms may increase a person's sense of self-worth, especially if the group is valued or has high prestige (Cialdini & Goldstein, 2004). The process may occur without our awareness (Lakin & Chartrand, 2003). For example, observations of interviews by Larry King, the television talk-show host, revealed that he tended to imitate the speech patterns of high-status guests but not low-status ones (Gregory & Webster, 1996).

Finally, norms influence the distribution of social rewards and punishments (Cialdini, 1995). From childhood on, people in many cultures learn that going along with group norms is good and earns rewards. (These positive outcomes presumably help compensate for not always being able to say or do exactly what we please.) People also learn that breaking a norm may bring punishments ranging from scoldings for small transgressions to imprisonment for violation of norms that have been translated into laws.

● When Do People Conform?

People do not always conform to social influence. In the original Asch studies, for example, nearly 30 percent of the participants did not go along with the research assistants' obviously incorrect judgments. Countless experiments have probed the question of what combinations of people and circumstances do and do not lead to conformity.

● **Ambiguity of the Situation** *Ambiguity*, or uncertainty, is very important in determining how much conformity will occur. As the physical reality of a situation becomes less certain, people rely more and more on others' opinions, and conformity to a group norm becomes increasingly likely (Cialdini & Goldstein, 2004).

TRY THIS →  You can demonstrate this aspect of conformity on any street corner. First, create an ambiguous situation by having several people look at the sky or the top of a building. When passersby ask what is going on, be sure everyone excitedly reports seeing something interesting but fleeting—perhaps a faint light or a tiny, shiny object. If you are especially successful, conforming newcomers will begin persuading other passersby that there is something fascinating to be seen.

● **Unanimity and Size of the Majority** If ambiguity contributes so much to conformity, why did so many of Asch's participants conform to a judgment that was so clearly wrong? The answer has to do with the *unanimity* of the group's judgment and the number of people expressing it. Specifically, people experience great pressure to conform as long as the majority is unanimous. If even one other person in the group disagrees with the majority view, conformity drops greatly. When Asch (1951) arranged for just one assistant to disagree with the others, fewer than 10 percent of the real participants conformed. Once unanimity is broken, it becomes much

easier to disagree with the majority, even if the other nonconformist does not agree with the person's own view (Turner, 1991).

Conformity also depends on the size of the group. Asch (1955) demonstrated this phenomenon by varying the number of assistants in the group from one to fifteen. Conformity to incorrect norms grew as the number of people in the group increased. But most of the growth in conformity occurred as the size of the majority rose from one to about three or four members. Further additions had little effect. Several years after Asch's research, Bibb Latané (pronounced "lat-a-NAY") sought to explain this phenomenon with his *social impact theory*. This theory holds that a group's impact on an individual depends not only on group size but also on how important and close the group is to the person. And according to Latané (1981), the impact of increasing the size of a majority depends on how big the majority was originally. Increasing a majority from, say, two to three will have much more impact than increasing it from, say, sixty to sixty-one. The reason is that the increase from sixty to sixty-one is psychologically much smaller than the change from two to three; it attracts far less notice in relative terms. Does this explanation sound familiar? The principles underlying it are similar to those of Weber's law, which, as described in the chapter on perception, governs our experience of changes in brightness, weight, and other physical stimuli.

● **Minority Influence** Conformity can also result from *minority influence*, by which a minority in a group influences the behavior or beliefs of a majority (Crano & Prislin, 2006). This phenomenon is less common than majority influence, but minorities can be influential, especially when they are established members of the group, they agree with one another, and persist in their views (David & Turner, 2001). Perhaps because the views of a numerical minority are examined especially carefully (Martin & Hewstone, 2003), minority-influenced change often takes a while to occur and may involve only a moderate adjustment of the majority view (Alvaro & Crano, 1997; Crano & Chen, 1998).

● **Gender** Early research on conformity suggested that women conform more than men, but this gender difference stemmed mainly from the fact that the tasks used in those experiments were often more familiar to men than to women. This fact is important because people are especially likely to conform when they are faced with an unfamiliar situation (Cialdini & Goldstein, 2004). No male-female differences in conformity have been found in research using materials that are equally familiar to both genders (Maupin & Fisher, 1989).

So why do some people still perceive women as more conforming than men despite evidence to the contrary? Part of the answer may lie in their perception of the relative social status of men and women. People who think of women as having lower social status than men in most social situations are likely to see women as easier to influence, even though men and women conform equally often (Eagly, 1987).

● Inducing Compliance

In the conformity experiments we have described, the participants experienced psychological pressure to conform to the views or actions of others, even though no one specifically asked them to do so. In contrast, *compliance* involves changing what you say or do because of a request.

How is compliance brought about? Many people believe that the direct approach is always best: If you want something, ask for it. But salespeople, political strategists, social psychologists, and other experts have learned that often the best way to get something is to ask for something else. Three examples of this strategy are the foot-in-the-door technique, the door-in-the-face procedure, and the low-ball approach.

The *foot-in-the-door technique* works by getting a person to agree to a small request and then gradually presenting larger ones. In the original experiment on this strategy, homeowners were asked to do one of two things. Some were asked

Sign Here, Please Have you ever been asked to sign a petition in favor of a political, social, or economic cause? Supporters of these causes know that people who comply with this small request are the best ones to contact later with requests to do more. Complying with larger requests is made more likely because it is consistent with the signer's initial commitment to the cause. If you were contacted after signing a petition, did you agree to donate money or perhaps become a volunteer?

to allow a large, unattractive “Drive Carefully” sign to be placed on their front lawns. Approximately 17 percent of the people approached in this way complied with the request. In the foot-in-the-door condition, however, homeowners were first asked only to sign a petition supporting legislation aimed at reducing traffic accidents. Several weeks later, when a different person asked these same people to put the “Drive Carefully” sign on their lawns, 55 percent of them complied (Freedman & Fraser, 1966).

Why should the granting of small favors lead to granting larger ones? First, people are usually far more likely to comply with a request that costs little in time, money, effort, or inconvenience. Second, complying with a small request makes people think of themselves as being committed to the cause or issue involved (Burger & Guadagno, 2003). This change occurs through the processes of self-perception and cognitive dissonance discussed in the chapter on social cognition. In the study just described, participants who signed the petition might have thought, “I must care enough about traffic safety to do something about it.” Compliance with the higher-cost request (displaying the sign) then became more likely because it was consistent with these people's self-perceptions and past actions (Burger & Caldwell, 2003).

The foot-in-the-door technique can be quite effective. Steven Sherman (1980) created a 700 percent increase in the rate at which people volunteered to work for a charity simply by first getting them to say that, in a hypothetical situation, they would volunteer if asked. For some companies, the foot in the door is a request that potential customers merely answer a few questions. The request to buy something comes later. Others offer a small gift, or “door opener,” as salespeople call it. Acceptance of the gift not only allows a foot in the door, but may also activate the reciprocity norm: Many people who get something free of charge feel obligated to reciprocate by buying something—especially if the request to do so is delayed for a while (Cialdini, 2001; Guadagno et al., 2001).

The *door-in-the-face procedure* offers a second way of obtaining compliance (Pascual & Guéguen, 2005). This strategy begins with a request for a favor that is likely to be denied. The person making the request then concedes that asking for the initial favor was excessive and substitutes a lesser alternative—which was what the person really wanted in the first place! Because the person appears willing to compromise and because the new request seems modest in comparison with the first

OK, OK, I'll Be Home by One! The door-in-the-face approach is sometimes used successfully by teenagers to influence parents to comply with many kinds of requests. After asking to stay out overnight, a youngster whose curfew is normally 11 P.M. might be allowed to stay out until 1 A.M.—a “compromise” that was actually the original goal.

one, it is more likely to be granted than if it had been made at the outset. Here again, compliance appears to be due partly to activation of the reciprocity norm. The door-in-the-face strategy often lies at the heart of the bargaining that takes place among political groups and between labor and management (Ginges et al., 2007).

A third technique for gaining compliance, called the *low-ball approach*, is commonly used by car dealers and other salespeople. The first step in this strategy is to obtain a person's oral commitment to do something, such as to purchase a car at a certain price. Once this commitment is made, the cost of fulfilling it is increased, often because of an "error" in computing the car's price. Why do buyers end up paying much more than originally planned for "low-balled" items? Apparently, once people say they will do something, they feel obligated to follow through, especially when the commitment was made in public and when the person who obtains the initial commitment also makes the higher-cost request (Burger & Cornelius, 2003). In other words, as described in relation to cognitive dissonance theory in the chapter on social cognition, people like to be consistent in their words and deeds. In this case, it appears that people try to maintain a positive self-image by acting in accordance with their previously stated intention, even though it may cost them a great deal to do so.

Obedience

FIGURE 18.3

Studying Obedience in the Laboratory

In this photograph from Milgram's original experiment, a man is being strapped into a chair with electrodes on his arm. Although participants in the experiment didn't know it, the man was actually one of the experimenter's research assistants and received no shock.

Compliance involves a change in behavior in response to a request. In the case of **obedience**, the behavior change comes in response to a *demand* from an authority figure. In the 1960s, Stanley Milgram developed a laboratory procedure at Yale University to study obedience. In his first experiment, he used newspaper ads to recruit forty male volunteers between the ages of twenty and fifty. Among the participants were professionals, white-collar businessmen, and unskilled workers (Milgram, 1963).

Imagine you are one of the people who answered the ad. When you arrive for the experiment, you join a fifty-year-old gentleman who has also volunteered and has been scheduled for the same session. The experimenter explains that the purpose of the experiment is to examine the effects of punishment on learning. One of you—the "teacher"—will help the "learner" remember a list of words by administering an electrical shock whenever he makes a mistake. Then the experimenter turns to you and asks you to draw one of two cards out of a hat. Your card says "TEACHER." You think to yourself that this must be your lucky day.

Now the learner is taken into another room and strapped into a chair, as shown in Figure 18.3. Electrodes are attached to his arms. Meanwhile, you are shown a shock generator featuring thirty switches. The experimenter explains that the switch on the far left administers a mild, 15-volt shock and that each succeeding switch increases the shock by 15 volts. The switch on the far right delivers 450 volts. The far left section of the shock generator is labeled "slight shock." Looking across the panel, you see "moderate shock," "very strong shock," and at the far right, "danger—severe shock." The last two switches are ominously labeled "XXX." The experimenter explains that you, the teacher, will begin by reading a list of word pairs to the learner. Then you will go through the list again, presenting just one word of each pair. It is the learner's task to say which word went with it. After the first mistake, you are to throw the switch to deliver 15 volts of shock. Each time the learner makes another mistake, you are to increase the shock by 15 volts.

You begin, following the experimenter's instructions. But after the learner makes his fifth mistake and you throw the switch to give him 75 volts, you hear a loud moan. At 90 volts, the learner cries out in pain. At 150 volts, he screams and asks to be let out of the experiment. You look to the experimenter, who says, "Proceed with the next word."

No shock was actually delivered in Milgram's experiments. The learner was always an employee of the experimenter, and the moans and other signs of pain came from a prerecorded tape. But you don't know that. What would you do in this

- **obedience** Changing behavior in response to a demand from an authority figure.

FIGURE 18.4**Results of Milgram's Obedience Experiment**

When Milgram asked a group of undergraduates and a group of psychiatrists to predict how participants in his experiment would respond, they estimated that no more than 2 percent would go all the way to 450 volts. In fact, 65 percent of the participants did so. What do you think you would have done in this situation?

Source: Milgram (1963).

situation? Suppose you continue and eventually deliver 180 volts. The learner screams that he cannot stand the pain any longer and starts banging on the wall. The experimenter says, “You have no other choice; you must go on.” Would you continue? Would you keep going even when the learner begged to be let out of the experiment and then fell silent? Would you administer 450 volts of potentially deadly shock to a perfect stranger just because an experimenter demanded that you do so?

Figure 18.4 shows that only 5 participants in Milgram's experiment stopped before 300 volts, and 26 out of 40 participants (or 65 percent) went all the way to the 450-volt level. The decision to continue was difficult and stressful for the participants. Many protested repeatedly; but each time the experimenter told them to continue, they did so. Here is a partial transcript of what a typical participant said:

[After throwing the 180-volt switch:] He can't stand it. I'm not going to kill that man in there. Do you hear him hollering? He's hollering. He can't stand it. What if something happens to him? I'm not going to get that man sick in there. He's hollering in there. Do you know what I mean? I mean, I refuse to take responsibility. He's getting hurt in there. . . . Too many left here. Geez, if he gets them wrong. There are too many of them left. I mean, who is going to take responsibility if anything happens to that gentleman?

[After the experimenter accepts responsibility:] All right. . . .

[After administering 240 volts:] Oh, no, you mean I've got to keep going up the scale? No, sir, I'm not going to kill that man. I'm not going to give him 450 volts.

[After the experimenter says, “The experiment requires that you go on”:] I know it does, but that man is hollering in there, sir.

This participant administered shock up to 450 volts. (Milgram, 1974, p. 74)

● Factors Affecting Obedience

Milgram had not expected so many people to deliver such apparently intense shocks. Was there something about his procedure that produced this high level of obedience? To find out, Milgram and other researchers varied the original procedure in a number of ways. The overall level of obedience to an authority figure was usually quite high, but the degree of obedience was affected by several factors.

Proximity and Obedience

Milgram's research suggested that the close physical proximity of an authority figure is one of several factors that can enhance obedience to authority (Rada & Rogers, 1973). This proximity principle is employed in the military, where no one is ever far away from the authority of a higher-ranking person.

● **Experimenter Status and Prestige** In Milgram's original study, the experimenter's status and prestige as a Yale University professor created two kinds of social power that affected the participants. The first was *expert social power*, which is the ability to influence people because they assume the person in power is a knowledgeable and responsible expert. The second was *legitimate social power*, which is the ability to influence people because they assume the person in power has the right or legitimate authority to tell them what to do (Blass & Schmitt, 2001).

To test the effects of reduced status and prestige, Milgram rented an office in a rundown building in Bridgeport, Connecticut. He then placed a newspaper ad for people to participate in research sponsored by a private firm. There was no mention of Yale. In all other ways, the experimental procedure was identical to the original. Under these less impressive circumstances, the level of obedience dropped, but not as much as you might expect; 48 percent of the participants continued to the maximum level of shock, compared with 65 percent in the original study. Milgram concluded that people still would obey instructions that could cause great harm to another even if the authority figure was not associated with a prestigious institution. Evidently, people's willingness to follow orders from an authority operates somewhat independently of the setting in which the orders are given.

● **The Behavior of Others** To study how the behavior of fellow participants might affect obedience, Milgram (1965) created a situation in which there were apparently three teachers. Teacher 1 (in reality, a research assistant) read the words to the learner. Teacher 2 (another research assistant) stated whether or not the learner's response was correct. Teacher 3 (the actual participant) was to deliver a shock when mistakes were made. At 150 volts, when the learner began to complain that the shock was too painful, Teacher 1 said he would not participate any longer and left the room. The experimenter asked him to come back, but he refused. The experimenter then instructed Teachers 2 and 3 to continue by themselves. The experiment went on for several more trials. However, at 210 volts, Teacher 2 said that the learner was suffering too much and refused to participate further. The experimenter then told Teacher 3 (the actual participant) to continue the procedure. In this case, only 10 percent of the participants (compared with 65 percent in the original study) continued to deliver shocks all the way up to 450 volts. In other words, as research on conformity would suggest, the presence of others who disobey appears to be the most powerful factor in reducing obedience.

Civil Disobedience Not everyone is blindly obedient to authority. In 1955, Rosa Parks was arrested and fingerprinted in Montgomery, Alabama, after refusing an order to move to the “colored” section in the back of a segregated bus. Her courageous act of disobedience sparked the civil rights movement in the United States.

● **Personality Characteristics** Were the participants in Milgram’s original experiment heartless creatures who would have given strong shocks even if there had been no pressure on them to do so? Quite the opposite; most of them were nice people who were influenced by experimental situations to behave in apparently anti-social ways. In a later demonstration of the same phenomenon, college students playing the role of prison guards behaved with aggressive heartlessness toward other students who were playing the role of prisoners (Zimbardo, 1973). A more recent illustration of this phenomenon occurred among some U.S. soldiers who were assigned to guard or interrogate prisoners in Afghanistan and Iraq.

Still, not everyone is equally obedient to authority. For example, people high in *authoritarianism* (a characteristic discussed in the chapter on social cognition) are more likely than others to comply with an experimenter’s request to shock the learner (Blass, 1991). Support for this idea comes from data suggesting that German soldiers who obeyed orders to kill Jews during World War II were higher on authoritarianism than other German men of the same age and background (Steiner & Fahrenberg, 2000).

● Evaluating Milgram’s Studies

How relevant are Milgram’s forty-five year-old studies in today’s world? Consider this fact: The U.S. Federal Aviation Administration attributes some commercial airline accidents to a phenomenon it calls “captainitis.” This phenomenon occurs when the captain of an aircraft makes an obvious error, but none of the other crew members is willing to challenge the captain’s authority by pointing out the mistake. As a result, planes have crashed and people have died (Kanki & Foushee, 1990). Obedience to authority may also have operated during the World Trade Center attack on September 11, 2001, when some people who had started for the exits returned to their offices after hearing an ill-advised public address announcement telling them to do so. Most of these people died as a result. Such events suggest that Milgram’s findings are still relevant and important. Similar kinds of obedience have

May I Take Your Order? In February of 2004, the managers of four fast-food restaurants in Boston, Massachusetts, received calls from someone claiming to be a police detective on the trail of a robbery suspect. The caller said that the suspect might be one of the restaurant's employees and told the managers to strip-search all of them for evidence of guilt. The calls turned out to be hoaxes, but every manager obeyed this bizarre order, apparently because it appeared to come from a legitimate authority. In a similar case, hospital nurses obeyed medical treatment orders given by a teenager who claimed he was a doctor (Kenrick, Neuberg, & Cialdini, 2005).

been observed in experiments conducted in many countries, from Europe to the Middle East, with female as well as male participants. In short, people appear to be as obedient today as they were when Milgram conducted his research (Blass, 2000; Smith & Bond, 1999).

Nevertheless, many aspects of Milgram's work still provoke debate. (For a summary of Milgram's results, plus those of studies on conformity and compliance, see "In Review: Types of Social Influence.")

in review Types of Social Influence

| Type | Definition | Key Findings |
|------------|--|--|
| Conformity | A change in behavior or beliefs to match those of others | <p>In cases of ambiguity, people develop a group norm and then adhere to it.</p> <p>Conformity occurs because people want to be right, because they want to be liked by others, and because conformity to group norms is usually reinforced.</p> <p>Conformity usually increases with the ambiguity of the situation, as well as with the unanimity and psychological size of the majority.</p> |
| Compliance | A change in what is said or done because of a request | <p>Compliance increases with the foot-in-the-door technique, which begins with a small request and works up to a larger one.</p> <p>The door-in-the-face procedure can be used, too. After making a large request that is denied, the person substitutes a less extreme alternative that was desired all along.</p> <p>The low-ball approach also elicits compliance. A person first obtains an oral commitment for something, then claims that only a higher-cost version of the original request will suffice.</p> |
| Obedience | A change in behavior in response to an explicit demand, typically from an authority figure | <p>People may inflict great harm on others when an authority demands that they do so.</p> <p>Even though people obey orders to harm another person, they often agonize over the decision.</p> <p>People are most likely to disobey orders to harm someone when they see another person disobey such orders.</p> |

● **Ethical Questions** Although the “learners” in Milgram’s experiment suffered no discomfort, the participants did. Milgram (1963) saw participants “sweat, stutter, tremble, groan, bite their lips, and dig their fingernails into their flesh” (p. 375). Against the potential harm inflicted by Milgram’s experiments stand the potential gains. For example, people who learn about Milgram’s work often take his findings into account when deciding how to behave in social situations (Sherman, 1980). But even if social value has come from Milgram’s studies, the question remains: Was it ethical for Milgram to treat his participants as he did?

In the years before his death in 1984, Milgram defended his experiments (e.g., Milgram, 1977). He argued that his debriefing of the participants after the experiment prevented any lasting harm. For example, to demonstrate that their behavior was not unusual, Milgram told participants that most people went all the way to the 450-volt level. He also explained that the learner did not experience any shock; in fact, the learner came in and chatted with each participant. On a later questionnaire, 84 percent of the participants said that they had learned something important about themselves and that the experience had been worthwhile. Milgram argued, therefore, that the experience was actually a positive one. Still, today’s committees charged with protecting human participants in research would be unlikely to approve Milgram’s experiments, and less controversial ways to study obedience have now been developed (Blass, 2004).

● **Questions about Meaning** Do Milgram’s dramatic results mean that most people are putty in the hands of authority figures and that most of us would blindly follow inhumane orders from our leaders? Some critics have argued that Milgram’s results cannot be interpreted in this way because his participants knew they were in an experiment and may simply have been playing a cooperative role. If so, the social influence processes identified in his studies may not explain obedience in the real world today (Berkowitz, 1999).

Most psychologists believe, however, that Milgram not only demonstrated the power of obedience to authority, but also revealed a basic truth about human behavior—namely, that under certain circumstances, human beings are capable of unspeakable acts of brutality toward other humans. Sadly, examples abound. And one of the most horrifying aspects of human inhumanity—whether it is the Nazis’ campaign of genocide against Jews sixty years ago or the campaigns of terror under way today—is that the perpetrators are not necessarily demented, sadistic fiends. Most of them are, in many respects, “normal” people who have been influenced by economic and political situations, and the persuasive power of their leaders, to behave in a demented and fiendish manner.

In short, inhumanity can occur even without pressure for obedience. For example, a good deal of people’s aggressiveness toward other people appears to come from within. Let’s now consider human aggressiveness and some of the circumstances that influence its expression.

Aggression

Aggression is an action intended to harm another person. It is all too common. Nearly 1.4 million violent crimes are committed each year in the United States, including nearly 94,000 rapes and nearly 17,000 murders (Federal Bureau of Investigation, 2006). In fact, homicide is the second-leading cause of death for people in the United States between the ages of fifteen and twenty-four (National Center for Injury Prevention and Control, 2002). One of the most disturbing aspects of these figures is that about 85 percent of all murder victims knew their assailants, and over 70 percent of rapists were romantic partners, friends, relatives, or acquaintances of their victims (U.S. Department of Justice, 2007). Further, about one-third of married

● **aggression** An act that is intended to cause harm to another person.

people in the United States, and a significant proportion of dating couples, display aggression toward each other that ranges from pushing, shoving, and slapping to beatings and the threatened or actual use of weapons (Cornelius & Resseguie, 2007; Durose et al., 2005).

LINKAGES (a link to *Introducing Psychology*, p. 10)

● Why Are People Aggressive?

An early theory of human aggression was offered by Sigmund Freud, who suggested it was partly due to *Thanatos*, the death instincts described in the chapter on personality. Freud proposed that aggression is an instinctive biological urge that builds up in everyone and must be released. Sometimes, he said, the release takes the form of physical or verbal abuse against others. At other times, the aggressive impulse is turned inward and leads to suicide or other self-damaging acts.

A somewhat more complicated view is offered by evolutionary psychologists. As discussed in the introductory chapter, these psychologists believe that human social behavior is related to our evolutionary heritage. From this perspective, aggression is seen to have helped prehistoric people compete for mates, thus resulting in the survival of their genes in the next generation. Through the principles of natural selection, then, aggressive tendencies were passed on through successive generations.

Evolutionary theories of the origins of aggression are popular, but even evolutionary theorists realize that “nature” alone cannot fully account for aggression. “Nurture,” in the form of environmental factors, also plays a large role in when and why people are aggressive. We know this partly because there are large differences in aggression from culture to culture. The murder rate in the Philippines, for example, is forty-six times higher than in China or Finland; and the U.S. murder rate is almost nine times higher than in those latter two countries (Barclay & Tavares, 2002). These data suggest that even if aggressive *impulses* are universal, the emergence of aggressive *behavior* reflects an interplay of nature and nurture (Malamuth & Addison, 2001). No equation can predict when people will be aggressive, but years of research have revealed a number of important biological, learning, and environmental factors that combine in various ways to produce aggression in various situations.

● **Genetic and Biological Mechanisms** There is strong evidence for hereditary influences on aggression, especially in animals (Cairns, Garipey, & Hood, 1990). In one study, the most aggressive members of a large group of mice were interbred. Then the most aggressive of their offspring were also interbred. After this procedure was followed for twenty-five generations, the resulting animals would immediately attack any mouse put in their cage. Continuous inbreeding of the least aggressive members of the original group produced animals that were so nonaggressive that they would refuse to fight even when attacked (Lagerspetz & Lagerspetz, 1983). Research on human twins reared together or apart suggests that there is a genetic component to aggression in people as well (Vierikko et al., 2006). However, other research suggests that people do not necessarily inherit the tendency to be aggressive; instead, they may inherit certain temperaments, such as impulsiveness or emotional oversensitivity in social situations, that in turn make aggression more likely (Eisenberger et al., 2007; Hennig et al., 2005).

Several parts of the brain influence aggression (Anderson & Bushman, 2002a). One is the limbic system, which includes the amygdala, the hypothalamus, and related areas (see Figure 3.13 in the chapter on biological aspects of psychology). Damage to these structures may produce *defensive aggression*, which includes heightened aggressiveness to stimuli that are not usually threatening or a decrease in the responses that normally inhibit aggression (Coccaro, 1989; Eichelman, 1983). The cerebral cortex may also be involved in aggression (e.g., Pietro et al., 2000; see Figure 3.16). For example, one study found that the prefrontal area of the cortex metabolized glucose significantly more slowly in murderers than in nonmurderers (Raine, Brennan, & Mednick, 1994).

FIGURE 18.5
Testosterone and Aggression

In the study illustrated here, the children of women who had taken testosterone during pregnancy to prevent miscarriage became more aggressive than the mothers' other children of the same sex who had not been exposed to testosterone during prenatal development. This outcome held for both males and females.

Source: Data from Reinisch, Ziemba-Davis, & Sanders (1991).

Hormones such as *testosterone*—the masculine hormone that is present in both sexes—may also play an important role in aggression (van Bokhoven et al. 2006). Experiments have shown that aggressive behavior increases or decreases dramatically with the level of testosterone in the human bloodstream (Klinesmith, Kasser, & McAndrew, 2006). Among criminals, those who commit violent crimes have higher levels of testosterone than those whose crimes are nonviolent. And among murderers, those with higher levels of testosterone are more likely than others to have known their victims and to have planned their crimes before committing them (Dabbs, Riad, & Chance, 2001).

Testosterone may have its most significant and durable influence not so much through its day-to-day variations as through its impact on early brain development. One natural test of this hypothesis occurred when pregnant women were given testosterone in an attempt to prevent miscarriages. Accordingly, their children were exposed to high doses of testosterone during prenatal development. Figure 18.5 shows that these children grew up to be more aggressive than their same-sex siblings who were not exposed to testosterone during prenatal development (Reinisch, Ziemba-Davis, & Sanders, 1991). Another study found that girls who had been prenatally exposed to elevated levels of testosterone by virtue of having shared the womb with a male twin were more aggressive than girls who had a female twin (Cohen-Bendahan et al., 2005).

Drugs that alter central nervous system functioning can also affect the likelihood that a person will act aggressively. Alcohol, for example, can substantially increase some people's aggressiveness. Canadian researchers have found that in almost 70 percent of the acts of aggression they studied, the aggressors had been drinking alcohol. And the more alcohol the aggressors consumed, the more aggressive they were (Wells, Graham, & West, 2000). No one knows exactly why alcohol increases aggression, but there is no doubt that many people associate drinking with both aggressive thoughts and aggressive actions (Bartholow & Heinz, 2006; Graham et al., 2006). As described in the consciousness chapter, this association may result in part from observing the drunken aggressiveness that is common in many cultures.

Research on the effects of other drugs on aggression has produced some surprising findings. One might expect, for example, that using stimulants would increase aggressiveness and that taking tranquilizers would reduce it, but the opposite appears to be true. Whereas amphetamine stimulants do not usually make people more aggressive, opiates (e.g., heroin and morphine) and some tranquilizers may do so (Taylor & Hulsizer, 1998). It is not clear why heroin users are more likely than amphetamine users to be aggressive. Some have suggested that heroin addicts' aggression reflects their desperate need to get money, by any means, to buy more drugs. But if this were so, we should also see increased aggression among people who are addicted to amphetamines and cocaine—because these addictions, too, are very expensive. Further, opiates increase people's aggressiveness even in controlled laboratory settings (Taylor & Hulsizer, 1998), suggesting that these drugs have biochemical effects that lead directly to aggression. The nature of these effects is presently unknown.

● **Learning and Cultural Mechanisms** Cross-cultural research makes it clear that although biological factors may increase or decrease the likelihood of aggression, learning also plays a role. Aggressive behavior is much more common in individualist than in collectivist cultures, for example (Oatley, 1993). Cultural differences in the expression of aggression appear to stem in part from differing cultural values. In contrast to many so-called advanced peoples, the Utku, an Inuit culture, view aggression in any form as a sign of social incompetence. In fact, the Utku word for “aggressive” also means “childish” (Oatley, 1993). The effects of culture on aggression can also be seen in the fact that the incidence of aggression in a given culture changes over time as cultural values change (Matsumoto, 2000).

Aggression can even differ from one part of a country to another. Consider the fact that more males in the southern United States commit homicide than do males in the northern states (Cassel & Bernstein, 2007). As discussed later, this regional

difference in the homicide rate may be related to the South's higher temperatures, but Richard Nisbett and his colleagues (e.g., Cohen & Nisbett, 1997) have proposed that it is due to a *culture of honor* that is more commonly endorsed by southern males. One key aspect of this cultural orientation is the need to defend one's honor, with violence if necessary, in response to a perceived insult. Studies testing this notion have indeed found that southern-born college students reacted much more angrily to a provocation than did northern-born students (Cassel & Bernstein, 2007; Cohen et al., 1996). The results of other regional U.S. studies, though, raise doubts about whether the culture of honor is any more prevalent in the south than in the north (Chu, Rivera, & Loftin, 2000).

The frequency of aggressive acts can certainly be altered by rewards or punishment. People become more aggressive when rewarded for aggressiveness and less aggressive when punished for aggression (Geen, 1998). People also learn many aggressive responses by watching others (Bingenheimer, Brennan, & Earls, 2005; Bushman & Anderson, 2001). Children, in particular, learn and perform many of the aggressive acts that they see modeled by others (Bandura, 1983). Albert Bandura's "Bobo" doll experiments, which are described in the chapter on learning, provide impressive demonstrations of the power of observational learning. The significance of observational learning is highlighted by studies of the effects of televised violence, also discussed in that chapter. For example, the amount of violent content watched on television when children are between six and ten predicts aggressiveness in these children even fifteen years later (Huesmann et al., 2003). Fortunately, not everyone who sees aggression becomes aggressive; individual differences in temperament, the modeling of nonaggressive behaviors by parents, and other factors can temper the effects of violent television. Nevertheless, observational learning, including the learning that comes through exposure to violent television, does play a significant role in the development and display of aggressive behavior (Anderson & Murphy, 2003; Bushman & Anderson, 2001). Even listening to music whose lyrics describe or endorse violence can increase aggressive thoughts and hostile feelings (Anderson, Carnagey, & Eubanks, 2003).

In short, a person's accumulated experiences—including culturally transmitted teachings—combine with daily rewards and punishments to influence whether, when, and how aggressive acts occur (Baron & Richardson, 1994; Bettencourt et al., 2006).

Following Adult Examples Learning to express aggression is especially easy for children who, like these children, see aggressive acts modeled for them all too often.

THINKING CRITICALLY

Do Violent Video Games Make People More Aggressive?

A lot of research has been conducted on the impact of violent television on aggressiveness, but what about other forms of violent entertainment, such as video games? When these games first appeared in the late 1970s they contained little or no violence, but by the 1990s violent versions such as *Mortal Kombat* and *Street Fighter* had become extremely popular, and the current flood of graphically violent games remain the favorites of young game-players. For example, one survey of fourth-graders found that 59 percent of girls and 73 percent of boys preferred violent video games over nonviolent ones. In response to complaints from parents groups, the video-game industry devised a rating system designed to keep the most violent games out of the hands of preteens and young teenagers, but many of the games that the system deems appropriate for these groups still contain considerable violent content (Funk et al., 1999). Further, fewer than 1 percent of young teenagers in one survey said that their parents had ever stopped them from buying a video game because of its violence rating (Walsh, 2000). In other words, children in the United States have essentially unrestricted access to violent video games. If they can't buy a violent game in a store, they can always download it from the Internet.

■ What am I being asked to believe or accept?

The parents groups who have objected to this situation are basing their concerns on the claim that playing violent video games can alter behavior in undesirable ways. Specifically, they say that exposure to violent video games increases the frequency of aggressive thoughts, feelings, and actions in people who play them (Anderson, Gentile, & Buckley, 2007).

■ What evidence is available to support the assertion?

Evidence for this claim comes from correlational and laboratory experiments on violent video games. Correlational studies have examined the relationship between the amount of time people spend playing these games and how aggressive they are. When Craig Anderson and Brad Bushman (2001) analyzed the combined results of a large number of these correlational studies, they found a statistically significant positive relationship. That is, the more time people spent playing violent video games, the more aggressive they tended to be.

In laboratory experiments on violent video games, researchers randomly assign participants to groups, then expose them for varying lengths of time to games that contain varying amounts of violence and allow varying degrees of player involvement. After manipulating these independent variables, the researchers measure some aspect of aggression, which is the dependent variable in these experiments. Finally, they compare the amount of aggressiveness displayed by participants in the various groups. In one such experiment, participants played a violent video game in which the researchers manipulated: (1) whether the player could actively participate as one of the characters in the game or could only watch the actions of the game's characters, and (2) whether or not the characters bled when they were wounded (Farrar, Krmar, & Nowak, 2006). They found that participants expressed more hostility and aggressive intentions when they were able to "be" characters in the game and when their victims bled when wounded. The combined results of several experiments like this one show that playing violent video games increases players' aggressive thoughts, feelings, and actions. There is also some evidence that playing violent video games may make people less likely to help other people (Anderson & Bushman, 2001).

■ Are there alternative ways of interpreting the evidence?

Like research on the effects of television violence, the results of correlational and experimental studies of violent video games have been questioned on several counts.

The correlational studies have been challenged mainly because correlations do not allow us to draw conclusions about cause and effect. True, greater aggressiveness is associated with longer exposure to violent video games, but is this because the games are causing aggressiveness or because aggressive people are more inclined to play violent video games? The laboratory experiments have been criticized mainly because their methods may not reflect, and their results may not apply to, what goes on in the world outside the laboratory (Goldstein, 2001). Do violent video games played in a lab have the same effects as they do when played at home, perhaps with friends? Do artificial laboratory measures of aggressiveness really tell us anything about how a person is likely to behave toward other people in daily life? Although experiments give researchers the control necessary to support cause-effect conclusions, critics argue that those conclusions might be of limited value in understanding the true impact of violent video games on aggressiveness.

At least one reviewer has suggested that studies whose results fail to show a relationship between violent video games and aggression are less likely to be published than those that do show such a relationship (Ferguson, 2007). Other skeptics point out that even if a statistically significant cause-effect relationship between violent video games and aggression does exist, it is not a very strong one (Sherry, 2001), especially when compared with other influences. They suggest, for example, that people's aggressiveness is affected far less intensely by violent video games (and violent television) than by other factors, such as what children learn by seeing their families and friends behaving aggressively.

■ What additional evidence would help to evaluate the alternatives?

Part of the controversy over the impact of violent video games could be resolved if we had data from longitudinal studies that track the behavior of people who choose to engage in varying amounts of violent game-playing over many years. If the relationship between amount of exposure and amount of aggression remains over ten or fifteen years, as it does in the case of violent television (Bushman & Huesmann, 2001), the claim that exposure to violent video games can make people more aggressive becomes that much more plausible.

It would also be valuable to know what happens in the brains of people who play violent video games, and scientists are currently studying this question using a variety of neuroscience techniques. In one recent study, changes in event-related brain activity (see Figure 8.4 in the cognition and language chapter) indicated that playing violent video games made participants less sensitive to, and less upset by, seeing violence (Bartholow, Bushman, & Sestir, 2006). Another study (Weber, Ritterfeld & Mathiak, 2006) using functional magnetic resonance imaging (fMRI) found that exposure to violent aspects of video games activates brain areas that are commonly associated with aggression. Such studies cannot confirm that violent video games cause aggression, but their results support the possibility of a causal link and begin to provide some explanations about why that link might exist.

■ What conclusions are most reasonable?

Given the evidence available so far, it appears reasonable to say that violent video games probably have at least some short-term effects on the people who play them. Questions about how strong the causal relationship is, and how long it might last, have not yet been answered. On the basis of the principles described in the chapter on learning, some researchers believe that violent video games might actually have a stronger impact on aggression than violent television because (1) game players can literally practice aggression as they engage in violent electronic acts and (2) they are rewarded for those violent acts by reaching the game's next level (e.g., Bushman & Anderson, 2007). Are these researchers correct? Are the effects of violent video games that strong, and are they likely to be long-lasting influences on aggressiveness? It will take much more research to definitively answer these questions, but it seems reasonable to suspect that the effects of prolonged exposure to violent video games will be quite similar to that of long exposure to violent television.

FIGURE 18.6

Pornography and Sexual Aggression

Extensive exposure to pornography does not by itself make most men more likely to engage in sexual aggression. However, among men who are hostile toward women and have a history of sexual promiscuity, those who view a lot of pornography are much more likely to engage in sexual aggression.

Source: Adapted from Malamuth (1998).

● When Are People Aggressive?

In general, people are more likely to be aggressive when they are both physiologically aroused and experiencing angry or hostile thoughts and feelings (Anderson & Bushman, 2002a). They tend either to lash out at those who make them angry or to displace their anger onto defenseless targets such as children or pets. However, aggression can also be made more likely by other forms of emotional arousal. One emotion that has long been considered to be a major cause of aggression is *frustration*, which occurs when we are prevented from reaching some goal.

● Frustration and Aggression Suppose that a friend interrupts your studying for an exam by coming over to borrow a book. If things have been going well and you are feeling confident about the exam, you are likely to be friendly and helpful. But what if you are feeling frustrated because your friend's visit is the fifth interruption in the last hour? Under these emotional circumstances, you may react aggressively, perhaps snapping at your startled visitor for bothering you.

Your aggressiveness in this situation conforms to the predictions of the **frustration-aggression hypothesis**, originally developed by John Dollard and his colleagues (Dollard et al., 1939). They proposed that frustration always results in aggression and that aggression will not occur unless a person is frustrated. Research on this hypothesis, however, has shown that it is too simple and too general. For one thing, frustration sometimes produces depression and withdrawal, not aggression (Berkowitz, 1998). In addition, not all aggression is preceded by frustration (Berkowitz, 1994).

After many years of research, Leonard Berkowitz (1998) suggested some substantial modifications to the frustration-aggression hypothesis. First, he proposed that it may be stress in general rather than frustration in particular that can produce a readiness to act aggressively. Once this readiness exists, cues in the environment that are associated with aggression will often lead a person to behave aggressively. The cues might be guns or knives, televised scenes of people arguing, violent song lyrics or game images, and the like. Neither stress alone nor the cues alone are sufficient to set off aggression. When combined, however, they often do set it off. Support for this aspect of Berkowitz's theory has been quite strong (Anderson & Bushman, 2002b).

Second, Berkowitz argues that the direct cause of most kinds of aggression is *negative affect*, or unpleasant emotion. He says that the greater the negative affect, whether it is caused by frustrating circumstances or other sources, the stronger the readiness to behave aggressively (Berkowitz, 1998). Negative affect can be aroused by pain, for example. Research suggests that people in pain do tend to become aggressive, no matter what caused their pain. In one study, participants whose hands were placed in painfully cold water became more aggressive toward other people than participants whose hands were in water of room temperature (Berkowitz, 1998).

● Generalized Arousal Imagine you have just jogged three miles. You are hot, sweaty, and out of breath, but you are not angry. Still, the physiological arousal caused by jogging may increase the probability that you will become aggressive if, say, a passerby shouts an insult (Zillmann, 1988). Why? The answer lies in a phenomenon described in the chapter on motivation and emotion: Arousal from one experience may carry over to an independent situation, producing what is called *excitation transfer*. So the physiological arousal caused by jogging may intensify your reaction to an insult (Harrison, 2003).

By itself, however, generalized arousal does not lead to aggression. It is most likely to produce aggression when the situation contains some reason, opportunity, or target for aggression (Zillmann, 2003). In one study, for example, people engaged in two minutes of vigorous exercise. Then they had the opportunity to deliver electrical shock to another person. The participants chose high levels of shock only if they were first

FIGURE 18.7

Effects of Temperature on Aggression

Studies from around the world indicate that aggressive behaviors are most likely to occur during hot summer months. These studies support the idea that environmental factors can affect aggression.

Source: Anderson & Anderson (1998).

insulted (Zillmann, Katcher, & Milavsky, 1972). Apparently, the arousal resulting from the exercise made aggression more likely; the insult “released” it.

Other research suggests that men who are aroused by watching violent pornography might be more likely to commit rape or other forms of aggression against women. In one experiment, for example, male participants were told that a person in another room (actually an employee of the experimenter) would be performing a learning task and that they were to administer an electric shock every time the person made a mistake. The intensity of shock could be varied (as in the Milgram studies, no shock actually reached the employee), but participants were told that changing the intensity would not affect the speed of learning. So the shock intensity (and presumed pain) that they chose to administer was considered to be a measure of aggression. Before the learning trials began, some participants watched a film in which several men had sex with the same woman, against her will. These participants’ aggressiveness during the learning experiment was greater than that of men who did not watch the film (Donnerstein, 1984). There was no parallel increase in aggression against other men, indicating that the films don’t create a generalized increase in aggression but do create an increase in aggressiveness directed toward women (Aronson, Wilson, & Akert, 2005).

Such effects do not appear in all men, however. One study of about 2,700 men in the United States found that men who are not hostile toward women and who do not tend to have a lot of casual sex showed little if any change in sexual aggressiveness after viewing aggressive pornography. In contrast, among men who are high in promiscuity and hostility, watching aggressive pornography was followed by a dramatic increase in the chances that these men would engage in sexual aggression (Malamuth, Addison, & Koss, 2000). In fact, 72 percent of the men who frequently used pornography and were high in promiscuity and hostility had actually engaged in sexually aggressive acts (see Figure 18.6).

These findings are in keeping with the notion that aggression is not caused solely by a person’s characteristics or by the particular situation a person is in. Instead, the occurrence and intensity of aggression are determined by the joint influence of individual characteristics and environmental circumstances (Klinesmith et al., 2006).

● **Environmental Influences on Aggression** The links between stress, arousal, and aggressive behavior point to the possibility that stressful environmental conditions can make aggressive behavior more likely (Anderson, 2001). This possibility is one of the research topics in **environmental psychology**, the study of the relationship between people’s physical environment and their behavior (Bell et al., 2000). One aspect of the environment that clearly affects social behavior is the weather, especially temperature. High temperature is a source of stress and arousal, so it might be expected to correlate with aggressiveness. The results of many studies conducted in several countries show that many kinds of aggressive behavior are indeed more likely to occur during hot summer months than at any other time of the year (Anderson et al., 2000; Bushman, Wang, & Anderson, 2005; see Figure 18.7).

Noise also tends to make people more likely to display aggression, especially if the noise is unpredictable and irregular (Geen & McCown, 1984). Living arrangements, too, can influence aggressiveness. Compared with the tenants of crowded apartment buildings, those in buildings with relatively few residents are less likely to behave aggressively (Bell et al., 2000). This difference appears to be due in part to how people feel when they are crowded. Crowding tends to create physiological arousal and to make people tense, uncomfortable, and more likely to report negative feelings (Oskamp & Schultz, 1998). This arousal and tension can influence people to like one another less and to be more aggressive. One study of juvenile delinquents found that the number of behavior problems they displayed (including aggressiveness) was directly related to how crowded their living conditions had become (Ray et al., 1982).

- **frustration-aggression hypothesis** A proposition that frustration always leads to some form of aggressive behavior.
- **environmental psychology** The study of the relationship between behavior and the physical environment.

Crowding and Aggression Studies of prisons suggest that as crowding increases, so does aggression (Paulus, 1988). Environmental psychologists are working with architects on the design of prisons that minimize the sense of crowding and that may help prevent some of the violence that endangers staff and prisoners.

Altruism and Helping Behavior

Like all acts of terrorism, the 2001 attacks on the World Trade Center and the Pentagon were examples of human behavior at its worst. But like all tragedies, they drew responses that provide inspiring examples of human behavior at its best. Michael Benfante and John Cerqueira were working in the World Trade Center when one of the hijacked planes struck their building. They headed for a stairwell, but they didn't just save themselves. Although it slowed their own escape, they chose to carry Tina Hansen, a wheelchair-bound co-worker, down sixty-eight flights of stairs to safety. David Theall was in his Pentagon office when another hijacked plane hit the building not far from his desk. He could have escaped the rubble immediately, but he first located a dazed officemate and led him, along with seven other co-workers, to safety. And no one will ever forget the heroism of the hundreds of New York City firefighters, police officers, and emergency workers who risked their lives, and lost their lives, while trying to save others. Acts of selflessness and sacrifice were common that day, and in the days and weeks and months that followed. Police officers, medical personnel, search-and-rescue specialists, and just ordinary people came to New York from all over the United States to help clear wreckage, look for survivors, and recover bodies. More than \$1 billion in donations to the Red Cross and other charitable organizations poured in to help victims; one celebrity telethon raised \$150 million in two hours. There was also a dramatic increase in many other forms of prosocial behavior, including volunteering to work for all kinds of charities (Penner et al., 2005; see Figure 18.8).

All of these actions are examples of **helping behavior**, which is defined as any act that is intended to benefit another person. Helping can range from picking up dropped packages to donating a kidney. Closely related to helping is **altruism**, an unselfish concern for another's welfare (Penner et al., 2005). Let's consider some of the reasons for helping and altruism, along with some of the conditions under which people are most likely to help others.

- **helping behavior** Any act that is intended to benefit another person.
- **altruism** An unselfish concern for another's welfare.

One of Many Heroes Along with his colleague Michael Benfante, John Cerqueira (shown here) risked his life on September 11, 2001, to help a handicapped co-worker escape from the sixty-eighth floor of the World Trade Center. Hundreds of other heroic acts of helping took place that day, and less dramatic examples occur every day throughout the world.

● Why Do People Help?

The tendency to help others begins early, although at first it is not spontaneous. In most cultures, very young children generally help others only when they are asked to do so or are offered a reward (Grusec, Davidov, & Lundell, 2002). Still, Carolyn Zahn-Waxler and her associates found that almost half of the two-year-olds they observed acted helpfully toward a friend, a family member, or even a stranger (Warneken & Tomasello, 2006; Zahn-Waxler et al., 1992). As they grow older, children use helping behavior to gain social approval, and their efforts at helping become more elaborate. The role of social influence in the development of helping is seen as children follow examples set by people around them. Their helping behaviors are

FIGURE 18.8

The Impact of 9/11 on Volunteering

The 2001 terrorist attacks on New York and Washington, D.C., prompted a flood of volunteers who offered to work for charities and service organizations nationwide. As shown here, volunteerism during the three weeks after the attacks nearly tripled in comparison to the same three weeks in the previous year.

A Young Helper Even before their second birthdays, some children offer help to those who are hurt or crying by snuggling, patting, or offering food or even their own teddy bears.

shaped by the norms established by their families and the broader culture (Grusec & Goodnow, 1994). In addition, children are praised and given other rewards for helpfulness but are scolded for selfishness. Eventually children come to believe that being helpful is good and that they are good when they are helpful. By the late teens, people often help others even when no one is watching and no one will know that they did so (Grusec et al., 2002). There are three major theories about why people help even when they cannot expect any external rewards for doing so.

● **Arousal: Cost-Reward Theory** One approach to explaining why people help is called the **arousal: cost-reward theory** (Piliavin et al., 1981). This theory proposes that people find the sight of a victim distressing and anxiety provoking, and that this experience motivates them to do something to reduce the unpleasant arousal. Several studies have shown that all else being equal, the more physiologically aroused bystanders are, the more likely they are to help someone in an emergency (Dovidio et al., 2006). Before rushing to a victim's aid, however, the bystander will first evaluate two aspects of the situation: the costs associated with helping and the costs (to the bystander and the other person) of not helping. Whether or not the bystander actually helps depends on the outcome of this evaluation (Dovidio et al., 1991). If the costs of helping are low (as when helping someone pick up a dropped grocery bag) and the costs of not helping are high (as when the other person is physically unable to do this alone), the bystander will almost certainly help. However, if the costs of helping are high (as when the task is to load a heavy box into a car) and the costs of not helping are low (as when the person is strong enough to manage the task alone), the bystander is unlikely to offer help. This theory is attractive partly because it is comprehensive enough to provide a framework for explaining research findings on the factors that affect helping.

One of these factors is the *clarity of the need for help*, which has a major impact on whether people provide help (Dovidio et al., 1991). In one study, undergraduate students were waiting alone in a campus building when a staged “accident” took place outside. A window washer screamed as he and his ladder fell to the ground. He then began to clutch his ankle and groan in pain. All of the students looked out a window to see what had happened, but only 29 percent of them did anything to help. Other students experienced the same situation with one important difference: The man *said* he was hurt and needed help. In this case, more than 80 percent of the students came to his aid (Yakimovich & Saltz, 1971). Why so many? Apparently, this one additional cue eliminated any uncertainty about whether the person needed help. This cue also raised the perceived costs to the victim of not offering help. As these costs become higher, helping becomes more likely. If this laboratory study seems unrealistic, consider the case of a sixty-two-year-old woman in Darby, Pennsylvania. She was walking to the grocery store in March 2000 when she was pushed from behind by an attacker. She fended him off and then did her shopping as usual. It was only when she got home and her daughter saw the handle of a knife protruding from her back that she realized that the assailant had stabbed her! No one in the grocery store said anything to her about the knife, let alone offered to help. Why? The most likely explanation is that the woman didn't say or do anything to suggest that help was needed.

The *presence of others* also has a strong influence on the tendency to help. Somewhat surprisingly, though, their presence actually tends to suppress helping behavior. One of the most highly publicized examples of this phenomenon was the Kitty Genovese incident, which occurred on a New York City street in 1964. During a thirty-minute struggle, a man stabbed Genovese repeatedly, but none of the dozens of neighbors who witnessed the attack intervened or even called the police until it was too late to save her life. A similar case occurred on November 27, 2000, in London, when a ten-year-old boy who had been stabbed by members of a street gang lay ignored by passersby as he bled to death. After each case, journalists and social commentators expressed dismay about the cold, uncaring attitudes that seem to exist among people who live in big cities. But psychologists believe that something about the situation surrounding such events deters people from helping.

- **arousal: cost-reward theory** A theory attributing people's helping behavior to their efforts to reduce the unpleasant arousal they feel in the face of someone's need or suffering.

Diffusion of Responsibility Does the man on the sidewalk need help? The people nearby probably are not sure and might assume that, if he does, someone else will assist him. Research on factors affecting helping and altruism suggests that if you ever need help, especially in a crowd, it is important not only to clearly ask for help but also to tell a specific onlooker to take specific action (for example, “You, in the yellow shirt, please call an ambulance!”).

The numerous studies of helping behavior stimulated by the Genovese case revealed a phenomenon that may explain the inaction of Genovese’s neighbors and those passersby in London. This phenomenon is known as the **bystander effect**: Usually, as the number of people who witness an emergency increases, the likelihood that one of them will help decreases (Garcia, et al., 2002). One explanation for why the presence of others often reduces helping is that each person thinks someone else will help the victim. That is, seeing other bystanders allows each individual to experience a *diffusion of responsibility* for taking action, which lowers the costs of not helping (Dovidio et al., 2006).

The degree to which the presence of other people inhibits helping may depend on who those other people are. When they are strangers, perhaps poor communication inhibits helping. People often have difficulty speaking to strangers, particularly in an emergency, and without speaking, they have difficulty knowing what the others intend to do. According to this logic, if people are with friends rather than strangers, they should be less uncomfortable, more willing to discuss the problem, and thus more likely to help.

In one experiment designed to test this idea, an experimenter left a research participant in a waiting room, either alone, with a friend, with a stranger, or with a stranger who was an assistant to the experimenter (Latané & Rodin, 1969). The experimenter then stepped behind a curtain into an office. For a few minutes, she could be heard opening and closing the drawers of her desk, shuffling papers, and so on. Then there was a loud crash, and she screamed, “Oh, my god . . . My foot, I . . . I can’t move it. Oh, my ankle . . . I can’t get this . . . thing off me.” Then the participant heard her groan and cry.

Would the participant go behind the curtain to help? Once again, people were most likely to help if they were alone. When one other person was present, participants were more likely to communicate with each other, and to offer help, if they were friends than if they were strangers. When the stranger was the experimenter’s assistant (who had been instructed not to help), very few participants offered to help. Other studies have confirmed that bystanders’ tendency to help increases when they know one another (Rutkowski, Gruder, & Romer, 1983).

Research suggests that the *personality of the helper* also plays a role in helping. Some people are simply more likely to help than others. Consider, for example, the Christians who risked their lives to save Jews from the Nazi Holocaust. Researchers

- **bystander effect** A phenomenon in which the chances that someone will help in an emergency decrease as the number of people present increases.

interviewed hundreds of these rescuers many years later and compared their personalities with those of people who had a chance to save Jews but did not do so (Midlarsky, Jones, & Corley, 2005; Oliner & Oliner, 1988). The rescuers were found to have more empathy (the ability to understand or experience another's emotional state), more concern about others, a greater sense of responsibility for their own actions, and a greater sense of self-efficacy (confidence in the success of their efforts). Louis Penner and his associates (Penner, 2002; Penner & Finkelstein, 1998) have found that these kinds of personality traits predict a broad range of helping behaviors, from the speed with which bystanders intervene in an emergency to the amount of time volunteers spend helping AIDS victims. Consistent with the arousal: cost-reward theory, these personality characteristics are also correlated with people's estimates of the costs of helping and not helping. For example, empathic individuals usually estimate the costs of not helping as high, and people with a sense of self-efficacy usually rate the costs of helping as low (Penner et al., 1995). These patterns of cost estimation may partially explain why such people tend to be especially helpful.

Valuable as it is, the arousal: cost-reward theory cannot account for all aspects of helping. For instance, it cannot easily explain why *environmental factors* affect helping. Research conducted in several countries has revealed, for example, that people in urban areas are generally less helpful than those in rural areas (Aronson et al., 2005). Why? The explanation probably has more to do with the stressors found in cities than with city living itself. Evidence for this possibility comes from a study conducted in thirty-six North American cities. Researchers found that people's tendency to help was related more strongly to a city's population *density* (the number of people per square mile) than to the size of the city (Levine et al., 1994). The higher the density, the less likely people were to help others. Similar results have been found in other places such as the United Kingdom, the Middle East, and Africa (Hedge & Yousif, 1992; Yousif & Korte, 1995). Two explanations have been suggested for this association between environmental stress and reduced likelihood of helping. The first is that stressful environments create bad moods—and generally speaking, people in bad moods are less likely to help (Salovey, Mayer, & Rosenhan, 1991). A second possibility is that noise, crowding, and other urban stressors create too much stimulation. To reduce this excessive stimulation, people may pay less attention to their surroundings, which might include individuals who need help.

It is also difficult for the arousal: cost-reward theory to predict what bystanders will do when the cost of helping and the cost of not helping are *both* high. In these cases, helping (or not helping) may depend on several situational factors and, sometimes, on the personality of the potential helper. There may also be circumstances in which cost considerations may not be the major cause of a decision to help or not help. A second approach to helping considers some of these circumstances.

● **Empathy-Altruism Theory** The second approach to explaining helping is embodied in **empathy-altruism theory**, which maintains that people are more likely to engage in *altruistic*, or unselfish, helping—even when the cost of helping is high—if they feel empathy toward the person in need (Batson, 1998). In one experiment illustrating this phenomenon, participants listened to a tape-recorded interview with a female student. The student told the interviewer that her parents had been killed in an automobile accident, that they had had no life insurance, and that she was now faced with the task of finishing college while taking care of a younger brother and sister. She said that these financial burdens might force her to quit school or give up her siblings for adoption. None of this was true, but the participants were told that it was. Further, before listening to the woman's story, half the participants were given additional information about her that was designed to promote strong empathy. Later, all the participants were asked to help the woman raise money for herself and her siblings (Batson et al., 1997). The critical question was whether the participants who heard the additional empathy-promoting information would help more than those who did not have that information. Consistent

● **empathy-altruism theory** A theory suggesting that people help others because of empathy with their needs.

FIGURE 18.9

The Effect of Empathy on Helping

After hearing a staged interview with a woman who supposedly needed to raise money for her family, participants in this experiment were asked to help her. Those who were led to empathize with the woman were much more likely to offer their help than those who did not empathize. These results are consistent with the empathy-altruism theory of helping.

Source: Adapted from Batson et al. (1997).

with the empathy-altruism theory, more participants in the empathy condition than in the nonempathy condition offered to help (see Figure 18.9).

Were those who offered help in this experiment being utterly altruistic, or could there be a different reason for their actions? This is a hotly debated question. Some researchers dispute the claim that this study illustrated truly altruistic helping. They suggest that people help in such situations for more selfish reasons, such as relieving the distress they experienced after hearing of the woman's problems (Maner et al., 2002). The final verdict on this question is not yet in.

● **Evolutionary Theory** The evolutionary approach to social psychology offers a third way of explaining helping. This approach views many human social behaviors as echoes of actions that contributed to the survival of our prehistoric ancestors (Buss, 2004a). At first glance, it might not seem reasonable to apply evolutionary theory to helping and altruism, because helping others at the risk of one's own well-being doesn't appear adaptive. If we die while trying to save others, it will be their genes, not ours, that will survive. In fact, according to Charles Darwin's concept of the survival of the fittest, helpers—and their genes—should have disappeared long ago. Contemporary evolutionary theorists suggest, however, that Darwin's thinking about natural selection focused too much on the survival of the fittest *individuals* and not enough on the survival of their genes in others. Accordingly, the concept of survival of the fittest has been replaced by the concept of *inclusive fitness*, the survival of one's genes in future generations (Hamilton, 1964; Kruger, 2003). Because we share genes with our relatives, helping or even dying for a cousin, a sibling, or above all, our own child potentially increases the likelihood that at least some of our genetic characteristics will be passed on to the next generation through the beneficiary's future reproduction (Burnstein & Branigan, 2001). So *kin selection*—helping a relative to survive—may produce genetic benefits even if it provides no personal benefits for the helper (Kruger, 2003).

There is considerable evidence that kin selection occurs among birds, squirrels, and other animals. The more closely the animals are related, the more likely they are to risk their lives for one another. Studies in a wide variety of cultures show the same pattern of helping among humans (Buss, 2004a). People in the United States are three times as likely to donate a kidney to a relative as to a nonrelative (Borgida,

Family Ties Research indicates that people are more likely to donate organs to family members than to strangers. This pattern may reflect greater attachment or a stronger sense of social obligation to relatives than to others. Psychologists who take an evolutionary approach suggest that such helpful attitudes and actions have evolved because they are adaptive. When, as in the case of these sisters, one family member donates a kidney to save the life of another, the genes they share are more likely to survive.

Conner, & Monteufel, 1992), and identical twins (who have exactly the same genes) are much more willing to help one another than are fraternal twins or siblings, who share only 50 percent of their genes (Segal, 1999).

FOCUS ON RESEARCH METHODS

Does Family Matter?

In and of themselves, data on kin selection do not confirm evolutionary explanations of helping and altruism. The greater tendency to donate organs to relatives could also be due to the effects of empathy toward more familiar people, pressure from family members, or other social influence processes. To control for the effects of these confounding variables, some researchers have turned to the laboratory to study the role of evolutionary forces in helping behavior.

■ What was the researchers' question?

Eugene Burnstein, Christian Crandell, and Shinobu Kitayama (1994) wanted to know whether people faced with a choice of whose life to save would behave in line with the concept of kin selection. These investigators reasoned that if kin selection does affect helping, the more genetically related two people are—the more genes they share in common—the more inclined they should be to save each other's life. Further, if this kind of helping evolved because it preserves one's own genes in others, the tendency to save a close relative should be lessened if that relative is unlikely to produce offspring and thereby help preserve the helper's genes.

■ How did the researchers answer this question?

The most direct way to test these predictions would be to put people's lives in danger and then observe which (if any) of their relatives try to save them. Such an experiment would be unthinkable, of course, so Burnstein and his colleagues used a simulation, or *analogue*, methodology. Specifically, they asked people to imagine a series of situations and then to say how they would respond if the situation were real.

The participants in their analogue experiment were 110 men and 48 women enrolled at universities in Japan and the United States. The first independent variable was the kind of help that was needed. On the basis of random assignment, some participants were asked to imagine life-or-death situations in which there was time to save only one of three people who were asleep in separate rooms of a burning house. The remaining participants were asked to imagine everyday situations in which they had time to help only one of three people who each needed a small favor. The other independent variables were the characteristics of the people needing help in each situation—their age, gender, physical health, and genetic relatedness to the potential helper. The dependent variable was the participants' choice of which person they would help.

■ What did the researchers find?

In accordance with evolutionary theory, the participants were more than twice as likely to say they would save the life of a close relative than that of an unrelated friend. Also, the more closely related the endangered people were to the potential helpers, the more likely they were to be saved. Did these results occur simply because people tend to help closer relatives in any situation? Probably not. When the participants imagined situations in which only small favors were involved, they were only slightly more likely to help a close relative than a distant one.

Another major prediction of evolutionary theory was supported as well. Several different findings indicated that even close relatives might not be saved if they were unlikely to produce offspring. For example, the participants were more willing to do a small favor for a seventy-five-year-old relative than for a ten- or eighteen-year-old

**FIGURE 18.10****Kin Selection and Helping**

In this analogue experiment, students said they would be more likely to save the life of a healthy relative than a sick one but more likely to do a favor for the sick relative. Results like these have been cited in support of evolutionary theories of helping behavior.

Source: Burnstein, Crandell, & Kitayama (1994).

relative, but they were much more likely to save the lives of the younger relatives. Similarly, they were more likely to do a favor for a sick relative than for a healthy one; but in a life-or-death situation, they chose to save the healthy relative more often than the sick one (see Figure 18.10). Finally, the participants were more likely to save the life of a female relative than that of a male relative, unless the female was past childbearing age. There were no substantial differences between the responses of students in the United States and those in Japan.

■ What do the results mean?

The results of this experiment generally support the concept of kin selection, which says that the tendency to help close relatives evolved because, genetically speaking, it helps the helper. Specifically, if we save the life of a relative and that relative is able to produce offspring, more of our genes will be represented in the next generation. Evolutionary psychologists see these results as providing confirmation that kin selection affects the decisions people make about saving the life of another person, and thus that there is an evolutionary basis for helping.

■ What do we still need to know?

The findings reported by Burnstein and his colleagues are consistent with the predictions of evolutionary theory, but they must be interpreted with caution and in light of the methods that were used to obtain them. Analogue studies give clues to behavior—and allow experimental control—in situations that approximate, but may not precisely duplicate, situations outside the laboratory. These studies tend to be used when it would be unethical or impractical to expose people to “the real thing.” The more closely the analogue approximates the natural situation, the more confident we can be that conclusions drawn about behavior observed in the laboratory will apply, or generalize, to the world beyond the laboratory.

In an analogue experiment such as this one, we might question how closely the natural situation was approximated. For one thing, the participants predicted what their responses would be in hypothetical situations. Those responses might be different if the students were actually in the situations described. So although the analogue methodology in this study allowed the researchers to show that kin selection *could* play a role in human helping behavior, they did not demonstrate that it *did* play a role.

The study also failed to identify the mechanisms whereby biological tendencies are translated into thoughts that lead to helpful actions (Kruger, 2003). It is highly unlikely that the participants were thinking, “I’ll help a close relative because it will preserve my genes.” So what conscious thoughts or feelings led to their choices? Another analogue study by Josephine Korchmaros and David Kenny (2001) may provide a partial answer to this question. The people who needed help in this simulation were described using the names of the participants’ actual family members. The researchers also measured the strength of the emotional ties between the participants and these particular people. The results suggested that genetic closeness was related to emotional closeness. Perhaps, then, emotional closeness provides the mechanism that drives the choice of whom to help. It may be that we are biologically predisposed to feel emotionally closer to closer relatives and thus more likely to help them if their lives are in danger. These feelings, in turn, serve to increase the chances that some of our genes will survive in those close relatives.

This is a reasonable possibility, but remember that even though evolutionary theory may explain some general human tendencies to help, it cannot predict the behavior of specific individuals in specific situations (Penner et al., 2005). Like all other behavior, helping and altruism depend on the interplay of many genetic and environmental factors—including interactions between particular people and particular situations. (See “In Review: Theories of Helping Behaviors” for a summary of the major reasons why people help and the conditions under which they are most likely to do so.) ■

in review Theories of Helping Behaviors

| Theory | Basic Premise | Important Variables |
|----------------------|--|--|
| Arousal: cost-reward | People help in order to reduce the unpleasant arousal caused by another person's distress. They attempt to minimize the costs of doing this. | Factors that affect the costs of helping and of not helping |
| Empathy-altruism | People sometimes help for utterly altruistic reasons. They are motivated by a desire to increase another person's well-being. | The amount of empathy that one person feels for another |
| Evolutionary | People help relatives because it increases the chances that the helper's genes will survive in future generations. | The biological relationship between the helper and the recipient of help |

Cooperation, Competition, and Conflict

Helping is one of several ways in which people *cooperate* with one another. **Cooperation** is any type of behavior in which people work together to attain a common goal (Dovidio et al., 2006). For example, several law students might form a study group to help one another pass a difficult exam. But people can also engage in **competition**, trying to attain a goal for themselves while denying that goal to others. So those same students might later compete with one another for a single job opening at a prestigious law firm. Finally, **conflict** results when one person or group believes that another stands in the way of their achieving a goal. When the students become attorneys and represent opposing parties in a legal dispute, they will be in

Cooperation, Competition, Conflict, and Cash Cooperation, competition, and conflict can all be seen on *Survivor*, a television series in which people try to win money by staying the longest in some remote location. Early on, contestants cooperate with members of their own teams, but as more and more people are eliminated, even team members compete with one another. When only two people remain, each stands in the way of the other's goal of winning, so they are in direct conflict.

conflict. One way in which psychologists have learned about all three of these behaviors is by studying social dilemmas (Weber, Kopelman, & Messick, 2004).

● Social Dilemmas

Social dilemmas are situations in which an action that produces rewards for one individual will, if adopted by all others, produce negative consequences for everyone (Dawes & Messick, 2000). For instance, it might be in a factory owner's short-term self-interest to save the costs of pollution control by releasing untreated toxic waste into the environment. But if all factories do the same, the air and water will eventually become poisonous for everyone. Social psychologists have studied situations like this by conducting experiments on the two-person "prisoner's dilemma."

● **The Prisoner's Dilemma** The **prisoner's dilemma** is based on a scenario in which two people are separated for questioning immediately after being arrested on suspicion of having committed a serious crime (Komorita & Parks, 1996). The prosecutor believes they are guilty but doesn't have enough evidence to convict them. Each prisoner can either confess or not, but they are told that if they both refuse to confess, each will be convicted of a minor offense and will be jailed for one year. If they both confess, the prosecutor will recommend a five-year sentence for each. However, if one prisoner remains silent and the other confesses to what they did, the prosecutor will allow the confessing prisoner to go free, whereas the other will serve the maximum ten-year sentence.

Each prisoner faces a dilemma. Figure 18.11(A) outlines the possible outcomes. Obviously, the strategy that will guarantee the best *mutual* outcome—short sentences for both prisoners—is cooperation. In other words, neither should confess. But the prisoner who remains silent runs the risk of receiving a long sentence if the other prisoner confesses. Further, the prisoner who confesses will benefit if the other prisoner doesn't talk. In other words, each prisoner has an incentive to compete for freedom by confessing. But if they *both* compete and confess, each will end up going to jail for longer than if they had kept quiet.

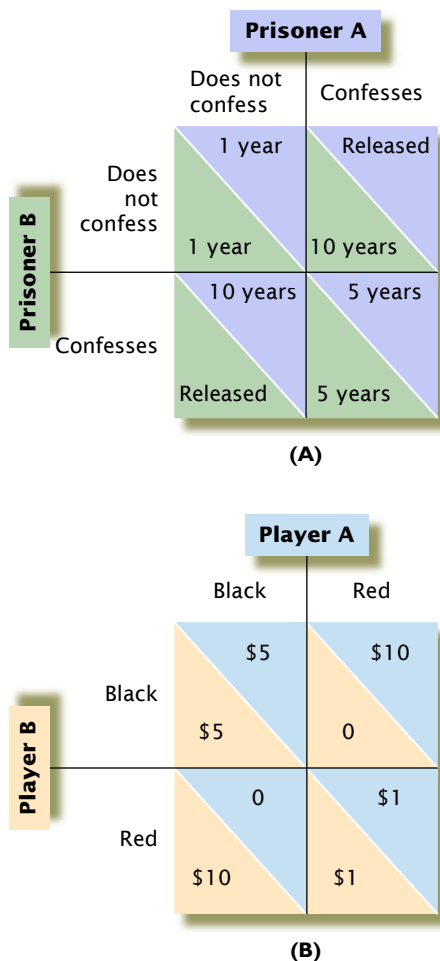

In the typical prisoner's dilemma experiment, two people sit at separate control panels. Each of them has a red button and a black button, one of which is to be pushed on each of many trials. Pressing the black button is a cooperative response. Pressing the red button is a competitive response. For example, on a given trial, if both participants press their black buttons, each wins \$5. If both press their red buttons, they earn only \$1. However, if one player presses the red button and the other presses the black button, the one who pressed the red button will win \$10, and the other will win nothing.

Figure 18.11(B) shows the possible outcomes for each trial. Over the course of the experiment, the combined winnings of the players are greatest if each presses the black button—that is, if they cooperate. By pressing the black button, however, a player becomes open to exploitation, because on any trial the other might press the red button and take all the winnings. So each player stands to benefit the most individually by pressing the red button occasionally. The prisoner's dilemma is what psychologists call a *mixed-motive conflict*—there are good reasons to cooperate and also good reasons to compete.

What happens when people play this game? Overall, there is a strong tendency to respond competitively. People find it difficult to resist the competitive choice on any given trial (Komorita & Parks, 1996). This choice wins them more money on that trial, but in the long run they gain less than they would have gained through cooperation.

If acting competitively leads to smaller rewards in the long run, why do people persist in competing? There seem to be two reasons (Komorita, 1984). First, winning more than an opponent seems to be rewarding in itself. In the prisoner's dilemma game, many people want to outscore an opponent even if the result is that

- **cooperation** Any type of behavior in which people work together to attain a goal.
- **competition** Behavior in which individuals try to attain a goal for themselves while denying that goal to others.
- **conflict** The result of a person's or group's belief that another person or group stands in the way of their achieving a valued goal.
- **social dilemmas** Situations in which actions that produce rewards for one individual will produce negative consequences if adopted by everyone.
- **prisoner's dilemma** A social dilemma in which mutual cooperation guarantees the best mutual outcome.

**FIGURE 18.11****The Prisoner's Dilemma**

In the prisoner's dilemma, mutual cooperation benefits each person and mutual competition is harmful to both. However, one party can take advantage of the other's cooperativeness. These diagrams show the potential payoffs for prisoners—and research participants—in prisoner's dilemma situations.

- **resource dilemma** A situation in which people must share a common resource, creating conflicts between the short-term interests of individuals and the long-term interests of the group.
- **zero-sum game** A social situation in which one person's gains are subtracted from another person's resources, so that the sum of the gains and losses is zero.

they win less money overall. Second, and more important, once several competitive responses are made, the competition seems to feed on itself (Insko et al., 1990). Each person becomes distrustful of the other, and cooperation becomes increasingly difficult. The more competitive one person acts, the more competitive the other becomes (McClintock & Liebrand, 1988).

● **Resource Dilemmas** Psychologists interested in cooperation, competition, and conflict have also concentrated on social dilemmas in which people share a common resource. In this situation, called a **resource dilemma** (Pruitt, 1998), there are built-in conflicts between the interests of the individual and those of the group, and also between people's short-term and long-term interests (Schroeder, 1995). There are two kinds of resource dilemmas. In the *commons dilemma*, people have to decide how much to take from a common resource. In the *public goods dilemma*, people must decide how much to contribute to a common resource. An example of the commons dilemma would be a situation in which farmers all want to draw water for their crops from the same lake. Each individual farmer would benefit greatly from unrestricted use of the water, but if all the farmers did the same, the water would soon be gone. Tax laws provide an example of the public goods dilemma. You would benefit greatly in the short run if you didn't pay any taxes, but if everyone failed to pay, no one would have police and fire protection, highway repairs, national defense, or other vital government services. How can people facing such dilemmas be prompted to cooperate?

● Promoting Cooperation

Communication can reduce people's tendency to act competitively (Pruitt, 1998). Unfortunately, however, not all communication increases cooperation, just as not all contact between ethnic groups reduces prejudice. If the communication takes the form of a threat, people may interpret the threat itself as a competitive response and are likely to respond competitively (Gifford & Hine, 1997). Furthermore, the communication must be relevant. In one social dilemma study, cooperation increased only when people spoke openly about the dilemma and how they would be rewarded for various responses. Praising one another for past cooperation was most beneficial (Orbell, van de Kragt, & Dawes, 1988).

People can also communicate silently through the strategy they use. In the prisoner's dilemma, the most effective strategy for producing long-term cooperation is to use basic learning principles and play *tit-for-tat*. This means rewarding cooperative responses with cooperation and punishing competitiveness by being competitive in return. Cooperating after a cooperative response and competing after a competitive response produces a high degree of cooperation over time (Nowak, May, & Sigmund, 1995). But competing after a cooperative response may harm the relationship and threaten future cooperation (Monterosso et al., 2002). So players usually learn that the only way to come out ahead is to cooperate. There is even evidence from computer simulation studies that societies whose members use cooperative strategies with one another are more likely to survive and prosper than are societies whose members act competitively (Ginges et al., 2007; Nowak et al., 1995).

● Interpersonal Conflict

In social dilemmas and other situations in which people are *interdependent*—that is, when what one person does always affects the other—cooperation usually leads to the best outcomes for everyone. This doesn't mean, however, that cooperation always occurs. People from collectivist cultures, in which cooperation is emphasized, are generally less likely to act selfishly in a social dilemma, but conflict in such situations does appear in all cultures (Smith & Bond, 1999). Conflict is especially likely when people are involved in a **zero-sum game**. This is a situation in which one person's gains are subtracted from the other person's resources. It is called *zero sum*

"There's quite a power struggle going on."

All Rights Reserved.

because when you add up the gains and losses, you get zero. Election campaigns, lawsuits over a deceased relative's estate, and competition between children for a toy are all examples of zero-sum games.

There are four major causes of interpersonal conflict (Baron, Byrne, & Branscombe, 2006). The first is traceable to incompatible interests. Suppose, for example, that at a company with twenty offices, only five have windows. Not all employees can have a window, so they will be in conflict as they compete for this scarce resource. Some managers report spending as much as 20 percent of their time dealing with interpersonal conflicts arising from incompatible interests (Thomas & Schmidt, 1976). More subjective factors play a role in the second cause of interpersonal conflict, namely attributing unfriendly or selfish motives to others. For example, conflict is likely to emerge if people who must share some resource, such as printer paper, attribute a shortage of that resource to the other people's selfishness (Samuelson & Messick, 1995). Sometimes these attributions are accurate, but often conflict results from the kinds of attributional errors discussed in the chapter on social cognition. In this case, the paper shortage might have occurred because someone simply forgot to order a new supply.

Attributional errors are related to a third source of interpersonal conflict: faulty communication. A comment intended as a compliment is sometimes interpreted as a snide remark, and constructive criticism is sometimes perceived as a personal attack. Such miscommunication can start a cycle of increasingly provocative actions, in which each person believes the other is being aggressive and unfair (Pruitt & Carnevale, 1993).

A final cause of interpersonal conflict is the tendency to magnify the differences between one's own views and those of others. For example, people may see themselves as fair and objective during discussions of a developer's plans for a wilderness area, but see the developer as utterly biased and concerned only with profit. This tendency often results in the impression that it will be harder to resolve a situation than is actually the case.

● **Managing Conflict** Interpersonal conflict can damage relationships among people and impair the effectiveness of organizations, but it can also lead to beneficial changes. Industrial/organizational psychologists have found that often it is much better to manage conflict effectively than to try to eliminate it. The most common way of managing organizational conflict is through *bargaining*. Each side—labor and management, for example—produces a series of offers and counteroffers until a solution emerges that is acceptable to both sides. At its best, bargaining can produce a win-win situation in which each side gets what is most important and gives up what is less important (Carnevale & Pruitt, 1992).

If bargaining fails, *third-party interventions* may be useful. Like a therapist working with a couple, an outside mediator can often help the two sides in an organizational conflict focus on important issues, defuse emotions, clarify positions and proposals, and make suggestions that allow each side to compromise without losing face (Pruitt, 1998).

Other techniques for managing conflict, especially conflict over resources, involve the introduction of *superordinate goals* or a *superordinate identity* (Williams, Jackson, & Karau, 1995). For example, if people who are competing for scarce resources can be made to feel that they are all part of the same group and share the same goals, they will act less selfishly and manage the limited resources more efficiently. Focusing on larger common goals was part of what created the unprecedented level of cooperation among people all over the United States following the terrorist attacks of September 11, 2001.

In short, although interpersonal conflict can be harmful if left unchecked, it can also be managed in a way that benefits the group. Much as psychotherapy can help people resolve personal conflict in a way that leads to growth, interpersonal conflict within an organization can be handled in a way that leads to innovations, increased loyalty and motivation, and other valuable changes.

Group Processes

Although Western industrialized cultures tend to emphasize individuals over groups, the fact remains that most important governmental and business decisions in those cultures and elsewhere are made by groups, not individuals (Kerr & Tindale, 2004). Sometimes group processes are effective. Perhaps you recall the extraordinary teamwork displayed by engineers, emergency workers, and volunteers that led to the dramatic rescue of nine men trapped in a flooded Pennsylvania coal mine in July 2002. At other times, group processes can have disastrous results, as we will see later. In the chapter on cognition and language, we describe some of the factors that influence the nature and quality of group decisions. Here, we consider some of the social psychological processes that often occur in groups to alter the behavior of their members and the quality of their collective efforts.

● Group Leadership

A good leader can help a group pursue its goals; a poor one can get in the way of a group's functioning. What makes a good leader? Psychologists once thought that the personalities of good and bad leaders were about the same, but we now know that certain personality traits often distinguish effective from ineffective leaders. For example, using tests similar to those that measure the big-five traits described in the chapter on personality, Colin Silverthorne (2001) examined the characteristics of leaders in the United States, Thailand, and China. He found that effective leaders in all three countries tended to score high on agreeableness, emotional stability, extraversion, and conscientiousness. Other researchers have found that in general, effective leaders are intelligent, success oriented, flexible, and confident in their ability to lead (Chemers, Watson, & May, 2000; Foti & Hauenstein, 2007). Having particular personality traits does not guarantee good leadership ability, however. People can be effective leaders in one situation, but ineffective in another (Chemers, 2000). The reason is that effective leadership also depends on the characteristics of the group members, the task at hand, and most important, the interaction between these factors and the leader's style (Yun, Faraj, & Sims, 2005).

For many years, leadership research focused on two main types of leaders, known as *task-oriented* and *person-oriented*. **Task-oriented leaders** provide close supervision, lead by giving directives, and generally discourage group discussion (Yukl & Van Fleet, 1992). Their style may not endear them to group members. **Person-oriented leaders** provide loose supervision, ask for group members' ideas, and are generally concerned with subordinates' feelings. They are usually well liked by the group, even when they must discipline a group member (Brehm, Kassin, & Fein, 2005).

More recently, some researchers have proposed that there are additional leadership styles. One of these is seen in *transactional leaders*, whose leadership behavior depends on the actions of those they lead. For example, transactional leaders reward those who behave as the leader wishes, and they correct or punish those who behave otherwise. In contrast, there are also *transformational or charismatic leaders* (Bass & Riggio, 2006). Rather than focusing on rewarding or punishing specific behaviors, these people concentrate on creating a vision of the group's goals, inspiring others to pursue that vision, and giving their followers reason to respect and admire them. Transformational leaders, such as Sir Winston Churchill and Dr. Martin Luther King, Jr., have dramatically changed the world for the better, and many less famous leaders of social or business groups have done the same on a smaller scale.

Do men or women make better leaders? Alice Eagly and her colleagues have studied differences between men and women in leadership styles (e.g., Eagly, Karau, & Makhijani, 1995). Their initial research found that, overall, men and women are equally capable leaders. It also looked as though men tend to be more effective when

- **task-oriented leader** A leader who provides close supervision, leads by directives, and generally discourages group discussion.
- **person-oriented leader** A leader who provides loose supervision, asks for group members' ideas, and is concerned with subordinates' feelings.

A Different Kind of Coach Many football coaches are task-oriented leaders whose tough discipline and emotional outbursts are legendary. Only a few, such as Indianapolis Colts coach Tony Dungy, are charismatic leaders. Dungy's leadership style is calm and low-key; rather than shouting at his players, he inspires them to focus on his vision of success and to do their best to achieve it. Their love for him is evident here as they carry Dungy off the field after winning the Super Bowl in 2007.

success requires a task-oriented leader, and that women tend to be more effective when success requires a more person-oriented leader. In other words, it appeared that people of each gender tend to be most effective when they are acting in a manner consistent with gender-role traditions (Eagly & Karau, 1991; Eagly et al., 1995). Perhaps this was because some people did not like female leaders who act in a “masculine” manner or occupy leadership positions traditionally held by men (Eagly, Makhijani, & Klonsky, 1992).

A somewhat different picture of gender differences in leadership has emerged from Eagly's more recent research (Eagly, Johannesen-Schmidt, & van Engen, 2003). She found that, compared with males, female leaders are generally more likely to display a transformational leadership style. Further, women whose leadership style is transactional tend to be more encouraging than transactional male leaders. That is, the transactional female leaders tend to focus more on using rewards rather than punishments to modify group members' behaviors. In addition, and in contrast to earlier findings, Eagly's results suggest that women may be slightly more effective leaders overall than men, even though they may still face challenges in convincing some followers to accept them as legitimate authorities (Eagly, 2005; Eagly et al., 2003).

 LINKAGES (a link to Health, Stress, and Coping, p. 576)

● Groupthink

The emphasis on group decisions in most large organizations is based on the belief that a group of people working together will make better decisions than will individuals working alone. As noted in the chapter on cognition and language, this belief is generally correct; yet under certain circumstances, groups have been known to make amazingly bad decisions (Kerr & Tindale, 2004). Consider an example from 1986, when officials at the National Aeronautics and Space Administration (NASA) ignored engineers' warnings about the effects of cold weather and decided to launch the space shuttle *Challenger*. The spacecraft exploded seventy-three seconds after liftoff, killing everyone aboard. After analyzing disastrous decisions such as this one, Irving Janis (1989) proposed that they can be attributed to a phenomenon called **groupthink**. Groupthink occurs, he said, when group members are unable to realistically evaluate the options available to them or to fully consider the potential negative consequences of the option they are considering. It is particularly likely when

- **groupthink** A pattern of thinking in which group members fail to evaluate realistically the wisdom of various options and decisions.

members of a group place a higher value on reaching a decision than on being sure they have reached the best decision.

Trying to reach a consensus before a group acts is not necessarily a bad strategy. In fact, it usually produces a good decision and positive feelings about the group (Smith & Mackie, 2000). But according to Janis, the drive toward consensus is likely to produce groupthink and bad decisions when four conditions are present: (1) the consensus is not based on all the facts at hand, (2) group members all share certain biases, (3) members who disagree with the majority view are punished or even ejected from the group, and (4) the group leader puts pressure on the members to reach consensus. This last condition appeared to play a crucial role in the U.S. government's decision to support a disastrously unsuccessful invasion of Cuba by anti-Castro Cubans in 1961. Before the final decision was made, several advisers were told that President John F. Kennedy had made up his mind to support the invasion and that it was time to "close ranks with the president." This situation created enormous pressure for conformity (McCauley, 1989).

Some researchers have questioned the prevalence and dangers of groupthink (e.g., Aldag & Fuller, 1993; Park, 2000). They point out that groupthink is not the only cause of poor group decisions and that the conditions that make for groupthink don't actually create it. These conditions can even lead to good decisions (Kerr & Tindale, 2004). For example, having a strong, directive leader can sometimes improve group performance, and occasionally highly cohesive groups do quite well. But there are instances where groupthink does occur, and some researchers have worked on developing techniques to help groups avoid it (Galinsky & Kray, 2004; Kray & Galinsky, 2003).

One way to avoid groupthink is to designate someone to take the unpopular role of "devil's advocate"—to constantly challenge the group's emerging consensus and offer additional alternatives. This person forces the group to consider all the facts and every possible decision option (Janis, 1985; Risen, 1998). Another technique is to encourage the expression of diverse opinions by allowing them to be presented anonymously. The group members might sit at separate computers and type out messages about all the options that occur to them. Each message is displayed for all to see on an electronic mail system that hides each sender's identity. This procedure allows the group to discuss the options via e-mail without knowing who is saying what. Research on this technique suggests that it is effective in stimulating logical debate and making people less inhibited about disagreeing with the group (O'Brien, 1991).

LINKAGES

As noted in the chapter on introducing psychology, all of psychology's subfields are related to one another. Our discussion of how the presence of other people affects a person's motivation to perform illustrates just one way in which the topic of this chapter, social influence, is linked to the subfield of motivation and emotion (see the chapter on that topic). The Linkages diagram shows ties to two other subfields as well, and there are many more ties throughout the book. Looking for linkages among subfields will help you see how they all fit together and help you better appreciate the big picture that is psychology.

SUMMARY

Social Influence

Norms establish the rules for what should and should not be done in a particular situation. Descriptive norms indicate what most other people do and create pressure to do the same. Injunctive norms provide specific information about what others approve or disapprove of. *Deindividuation* is a psychological state in which people in a group temporarily lose their individuality, focus on the group's norms, and may engage in antisocial acts that they would not normally perform. *Social facilitation*, *social impairment*, and *social loafing* provide three other examples of how the presence of other people can affect an individual's behavior.

Conformity and Compliance

When behavior or beliefs change as the result of unspoken or implicit group pressure, *conformity* has occurred; when the change is the result of a request, *compliance* has occurred.

The Role of Norms People tend to follow the normative responses of others, and groups create norms when none already exist.

Why Do People Conform? People sometimes exhibit public conformity without private acceptance. At other times, the responses of other people have a genuine impact on private beliefs. People conform because they want to be right, because they want to be liked, and because they tend to be rewarded for doing so.

When Do People Conform? People are most likely to conform when the situation is ambiguous, as well as when others in the group are in unanimous agreement. Up to a point, conformity usually increases as the number of people holding the majority view grows larger. Persistent and unanimous *minority influence* can also produce some conformity.

Inducing Compliance Effective strategies for inducing compliance include the foot-in-the-door technique, the door-in-the-face procedure, and the low-ball approach.

Obedience

Obedience involves complying with an explicit demand, typically from an authority figure. Research by Stanley Milgram indicates that levels of obedience are high even when obeying an authority appears to result in pain and suffering for another person.

Factors Affecting Obedience

People obey someone who has certain kinds of social power. Obedience declines when the status of the authority figure declines, as well as when others are observed to disobey. Some people may be more likely to obey orders than others.

Evaluating Milgram's Studies

Because participants in Milgram's studies experienced considerable stress, the experiments have been questioned on ethical grounds. Nevertheless, Milgram's research showed that even apparently "normal" people can be influenced to inflict pain on others.

Aggression

Aggression is an act intended to harm another person.

Why Are People Aggressive? Sigmund Freud saw aggression as due partly to self-destructive instincts. More recent theories attribute aggressive tendencies to genetic factors, brain dysfunctions, and hormonal influences. Learning is also important. People learn to display aggression by watching others and by being rewarded for aggressive behavior. There are wide cultural differences in the incidence of aggression.

When Are People Aggressive? A variety of emotional factors play a role in aggression. The *frustration-aggression hypothesis* suggests that frustration can lead to aggression, particularly if cues that invite or promote aggression are present. Recent research indicates that stress and negative feelings play a major role in aggression. Arousal from sources unrelated to aggression, such as exercise, can also make aggressive responses more likely. Research in *environmental psychology* suggests that factors such as high temperature, noise, and crowding increase the likelihood of aggressive behavior.

Altruism and Helping Behavior

Human behavior is also characterized by *helping behavior* and *altruism*.

Why Do People Help? There are three major theories of why people help others. According to the *arousal: cost-reward theory*, people help in order to reduce the unpleasant arousal they experience when others are in distress. Their specific reaction to a suffering person depends on the costs associated with helping or not helping. Helping behavior is most likely when the costs of helping are low and the costs of not helping are high. Perceptions of cost are affected by the clarity of the need for help, diffusion of responsibility, and personality traits. Environmental factors also affect willingness to help. The *empathy-altruism theory* suggests that helping can be truly unselfish if the helper feels empathy for the person in need. Evolutionary theory suggests that humans have an innate tendency to help others, especially relatives, because doing so increases the likelihood that family genes will survive.

Cooperation, Competition, and Conflict

Cooperation is behavior in which people work together to attain a goal. *Competition* exists when individuals try to attain a goal while denying that goal to others. *Conflict* occurs when a person or group believes that someone stands in the way of something of value.

Social Dilemmas In *social dilemmas*, selfish behavior that benefits individuals in the short run may spell disaster in the long run if adopted by an entire group. Two kinds of social dilemmas are the *prisoner's dilemma* and *resource dilemmas*. When given a choice between cooperation and competition in a social dilemma, people often compete with one another. This is true even though they may receive fewer rewards for competing than for cooperating.

Promoting Cooperation Communication between competing parties can increase cooperation, especially if the communication is not threatening and is relevant to the situation. One of the most effective strategies for producing long-term cooperation in a prisoner's dilemma is rewarding cooperative responses with cooperation and punishing competitive responses with competitiveness.

Interpersonal Conflict In *zero-sum games*, competition is almost inevitable, because there can be only one winner.

Incompatible interests, attribution of another's behavior to unfriendly motives, faulty communication, and magnification of differences are frequent sources of interpersonal conflict. Bargaining, third-party interventions, and reminders about broader goals and shared identity are helpful procedures for managing conflict.

Group Processes

Many of the world's most important decisions are made by groups.

Group Leadership No single personality type or behavioral style always results in good leadership. *Task-oriented leaders* provide close supervision, lead by giving directives, and generally discourage group discussion. *Person-oriented leaders* provide loose supervision, ask for group members' ideas, and are generally concerned with subordinates' feelings. Transformational leaders try to inspire and motivate the group; transactional leaders tend to reward appropriate behaviors and punish inappropriate ones.

Groupthink The pattern of thinking called *groupthink* can occur when the desire to reach a group decision becomes more important than the need to reach the best decision.

SUBJECT INDEX/GLOSSARY

Key terms, which appear in **boldface**, are followed by their definitions. Entries that appear in **blue** refer to the Neuropsychology or Industrial/Organizational Psychology chapters or the appendixes.

- AA. *See* Affirmative action (AA)
- Abecedarian Project, 382
- Abilify, 677, 680
- Abnormal behavior, 589, 590
- Absenteeism**, 808, 811
- Absolute threshold** *The minimum amount of stimulus energy that can be detected 50 percent of the time*, 155–156
- Abstract thought, 472, 499
- Abuse, child. *See* Child abuse
- Acceptance, 650–651
- Accessory structures** *Structures, such as the lens of the eye, that modify a stimulus*, 108
- auditory, 108, 118
- olfactory, 134
- visual, 120
- Accidental reinforcement, 214
- Accidents, workplace**, 814–815
- Accommodation** (in cognitive development) *The process of modifying schemas when familiar schemas do not work*, 466
- Accommodation** (in eye structure) *The ability of the lens to change its shape and bend light rays so that objects are in focus*, 120, 168, 181
- Acetylcholine** *A neurotransmitter used by neurons in the peripheral and central nervous systems in the control of functions ranging from muscle contraction and heart rate to digestion and memory*, 96, 99, 268, 357, 440, 784
- Achievement motivation, 428–433, 582
- Achievement test** *A measure of what a person has accomplished or learned in a particular area*, 372, 375
- Acoustic encoding** *The mental representation of information as a sequence of sounds*, 238, 246
- Acquired immune deficiency syndrome (AIDS), 102, 423, 517, 519, 533–534, 537, 538, 542, 588, 637, 813
- Acquisition, in classical conditioning, 199, 203
- Acronyms, 273, 276
- Acrophobia, 604
- ACTH. *See* Adrenocorticotropic hormone (ACTH)
- Action potential** *An abrupt wave of electrochemical changes traveling down an axon when a neuron becomes depolarized*, 62–64, 63–67, 70, 109, 110, 123, 139
- Action tendency, 437
- Activation-synthesis theory, 346
- Active learning, 231–232
- Active listening, 651
- Actor-observer bias** *The tendency to attribute other people's behavior to internal causes while attributing one's own behavior (especially errors and failures) to external causes*, 699–700
- Actual criterion, for job performance**, 795
- Actualizing tendency** *According to Rogers, an innate inclination toward growth that motivates all people*, 572
- Acuity** *Visual clarity, which is greatest in the fovea because of its large concentration of cones*, 121, 181
- Acupuncture, 73, 144–146
- Adaptation** *The process through which responsiveness to an unchanging stimulus decreases over time*
- to changing environments, 194, 195, 200
- in sensory systems, 109, 121, 140
- Addiction** *Development of a physical need for a psychoactive drug. See also Physical dependence*
- dependence and, 352, 355, 357, 361, 635–638
- opponent-process theory and, 196
- research on, 83
- Additive color mixing, 128
- A-delta fibers, 141, 142
- ADHD. *See* Attention deficit hyperactivity disorder (ADHD)
- Adjustment disorders, 598
- Adolescence, 494–503
- AIDS in, 496
- cognitive development in, 499–501, 511
- identity in, 498–499
- moral reasoning in, 500, 501
- parenting and, 496, 497
- puberty and, 494, 497–498, 511
- sexual activity in, 496–497
- sleep patterns in, 339
- suicide in, 495, 616
- violent behavior in, 457, 497–498
- Adoption studies, 48, 378, 380, 381, 425, 565, 625, **A-3**, **A-7**
- Adrenal cortex, 100, 537
- Adrenal glands, 102, 144, 425, 523, 524, 538, 540
- Adrenaline, 96, 524, 540
- Adrenal medulla, 100, 441
- Adrenocorticotropic hormone (ACTH), 101, 524
- Adulthood, 339, 501–503. *See also* Late adulthood
- career choice, 502–503
- cognitive changes in, 503–507
- identity crisis, 501–502
- physical changes in, 503
- social changes in, 507–511
- Affect, 614
- Affection, in intimate relationships, 715–716
- Affective disorders, 598, 614, 618. *See also* Mood disorders
- Afferent neurons, 70
- Affirmative action (AA)**, 800
- Afterimages, 130
- Age-graded test items, 367
- Age regression, 347–349
- Aggression** *An act that is intended to cause harm to another person*, 18, 20, 38, 567, 569, 736–744
- alcohol and, 738
- arousal and, 489
- biological factors in, 737–738
- in childhood, 497, 512
- circumstances for, 742–744
- cognitive factors in, 20
- cultural factors in, 738–739
- defensive, 737
- emotional factors in, 742
- environmental influences on, 743–744
- frustration and, 742
- gender differences in, 491, 497
- generalized arousal and, 742–743
- genetic factors in, 406, 737–738
- instrumental**, 811, 812
- observational learning of, 226, 227
- parenting style and, 486
- pornography and, 742, 743
- punishment and, 216
- reasons for, 737–739
- serotonin and, 97
- stress and, 526
- television and, 227–229
- temperature and, 739, 743
- testosterone and, 97, 738
- video games and, 740–741
- in workplace**, 811
- Aggressive pornography, 742, 743
- Agonist** *Drug that mimics the effects of the neurotransmitter that normally binds to a neural receptor*, 351, 353, 357, 358
- Agoraphobia** *An anxiety disorder involving strong fear of being alone or away from the security of home*, 603, 605, 606, 653, 656, 669, 679, 680
- Agranulocytosis, 677
- Agreeableness, 561, 581, 756
- AI. *See* Artificial intelligence (AI)
- AIDS. *See* Acquired immune deficiency syndrome (AIDS)
- Alarm reactions, 523–524
- Alcohol, 59, 66, 78, 97, 497, **A-6**
- aggression and, 738
- anxiolytics and, 679
- as depressant, 353–355, 359
- illness and, 518, 539
- medications and, 678, 679
- memory and, 353, 636
- prenatal risks and, 398, 461, 636
- sleeping pills and, 339
- stress and, 526, 531, 546
- in substance-related disorder, 635–637
- Alcohol abuse, 635–637, 669, 696, 723
- Alcohol dependence, 635–637, 669
- Alcoholism** *A pattern of drinking that may lead to addiction and almost always causes severe social, physical, and other problems*, 272, 635–638, 683
- Alexia without agraphia**, 765–766
- Algorithm** *A systematic procedure that cannot fail to produce a correct solution to a problem, if a solution exists*, 290, 292
- ALI. *See* American Law Institute (ALI)
- Alpha waves, 336, 337, 349
- Alprazolam, 679, 680
- Altered state of consciousness** *A condition in which changes in mental processes are extensive enough that a person or others notice significant differences in psychological and behavioral functioning*, 335, 346, 347, 349–350
- Altruism** *An unselfish concern for another's welfare*, 744–752
- Alzheimer's disease, 49, 61, 394, 506–507
- background of, 80–81
- chemistry of, 96, 269
- dementia and, 80, 593, **784–785**

- diagnosis of, 82
genetic factors in, A-5–A-6
 linguistic abilities and, 506–507
 memory and, 80–82, 770, 771
 prediction of, 203, 205
 research on, 81–83
 treatment of, 82–83
- Ambiguity**
 conformity and, 728, 735
 helping behavior and, 746
- Ambivalent attachment**, 482
- American College Testing Assessment (ACT)**, 371
- American Law Institute (ALI)**, 639
- American Psychological Association (APA)**, 22, 55–56, 584, 668–670, 673, **A-4**
- American Sign Language (ASL)**, 246, 318, 319
- Amitid**, 680
- Amitriptyline**, 680
- Amnesia**, 598
 anterograde, 11, 12, 80, 270–271, 333–334, 706, 772
disorders and, 770–773
 dissociative, 612
 infantile, 475
 posthypnotic, 347
 retrograde, 271–272
- Amnesic disorders** *Neuropsychological disorders, such as anterograde amnesia, that involve memory loss, 598, 770–773, 784*
- Amphetamines**, 355–357, 359, 635, 738
- Amplitude** *The difference between the peak and the baseline of a waveform, 111–113, 118, 119, 336, 337*
- Amygdala** *A structure in the forebrain that, among other things, associates features of stimuli from two sensory modalities, 80, 95, 134, 135, 423, 771, 773*
 aggression and, 737
 emotion and, 438, 446, 707
- Amyloid plaques**, 784
- Amyloid precursor protein**, 81
- Anafranil**, 679, 680, 684
- Analgesia** *The absence of pain sensations in the presence of a normally painful stimulus, 142, 143, 145*
- Analgesics**, natural, 143–144
- Analogical representations**, 289
- Analogies**, 296–298
- Analogue studies**, 750, 751
- Anal stage** *The second of Freud's psychosexual stages, usually occurring during the second year of life, in which the focus of pleasure and conflict shifts from the mouth to the anus, 555*
- Analysis of variance, A-17**
- Analytic intelligence**, 389, 391
- Analytic psychology**, 555–556
- Ananda(mide)**, 359
- Anchoring heuristic** *A mental shortcut that involves basing judgments on existing information, 293, 294, 300, 303*
- Androgen** *A sex hormone that circulates in the bloodstream in both sexes; relatively more androgens circulate in men than in women, 99, 100, 421, 422, 425*
- Anger**
 aggression and, 353, 354, 742, 811
 autonomic activity in, 443, 444, 448
 emotional expression of, 450
- Animals**
 language and, 317–320
 in research, 55–56
- Animal Welfare Act**, 55
- Animism**, 471
- Anomia**, 784
- Anorexia nervosa** *An eating disorder characterized by self-starvation and dramatic weight loss, 418, 598*
- Anosmia**, 137
- Anosognosia**, 774–776, 785
- ANS.** *See* Autonomic nervous system (ANS)
- Antagonist** *Drug that binds to a receptor and prevents the normal neurotransmitter from binding, 351, 355, 356, 358, 422, 684*
- Anterior cingulate cortex**, 142
- Anterograde amnesia** *A loss of memory for any event that occurs after a brain injury, 11, 12, 80, 270, 271, 333–334, 706, 772*
- Antianxiety drugs**, 679–681. *See also* Anxiolytics
- Antibodies**, 537
- Antidepressants** *Drugs that relieve depression, 92, 419, 677–681, 684*
- Antipsychotics**, 677, 680
- Antisocial behavior, A-5, A-6**
- Antisocial personality disorder** *A personality disorder involving impulsive, selfish, unscrupulous, even criminal behavior, 589, 629–631, 633, 638*
- Anvil**, in ear structure, 113, 114
- Anxiety**
 anxiolytics and, 679–681
 attention and, 437
 behavior therapy for, 655
 in childhood, 634
 cognitive-behavior therapy for, 658, 660
 cognitive therapy for, 658, 659, 683
 depression and, 605, 615, 617, **A-5**
genetic factors in, A-5
 interpersonal psychotherapy for, 683
 meditation and, 349
 motivational conflicts and, 435
 self-esteem and, 691–692
 stress and, 525, 527, 530, 811
 test, 376–377, 385, 525
- Anxiety disorder** *A condition in which intense feelings of apprehension are long-standing and disruptive, 338, 589, 593, 598, 599, 603–610, 614, 615, 617, 670, 680*
 biological factors in, 606–607
 learning and, 608–609
 psychoactive drugs for, 679–681
 psychological factors in, 607
 types of, 603–609
- Anxiolytics** *Drugs that reduce feelings of anxiety, 679–681*
- Anxious-fearful cluster**, 629
- APA.** *See* American Psychological Association (APA)
- Aphasia**, 86
- Aphasias**, 780–781, 785
- Apnea**, sleep, 340, 345
- Appetite**, 355, 412–414
- Appraisal**, of stressors, 529, 536
- Approach-approach conflicts**, 435
- Approach-avoidance conflicts**, 435, 436
- Approach-inhibition theory**, 563
- Apraxia**, 782–783, 785
- Aprosodia**, 782, 785
- Aptitude test** *A test designed to measure a person's capacity to learn certain things or perform certain tasks, 371*
- Aripiprazole**, 677, 680
- Arithmetic average.** *See* Mean
- Arousal: cost-reward theory** *A theory attributing people's helping behavior to their efforts to reduce the unpleasant arousal they feel in the face of someone's need or suffering, 746–748, 752*
- Arousal** *A general level of activation that is reflected in several physiological systems, 77, 95, 96, 157, 158, 335, 337, 357*
 aggression and, 489, 742–743
 deindividuation and, 723, 724
 emotions and, 376, 446, 448
 helping behavior and, 746–748, 752
 motivation and, 407, 409–410
 optimal level of, 409, 410, 563
 pain and, 142
 presence of others and, 725
 regulation of, 409–410
 stress and, 529
- Arousal disorder**, 427
- Arousal theories** *Theories of motivation stating that people are motivated to behave in ways that maintain what is, for them, an optimal level of arousal, 409–411*
- Arteries**, 769
- Arthritis**, 102, 519
- Artificial intelligence (AI)** *The field that studies how to program computers to imitate the products of human perception, understanding, and thought, 10, 21, 70, 302, 304*
- ASL.** *See* American Sign Language (ASL)
- Asperger's disorder**, 634
- Assertiveness training and social skills training** *Methods for teaching clients how to interact with others more comfortably and effectively, 656*
- Assessment center** *An extensive set of exercises designed to determine an individual's suitability for a particular job, 793, 794, 797*
- Assimilation** *The process of trying out existing schemas on objects that fit those schemas, 466*
- Association cortex** *Those parts of the cerebral cortex that receive information from more than one sense or that combine sensory and motor information to perform complex cognitive tasks, 83, 84, 86–88, 90, 93, 110, 623*
- Associations**
 learning and, 195, 196
 memory and, 244, 254–255, 257, 261
- Associative networks**, 219
- Astringent**, 136
- Ataques de nervios**, 595
- Atherosclerosis**, 540

- Attachment** *A deep and enduring relationship with the person with whom a baby has shared many experiences*, 481–484, 507, 508
day care and, 483–484
object relations and, 556–557, 593, 649
Attention deficit disorders, 78, 400, 593
Attention deficit hyperactivity disorder (ADHD), 78, 633–634, 680
- Attention** *The process of directing and focusing psychological resources to enhance perception, performance, and mental experience*, 181–187, 335, 355
aging and, 395, 504–505
anxiety and, 437
automatic processing and, 186–187
brain and, 187
brain function and, 74, 77, 78, 90, 95
characteristics of, 182
in childhood, 473
in classical conditioning, 201
cognitive ability and, 388
covert, 182–183
directing, 184
dissociation and, 266
divided, 185–186, 185–186, 189, 506
hypnosis and, 346–347, 349
ignoring information and, 184
intelligence and, 388
schizophrenia and, 623, 627
selective, 184, 245, 246
stress and, 525
thought and, 282, 284
- Attitude** *A predisposition toward a particular cognitive, emotional, or behavioral reaction to objects*, 708–710, 714, 716, 805
changing, 703–706
forming, 702–703
structure of, 701–707
- Attraction, 713–714
physical attractiveness and, 714
similar attitudes and, 714
- Attributes, in decision making, 305
Attributional biases, 699–700
Attributional style, 620
- Attribution** *The process of explaining the causes of people's behavior, including one's own*
biases in, 699–700
cultural factors in, 698
emotions and, 447, 449
interpersonal conflict and, 755
sources of, 697–698
- Atypical neuroleptics, 677
Audition. *See* Hearing
Auditory cortex, 84, 86, 90, 110, 115, 118, 133, 272
- Auditory nerve** *The bundle of axons that carries stimuli from the hair cells of the cochlea to the brain*, 109, 110, 113–115, 117, 118, 146
- Authoritarianism, 708, 734
- Authoritarian parents** *Firm, punitive, and unsympathetic parents who value obedience from the child and authority for themselves*, 381, 485–487
- Authoritative parents** *Parents who reason with the child, encourage give and take, and are firm but understanding*, 486–487, 493
- Authority figures, 734–736
Autism, 593, 634, 657
Autistic disorder, 598, 634
Autistic spectrum disorders, 634
Auto accidents, 354
- Autoimmune disorders** *Physical problems caused when cells of the body's immune system attack normal body cells as if they were foreign invaders*, 102
- Autokinetic phenomenon, 727
Automatic processing, 186–187
- Autonomic nervous system (ANS)** *The subsystem of the peripheral nervous system that carries messages between the central nervous system and the heart, lungs, and other organs and glands*, 68–69, 102, 630
amphetamines and, 356
consciousness and, 333
emotions and, 438, 439–441, 443–446
nicotine and, 357
stress and, 523–524, 537–538, 607
vestibular sense and, 146
- Autonomic reactivity, 540
- Autonomous work teams (AWTs)** *Self-managed employee groups that do not report to anyone for routine daily supervision*, 816–817
- Availability heuristic** *A mental shortcut through which judgments are based on information that is most easily brought to mind*, 294–295, 303, 306
- Aversion conditioning** *A method that uses classical conditioning to create a negative response to a particular stimulus*, 654, 655
- Aversion therapy, 655, 657–658
Aversive racism, 711–713
Aviation psychology, 187–188
Avoidance-avoidance conflicts, 435
- Avoidance conditioning** *A type of learning in which an organism responds to a signal in a way that prevents exposure to an aversive stimulus*, 207–209, 218
- Avoidant attachment, 482
Avoidant personality disorder, 629
Axes, 597, 598
- Axon** *A neuron fiber that carries signals from the body of a neuron out to where communication occurs with other neurons*, 62, 63, 65–67, 69–71, 73, 78, 91, 92, 96, 97, 109, 110, 113, 115, 122–125, 135, 138, 139, 141, 269, 440
- Babbling** *The first sounds infants make that resemble speech*, 314
- Baby talk, 463, 479
Backward conditioning, 200
Baclofen, 356
Balance, sense of, 146, 147
Balanced bilinguals, 317
Balanced relationships, 714, 716
Barbiturates, 355, 359, 635, 679
Bargaining, 755
Bariatric surgery, 417
BAS. *See* Behavioral approach system (BAS)
Basal ganglia, 438
Basal nucleus, 85
- Basilar membrane** *The floor of the fluid-filled duct that runs through the cochlea*, 113, 114, 117
- B-cells, 102, 537, 538
Bed nucleus of the stria terminalis (BnST), 422
Bed-wetting, 598
- Behavioral approach** *An approach to psychology emphasizing that human behavior is determined mainly by what a person has learned, especially from rewards and punishments*, 19–20, 22
to learning, 220, 223
to personality, 567, 570
to psychology, 653–660
to treatment, 661, 664
- Behavioral approach system (BAS), 563
Behavioral coping strategies, 546, 547
Behavioral dependence, 635
Behavioral family therapy, 669
- Behavioral genetics** *The study of the effect of genes on behavior*, 46–49, 426, 563–566, 625, A-1–A-8
Behavioral inhibition system (BIS), 563
Behavioral marital intervention, 663
Behavioral marital therapy, 669
Behavioral medicine, 517
Behavioral signatures, 569
Behavioral stress responses, 526
[Behavior-focused rating forms](#), 797
Behaviorism, 16, 17, 19, 220, 327, A-3
- Behavior modification** *Treatments that use operant conditioning methods to change behavior*, 654
- Behavior therapy** *Treatments that use classical conditioning principles to change behavior*, 653–660, 669, 670
cognitive-behavior therapy as, 658–660
techniques of, 654–658
- Belief bias, 291
[The Bell Curve \(Herrnstein & Murray\)](#), A-4
Belongingness, 433, 434, 574
Benzedrine, 355
Benzodiazepines, 679–682, 684
Beta-amyloid, 81–83
Beta-endorphin, 523
- Bias
attributional, 699–701
confirmation, 32, 291–292, 300–301
in decision making, 306–307
[employee selection interviews and](#), 794
experimenter, 41, 43, 43–44, 319–320, 631
in heuristics, 294
in IQ tests, 372, 375–376, 384–386

- Nonverbal communication
culture and, 24
- Noradrenaline, 96, 524, 540
- Norepinephrine** *A neurotransmitter involved in arousal, as well as in learning and mood regulation*, 96–97, 99, 344, 345, 355, 356, 440, 441, 607, 619, 678, 684
- Norm** *A description of the frequency at which particular scores occur, allowing scores to be compared statistically*
- in intelligence tests, 372
- in neuropsychological tests, 763
- in personality tests, 580
- Normal curve, A-12–A-13
- Normal distribution** *A dispersion of scores such that the mean, median, and mode all have the same value. When a distribution has this property, the standard deviation can be used to describe how any particular score stands in relation to the rest of the distribution*, 371, A-12–A-13
- Norms** *Socially based rules that prescribe what people should or should not do in various situations*
- norm violation, 590
- social, 589, 590, 722–723, 745–746
- subjective, 701–702
- Nose, 134
- Note-taking, 275–276
- Novelty-seeking, 410
- Nuclei** *Collections of nerve cell bodies in the central nervous system*, 69, 95
- Null hypothesis** *The assertion that the independent variable manipulated by the experimenter will have no effect on the dependent variable measured by the experimenter*, A-10
- Nun Study, 506–507
- Obedience** *Changing behavior in response to a demand from an authority figure*, 381, 731–736
- factors affecting, 732–734
- Milgram's studies of, 734–736
- Obesity** *A condition in which a person is severely overweight, as measured by a body-mass index greater than 30*, 83, 97, 413, 414, 416–418
- Object, 649
- Objective measures, of job performance**, 796
- Objective personality tests** *Tests containing direct, unambiguous items relating to the individual being assessed*, 580–582, 584
- Objective tests, 372
- Object permanence** *The knowledge that objects exist even when they are not in view*, 467–468, 474
- Object relations theory, 556, 594, 620, 667
- Object relations therapy, 649
- Object superiority effect, 178
- Observational learning** *Learning how to perform new behaviors by watching others*, 225–226, 479, 608–609, 653–654, 739
- Observer ratings, 579
- Obsessions, 606, 607
- Obsessive-compulsive disorder (OCD)** *An anxiety disorder involving repetitive thoughts and urges to perform certain rituals*, 598, 603, 606, 607, 614, 656, 669, 679, 681
- Obsessive-compulsive personality disorder, 629
- OCB. *See* Organizational citizenship behavior (OCB)
- Occipital lobes, of brain, 83, 84, 91, 125, 133
- Occlusion cue, in depth perception, 166
- Occupational health psychology** *A field concerned with psychological factors that affect the health, safety, and well-being of employees*, 812–818
- Occupational Information Network (ONET), 792
- Occupational Safety and Health Administration (OSHA), 812–813
- Odd-eccentric cluster, 628
- Odor. *See* Olfaction
- Odortypes, 136
- Oedipus complex** *A pattern described by Freud in which a boy has sexual desire for his mother and wants to eliminate his father's competition for her attention*, 555
- Oedipus Rex (Sophocles), 555
- Olanzapine, 677
- Olfaction** *The sense of smell*, 133–136
- Olfactory bulb** *A brain structure that receives messages regarding olfaction*, 134, 135, 138
- ONET. *See* Occupational Information Network (ONET)
- One-word stage** *A stage of language development during which children tend to use one word at a time*, 315
- Openness, to experience, 561, 581
- Operant** *A response that has some effect on the world*, 207
- Operant behavior, 210–214
- Operant conditioning** *A process through which an organism learns to respond to the environment in a way that produces positive consequences and avoids negative ones*, 16, 205–219
- applications of, 217–219
- attitude formation and, 703
- background of, 205–206
- in behavior therapy, 653–654, 657
- components of, 206–210
- as educational technique, 230
- effect of reinforcers and, 214–215, 218
- in family therapy, 662

- Speech spectrograms, 313
- Speed, 355–356
- Speed-accuracy tradeoff, 283
- Spinal cord** *The part of the central nervous system within the spinal column that relays signals from peripheral senses to the brain and conveys messages from the brain to the rest of the body*, 60, 62, 66, 71, 77, 87, 91, 109, 139–143, 147, 438, 443, [1215](#)
function of, 70, 71
injury to, 93
- Spleen, 102
- Split-brain studies, 87–89
- Split-half method, 373
- Spontaneous generalization** *The reappearance of the conditioned response after extinction and without further pairing of the conditioned and unconditioned stimuli*, 199, 258
- Spontaneous recovery** *The reappearance of the conditioned response after extinction and without further pairings of the conditioned and unconditioned stimuli*, 198–199, 207
- Sport psychologists** *Psychologists who explore the relationships between athletic performance and such psychological variables as motivation and emotion*, 8, 170
- Spreading activation** *A principle that explains how information is retrieved in semantic network theories of memory*, 255
- SRRS. *See* Social Readjustment Rating Scale (SRRS)
- SSRIs. *See* Selective serotonin reuptake inhibitors (SSRIs)
- Stage fright, 604
- Stammering, 683
- Standard deviation (SD)** *A measure of variability that is the average difference between each score and the mean of the data set*, 50–51, 53, [A-11](#), [A-12](#), [A-13](#), [A-15](#)–[A-17](#)
- Standard score** *A value that indicates the distance, in standard deviations, between a given score and the mean of all the scores in a data set*, [A-13](#)
- Stanford-Binet** *A test for determining a person's intelligence quotient, or IQ*, 367–369, 374, 387
- Stapes, in ear structure, 113, 114
- State-dependent memory** *Memory that is aided or impeded by a person's internal state*, 253, 254
- State of consciousness** *The characteristics of consciousness at any particular moment*, 334–335
- State theory** *A theory that hypnosis is an altered state of consciousness*, 346
- Statistical analyses, 49–53, [A-10](#)–[A-17](#)
- Statistical infrequency, 590
- Statistically significant** *A term used to describe research results when the outcome of a statistical test indicates that the probability of those results occurring by chance is small*, 53, 667–668, [A-15](#), [A-17](#)
- STDs. *See* Sexually transmitted diseases (STDs)
- Stem cells, 92
- Stepping reflex, 463
- Stereotypes** *False assumptions that all members of some group share the same characteristics*, 241, 331, 602, 707–713
- Stereotype threat, 376–377
- Stevens's power law, 162
- Stimulant** *Psychoactive drug that has the ability to increase behavioral and mental activity*, 353, 355–357, 359, 635
- Stimulus control, 209–210, 219, 340
- Stimulus discrimination** *A process through which individuals learn to differentiate among similar stimuli and respond appropriately to each one*, 200, 203, 207, 209–210
- Stimulus generalization** *A phenomenon in which a conditioned response is elicited by stimuli that are similar but not identical to the conditioned stimulus*, 199–200, 203, 207, 210
- Stimulus-response compatibility, 283, 284
- Stirrup, in ear structure, 113, 114
- STM. *See* Short-term memory (STM)
- Stomach, 412, 419
- Storage** *The process of maintaining information in memory over time*, 238
in long-term memory, 250–251
in short-term memory, 246–247
