A third cell (the *water cell*) responds best to plain water (although a very dilute salt concentration is necessary for recording). The response of the water cell diminishes with increasing concentration of any dissolved substances. Some sensilla have a fourth cell termed the *deterrent cell*, which responds to deterrent alkaloids as well as to very high salt concentrations. (The deterrent cell is sometimes called the *bitter cell*, by imperfect analogy with bitter taste in mammals.)

The molecular mechanisms of insect taste transduction are diverse and not completely clear. Responses to sugars and to bitter substances are probably mediated by receptor proteins with seven transmembrane segments. In *Drosophila* a large family of proteins has been described, the genes for which are specifically expressed in the taste bristles. This family of protein molecules (called GR, or gustatory receptor, proteins) comprises 68 proteins in several subfamilies, which are selectively expressed in genetically predetermined places such as on the labellum of the proboscis. A single gustatory receptor cell expresses the genes for several receptor proteins, but with genes for different groups of proteins expressed in different cells. In some cells, receptor proteins of one subfamily appear to mediate taste of sugars, and in different cells the proteins of another subfamily detect deterrent compounds, that is, compounds that signal repulsion from the stimulus. A third subfamily of receptor proteins is implicated in detecting attractive and inhibitory pheromones in courtship. (GR proteins are unrelated to G protein-coupled receptors [GPCRs], and their N-terminal and C-terminal ends are on opposite sides of the membrane from GPCRs.) Their mechanism of action is not clear but may be ionotropic. Mechanisms of detecting salt and water are probably ionotropic (as for mammals; see below) but are little understood.

Taste in mammals is mediated by receptor cells in taste buds

Vertebrate taste receptor cells are epithelial sensory cells that synapse onto terminals of cranial sensory neurons, which then carry the signals to taste centers in the brain. The taste cells are grouped together on the tongue and back of the mouth in **taste buds**. In mammals, the taste buds of the tongue are confined to small swellings known as **papillae** (Figure 14.15a), of which there are three kinds: the *fungiform papillae* near the front of the tongue, the *foliate papillae* on the lateral borders, and the large *circumvallate papillae*, which are at the very back and easily seen with the naked eye. The taste buds are located within the papillae, with only a few on a single fungiform papilla but with thousands on a single circumvallate papilla (Figure 14.15b).

All taste buds have a similar structure (Figure 14.15c). Each includes 50 to 150 slender, elongate cells of at least four types that differ in morphology and staining properties. Until recently investigators thought that only one of these cell types (type III) was a mature taste receptor, since it was the only type that made defined synapses with taste sensory neurons. Recent studies, however, show that types I, II, and III taste cells all mediate different taste qualities. Type IV cells (basal cells) are round, basally located, and serve as precursors to new taste receptor cells. Studies with markers of cell division such as bromodeoxyuridine (BrdU) have shown that individual taste receptor cells have lifetimes of only about 5 to 10 days and that they are constantly being replaced by new receptor cells derived from the basal cells.

Mechanisms of taste transduction differ for different taste qualities. In mammals, including humans, there are five distinct categories of tastes: the familiar sour, salty, sweet, and bitter and the more recently characterized *umami* (from a Japanese word meaning “delicious”), which is the taste of monosodium glutamate and aspartate, common in proteinaceous food. These five tastes and their distinct transduction mechanisms appear to be separately localized in different taste receptor cells. Two of these mechanisms

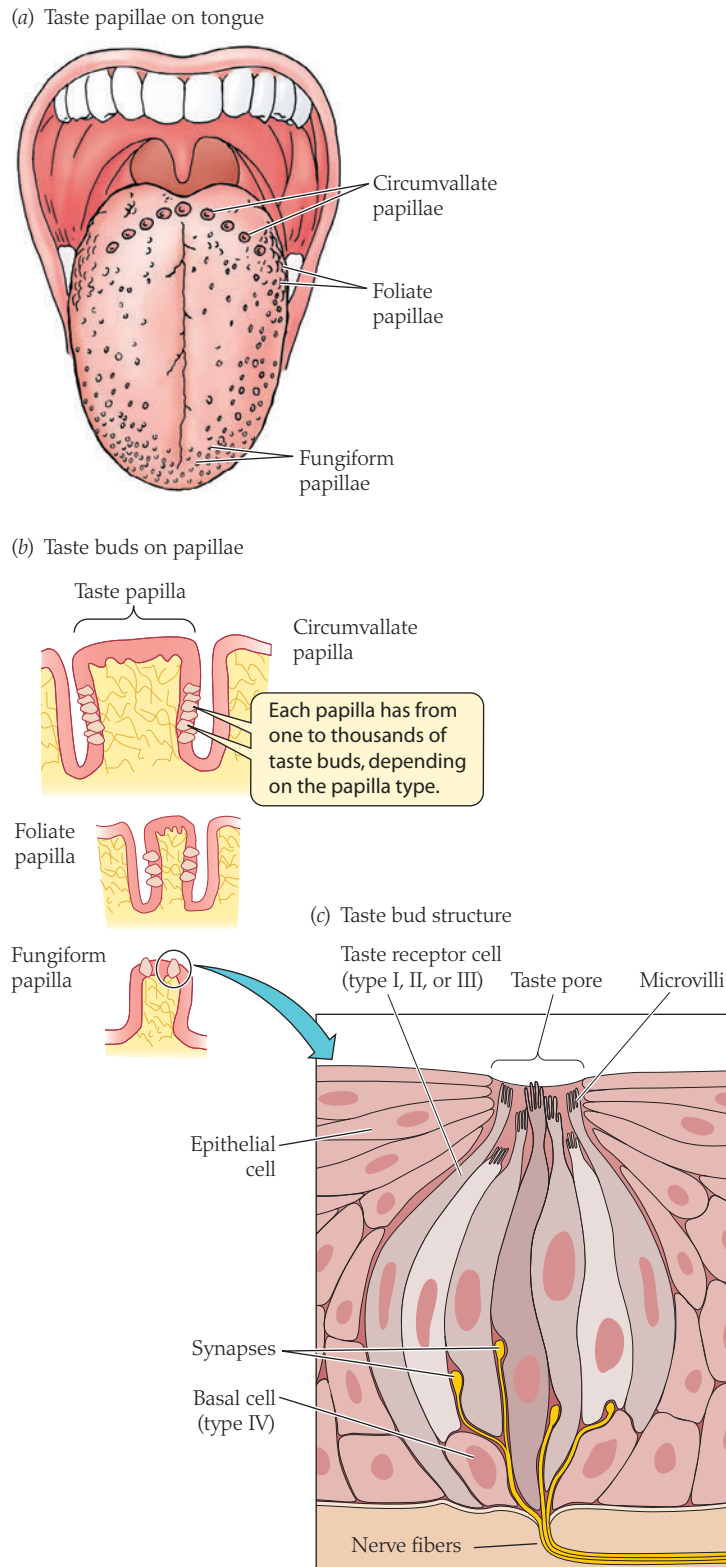

FIGURE 14.15 Mammalian taste buds (a) Taste buds are localized at taste papillae on the tongue. (b) Different kinds of taste papillae contain differing numbers of taste buds. (c) A taste bud contains many taste cells of different types; some form discrete synapses onto afferent sensory neurons. The taste cells of a taste bud extend microvilli through a taste pore to contact saliva. Receptor molecules in the microvillar membrane are exposed to taste stimuli at the surface of the tongue. (c from Kandel et al. 2000.)

are ionotropic (for salty and sour), and the remaining three are metabotropic, mediated by GPCRs.

The simplest transduction scheme is for salty taste (Figure 14.16). Here the taste receptor cells have channels permeable to Na^+ . When the Na^+ ion concentration within the mouth increases, the membrane potential of a salt receptor cell depolarizes. The reason can be seen from the Goldman equation (see page 308): Any increase in external concentration of permeable Na^+ ions will cause a positive change in membrane potential. The Na^+ channels of taste receptor cells are not voltage-gated and are unrelated to the voltage-gated Na^+ channels of axons. In some species they can be blocked by the compound amiloride and seem to be related to the voltage-independent Na^+ channels of the kidney. Sensation of salt by a direct, ionotropic permeability to Na^+ would seem an insensitive mechanism for salt sensation, because a fairly large increase in Na^+ ion concentration would be required to produce a depolarization. However, salt taste *is* insensitive: For a food to taste salty, the concentration of NaCl must be of the order of 50 millimolar (mM), a relatively high level.

The sour taste of acidity is also mediated by a channel (see Figure 14.16). Recent experiments have shown that the channel is probably formed from two members of the polycystic kidney disease–like ion channel subfamily (PKD1L3 and TRPP3, also known as PKD2L1). Both of these channel subunits are expressed together in a distinct subset of taste receptor cells. In mice, when the gene for TRPP3 is knocked out so that this protein is no longer expressed, the mice have no reaction to sour stimuli, even though responses to the other four classes of taste stimuli are unaffected. It is unlikely that the channels formed by interaction of these proteins function simply by being permeable to H^+ and depolarizing the membrane as described by the Goldman equation, because H^+ is normally too low in concentration to adequately depolarize the receptor cell by this means. Instead, H^+ may modulate the permeability of the channels to more numerous cations.

The other three tastes are all sensed by metabotropic GPCRs (see Figure 14.16). The receptor for sweet is apparently a dimer of two related receptor molecules called T1R2 and T1R3. Both of these membrane proteins have large, extracellular amino terminal regions, which probably together form the binding site for the sugars. Umami is sensed by a similar dimer, of T1R3 and another related protein, T1R1. The T1R3 receptor is therefore common to both the sweet- and umami-sensing cells, whereas the T1R2 and T1R1 receptors are expressed in different cell populations, indicating that different groups of taste bud cells mediate the sweet and umami flavors. The T1R2 and T1R3 proteins seem to be the only GPCRs required for sweet taste, as shown by knockout experiments. When the genes for T1R2 and T1R3 are both knocked out in mice, the ability of the mice to detect sweet compounds disappears, and similar experiments show that T1R1 and T1R3 are required for the detection of amino acids (umami).

The family of GPCRs that sense bitter compounds is much larger and more disparate in amino acid sequence than those that sense sweet or umami, probably because we sense as bitter a much greater variety of chemical compounds with differing structures. The receptor molecules are nevertheless related to one another and form the T2R family of GPCRs, which has approximately 30 members. The T2R receptors are expressed in a unique population of taste bud cells that do not also express any of the T1R receptors.

FIGURE 14.16 Taste-transduction mechanisms differ for different tastes The molecules for reception and transduction of different taste qualities are localized in different taste cells. Type I cells mediate salt taste, type III cells mediate sour taste, and separate subpopulations of type II cells mediate sweet, umami, and bitter taste. For salt taste, sodium ions enter a taste bud cell through cation channels, directly depolarizing the cell. Sour taste is mediated by a channel (a complex of a TRP channel protein [TRPP3] and a related protein, PKD1L3). Sweet,

umami, and bitter responses are mediated by GPCRs. Their signal transduction effects are similar to each other but occur in different cells. In sweet taste, sugars bind to a particular dimer of GPCRs (T1R2 and T1R3), which acts via a G protein to activate phospholipase C to produce IP₃; IP₃ releases Ca²⁺ from intracellular stores to activate a TRP channel. In the taste quality umami, glutamate (monosodium glutamate [MSG]) and other amino acids stimulate another GPCR dimer. Bitter substances bind to a different family of GPCRs (the T2R family).

The different bitter receptor molecules, however, do not seem to be expressed in distinct cell populations. Rather, a single “bitter” taste cell seems able to express many or most of the T2R receptor types, which may account for our limited ability to distinguish between different bitter compounds.

The signal transduction cascades for sweet, umami, and bitter all seem to use similar G proteins, which activate a phospholipase C, producing the two second messengers IP₃ and diacylglycerol

(DAG; see Figure 13.21). The IP₃ leads to release of Ca²⁺ from intracellular stores, which opens yet another TRP channel in the outer cell membrane (called TRPM5). In mice, knocking out the genes for either the phospholipase C or TRPM5 produces major deficits in the sensing of sweet, umami, and bitter but leaves the sensing of salty and sour entirely intact. This shows again that the metabotropic mechanisms of detection in the tongue are independent of the ionotropic mechanisms.

Because single taste bud cells seem to contain only one of the kinds of channels or GPCR combinations shown in Figure 14.16, the transduction of taste would appear to be segregated into separate cell populations distributed throughout the tongue. These cells make synapses onto the cranial sensory neurons, which carry their signals into the brain. Recent studies indicate that some of the synaptic interactions between taste cells and sensory neurons are diffuse and perhaps indirect, via other taste cells. Perhaps for this reason, recordings from single cranial axons and from single CNS taste neurons often reveal sensitivities to more than one taste. These observations have spawned many theories about how axons with multiple sensitivities can mediate our distinct sensations of salty, sour, sweet, bitter, and umami.

Recent experiments indicate that processing in the CNS somehow segregates the signals of the different taste responses despite their apparent mixing at the level of the cranial nerve fibers. It is possible to induce in a mouse the expression of the gene for a novel GPCR, which is activated by a compound that is normally tasteless. With the novel GPCR, the mouse can taste this compound; the taste is sensed as sweet if the novel receptor is directed to be expressed in the taste bud receptor cells that normally express T1R2 receptors (the “sweet” taste bud cells), or the taste is sensed as bitter if expressed in cells that normally express T2R receptors. Thus even if single cranial nerve axons transmit signals from more than one type of cell, the CNS sorts these signals to produce distinct sensations, which seem to depend entirely on which taste bud receptor cells have been stimulated. Some taste neurons in the brain respond to many taste qualities, whereas others are more selective to one taste, leading to ongoing questions about how the coding and decoding of taste information works.

SUMMARY Chemoreception and Taste

- Most animals possess two types of chemoreceptors for external stimuli: contact or taste chemoreceptors that respond to near-field chemicals at relatively high concentrations, and distance or olfactory chemoreceptors that respond to low concentrations of chemicals from sources over a larger area. This generalization is useful but oversimplifies a greater diversity of external chemical senses, as well as internal chemoreceptors involved in homeostatic regulation.
- Taste chemoreceptors of mammals monitor five taste qualities: sweet, sour, salty, bitter, and umami. Insects have taste sensilla that provide at least analogous information.
- Transduction mechanisms of chemoreceptors are diverse, both within an animal and across animal phyla. Taste sensory transduction in mammals may involve ionotropic activation of ion channels (salty, sour) or G protein-coupled receptors (sweet, bitter, umami).

Olfaction

Some insects, such as male moths, have elaborate olfactory systems (Figure 14.17). Each pinnate antenna of a male hawkmoth (*Manduca sexta*) contains an estimated 360,000 olfactory receptor cells, and each antenna of a male polyphemus moth (*Antheraea polyphemus*) (shown in the figure) has about 260,000. Such numbers represent a

substantial fraction of the neurons in the insect’s nervous system, and represent a large energy investment.

The sensilla on the antennae of insects that detect chemicals at a distance are similar in structure to the taste sensilla (see Figure 14.14a). Instead of one or a few small holes at the tip of the sensillum shaft, however, the entire shaft length is perforated by numerous tiny pores only 10 nanometers (nm) in diameter, which lead into tiny channels called *tubules* penetrating the exoskeleton. The receptor cells send thin dendritic processes into the shaft, where they are bathed in a fluid called the *sensillar lymph*. Odorant molecules enter the pores, travel down the tubules, and dissolve in the sensillar lymph. Terrestrial insects (and terrestrial mammals) have *odorant binding proteins* that help the volatile odorant molecules move into the aqueous environment surrounding the olfactory receptors. Ultimately the odorant molecules bind to olfactory receptor (OR) protein molecules on the dendrite’s cell membrane. The *Drosophila* antennal OR proteins have been identified; they are not related to classical GPCRs but rather appear to form heteromers with an ion channel protein (OR83b) in which the OR provides the odorant binding specificity and leads to fast opening of the OR83b channel. Other studies suggest that the ORs may also have a slower G protein-linked action that reinforces and prolongs their ionotropic action.

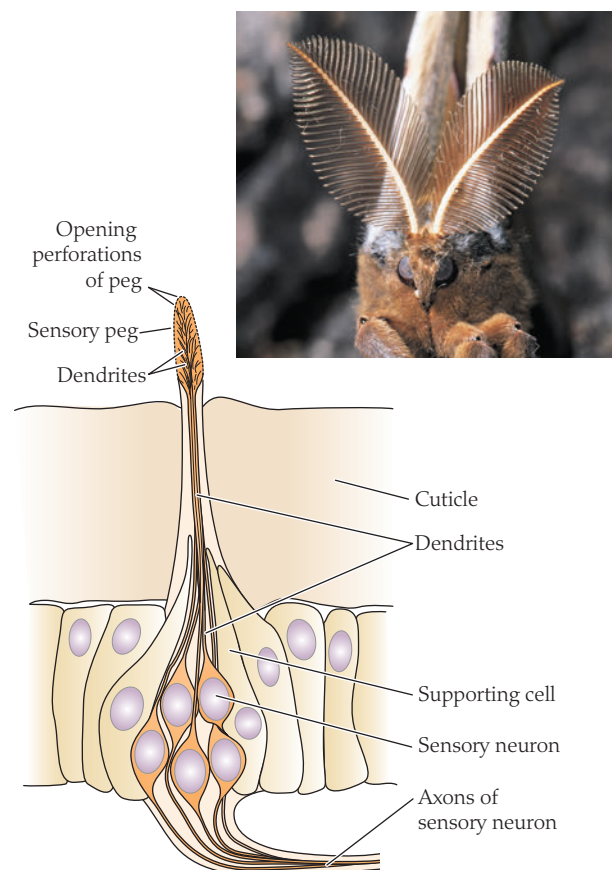

FIGURE 14.17 Insect olfactory receptors detect pheromones and other chemicals Each pinnate antenna of a male *Antheraea polyphemus* moth may have as many as 260,000 chemosensory neurons, many of which are specialized to detect a chemical signal (pheromone) released by a female moth.

Most varieties of insect olfactory receptor neurons are classed as *odor generalist cells* and are used to detect a wide variety of odors. Insects, however, have another olfactory system on their antennae, specialized to detect only a very few chemicals with high sensitivity. The chemoreceptor cells used in this system are sometimes referred to as *odor specialist cells* and are typically responsive to pheromones.

As we describe in Chapter 16 (see pages 447–448), a *pheromone* is a metabolite released into the outside world by an individual that is used for communicating with other individuals of the same species, including eliciting specific behavioral or systemic responses when detected by those individuals. Various insects have sex-attractant (and sex-deterrent) pheromones, oviposition-deterrent pheromones, trail-marking pheromones, alarm pheromones, and colony-recognition pheromones, and it is these chemicals that the odor specialist cells are programmed to detect.

Chemoreception of pheromones has been most thoroughly studied for the sex attractants of moths. Female moths release pheromones that, when detected, induce the males to fly upwind to find the females. Males are extraordinarily sensitive to the attractant released by females of their species and can respond over large distances. A female gypsy moth produces 1 milligram (mg) of disparlure, its sex attractant, an amount theoretically sufficient to attract a billion males.

In the silkworm moth (*Bombyx mori*), the first insect species for which a sex-attractant pheromone was characterized, the male has large pinnate or comblike antennae (like those of *Antheraea polyphemus* shown in Figure 14.17) with up to 50,000 sensilla responsive to the sex-attractant pheromone. Because of their pinnate branching and the density of their pheromone-sensitive olfactory hairs, the antennae of *Bombyx* males are estimated to catch up to one-third of the pheromone molecules in the air passing over them. The pheromone receptor cells are exquisitely sensitive and very specific in their responses. The major sex-attractant pheromone in *Bombyx* is bombykol, a 16-carbon unsaturated alcohol. The hair sensilla contain chemoreceptor cells specifically sensitive to bombykol, and recordings indicate that binding of one or two molecules of bombykol to a receptor cell elicits enough depolarization to generate an impulse. The threshold for the behavioral response of a male moth is reached with activation of about 200 receptor cells per second, which occurs at a phenomenally low concentration of 1000 molecules per cubic centimeter of air!

The sex-attractant detectors of a male moth are specialized to detect one or a very few compounds with exceedingly high sensitivity. This is quite different from the odor-generalist chemoreceptors, which detect a much broader range of chemicals at higher concentrations. The division of odor detection cells into odor specialists and odor generalists is also found in many mammals, which have two major olfactory systems for detecting chemicals.

The mammalian olfactory epithelium contains odor generalist receptor cells

All vertebrates have a main olfactory system, and most land vertebrates also have an accessory (vomeronasal) system. The main system's olfactory receptive surface, termed the *olfactory epithelium*, lines part of the internal nasal cavity. The area of the nasal mucosa that constitutes the olfactory epithelium varies greatly among species, being only 2 to 4 cm² in humans but 18 cm² in dogs and 21 cm² in cats. Humans have an estimated 10⁷ olfactory receptor

neurons, and dogs up to 4 × 10⁹. In contrast to this large number of olfactory neurons, a mammalian auditory nerve contains the axons of only 3 × 10⁴ neurons.

Each olfactory receptor cell is a bipolar neuron with a cell body in the olfactory epithelium (Figure 14.18). A single, narrow dendrite extends from the cell body to the mucus-covered epithelial surface and ends in a dendritic knob, which projects into the layer of mucus (secreted by supporting cells and glands). From this knob project 20 to 30 olfactory cilia, which extend and intermesh within the mucous layer. The membranes of these cilia are the sites of olfactory transduction. As with insect olfactory sensilla, odorant molecules first dissolve in the liquid of the mucus and interact with odorant-binding proteins before interacting with receptor molecules of the mammalian olfactory cilia.

The olfactory receptor cells have fine, unmyelinated axons that extend a short distance (through the cribriform plate of the ethmoid bone) to the olfactory bulb of the forebrain, where they synapse with second-order cells in the olfactory bulb. The receptor axons are typically only 0.2 μm in diameter, and are among the smallest axons in the nervous system. Olfactory receptor cells undergo continuous turnover throughout adult life, and they were the first mammalian neurons discovered to do so. The receptor cells differentiate from basal cells in the epithelium, develop dendrites and axons that connect with the second-order cells in the olfactory bulb, and have life spans of about 60 days before they degenerate.

The function of the olfactory receptor cells has been clarified by molecular genetic and physiological approaches. In the 1990s, Linda Buck and Richard Axel cloned the first of the olfactory receptor (OR) proteins. Inferring that the OR proteins would be GPCRs specifically expressed in the olfactory epithelium, they looked for olfactory proteins with sequences known to be widely shared by GPCR molecules. This led to the discovery of the first 18 members of a family of genes, now known in mice to contain nearly 1000 members and to constitute about 3% of the total number of genes in the mouse genome. For this groundbreaking work, Buck and Axel were awarded the Nobel Prize in 2004.

The OR proteins all have seven transmembrane domains like other GPCRs (see Figure 13.18), with considerable sequence variability in transmembrane regions 3, 4, and 5. These variable regions are thought to be the areas of the molecule that bind to a diverse array of odorants. Similar OR protein families are found in all vertebrates so far studied. The activation of olfactory GPCRs leads to the opening of cyclic nucleotide-gated channels to produce a receptor potential (Figure 14.19). Stuart Firestein and colleagues placed a patch pipette on the dendrite of an olfactory receptor cell from a salamander and stimulated the cell with odorant.³ The odorant bound to receptor molecules lateral to the cell-attached patch, and yet channels opened inside the patch area, showing the involvement of a second messenger. The odorant receptor molecules initiated a G protein-mediated signal cascade, producing intracellular cAMP that diffused in the cytoplasm and opened cyclic nucleotide-gated channels in the patch.

³In this cell-attached patch recording the patch pipette was sealed to the dendrite membrane, but the patch remained attached to the rest of the cell. Odor stimuli were applied to the outer face of the membrane lateral to the patch, and the sealed electrode prevented receptor molecules from diffusing in the membrane from outside the patch area to within it.

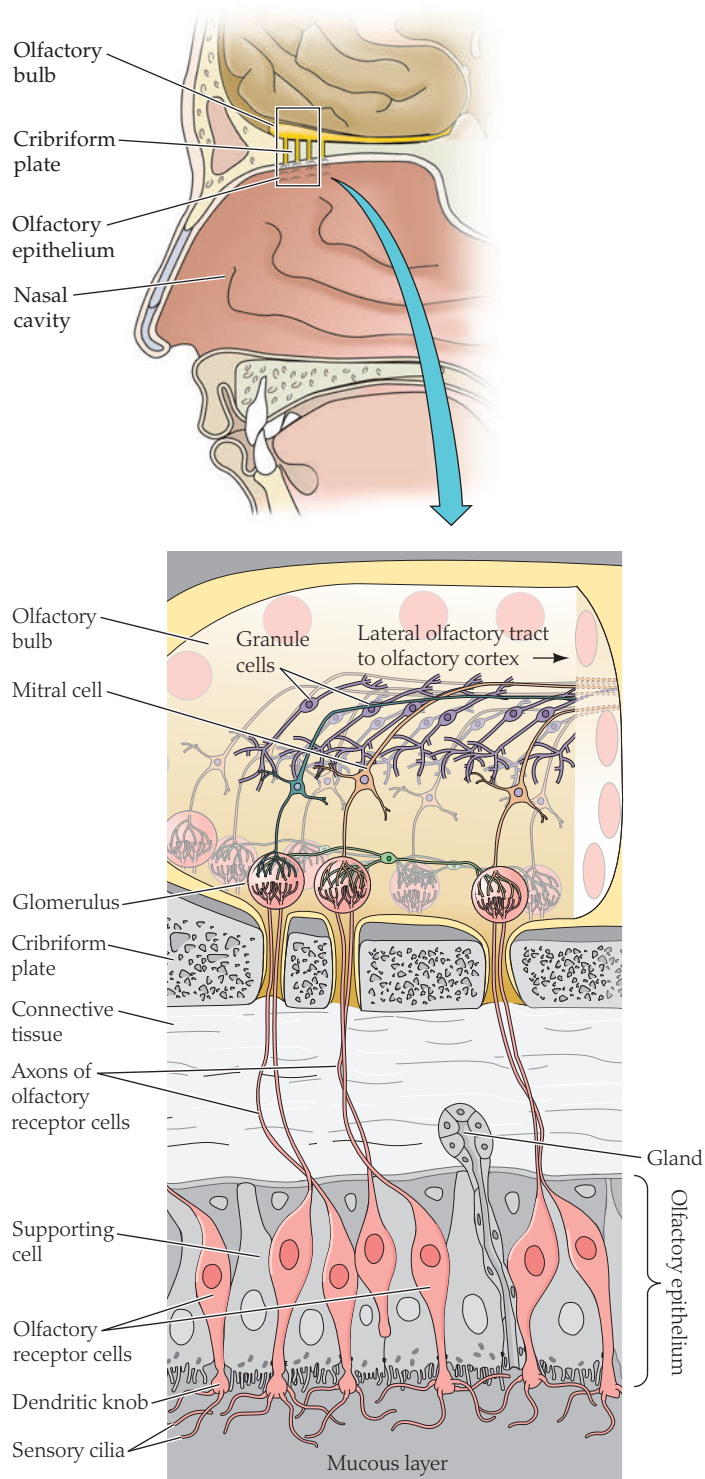

FIGURE 14.18 Vertebrate olfactory receptors Olfactory receptor cells are small bipolar neurons, the sensory cilia of which extend into the mucous layer of the nasal cavity. Their axons perforate the bone of the cribriform plate to end in glomeruli of the olfactory bulb of the brain. Mitral cells and granule cells integrate olfactory information, and the mitral cell axons carry the information to the olfactory cortex.

Figure 14.20 diagrams the signal cascade in mammalian olfactory receptor cells. The binding of an odorant to an OR protein initiates the exchange of GTP in place of GDP on the α subunit of a G protein (G_{olf}) specifically expressed in olfactory receptor cells. The $G_{\text{olf}} \alpha$ -GTP then binds to and activates an adenylyl cyclase, which synthesizes cAMP. The cAMP attaches to the cytoplasmic surface of the channel, which closely resembles a voltage-gated K^+

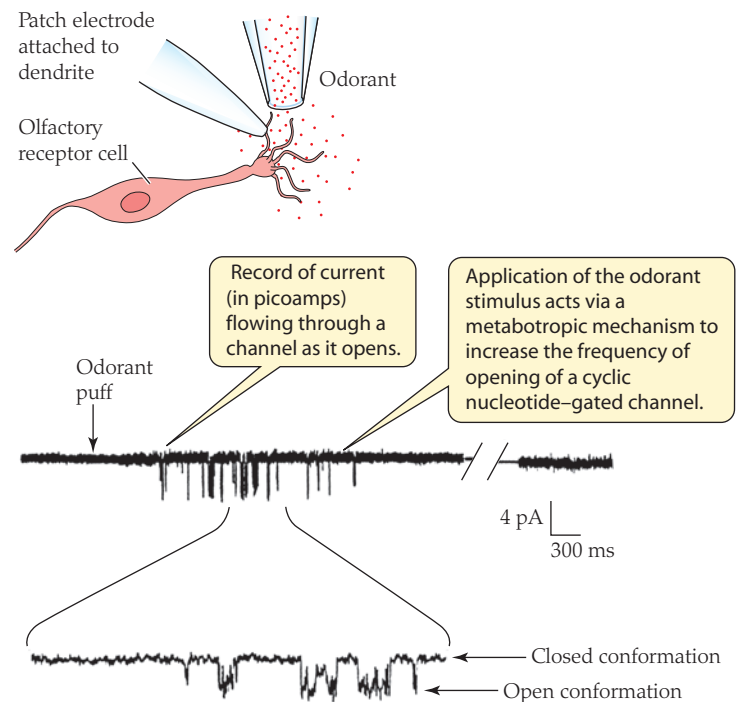

FIGURE 14.19 Odorant excitation of a vertebrate olfactory receptor cell opens individual ion channels An individual olfactory receptor cell was isolated from the olfactory epithelium of a salamander, and its response to odor stimulation was recorded with a patch electrode. The membrane patch remained attached to the cell. A brief puff of odorant led to opening of single channels in the patch, as shown by recorded single-channel currents. (After Firestein et al., 1991, in Fain 2003.)

channel in its structure but has a binding site for cyclic nucleotides near its $-\text{COOH}$ terminus (see Box Extension 12.1). The opening of the channel causes Na^+ to flow into the cell and depolarize it.

The cyclic nucleotide-gated channels are also permeable to Ca^{2+} , and the flow of Ca^{2+} into the cell stimulates the opening of a Ca^{2+} -activated Cl^- channel, causing negatively charged Cl^- to flow *out* of the cell, producing further depolarization. The outflow of Cl^- through the Ca^{2+} -activated Cl^- channels ensures that the olfactory cells will continue to respond even if the Na^+ concentration in the mucus is decreased, as can occur, for example, after immersion of the animal's head in water. When the mucus, which has high Na^+ and Cl^- concentrations relative to the receptor cell cytoplasm, is diluted by water, the concentration gradient for Cl^- favors its leaving the cell (whereas the gradient for Na^+ entry is reduced). The transduction cascade shown in Figure 14.20 is the primary cascade used by the olfactory receptor cells. Knocking out the genes for either G_{olf} adenylyl cyclase, or the cyclic nucleotide-gated channel produces mice with greatly reduced electrical responses to odorants and almost no sense of smell.

Each olfactory receptor cell expresses the gene for only one kind of GPCR. However, recordings from the receptor cells show that many cells have rather broad sensitivities to different odorant molecules. This means that many odorants can bind to one kind of receptor protein, and that any particular odorant is likely to bind to several different receptor proteins, probably with greater affinity (and at lower concentration) for some proteins than for others.

FIGURE 14.20 Olfactory transduction mechanisms in cilia membranes of olfactory receptor cells Many odorants act to increase cAMP. The odorant binds to an odorant receptor on the ciliary membrane; the receptor activates a G protein to activate adenylyl cyclase, producing cAMP. Cyclic AMP binds to and opens a cation channel, allowing entry of Na^+ and Ca^{2+} ions and depolarizing the cell. Ca^{2+} binds to Ca^{2+} -activated Cl^- channels, which permit Cl^- efflux that augments the depolarization.

Different odorants would then stimulate different *populations* of receptor cells expressing different proteins, and the combined signal from the different populations would constitute the combinatorial code for each different odorant stimulus. Such a system is likely to provide greater flexibility and adaptability than one in which each olfactory GPCR is absolutely specific for a single chemical structure. The broader binding affinities of olfactory GPCRs may also allow the olfactory system to respond to more odors than if each of the several hundred or even 1000 genes coded for proteins with narrow selectivity.

The olfactory receptor cells send their axons to the neighboring olfactory bulb in the CNS. The axon of each receptor cell terminates within a globular cluster called a *glomerulus* (see Figure 14.18). All of the receptor cells expressing a particular receptor molecule terminate in the same two or so glomeruli, so that the many receptor types are kept segregated in distinct regions of processing within the bulb. This segregation seemed puzzling at first, since if responses from many GPCRs are to be used collectively to detect distinct odors, the signals must at some point be combined and compared. Recent evidence indicates that signals from different glomeruli converge at the next level in the olfactory cortex, allowing the necessary comparison and integration.

The vomeronasal organ of mammals detects pheromones

The olfactory system we have been describing is the one that vertebrates normally use to detect airborne odors in the environment and resembles in its function the odor-generalist system of insects.

In addition, many vertebrates, including most mammals,⁴ have a second olfactory system called the **vomeronasal organ**, located below the main olfactory epithelium on each side of the nose (Figure 14.21a). The vomeronasal organ appears to function in a more odor-specialist way, detecting pheromones and other chemical signals. In mammals, each of the paired vomeronasal organs forms a self-enclosed pouch normally isolated from the air breathed through the nose. When an animal detects an unusual odor such as that associated with a pheromone, the organ pumps air into its lumen so that the air wafts over the vomeronasal receptor cells. In some reptiles, pheromones are delivered to the organ from the tongue. A snake or lizard repeatedly flicks out and withdraws its tongue to sample the air and deposit molecules such as pheromones or prey odorants onto the surface of the vomeronasal organ. The forked tongue provides two-point sampling for the detection of gradients of the concentration of chemical stimuli.

The histology of the mammalian vomeronasal epithelium is similar to that of the main olfactory epithelium, but the receptor cells have microvilli instead of cilia at their locus of transduction. The vomeronasal receptor cells in mice express about 300 genes for receptors in two families, called *V1R* and *V2R* (Figure 14.21b). These receptors are GPCRs only distantly related to the OR proteins of the primary epithelium. The *V1R* and *V2R* receptors are expressed

⁴In humans and apes the vomeronasal organ regresses during fetal development and is thought to be nonfunctional in adults. There is behavioral evidence for human detection of pheromones, but it may be via the main olfactory epithelium rather than the regressed vomeronasal organ.

FIGURE 14.21 The vomeronasal organ is an accessory olfactory organ in most terrestrial vertebrates (a) The paired vomeronasal organs lie ventral to the main olfactory epithelium (left side shown here). The axons of vomeronasal sensory neurons project to the accessory olfactory bulb, separate from the main olfactory bulb. Apical and basal parts of the vomeronasal organ have different populations of vomeronasal sensory neurons that project to different parts of the accessory olfactory bulb. (b) The apical and basal vomeronasal sensory neurons contain different GPCR families and bind different classes of chemicals, including some pheromones: Receptor molecules in apical neurons bind small-molecule pheromones, whereas receptor molecules in basal neurons bind peptide pheromones. The two kinds of GPCRs (V1R, V2R) act through different G proteins to activate phospholipase C, producing IP_3 and DAG. (Adapted from Spehr and Munger 2009.)

in separate cell types in different regions of the vomeronasal organ; the two receptor classes act via different G proteins to activate phospholipase C, producing IP_3 and DAG from PIP_2 (as in some synapses, see Figure 13.21, and in some taste receptors, see Figure 14.16). Ultimately this cascade (which may also involve generation of arachidonic acid) leads to opening of a TRP channel to depolarize the membrane of the vomeronasal receptor cell.

Preliminary recordings from neurons in the vomeronasal organ seem to show that, like the odor-specialist cells of male moths, the vomeronasal receptor cells respond specifically to one or only a few compounds with high sensitivity. They predominantly mediate responses to pheromones, which play important roles in a variety of rodent behaviors, including pregnancy block, defense and recognition of the young, mating, and intraspecific aggression. Whether pheromones also play a role in human behavior is a question still widely debated. Although most pheromonal sensory responses in mammals are mediated by the vomeronasal organ, recent rodent studies show that the main olfactory epithelium is also involved in pheromonal communication, whereas the vomeronasal organ also processes some non-pheromonal odors.

SUMMARY Olfaction

- Olfactory chemoreceptors of the main olfactory epithelium of vertebrates are neuronal receptor cells with cilia that contain intramembrane receptor proteins. Each receptor cell expresses the gene for one of these membrane receptor proteins, and all the receptor neurons that express that same protein synapse in the same glomerulus of the olfactory bulb. Insect olfactory neurons have broadly similar connection patterns but unrelated receptor proteins.
- Vertebrate olfactory receptor proteins are G protein-coupled receptors, which stimulate production of a second messenger, cAMP.
- The vomeronasal organ of vertebrates is an accessory olfactory organ that senses pheromonal and other stimuli. Vomeronasal sensory cells are microvillar rather than ciliary, and express GPCR proteins that stimulate production of IP_3 and DAG.

Photoreception

Visual systems—the systems that carry out photoreception and the processing of visual signals—have been more extensively studied and are better understood than any other sensory system. This is in part a reflection of the importance of vision in our lives, but it is also due to certain technical advantages. **Photoreceptors**—sensory receptor cells that are sensitive to light—are easier to identify, isolate, grind up, clone, and study with physiological techniques than other receptor cells. The photoreceptor protein *rhodopsin* was the first G protein-coupled receptor to be sequenced, cloned, and examined with X-ray crystallography, and the details of the G protein cascade in vertebrate photoreceptors are more fully understood than any other G protein cascade in nature. Visual processing in the brain, treated in the next section, has provided unique insight into the working of the visual cortex, which has illuminated not only the study of sensory processing but also basic mechanisms of synaptic integration in the CNS.

Photoreceptor cells and eyes of different groups have evolved similarities and differences

Photoreception—the response of a sensory cell to light—arose early in evolution. All organisms detect light by using a pigment, termed a **photopigment**, that absorbs the light. Although bacteria have several kinds of photopigments, all animals employ one dominant photopigment, rhodopsin, for photoreception. Because the photopigment is associated with cell membranes, all photoreceptor cells (light-responsive cells) have greatly increased membrane surface areas that increase their light sensitivity. Photoreceptor cells are subdivided into ciliary and rhabdomic. In **ciliary photoreceptor** cells, modified cilia contain the rhodopsin molecules. **Rhabdomic photoreceptor** cells, in contrast, have collections of microvilli that increase the membrane surface area. Vertebrate photoreceptor cells are ciliary, and arthropod photoreceptor cells are rhabdomic, but many other phyla have examples of both photoreceptor types, sometimes in the same animal.

Most animal phyla contain examples of eyes (light-responsive sense organs) that differ in type and complexity. Eyes, as noted earlier, are sense organs that contain photoreceptors mediating light responses; eyes may also form images of the visual world that provide information to allow an animal to localize and identify visual stimuli. There are two major kinds of image-forming eyes. In a **camera eye** (see Figure 1.5), a lens forms an inverted image on an array of photoreceptors at the back of the eye. In a **compound eye**, many facets called *ommatidia* (singular *ommatidium*), each with its own lens, together produce what is called a **mosaic image**—each ommatidium conveys information about one part of the visual world, and the animal’s nervous system constructs the image as a mosaic of “tiles” of individual ommatidial responses.

The evolution of eyes is a subject of considerable speculation, now informed by recent genomic studies. There is evidence that most eyes evolved from a common ancestor, despite many differences in the organization of different eyes. As stated above, all eyes employ the same kind of photopigment (rhodopsin, discussed further below). Moreover, disparate eyes share homologous genes that regulate eye development. A single gene, *PAX6*, can initiate eye development in diverse animals, and *PAX6* interacts similarly with other regulatory genes in the eye development of many phylogenetic groups of animals. It is likely that basic genetic plans for eye development and function evolved very early, but specific eye lineages (such as the camera eyes of cephalopods [squids and octopuses] and of vertebrates; see Figure 1.5) evolved separately, using parallel expressions of these developmental and functional modules. **Figure 14.22** shows one hypothesis of a common evolution of photoreceptors and eyes. A rhodopsin-based photoreceptor cell could have become a directionally sensitive prototype eye by assembly with a pigment cell that screened the photoreceptor from light on one side; this assembly may have been under control of *PAX6*. Such a prototype eye may then have evolved into other simple eyes with multiple receptor cells, and into more complex eyes with lenses. The examples shown in **Figure 14.22** include simple camera eyes (snail, scallop), more complex camera eyes (cephalopod, vertebrate), and compound eyes (ark clam, fly).

Rhodopsin consists of retinal conjugated to opsin, a G protein–coupled receptor

A photopigment consists of a protein containing an associated nonpeptide organic molecule called a *chromophore* (from the Greek meaning “color bearing”). The absorption of a photon of light by a chromophore produces a chemical reaction, and this triggers a transduction cascade.

The chromophore of animal photoreceptors is *retinal*, which is bound to an integral membrane protein *opsin*, to produce the light-sensitive pigment **rhodopsin**. **Figure 14.23a** shows the chemical structure of retinal, which is the aldehyde of vitamin A. The form of retinal used in vision in most animals, including all mammals, is 11-*cis* retinal.⁵ Investigators have identified many mammalian rhodopsins with different light-absorption spectra. Because they all use the same chromophore, the differences among rhodopsins must result mostly from differences in the amino acid composition of the opsin moiety. In all species so far investigated, the aldehyde end of retinal is covalently bound to the amino group of a lysine of the opsin protein. This bond buries the chromophore deep within the middle of the rhodopsin molecule. The structure of rhodopsin in **Figure 14.23b** shows the seven transmembrane α -helices characteristic of all G protein–coupled receptors (GPCRs), and the position of the bound retinal.

The absorption of light by 11-*cis* retinal produces a **photochemical reaction**, which twists the aldehyde tail of the chromophore around one of its double bonds and produces all-*trans* retinal (see **Figure 14.23a**). Because retinal is intimately associated with opsin, the photoconversion to all-*trans* retinal is followed by a series of spontaneous changes in conformation of opsin, producing activated rhodopsin (also called metarhodopsin II). This action induced by light is very rapid, producing activated rhodopsin in about 1 millisecond (ms).

Rhodopsin activates a G protein signal-transduction cascade, like other members of the GPCR superfamily (see Chapter 13, pages 347–349). The details of this cascade can differ in different kinds of animals and sometimes even in different photoreceptors of the same animal. We once again take as our representative examples *Drosophila* and vertebrates, including mammals.

Phototransduction in *Drosophila* leads to a depolarizing receptor potential

All insects and many other arthropods have compound eyes, which (as noted earlier) consist of many clustered cell groups called ommatidia, each ommatidium with its own lens and photoreceptors called **retinular cells** (**Figure 14.24**). The eight or more retinular cells of an ommatidium are arranged in a circle, like sections of an orange but more elongate. The transduction cascade of a retinular cell is localized to the membranes of its microvilli, which are arranged along one edge of the retinular cell in an array called a **rhabdomere**. The microvillar membranes of the rhabdomere contain not only the rhodopsin photopigment, but also the G proteins and associated proteins, including the channels that produce the electrical response to light.

⁵Insects use a slightly different 3-hydroxy-11-*cis* retinal, and some vertebrate species living in freshwater use 3-dehydro-11-*cis* retinal, with two double bonds in the ring.

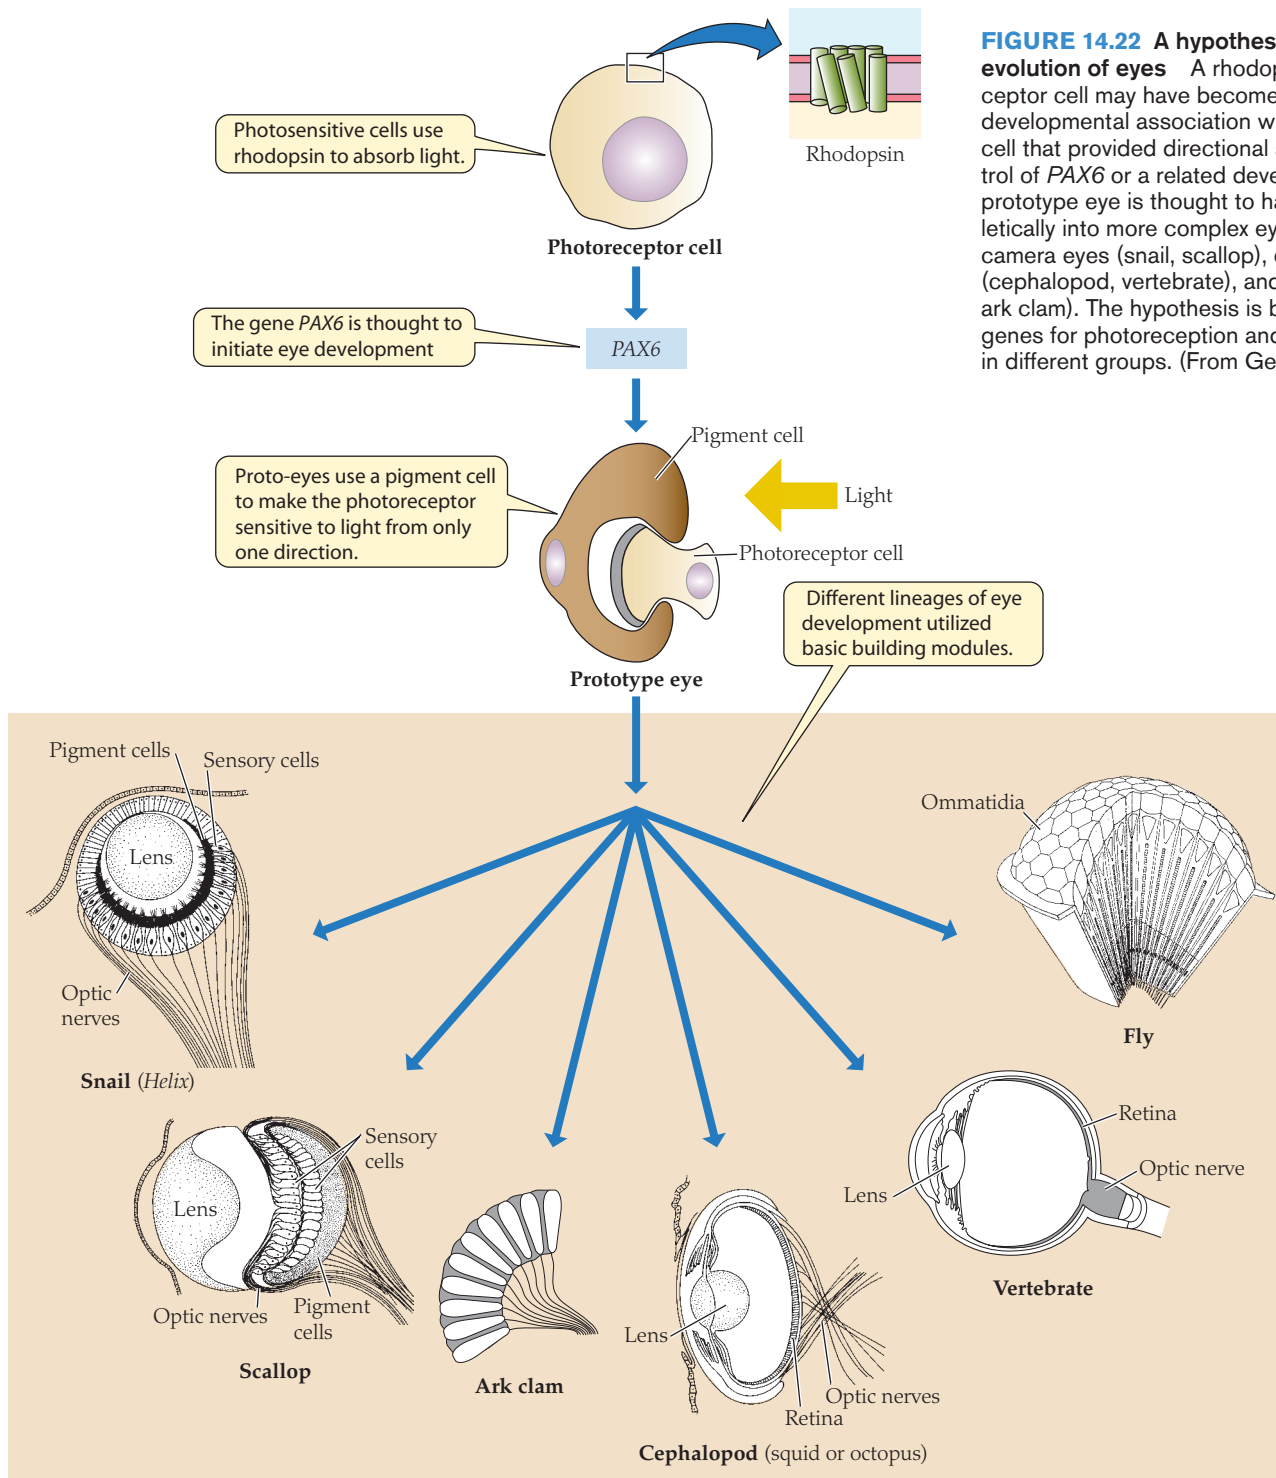

FIGURE 14.22 A hypothesis showing the evolution of eyes A rhodopsin-based photoreceptor cell may have become a prototype eye by a developmental association with a screening pigment cell that provided directional selectivity, under control of *PAX6* or a related developmental gene. The prototype eye is thought to have evolved monophyletically into more complex eyes, including simple camera eyes (snail, scallop), complex camera eyes (cephalopod, vertebrate), and compound eyes (fly, ark clam). The hypothesis is based on homologies of genes for photoreception and for eye development in different groups. (From Gehring 2005.)

Phototransduction in insects is similar at the outset to that in vertebrates (described later) but involves a different second messenger. Figure 14.24c shows the phototransduction cascade in *Drosophila* photoreceptors. Absorption of a photon causes a change in the conformation of rhodopsin, leading to activation of a G protein by exchange of GTP for GDP on the G protein α subunit. The activated G protein then activates a phospholipase C, which produces the second messengers IP_3 and diacylglycerol (DAG). DAG (or a lipid metabolite of it) is thought to directly open two cation channels, both of which are TRP channels. Opening of the cation-permeable channels produces a

depolarization, which spreads along a short axon to the photoreceptor synaptic terminal and triggers the release of synaptic transmitter. *Drosophila* photoreceptors, like most arthropod photoreceptors, do not generate action potentials.

As shown in Figure 14.24c, several of the proteins involved in photoreceptor transduction are bound together by a cytoplasmic scaffolding protein. This tight organization may minimize the time required for the interactions of the proteins of the cascade and the production of the electrical signal, thereby increasing the speed of phototransduction.

(a) Skeleton structure of retinal

(b) Rhodopsin structure

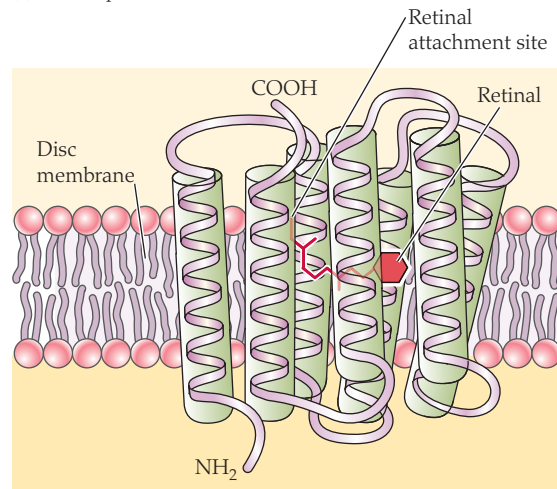

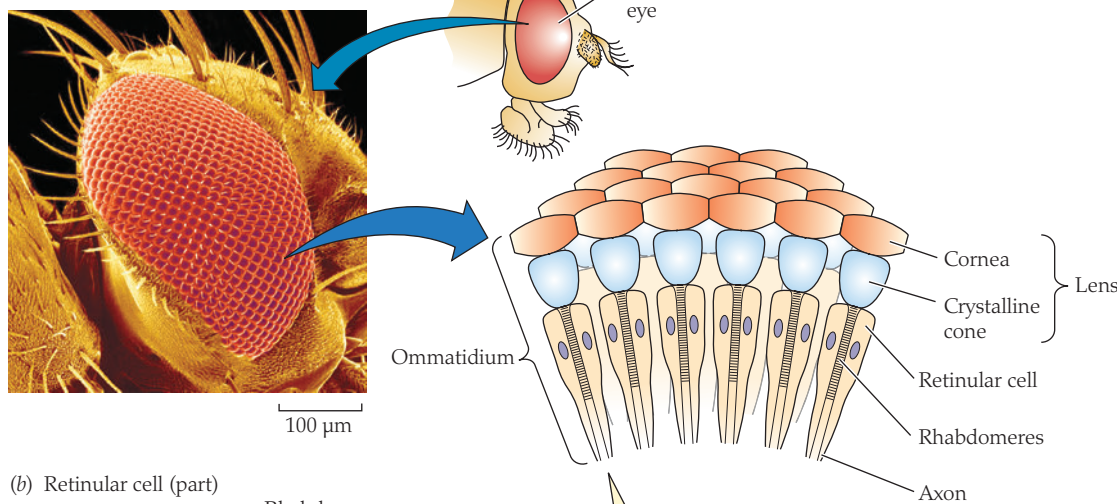

FIGURE 14.23 Rhodopsin is a photopigment composed of two parts: retinal and opsin
 (a) Skeleton chemical structure of retinal, which exists in two isomers (11-*cis* and all-*trans*). Light triggers a conformation change from 11-*cis* to all-*trans* retinal. (b) Three-dimensional structure of the protein (opsin) in vertebrate rhodopsin. Seven α -helical regions of the protein span the membrane; retinal is attached to an amino acid residue in the seventh helix. (The red retinal would actually be hidden behind the nearer helices but is shown as if it were visible through them.)

(c) Transduction of the light signal

FIGURE 14.24 Photoreceptor transduction in the compound eye of the fruit fly *Drosophila*
 (a) Scanning electron micrograph of a compound eye. Each ommatidium of the compound eye contains its own lens system and eight elongated photoreceptive reticular cells. (b) Part of one of the reticular cells; each reticular cell has a rhabdomere composed of microvilli facing the midline of the ommatidium. (c) The microvillar membrane contains rhodopsin and the other molecular constituents of the signal-transduction cascade, bound together by a scaffolding protein. Light-activated rhodopsin activates a G protein ① to activate phospholipase C ②, catalyzing the formation of IP₃ and DAG ③. These second messengers lead to opening of TRP cation channels ④.

The vertebrate eye focuses light onto retinal rods and cones

In contrast to the compound eye of insects, all vertebrates have camera eyes. In this type of eye, the cornea and lens focus an inverted image of the visual field on the **retina**, the photoreceptor-containing layer at the back of the eye (Figure 14.25a). Light is *refracted* (light rays are bent) at surfaces where materials differ

in density (quantified as the refractive index). For *terrestrial* vertebrates the greatest amount of refraction occurs at the interface between the air and the cornea, which differ greatly in refractive index and thus produce greater bending. Refraction by the lens is secondary because the lens and the aqueous humor have more similar refractive indices. Lens refraction serves primarily to focus the image by changing the shape of the lens. In the eye of *aquatic*

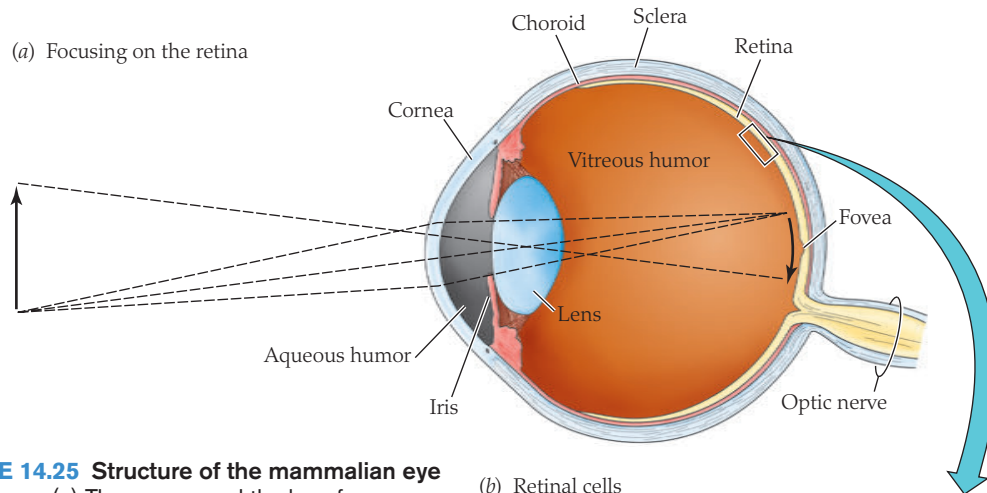

FIGURE 14.25 Structure of the mammalian eye and retina (a) The cornea and the lens focus an inverted image on the retina at the back of the eye. (b) The photoreceptors (rods and cones) are in an outer nuclear layer at the back of the retina. They are connected via bipolar cells to ganglion cells, in a "straight-through" pathway. Horizontal cells form a lateral pathway in the outer plexiform layer, and amacrine cells form a lateral pathway in the inner plexiform layer. The ganglion cells are the output of the retina, their axons forming the optic nerve. (After Dowling 1979 in Kandel et al. 1995.)

(b) Retinal cells

vertebrates, the cornea does little refraction, because its refractive index is similar to water. Instead, a thick, nearly spherical lens accomplishes most of the refraction; the refractive index of the lens is greater at its center than at its edges, thereby minimizing distortion. A spherical fish lens cannot change shape, but instead focuses by moving anteriorly and posteriorly, like a camera lens.

The retina of the vertebrate eye is a developmental outgrowth of the brain. It contains rod and cone photoreceptor cells, as well as a network of neurons—*horizontal cells*, *bipolar cells*, *amacrine cells*, and *ganglion cells*—which perform the first stages of visual integration (Figure 14.25b). A pigmented epithelium lies at the back of the retina. It absorbs light not captured by the photoreceptors and performs many important metabolic functions, including the control of the ionic environment around the rods and cones and the synthesis of 11-*cis* retinal. The retina is said to be inverted, with the photoreceptors in the outermost layer, farthest away from incoming light. This inverted structure is a consequence of the way in which the retina develops in the embryo, as the more distal layer of a two-layered optic cup.

Although light must pass through all the retinal layers to reach the outer segments of the rods and cones, the retinal layers do not degrade the image greatly because they are quite transparent. Some light scattering does occur, however, and many retinas have a central high-acuity region in which the intervening cell layers and blood vessels are displaced to the side. In humans this region is the **fovea**, a depression 1.5 millimeters (mm) in diameter (5° of visual angle) (see Figure 14.25a). The central 1° of the fovea contains tightly packed cones to the exclusion of other neurons. Rod photoreceptors are absent in this central part of the human fovea but greatly outnumber cones elsewhere in the retina. Primates and some birds have well-developed foveas, and many other vertebrates have a less elaborate and broader area of relatively high acuity called the *area centralis*.

Another consequence of the inverted retina is that the axons of retinal ganglion cells, which form the optic nerve, come off the inner side of the retina, facing the lens. The axons exit through the retina at the *optic disc*, producing a blind spot in the visual field. Humans are normally unaware of this blind spot because it falls in the binocular visual field, so that one eye supplies the information missing in the blind spot of the other eye. Moreover, we depend on the fovea for much of our high-acuity vision, and we make unconscious rapid eye movements, further decreasing any visual deficit resulting from the blind spot.

Rods and cones of the retina transduce light into a hyperpolarizing receptor potential

Figure 14.26 shows the two kinds of photoreceptors in the retina, **rods** and **cones**. The more-sensitive rods are used in dim light, and the cones are used in brighter light, for color vision, and for

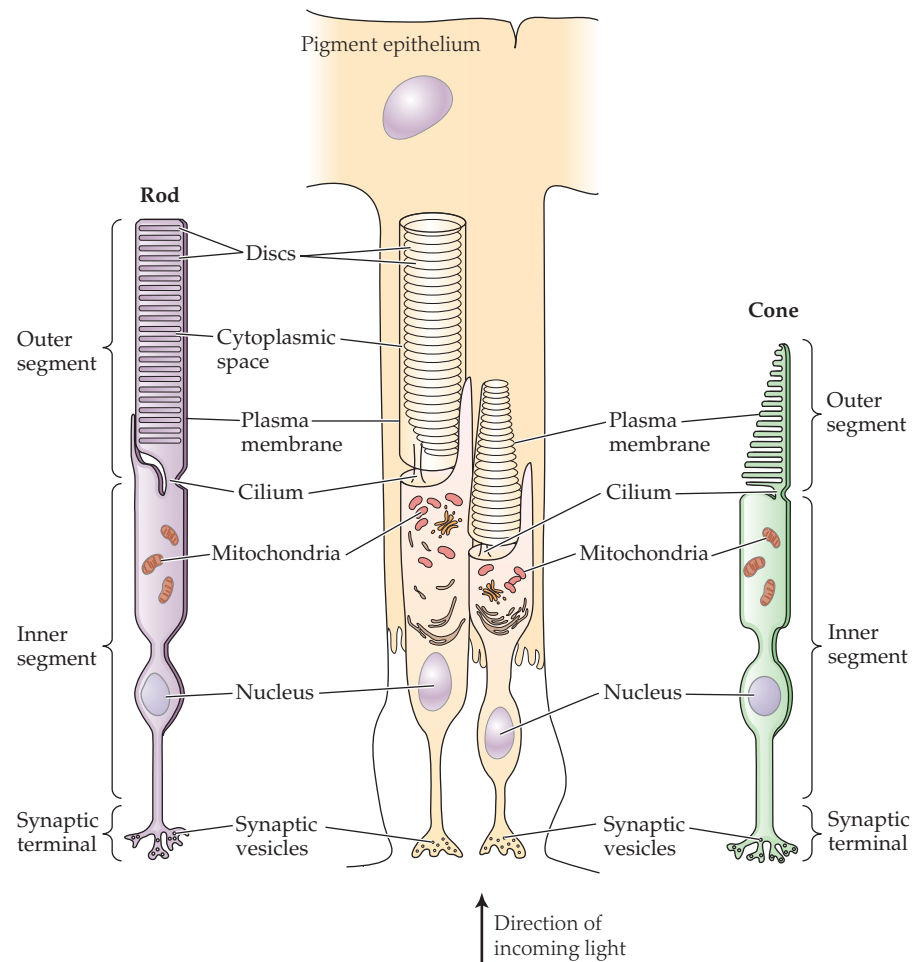

FIGURE 14.26 Vertebrate photoreceptors Both rods and cones have an inner segment that contains the nucleus and synaptic terminal, and an outer segment that contains ordered lamellae bearing photopigment molecules. In cones these lamellae are invaginations of the outer membrane, but in rods they are internalized discs that are discontinuous with the outer membrane.

high-acuity vision in humans and other animals having a fovea. Nocturnal animals tend to have retinas in which most or all photoreceptors are rods, whereas cones predominate in retinas of strongly diurnal animals. Both rods and cones have an **outer segment** containing the photosensitive membranes, and an **inner segment** containing the nucleus, mitochondria, other cell organelles, and the synaptic terminal. The inner and outer segments are connected by a short ciliary stalk, and the outer segment is derived from a modified cilium. The photoreceptor outer segments contain many flattened *lamellae* of membranes derived from the cell membrane. In the cones, these lamellae retain continuity with the outer cell membrane, so the lumen of each lamella is continuous with extracellular space. In rods, in contrast, the lamellae become separated from the outer membrane and form internalized flattened **discs** (see Figure 14.26). Several hundred to 1000 discs, stacked like pancakes, fill the rod outer segment. The membranes of rod discs and cone invaginated lamellae contain the photopigment rhodopsin. Because the disc membranes and the cell membrane are discontinuous in rods, the light-induced changes in rhodopsin at the disc membrane must somehow affect the ion permeability of the outer membrane. An electrical

change in the disc membrane will not directly affect the surface membrane because these two membranes are not in continuity. Instead, there is an *intracellular messenger* that conveys a change from the discs to the outer surface membrane. This intracellular messenger is **cyclic GMP (cyclic guanosine monophosphate, or cGMP)**; see Figure 2.30).

The transduction of light into an electrical signal in rod and cone photoreceptors has four stages: First, light activates rhodopsin; second, activated rhodopsin stimulates a G protein to activate a phosphodiesterase enzyme; third, the enzyme decreases the concentration of cyclic GMP in the photoreceptor cytoplasm; and fourth, the decrease in cyclic GMP closes cyclic nucleotide-gated ion channels similar to the channels in olfactory receptor cells. Because the photoreceptor channels close, the Na^+ influx decreases and the photoreceptor *hyperpolarizes* rather than depolarizes. Most of our knowledge of phototransduction comes from rods (which are bigger than cones), but the mechanisms are qualitatively similar for both.

Figure 14.27 shows the mammalian transduction cascade in more detail. In the dark, the cGMP concentration within a rod outer segment is relatively high. The cGMP binds to cyclic nucleotide-gated channels, opening them and thereby keeping the permeability of the outer segment membrane high for cations, including Na^+ . The cGMP-gated channels of vertebrate photoreceptors are not voltage-gated, although they are structurally and evolutionarily related to voltage-gated channels. Instead they open when they bind cGMP on the cytoplasmic surface (see Box Extension 12.1).

The light-induced change in rhodopsin activates a series of reactions at the disc membrane that result in an enzymatic degradation of cGMP. **Figure 14.27** shows this process. Light-stimulated rhodopsin (metarhodopsin II) activates the G protein **transducin**, which is closely related to the G proteins that mediate metabotropic

synaptic actions (see Figure 13.19) and chemoreception (see Figure 14.20). The activated G protein stimulates **cGMP phosphodiesterase (PDE)**, an enzyme in the disc membrane that hydrolyzes cGMP to 5'-GMP. Activation of PDE involves dissociation of its catalytic subunit from a regulatory subunit that inhibits its activity. The activated PDE decreases the cytoplasmic concentration of cGMP, and the cation channels close. Thus the second messenger-mediated response to light in a rod outer segment is decreased Na^+ influx, producing hyperpolarization.

Because the channels are relatively open in the dark, cations flow into the cell and keep it depolarized (**Figure 14.28a**). Recall from the Goldman equation in Chapter 12 (Equation 12.6, page 308) that the membrane potential depends on the ratio of permeabilities to Na^+ and K^+ . Because the resting Na^+ permeability of a rod or cone is higher than in a normal neuron, the membrane potential is less negative. In fact, the resting membrane potential of a rod or cone is about -30 millivolts (mV), much more depolarized than the resting membrane potential of a typical neuron. This constant flow of Na^+ into the cell produces a **dark current** (**Figure 14.28b**), which must be constantly counteracted by the expenditure of ATP to pump Na^+ out of the cell with a very active Na^+/K^+ ATPase located in the inner segment. This large expenditure of ATP makes the metabolic rate of a rod in darkness perhaps the highest of any cell in the body.

The dark current keeps the rod relatively depolarized. The light-induced decrease in cytoplasmic concentration of cGMP shifts the equilibrium of cGMP binding to the channel protein so that cGMP dissociates from the channel and the channel closes. The response to light is thus a decrease in the dark current (**Figure 14.28c**), which causes the membrane potential to become more negative, producing a hyperpolarizing receptor potential that is graded according to the intensity of the light flash (see Figure 14.28a).

FIGURE 14.27 Phototransduction closes cation channels in a rod outer segment In the dark, the cation channels are kept open by intracellular cGMP; they conduct an inward current, carried largely by Na^+ . When light strikes the photoreceptor, these channels are closed by a G protein-coupled mechanism. ❶ Rhodopsin molecules in the

disc membrane absorb light and are activated. ❷ The activated rhodopsin stimulates a G protein (transducin), which in turn activates cGMP phosphodiesterase. ❸ The phosphodiesterase catalyzes the breakdown of cGMP to 5'-GMP. ❹ As the cGMP concentration decreases, cGMP detaches from the cation channels, which close.

(a) Rod receptor potential

(b) Dark

(c) Light

FIGURE 14.28 Light hyperpolarizes vertebrate photoreceptors

(a) Retinal rods and cones are relatively depolarized in the dark, and their receptor potential in light is a graded hyperpolarization. The brighter the light, the greater is the hyperpolarization. (b) A dark current, carried largely by Na⁺ ions, enters the rod outer segment in the dark and depolarizes it. (c) Light acts to decrease the dark current by closing cGMP-gated Na⁺ channels, leading to hyperpolarization.

Vertebrate rods, like the photoreceptors of *Drosophila*, can produce a detectable change in dark current from the absorption of a single photon. Each photon absorbed by rhodopsin leads to approximately 10^6 Na⁺ ions *not* entering a rod outer segment. One functional attribute of an intracellular messenger is to provide the necessary amplification for this process. The activation of one rhodopsin molecule can lead to the activation of many transducin and phosphodiesterase molecules, causing the enzymatic degradation of a large number of cGMP molecules. This decreased cGMP concentration can close many Na⁺ channels, blocking the entry of enough Na⁺ ions to produce a change in membrane potential of

the order of 1 mV. If phototransduction were to use an ionotropic mechanism, the absorption of a photon would only be able to open or close a single channel, and the sensitivity would be insufficient to achieve the detection of a single quantum of light.

Enzymatic regeneration of rhodopsin is slow

If rods are stimulated by very bright light, the photoreceptors recover very slowly. This is because the bright light has converted 11-*cis* retinal to all-*trans* retinal in a large fraction of the pigment of the eye, a process called *bleaching*. After a bleach greater than about 1% of the photopigment, recovery of rod vision is prolonged; this slow adjustment to darkness is called **dark adaptation**.

Complete recovery of sensitivity after bleaching illumination requires the regeneration of the all-*trans* retinal back to 11-*cis* retinal. Regeneration can occur either photochemically or enzymatically. In insects, most regeneration occurs photochemically. The metarhodopsin with all-*trans* retinal can absorb a second photon and convert directly back to 11-*cis* rhodopsin without requiring metabolic energy. This has obvious advantages but one disadvantage: Because light illuminating the eye will generally stimulate both rhodopsin and metarhodopsin, the photoreceptors will usually contain some combination of both pigments. Many arthropods start afresh every day, breaking down and resynthesizing the light-sensitive microvilli and regenerating the rhodopsin on a circadian basis.

For vertebrate rods, most if not all regeneration normally occurs by an enzymatic mechanism. After bleaching of the 11-*cis* retinal to all-*trans* retinal, the all-*trans* retinal becomes unbound from the opsin protein. The all-*trans* retinal (aldehyde) is then converted to all-*trans* retinol (alcohol) by an enzyme in the photoreceptor called *retinol dehydrogenase*. The retinol is then transported by a specialized transport protein called *interphotoreceptor retinoid binding protein*, or *IRBP*, to the layer of cells behind the photoreceptors called the *pigment epithelium* (see Figures 14.22, 14.25b, and 14.26). The all-*trans* retinol is taken up by the pigment epithelial cells and re-isomerized back to 11-*cis* retinol and then converted to 11-*cis* retinal. The 11-*cis* retinal is transported back to the photoreceptors again by IRBP, and it then recombines with opsin by the reformation of the covalent bond between the retinal aldehyde and the amino group of the lysine in opsin. This procedure, although cumbersome and slow, assures the regeneration of the full complement of visual pigment in the rod, and visual sensitivity returns to its maximum dark-adapted value only after all of the pigment has been restored.

SUMMARY Photoreception

- The vertebrate eye is a camera eye that focuses light onto retinal rod and cone photoreceptors. Rods and cones are unusual in that light produces a hyperpolarizing receptor potential.
- The photopigment rhodopsin is a GPCR molecule conjugated to retinal. It is contained in membranes of outer segments of vertebrate rods and cones. When rhodopsin absorbs light, it acts via a G protein to decrease the concentration of cGMP in the cytoplasm, leading to closing of cGMP-gated Na⁺ channels that keep the photoreceptor depolarized in the dark. Light-induced closure of these channels hyperpolarizes the photoreceptors.

- In arthropods such as *Drosophila* the photopigment rhodopsin is similar to that of vertebrates and activates a similar G protein, but it is linked to a different intracellular effector and leads to the production of DAG and IP₃, opening ion channels and producing a depolarizing receptor potential.
- Rhodopsin is deactivated and ultimately regenerated to 11-*cis* rhodopsin after activation. In vertebrates, most regeneration is a slow enzymatic process, part of which occurs outside the photoreceptors in the adjacent pigment epithelium.

Visual Sensory Processing

Photoreceptors respond to light, but the vertebrate visual system responds to pattern: *contrasts*, or changes in light level and color over space and time. This conversion—from sensitivity to light into sensitivity to contrast—occurs partly in the retina and partly in higher visual-processing areas of the brain.

Retinal neurons respond to contrast

The aspects of visual stimuli that are most important for the behavior of animals (including humans) are *patterns* of light and darkness and color, rather than the overall light level. In behavioral terms, the significant features of the visual world are spatial patterns of visual stimuli that represent objects in the world, and temporal patterns that indicate movements. To a frog, for example, a small dark area in the visual field may have great behavioral importance (a fly for lunch)—particularly if it moves relative to the rest of the visual field. Changes in overall illumination may be less important, merely indicating, for example, that a cloud has passed in front of the sun.

The photoreceptors themselves respond primarily to the light level in one point in space. Therefore, we would expect that visual systems might integrate signals from receptors in ways that abstract the behaviorally significant spatial patterns and movements of stimuli. Although considerable progress has been made in understanding how visual signals are processed and used behaviorally in insects, visual integration has been studied most extensively in the vertebrate visual system. In this section we consider how neural circuits in the retina perform the early stages of this visual integration.

The retina contains the rod and cone photoreceptors and four kinds of integrating neurons (see Figure 14.25*b*): bipolar cells, horizontal cells, amacrine cells, and ganglion cells. **Bipolar cells** receive input from photoreceptors at the *outer plexiform layer* near the photoreceptors, and they synapse on amacrine and ganglion cells in the *inner plexiform layer*. **Horizontal cells** extend tangentially, connecting different regions of the outer plexiform layer. **Amacrine cells** mediate similar tangential interconnections in the inner plexiform layer. Retinal **ganglion cells** are the output of the retina; their axons form the optic nerve that extends to the brain.

How is sensory input from the photoreceptors transformed by these neurons as it makes its way through the retina? We begin our examination of retinal integration by looking at the response properties of the retinal ganglion cells, which provide the sensory output from the retina. This will give us an overview of how the visual image is processed by the retinal cells. The ganglion cells, in contrast to photoreceptors, each respond to stimulation over a

relatively large visual area—the ganglion cell’s *receptive field*. For the vertebrate visual system, the **receptive field** of a neuron such as the ganglion cell is defined as the area of the retina (or the area of the visual field) within which the membrane potential or impulse activity of that neuron can be influenced by light. For a rod or cone, the receptive field corresponds for the most part to the retinal area occupied by the receptor itself. For visual interneurons such as retinal ganglion cells, in contrast, the receptive field is typically much larger, embracing an area containing many photoreceptors, and can also include different regions giving responses of different polarity.

Let’s begin by examining the receptive fields of two ganglion cells that are sensitive to contrast. The fields of these cells are typical of many of the ganglion cells in mammals and 90% of those in the human retina. We can record from ganglion cells with an extracellular microelectrode, etched to a fine tip and insulated with resin except for a few microns at the tip. Such a microelectrode records the impulses of neurons in the immediate vicinity. We can map the receptive fields of a neuron by recording its responses when small spots of light are shone either directly onto the retina or onto a screen in front of the eye. If light on a particular spot elicits a response, then that spot is considered to be part of the receptive field of the neuron being recorded.

Figure 14.29 shows the responses of the two retinal ganglion cells to different kinds of light stimulation. The cells have receptive fields divided into two areas: a *center* and a *surround*. The first cell to the left, termed an **on-center cell**, increases its rate of impulse discharge when the center of its receptive field is illuminated by a spot of light (see Figure 14.29*a*). The same spot of light, however, suppresses activity when it is presented in the larger surrounding part of the receptive field. The on-center cell is maximally stimulated when the entire center of its receptive field, but none of its surround, is illuminated. The cell’s activity is maximally inhibited or suppressed when the surround, but not the center, is illuminated by an annulus (ring) of light. Such suppression is followed by an increased discharge when the light is turned off (an “off response”). Diffuse light stimulation, covering the entire receptive field of the ganglion cell, has little effect on the cell’s activity because the excitatory effect of light at the center and the inhibitory effect of light in the surround are antagonistic, canceling each other out.

The second cell to the right, called an **off-center cell**, also has a receptive field with a concentric, antagonistic center and surround (see Figure 14.29*b*). The off-center cell, however, is inhibited by light in its center and excited by light in its surround. Its receptive field is thus the opposite of the field of the on-center cell.

The two retinal ganglion cells just described are typical of many of the ganglion cells in cat and monkey retinas, which contain roughly equal numbers of these two types. There are other classifying features of ganglion cell organization, which we discuss later (see Box 14.2). Furthermore, many mammals and other vertebrates have ganglion cells with properties that are more complex than those illustrated in Figure 14.29. Nevertheless, the preceding description of response properties of contrast-sensitive on-center and off-center ganglion cells is a sufficient starting place for an analysis of retinal integration.

In order to see how the response properties and receptive fields of contrast-sensitive ganglion cells are derived from neural

(a) Straight-through pathways

(b) Lateral pathways

FIGURE 14.30 The synaptic connections of the retina produce the center-surround, concentric receptive field of retinal ganglion cells (a) The radial, straight-through pathways from receptors to bipolar cells (in red) to the dendritic tree of a retinal ganglion cell produce the center of the ganglion cell's receptive field. (Horizontal cells and amacrine cells are present but not shown.) (b) Lateral pathways such as the horizontal cell pathways shown (in red) produce the surround of the ganglion cell's receptive field. (Amacrine cells, not shown, also contribute to lateral pathways.) (After Masland 1986.)

rods and cones, bipolar cells, and horizontal cells do not normally generate action potentials.

Light in the surround of a ganglion cell's receptive field antagonizes these effects, in part by activating horizontal cells of the lateral pathway (**Figure 14.31b**). Stimulated cones in the surround area synapse onto horizontal cells, the lateral processes of which synapse back onto cone terminals to oppose the effects of light on the cones (i.e., horizontal cells depolarize cone terminals). This produces bipolar cells with receptive fields having an antagonistic center and surround. Light in the *surround* of an off-center bipolar cell depolarizes it (leading to depolarization of the surround of an off-center ganglion cell), and light in the surround of an on-center bipolar cell hyperpolarizes it (leading to hyperpolarization of the surround of an off-center ganglion cell). This inhibition of neighboring cells in an array is termed *lateral inhibition*. Horizontal cells do not mediate *all* of the lateral inhibition that produces the surround of a ganglion cell's receptive field. Amacrine cells provide a second layer of lateral inhibitory interaction in the retina, enhancing the center-surround antagonism and in some cases imparting to ganglion cells a sensitivity to moving light stimuli.

Amacrine cell pathways can contribute to more complex receptive field properties of ganglion cells. In mammals (including primates) and most other vertebrates, there are ganglion cells that respond to movement and even to the direction of movement, firing rapidly when a stimulus moves in one direction and not at all for motion in the opposite direction. Amacrine cells are thought to play a key role in producing these receptive fields. In frogs, they probably also contribute to the receptive fields of ganglion cells that respond to quite specific features of a visual stimulus. One type of ganglion cell responds only to a small, dark convex edge that moves relative to the background. The optimal size of a dark stimulating object (1°) is about the size of a fly at striking distance, and stimuli that activate these ganglion cells tend to trigger the frog's feeding-strike movements. It is plausible to interpret ganglion cells with these properties as "fly detectors" adapted to respond to a specific, behaviorally significant feature of the visual world. A small population of ganglion cells with similar response properties may also exist in mammals, where instead of catching flies they may help direct eye and head movements to bring moving objects to the center of gaze.

FIGURE 14.32 Central visual projections of a mammal As shown in this cutaway view of the brain (seen from above), only part of the optic tract crosses the midline at the optic chiasm. Therefore, a stimulus in the *left* visual field (the left half of the visible world) projects to the *right* lateral geniculate nucleus (LGN) via both eyes (red pathway). Conversely, a stimulus in the *right* visual field projects to the *left* LGN and visual cortex (green pathway).

in Figure 14.29, are sensitive to the absolute level of illumination regardless of its pattern, and they project to centers in the CNS controlling pupillary movements, as well as to the suprachiasmatic nucleus (see Chapter 15 and Figure 15.16), where they play a critical role in the regulation of circadian rhythms.

The major visual projection of mammals, however, is the *geniculostriate system* (Figure 14.32). In this pathway the axons of retinal ganglion cells that form the optic nerve synapse in a region of the thalamus termed the **lateral geniculate nucleus (LGN)**. Neurons of the LGN project to the **primary visual cortex** at the posterior end of the cerebrum. Unlike the optic projections of lower vertebrates, the projections of most mammals are only partially crossed at the optic chiasm (called *partial decussation*). In cats and primates, the projections of the nasal (inner) half of the retina cross to the contralateral (opposite) side, whereas those of the temporal (outer) half go to the ipsilateral (same) side LGN. This mixing of input from the two eyes allows mammals with forward-facing eyes to merge binocular input for depth perception at the visual cortex.

David Hubel and Torsten Wiesel contributed greatly to our understanding of the central processing of visual information with a series of studies of the response properties of visual neurons in cats and monkeys, for which they won the Nobel Prize in 1981. They recorded from visual cells of anaesthetized animals while projecting patterned stimuli (light and dark bars, edges, and spots) onto a screen in front of the animal. They found that LGN neurons had response properties similar to those of retinal ganglion cells: They respond to stimuli to only one eye and have concentric receptive fields with an antagonistic center and surround, either on-center or off-center.

FIGURE 14.33 Receptive fields of simple cells in the visual cortex of a cat Each receptive field is an area of the retina that affects the activity of a single cortical cell. All three receptive fields shown here are of cells with the same axis of stimulus orientation; other cell fields have different axes of orientation. Cortical simple cells typically respond best to (a) a dark bar, (b) a light bar, or (c) a light–dark edge.

The receptive fields of neurons in the visual cortex are quite different from those of the retina and LGN. We can differentiate two major kinds of neurons in the visual cortex: *simple cells* and *complex cells*. Both types are binocular: They can respond to visual stimuli presented to either eye, although one eye may predominate (an effect called *ocular dominance*). Both kinds of cells have a preferred *axis of orientation* of the visual stimulus, a term best explained if we describe the receptive fields of a few simple cells in the visual cortex of a cat.

First, recall that a receptive field is the area of the retina or of the visual field in which light stimuli influence the activity of a particular neuron. Figure 14.33 shows the receptive fields of three **simple cells**, as they might be mapped with small spots of light shone either directly onto the retina or onto a projection screen viewed by the animal. Plus signs (+) denote areas in which a light spot excites the simple cell, increasing the frequency of its discharge of action potentials. Minus signs (–) denote areas in which the frequency of action potentials decreases when the light spot is on and increases when the spot is turned off (“off response”). The positions of excitatory and inhibitory responses to spots of light reveal the extent of the receptive field of the cell and also the type of visual stimulus that most effectively elicits its response.

Each of the receptive fields in Figure 14.33 has a line drawn through it that defines its axis of orientation. To be most effective, a stimulus must be aligned with this axis of orientation. The optimal stimuli producing the largest number of action potentials for these three cells are as follows: a dark bar in the central band of the receptive field; a light bar in the central band of the field; and an edge on the center line that is light on the upper left and dark on the lower right. In all cases the stimulus pattern must be correctly aligned and oriented. In Figure 14.33a, for example, a vertical dark bar will be a weak or ineffective stimulus because it falls on both excitatory and inhibitory areas. For the same reason, visual cortical cells are insensitive to changes in overall illumination.

The three receptive fields shown in Figure 14.33 have the same axis of orientation, which is to say that the best edge or bar stimulus in the visual field is at the same angle for each cell.

In fact, all of the cells in a small area of the primary visual cortex have a similar axis of orientation. All possible axes of orientation, however, are represented in the cortex. If the recording electrode is advanced sideways through the cortex, it records from cells with progressively changing axes of orientation, a finding that suggests that the primary visual cortex is organized in columns or wedges with an orderly arrangement of axes. There is also an orderly arrangement of bands of ocular dominance, some areas containing neurons dominated by input from the ipsilateral eye and some by the contralateral eye. Overall, a pinwheel-shaped region of the cortex about 1×1 mm is subdivided into areas containing cells responding to all axes of orientation, as well as ocular-dominance bands from both eyes.

Interspersed in the cortex among the simple cells are **complex cells**, which are also responsive to bars and edges and have receptive fields with a preferred axis of orientation. Unlike simple cells, however, complex cells are insensitive to the *position* of a stimulatory bar or edge within the receptive field. As illustration of this defining feature of a complex cell, **Figure 14.34** shows the receptive field of a complex cell that responds to a horizontal bar anywhere within its sizeable receptive field. The same bar stimulus presented at an angle different from the preferred axis of orientation is much less stimulatory. No part of the receptive field of a complex cell can be defined as excitatory or inhibitory; instead the stimulus *pattern* (a dark horizontal bar) is excitatory. Therefore, complex cells have strict requirements about stimulus form and orientation, but less-strict requirements about stimulus position within the field.

It is not completely clear how the receptive field properties of cortical simple and complex cells result from synaptic input from other cells. Early experiments suggested a *hierarchical* organization in which many similar geniculate cells with receptive field centers aligned in a row converged onto a single simple cell in the cortex. Careful studies of cortical physiology indicate that this notion is probably true for simple cells. Complex cells were envisioned to receive convergent synaptic input from several simple cells, and in turn to synapse upon still higher-order cells. Aspects of this scheme are no doubt correct, but complex cells have been shown to receive some synaptic input directly from geniculate axons. These

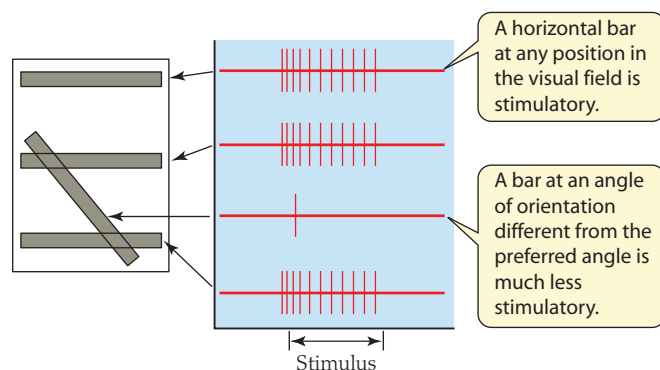

FIGURE 14.34 The receptive field of a complex cell in the visual cortex. Complex cells respond best to a bar (or edge) at the correct angle of orientation, which in this case is horizontal. Unlike simple cells, however, the stimulatory bar may be anywhere within the receptive field.

BOX 14.2 WHAT ROLES DO INDIVIDUAL NEURONS PLAY IN HIGHER VISUAL INTEGRATION?

Central integration of visual information in mammals and other vertebrates involves both a hierarchical organization and a parallel organization. That is, several parallel pathways each consist of a hierarchy of projections to higher visual centers through multiple neurons and synapses. Three classes of visual pathways project from the retina to the lateral geniculate nucleus (LGN), each consisting of different kinds of matched retinal ganglion cells and LGN cells that differ in size and in response properties. In primates these classes have been termed *magnocellular* (large cells), *parvocellular* (smaller, medium-sized cells), and *koniocellular* (still smaller cells). **Box Extension 14.2** describes how these parallel paths convey different sorts of visual information, and asks how individual neurons and ensembles of neurons process visual information in the brain.

and other studies show that there is also a *parallel* organization of central visual projections. **Box 14.2** discusses further these aspects of higher visual integration.

Color vision is accomplished by populations of photoreceptors that contain different photopigments

The ability to distinguish color depends on the differential sensitivities of photopigments to different wavelengths of light. Although many animals are color-blind, many other animals with well-developed diurnal visual systems have evolved color vision. Examples include several orders of insects, crustaceans such as mantis shrimp, teleost fish, frogs, turtles, lizards, birds, and primates.

Theories of color vision are strongly based on human perceptual studies. In 1801, Thomas Young (1773–1829) proposed that human color perception was based on separate receptor classes sensitive to red, green, and blue light. This theory was supported by perceptual observations that any color could be duplicated by a mixture of three primary colors.

The physiological basis of this trichromaticity theory has been clarified in the last 35 years. Humans and other primates have three populations of cone photoreceptors, which are sensitive to different wavelengths of light. The three cone classes have slightly different photopigments of the rhodopsin family, each with a somewhat different opsin sequence that alters its sensitivity to light wavelengths. **Figure 14.35** illustrates the absorption spectra of the three classes of primate cones determined by measuring light absorption by each pigment at different wavelengths. Spectral characteristics can also be determined by testing the effectiveness of stimulation by light of different wavelengths to define an action spectrum. The three types of cones are usually called *red cones*, *green cones*, and *blue cones*, loosely approximating the color of light to which they are most sensitive. The spectral sensitivities of the three types of cones are rather broad and overlapping, so that the perception of color must be based on the ratio of excitation of different cone populations. For example, we might expect perception of long-

FIGURE 14.35 Spectral sensitivities of human retinal cones
Spectral sensitivities were determined by measuring the absorption spectra of single cones. The three types of cones have photopigments with different absorption maxima: 420 nm (blue cones), 530 nm (green cones), and 560 nm (red cones). Note that the “green” and “red” cones have similar spectral sensitivities and are both most excited by yellowish light. Rods have an absorption peak of 496 nm.

wavelength red light to depend on an analyzer that is excited by red cones but inhibited by green cones. Just this sort of integration occurs in the retina.

Two kinds of *color opponent* processes are present in the mammalian retina: red–green opponency and blue–yellow opponency. These opponent processes explain why we can perceive a color as bluish green or as reddish yellow (orange), but we do not ordinarily perceive a color as reddish green or as bluish yellow. Many of the ganglion cells of a primate retina that are stimulated by cones have color-opponent properties. Red–green opponent ganglion cells, for example, have concentric antagonistic receptive fields but are also color-opponent. One cell may be inhibited by red light in its receptive-field center and excited by green light in its surround; another may be excited by red light in the center and inhibited by green in the surround, and so on. Other classes of ganglion cells may be excited by blue light and inhibited by yellow (a sum of red and green cone input). Blue–yellow opponent cells lack center–surround antagonism.

Color opponent retinal ganglion cells project to the LGN and are relayed to the primary visual cortex. Color information in the visual cortex appears to be integrated by clusters of cells in separate districts in the cortex, located separately from other cells that are not color-selective but instead process information about brightness contrast. This apparent segregation of color channels and so-called achromatic channels is another example of parallel organization in the mammalian visual system.

Mechanisms for color vision in animals other than mammals are always based on several populations of receptor cells with different spectral sensitivities, although these receptors are not always cones.

Fish such as carp have three populations of cones analogous to those of primates, with absorption maxima of 455 nm, 530 nm, and 625 nm, respectively. In contrast, frogs have two or more classes of rod photopigments; their color vision involves input from both rods and cones. Birds, mice, and some other vertebrates have ultraviolet visual sensitivity. Many insects have well-developed mechanisms for color vision, including receptors sensitive to ultraviolet radiation. The different retinal cells in an insect ommatidium often contain different photopigments, and these provide information for making color discriminations. The honeybee has photoreceptors with maximum sensitivities to 350 nm, 450 nm, and 550 nm, and readily distinguishes both ultraviolet radiation and colors of visible light. Many white flowers seem featureless to us but reveal striking patterns under ultraviolet illumination, and the bees use these patterns to identify pollen sources.

This last example is a reminder that many animals use sensory abilities foreign to us, and in fact we use many sensory faculties of which we are largely unaware, as well as the senses of which we are conscious. Several of the following chapters will consider additional roles and uses of sensory information.

SUMMARY Visual Sensory Processing

- Neural circuits of the vertebrate retina integrate the responses of retinal photoreceptors to excite and inhibit retinal ganglion cells. Ganglion cell receptive fields may be excited or inhibited by light at the center of the field, whereas light in the surround antagonizes the effect of light in the center.
- Straight-through pathways (photoreceptor → bipolar cell → ganglion cell) produce the center (on- or off-center) of a ganglion cell's receptive field. Lateral pathways through horizontal cells and amacrine cells produce the antagonistic surround.
- Axons of ganglion cells make up the optic nerve, relaying visual information to several brain areas. The geniculostriate pathway projects to the lateral geniculate nucleus (LGN) and from there to the primary visual cortex.
- Simple and complex cells in the primary visual cortex respond to light or dark bars or edges oriented at particular angles.
- Parallel pathways in the visual cortex convey information about different aspects of a visual stimulus, such as details of visual form, movement, color, and binocular determination of object distance.
- Color vision depends on the ratio of activation of three classes of cone photoreceptors sensitive to different wavelengths of light. Retinal circuitry integrates color contrasts based on red–green and blue–yellow opponencies.

Study Questions

1. Suppose that a sensory neuron in the periphery generates a train of action potentials, and synaptically excites an interneuron in the central nervous system. What does this signal mean? What additional information does the interneuron need in order to decode the message?
2. Suppose that in a particular sensory receptor, the amplitude of the receptor potential increases linearly with the log of the stimulus intensity. The receptor potential depolarizes the cell to produce a train of action potentials, and the frequency of the action

potentials increases linearly with increasing receptor-potential depolarization (above threshold). There is a maximum frequency of action potentials, beyond which additional increase in stimulus intensity does not further increase action-potential frequency. Graph these results as the amount of response as a function of stimulus intensity (or log intensity). If these results are typical of many receptors, what do they tell you about how sensory receptors encode stimulus intensity?

3. What is adaptation of a sensory receptor? At what stage(s) does it occur? What are its functions?
4. Where is rhodopsin localized in a vertebrate retinal rod? Where is the receptor potential generated? How does the transduction mechanism of the rod connect these two sites? How does it increase light sensitivity?
5. Diagram and describe how lateral inhibition via horizontal cells produces the surround of a retinal ganglion cell's receptive field.
6. To what features of the visual world do simple and complex cells of the mammalian visual cortex respond? How do these cells differ?
7. Insects and vertebrates have analogous proprioceptors that monitor muscle length and tension, joint positions, limb forces, and so on. Insects, however, do not have statocysts to monitor the direction of gravitational force. How could an insect detect gravity when at rest? What could be the possible adaptive advantage of the *absence* of statocysts for a flying insect?
8. Among vertebrates, acoustico-lateralis hair cells are used to detect water currents in lateral line organs of fish, gravity and acceleration in the labyrinth, and sound in the cochlea. How can similar receptor cells mediate all these responses?
9. Compare the mechanisms and accuracy of auditory localization of a sound source in a human, an owl, and a bat.
10. Mechanisms of chemoreceptor transduction are of two broad kinds, which parallel the two major mechanisms of synaptic transmission. Describe these, and suggest an evolutionary speculation for the similarities.

Nervous System Organization and Biological Clocks

Pictured here is a star-nosed mole (*Condylura cristata*). Star-nosed moles, like other moles, are *fossorial*: they live underground and dig for their food, which consists of small invertebrates. Moles have greatly reduced visual systems and are often considered blind, but some are sensitive at least to light levels. Star-nosed moles have evolved a stellate array of fleshy fingerlike structures (shown in the photograph). The function of this “star” is tactile; it contacts the ground as many as 10–15 times per second and enables the mole to forage efficiently on small prey. The star-nosed mole may seem like an odd animal with which to introduce the integrative functions of nervous systems. But it illustrates two general points. First, the activities of the many cells in the mole’s body must be controlled and coordinated in order for the mole to function and behave as a mole, rather than as just a mass of cells. In Chapter 2 we introduced controls *within* cells, mediated by cell-membrane receptors, second messengers, enzymes, transcription factors, and the like. Our focus here is control, coordination, and integration of activities *among* cells—that is, *intercellular* control. Such control is the major functional role of the nervous system, and of the endocrine system. In the last three chapters we considered the cellular elements of nervous systems, the synaptic interactions of neurons, and the ways in which environmental information is acquired by sensory processes. In this chapter we consider how entire nervous systems are organized for the specific and adaptive control of sets of cells. (Endocrine control is treated separately, in Chapter 16.)

The second point that the star-nosed mole illustrates is that control systems such as the nervous system are not only reactive, but also proactive. That is, although a nervous system functions to respond to changes in the outside world—stimuli in the animal’s environment—it also coordinates its own activities without waiting for stimuli. Animals have *intrinsic* or *endogenous* functions such as daily rhythms of activity. Even if an animal cannot see day and night in its environment, its behavioral and physiological activities continue to cycle on a daily basis that anticipates the day–night cycle. This anticipatory activity is controlled by a *biological clock*—an endogenous, physiological timekeeping mechanism—that allows the animal to know when day will start, whether the animal sees light or not. Anticipation of this sort can be highly advantageous to an animal because it permits the animal to prepare physiologically and behaviorally for the new day, rather than merely waiting in a state of total ignorance about when the day will arrive. That this intrinsic rhythm persists without environmental cues doesn’t diminish their importance, however. Environmental cues are necessary to reset the clock, *entraining* it to the outside world so that it does not drift earlier or later. In this chapter, in addition to discussing nervous systems in general, we will examine the biological clocks that control endogenous rhythms, as an example of the intrinsic, anticipatory functions of nervous systems.

How does this star-nosed mole control and integrate the functions of all the cells in its body?

The Organization and Evolution of Nervous Systems

The organization of neurons into functional nervous systems is what allows for the complexity of the neural control of animal physiology and behavior. We can define a **nervous system** as an organized constellation of cells (neurons and support cells) specialized for the repeated conduction of electrical signals within and between cells. These signals pass from sensory cells and neurons to other neurons and then to muscles, glands, or other organs that carry out actions. Nervous systems integrate the signals of converging neurons, generate new signals, and modify the properties of neurons based on their interactions. Nearly all animals have nervous systems. All nervous systems share similar characteristics, although they vary in the complexity of their organization and of their behavioral output.

Before we proceed to a closer look at the organization and evolution of nervous systems, we need to develop a framework of basic terms and organizational concepts that will facilitate our discussion. Some of these terms and concepts, although initially presented here, will be revisited and refined later in the chapter as well.

The nervous system in most types of animals consists of two major divisions: the *central nervous system* and the *peripheral nervous system*. The **central nervous system (CNS)** consists of relatively large structures such as the brain and spinal cord in which large numbers of neurons and support cells are anatomically juxtaposed and interact to achieve integrative functions. The CNS is rich with the cell bodies and processes (axons and dendrites) of neurons. Some neurons, called **interneurons**, are confined to the CNS. Other neurons are at least partially outside the CNS: Those that convey information to the CNS are **sensory neurons**, and those that convey information out of the CNS to control muscles or other effectors are **motor neurons**. An **effector** is an organ, tissue, or cell that *acts*—that carries out functions such as motion or secretion—under the direction of the nervous system (or endocrine system). Muscles and glands are examples of effectors. The **peripheral nervous system (PNS)**, then, consists of all the processes and cell bodies of sensory and motor neurons that are present outside the CNS (including autonomic ganglia and the enteric nervous system, considered later).

In the PNS, a **nerve** consists of the axons of multiple neurons bundled together into a structure resembling a cable of telephone wires. Although individual axons are too minute to be seen without a microscope, a nerve is macroscopically visible because it consists of many axons. If one transects a nerve and looks at either stump under a microscope, one sees many axons in cross section, just as one sees the cross sections of many wires when one cuts a wire cable. Axons of multiple neurons are often bundled together in the CNS as well as in the PNS. Such bundles in the CNS are not called *nerves*, however. Instead they are called *tracts*, *commissures*, or *connectives*, as we will discuss later. Another term of importance in describing the anatomy of nervous systems is *ganglion*. A ganglion, speaking macroscopically, is a swelling positioned along a nerve or connective. Because further details of ganglion structure and function differ in different groups of animals, we will postpone a closer look at them until later in this chapter.

Physiologists recognize two primary divisions of the vertebrate PNS: the *somatic* and the *autonomic nervous systems*. These same

divisions are sometimes recognized in the PNSs of invertebrates. The **somatic nervous system** is the part of the PNS that controls the skeletal (striated) muscles that generally produce voluntary movements; skeletal muscles are thus called **somatic effectors**. Sensory reception of external stimuli and transmission of this sensory information are also functions of the somatic nervous system. The **autonomic nervous system**, by contrast, is the part of the PNS that controls **autonomic effectors** (or **internal effectors**), defined to include all neuron-controlled effectors other than the striated muscles, such as cardiac muscle, smooth (nonstriated) muscles, and glands. The autonomic nervous system also has sensory neurons that convey information to the CNS about the internal organs. The somatic nervous system controls most observable behavior and therefore is the part of the PNS with which we are most familiar. Autonomic effectors exert most of their effects on visceral organs, internally and invisibly.

Nervous systems consist of neurons organized into functional circuits

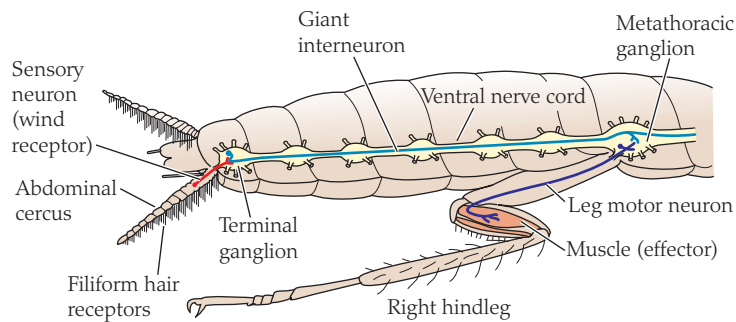

A good way to start a discussion of the cellular organization of nervous systems is to recall the example of the cockroach in Chapter 12 (page 299). As is typical of nervous systems in general, in the nervous system of the cockroach, cellular elements sense the environment, send signals to other cells (neurons) in the CNS, and ultimately control and coordinate cells of effectors to generate physiological or behavioral outputs. In the specific case we discussed (see Figure 12.3), wind-receptor sensory neurons were excited by an environmental mechanical stimulus, and those sensory neurons in turn synaptically stimulated interneurons that excited motor neurons to induce contraction of muscle cells, producing a reflexive behavioral response—a jump. **Figure 15.1** represents the cockroach's neural circuit as a block diagram, simplified to illustrate how this simple reflex in a cockroach exemplifies the general functional features of nervous systems:

- Neurons are organized in circuits in such a way that they can elicit a coordinated, adaptive response of effectors.
- Sensory receptor cells (which, like neurons, are excitable cells) transform environmental stimuli into electrical signals.
- Central interneurons integrate signals from sensory receptors and other signals arising within the animal, generating an integrated pattern of impulses.
- Motor commands are sent out from the CNS to effectors.

Many types of animals have evolved complex nervous systems

We have little direct knowledge of the evolution of nervous systems, which are rarely preserved in the fossil record. Theories of nervous system evolution are based on interpretations of the anatomy and the molecular genetics of living groups, a risky proposition because all groups alive today are highly evolved and none can be taken as representing a primitive condition. Comparative studies of living animals show that the *neurons* of the nervous systems of all animals, although diverse in form, are quite similar in their functional properties. For example, the neurons of all phyla have common molecular bases for their excitability and intercellular communication, with homologous voltage-gated channels and

(a) The startle response circuit of the cockroach

(b) Simplified diagram of the response circuit

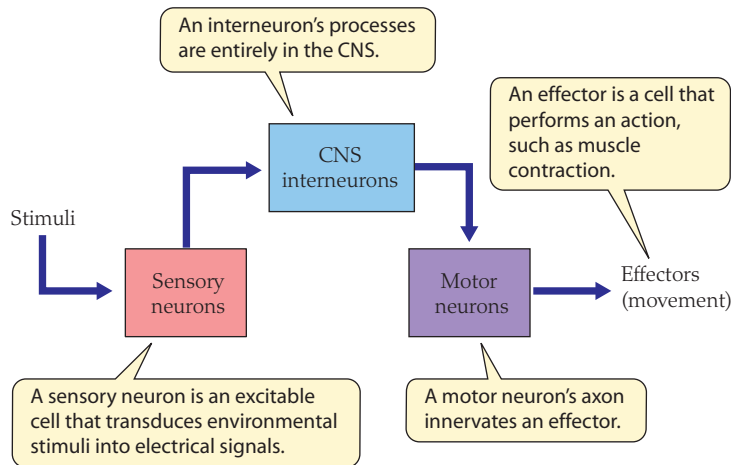

FIGURE 15.1 Neuronal elements in a nervous system: a neural circuit mediating the cockroach startle response (a) The startle response circuit (introduced in Figure 12.3) involves three neuronal elements: sensory neurons, interneurons, and motor neurons. (b) A simplified diagram of this circuit shows the basic functions of neural circuits in nervous systems. Sensory neurons convey signals about environmental stimuli to the central nervous system. These signals are integrated by central neurons and can trigger or modulate output signals of motor neurons to control effectors such as contracting muscle cells.

synaptic mechanisms. Moreover, the genetic controls of nervous system development show striking homologies in a wide range of phyla. The major changes in the evolutionary history of nervous systems appear to have involved changes in the *complexity of organization* of neurons into systems, rather than changes in the neurons themselves.

Two major trends characterize the evolution of nervous systems in the bilaterally symmetrical phyla of animals: centralization and cephalization. **Centralization** of nervous systems refers to a structural organization in which integrating neurons are collected into central integrating areas rather than being randomly dispersed. **Cephalization** is the concentration of nervous structures and functions at one end of the body, in the head. **Box 15.1** further discusses the evolution of diverse nervous systems; here we consider two major types of relatively complex nervous systems, those of arthropods and of vertebrates.

ARTHROPOD CENTRAL NERVOUS SYSTEMS ARE ORGANIZED AS CHAINS OF SEGMENTAL GANGLIA Animals with relatively complex central nervous systems exhibit two different major forms of

BOX 15.1 EVOLUTION OF NERVOUS SYSTEMS

All multicellular animals except sponges have neurons and nervous systems. Sponges are primitive multicellular animals without organs and organized tissues. Although they lack neurons and synapses, they possess genes for many of the proteins that make up synaptic structures. In fact, genomic analyses have found many genes important for nervous system organization to be present in primitive, unicellular choanoflagellate protists. **Box Extension 15.1** describes the organization and evolution of nervous systems in different animal groups.

Azure vase sponge
(*Callyspongia plicifera*)

CNS organization: *ganglionic* central nervous systems characteristic of protostomes, and *columnar* nervous systems characteristic of vertebrates and other deuterostomes (see the back endpapers for the protostome/deuterostome distinction). To see the features of ganglionic nervous system organization, we focus here on arthropods. Aspects of the organization of a ganglionic nervous system are also present in annelids and molluscs.

In arthropods, the CNS consists of a chain of segmental ganglia. **Ganglia** (singular *ganglion*) are swellings containing discrete aggregations of nerve cell bodies and processes. The chained ganglia are linked by paired bundles of axons called **connectives** (Figure 15.2). The CNS of an arthropod such as a cockroach consists of an anterior *brain* and a *ventral nerve cord* that is linked to the brain by connectives encircling the esophagus. The ventral nerve cord is a chain of ganglia linked by connectives—one ganglion for each thoracic and abdominal body segment. (Some arthropods show secondary fusion of some of these segmental ganglia.)

Each ganglion in the CNS of an arthropod consists of an outer *rind* and an inner *core*. The rind consists mostly of cell bodies of neurons and is devoid of axons and synapses. Indeed, nearly all neuronal cell bodies of arthropods are confined to the rinds of the central ganglia, the major exceptions being cell bodies of sensory neurons, many of which are located in the PNS. The inner core of each ganglion contains two regions: a region of synaptic contacts between axons and dendrites that is termed the **neuropil** (or *neuropile*) and a region of **tracts** (bundles) of axonal processes within the ganglion.

In arthropod or other ganglionic nervous systems, there are four terms for a bundle of nerve axons, depending on where the bundle is located. In the PNS a bundle of axons is a *nerve*, between ganglia in the CNS it is a *connective*, within a ganglion it is a *tract*,

(a) Dorsal view of the central nervous system

FIGURE 15.2 The organization of an arthropod central nervous system

(a) The CNS, shown here in a dorsal view, consists of a chain of segmental ganglia linked by connectives. The circumesophageal connectives link the anterior *brain* to the *ventral nerve cord*, which consists of the linked ganglia posterior to the circumesophageal connectives. (Some abdominal ganglia are omitted.) (b) A ganglion, shown in cross section, contains an outer rind of cell bodies and an inner core of synaptic neuropil and of axons (tracts and commissures).

and between right and left sides of a bilaterally symmetrical ganglion it is a **commissure**. The terms *nerve*, *tract*, and *commissure* have the same meanings for vertebrate nervous systems, but vertebrate central nervous systems do not have connectives.

THE VERTEBRATE CENTRAL NERVOUS SYSTEM IS A CONTINUOUS COLUMN

Vertebrate central nervous systems, in contrast to those of arthropods, are classed as columnar because they consist of a continuous column of neural tissue, with cell bodies and synaptic areas intermingled. The CNS of vertebrates consists of a brain and a spinal cord (Figure 15.3). It differs from the ganglionic CNSs of arthropods (and other protostomes) in several respects, some of which have already been mentioned. The vertebrate CNS is dorsal and hollow, and it develops from a neural tube that invaginates from the dorsal surface of the embryo. The nerve cords of arthropods, in contrast, are ventral and solid, do not arise by invagination, and have connectives between central ganglia. The vertebrate CNS, reflecting its origin as a continuous tube, is not clearly divided into ganglia and connectives, as is the arthropod CNS (compare Figure 15.3a with Figure 15.2a).

(a) Dorsal view of the central nervous system

FIGURE 15.3 The organization of a vertebrate CNS

(a) A schematic vertebrate CNS, shown in dorsal view, consists of a single continuous column of cells and axons. (b) A cross section of the spinal cord shows the histological division of a vertebrate CNS into gray matter (containing a few representative neurons) and white matter.

The **gray matter** consists of cell bodies, synapses, and unmyelinated neural processes. The **white matter** consists of tracts of myelinated axons. Segmental nerves of the peripheral nervous system connect to the spinal cord via sensory dorsal roots and motor ventral roots.

Despite the differences in organization between ganglionic and columnar CNSs, there is good evidence that the centralized organization of nervous systems in bilaterally symmetrical animals is an ancient characteristic that evolved once. In 1822, the French biologist Étienne Geoffroy Saint-Hilaire suggested that vertebrates were related to other Bilateria (animal phyla with bilateral symmetry) such as worms and arthropods, but that vertebrates were inverted, so that what had been a ventral nervous system in other groups became dorsal in the inversion. Anton Dohrn and others championed this idea in the later nineteenth century, but the idea was not taken very seriously until it received strong support from recent studies of expression of homologous patterning genes in the development of nervous systems in different phyla. Similarities in patterns of gene expression and control between vertebrates and protostomes (such as fruit flies and annelid worms) strongly suggest a common origin of CNS organization, with an inversion of the body axis of vertebrates as Saint-Hilaire envisioned.

SUMMARY The Organization and Evolution of Nervous Systems

- Animals have evolved nervous systems with varying degrees of centralization and complexity. There are homologies between the nervous systems of different animal groups.
- Most phyla of animals have bilateral symmetry and have evolved central nervous systems (CNSs) that centralize control functions. Sensory neurons convey information into the CNS, and motor neurons convey outward commands to effectors. CNSs usually have some degree of cephalization (concentration of neural structures into a clear anterior brain).
- Arthropods have a ganglionic nervous system, one major form of nervous system organization. The arthropod CNS is a ventral ladderlike chain of segmental paired ganglia joined by connectives. A vertebrate CNS, in contrast, is a continuous column of cells and axons.

The Vertebrate Nervous System: A Guide to the General Organizational Features of Nervous Systems

The nervous systems of most animals tend to share common organizational features. Here we discuss these organizational features using vertebrate nervous systems as examples. Keep in mind, however, that many of these organizational features apply to nervous systems in general. The vertebrate nervous system is organized into different regions that are discrete in gross structure, although neurons and their functions may cross these boundaries.

Nervous systems have central and peripheral divisions

The division of nervous systems into central and peripheral divisions was stressed earlier but deserves reiteration because it is of such pivotal importance. For a vertebrate, the CNS consists of the brain and spinal cord, and the PNS consists of nerves that connect the CNS to various parts of the body (Figure 15.4). Peripheral nerves contain axons of **afferent** neurons—neurons that carry nerve impulses *toward* the CNS (e.g., sensory neurons)—and axons of **efferent** neurons that carry nerve impulses *away* from the CNS (e.g., motor neurons). The vertebrate PNS also includes **peripheral ganglia**, which are collections of neuronal cell bodies associated with peripheral nerves. (These should not be confused with the *central* ganglia of arthropod nervous systems.) As in other animals, the vertebrate PNS conveys sensory input to the CNS, and it conveys motor output (to control muscles and other effectors) from the CNS to the periphery. Effector functions include contraction, secretion, emission of light and heat, electric organ discharge, and other actions.

The central nervous system controls physiology and behavior

The vertebrate CNS demonstrates the two general principles of organization of complex nervous systems: centralization and

FIGURE 15.4 Divisions of the vertebrate nervous system are interconnected The most basic distinction is between the central nervous system (CNS) and the peripheral nervous system (PNS). The PNS has sensory and motor divisions. The somatic nervous system includes somatic receptors and afferent sensory neurons (these might be parts of the same sensory cell, or different cells), and efferent motor neurons

controlling striated skeletal muscle. The autonomic nervous system includes autonomic sensory neurons and efferent neurons controlling internal autonomic effectors. The enteric division of the autonomic nervous system has some communication with the CNS but functions rather independently to control the gut.

cephalization. Functionally, all neural activity is funneled into the CNS via afferent sensory neurons and sent out from the CNS by efferent motor neurons to effectors (see Figure 15.4). All significant integration and processing of neural activity occurs in the CNS: There are no sensory-to-motor synapses in the PNS, and therefore no peripheral integration takes place.¹

Histologically, the vertebrate CNS consists of two types of tissue: gray matter and white matter. **Gray matter** is composed of intermingled neuronal cell bodies, processes, and synaptic contacts. **White matter**, by contrast, consists entirely of tracts of myelinated axons (see page 300); it is the myelin that imparts a distinctive white appearance to the tissue. In the spinal cord the white matter is external and the gray matter is internal (see Figure 15.3*b*). This arrangement does not hold in the brain, however, where gray matter is often external to white matter and the arrangement is considerably more complicated. For example, brains have a more layered gross organization: Often the outer surface layer is called a **cortex**.

Two types of circuits characterize the functional organization of the spinal cord: local and ascending/descending. Local circuits exist within single segments of the spinal cord. In a local circuit (such as the type of circuit that mediates a simple spinal reflex; see Chapter 19), sensory neurons entering a segment—and interneurons in the segment—control motor output of the same segment. This local control is thought to be primitive. In addition to this local control, sensory input is relayed to the brain and contributes to higher integration. Such transmission of information from the spinal cord to the brain is called *ascending*. In addition, *descending* transmission of information occurs from the brain to the spinal cord, permitting the brain to exert dominance over the rest of the CNS.

The nerves in the PNS that connect to the CNS are called **cranial nerves** if they connect to the brain and **spinal nerves** if they connect to the spinal cord. The brain receives sensory input from sensory neurons in its cranial nerves, and also via ascending pathways from the spinal cord. Brain motor neurons traveling within cranial nerves directly control effectors of the head. Much of the brain's output, however, serves to control or modulate the spinal cord. The spinal nerves are arranged segmentally, as we will discuss shortly. The spinal cord receives sensory input through the dorsal roots of its spinal nerves (see Figure 15.3*b*). It sends motor output to the periphery of the body via the ventral roots of the spinal nerves.

All vertebrate brains share a common structural organization, exhibiting three major regions: **forebrain**, **midbrain**, and **hindbrain** (Figure 15.5). Five subdivisions of these regions are recognized: **telencephalon** and **diencephalon** (forebrain), **mesencephalon** (midbrain), and **metencephalon** and **myelencephalon** (hindbrain). Each of these divisions contains many tracts of nerve axons and many clusters of cell bodies termed **nuclei** (singular *nucleus*).² Two major outgrowths of the dorsal portion of the brain become increasingly prominent in higher vertebrates: the **cerebellar cortex** of the metencephalon and the **cerebral cortex** of the telencephalon. The cerebral cortex includes the olfactory cortex, hippocampus, and (in mammals) neocortex. Table 15.1 lists some brain structures and

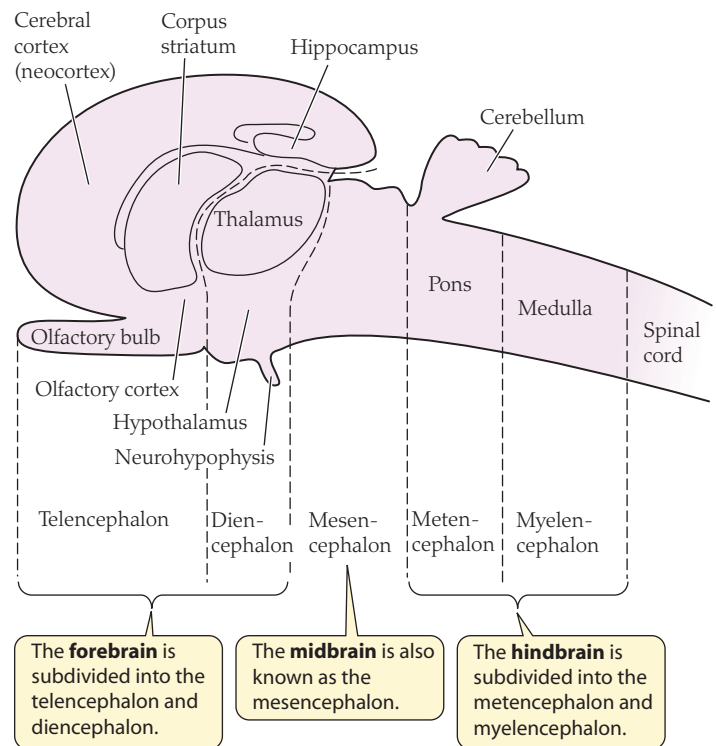

FIGURE 15.5 A schematic of vertebrate brain structure The brain has three major parts—forebrain, midbrain, and hindbrain—that are divided into five subdivisions, as shown. Some major structures of these five brain regions are labeled. In this side view, the anterior end is to the left.

their functions. We discuss several aspects of brain function in the next section, and we discuss several of the brain regions further in Chapters 14 and 19.

The CNS, along with the endocrine system, exerts control over the functions of an animal's organ systems (its physiology) and also over its behavior, including all movements and externally observable activity. We will take the simplifying view that behavior is the province of the skeletal muscles, controlled via the somatic nervous system. In contrast, the autonomic nervous system exerts physiological control of internal organ systems via other effectors. This distinction is not completely true, because (for example) reproductive behavior includes glandular secretion and smooth muscle contractions mediated by the autonomic nervous system, whereas breathing (lung ventilation) is a physiological function mediated by somatic control of skeletal muscles of the diaphragm and ribs. Still, the distinction between somatic control of behavior through skeletal muscle and autonomic control of organ systems through other effectors, although imprecise, is a useful generalization.

Five principles of functional organization apply to all mammalian and most vertebrate brains

PRINCIPLE 1: BRAIN FUNCTION IS SOMEWHAT LOCALIZED

Neurons in different anatomical regions of the brain play different functional roles. That is, you can point to a part of the brain and reasonably ask what functional activities occur there. For example, Figure 15.6 shows some major areas of the cerebral cortex that are

¹This generalization is not true for the enteric nervous system, the branch of the autonomic nervous system that controls the gut (discussed later in this section).

²In vertebrates, clusters of neuronal cell bodies are usually called *nuclei* in the CNS and *ganglia* in the PNS. The basal ganglia of the brain constitute an exception to this terminology; they are actually central nuclei.

TABLE 15.1 Some major areas of the mammalian brain and their general functions

Most functions involve several brain areas, and many brain areas and functions are omitted.

Major brain division	Brain subdivision	Area	Major functions
Forebrain	Telencephalon	Cerebral cortex	Higher sensory, motor, and integrative functions
		Hippocampus	Learning and memory
		Basal ganglia	Motor control
		Limbic system	Emotions
	Diencephalon	Thalamus	Major sensory relay
	Hypothalamus	Homeostatic and endocrine regulation; circadian clock	
Midbrain	Mesencephalon	Superior colliculus	Visual integration
		Inferior colliculus	Auditory integration
Hindbrain	Metencephalon	Cerebellum	Motor coordination
		Pontine motor nuclei	Descending motor control
	Myelencephalon	Medulla oblongata	Autonomic and respiratory control

involved in sensory processing and in speech. Several kinds of studies demonstrate localization of function: stimulation studies, lesion studies that destroy or isolate brain tissue in a region, strokes (which interfere with blood circulation to a particular part of the brain, resulting in death of neurons and disruption of a particular sensory or motor process), and functional imaging studies.

Modern imaging studies are particularly important in clarifying location of function. Imaging methods such as functional magnetic resonance imaging (fMRI) (Figure 15.7 and Box 15.2) show localized increased metabolic activity that results from increases in neuronal electrical activity. These areas of increased activity show where particular functions are localized. Note that localization of function does *not* mean that a particular brain area is involved in only one function, or that any function involves only one discrete brain area. A function is often apt to involve a *circuit* in the brain (a network of synaptically interconnected and interacting neurons, which may be widespread) rather than a discrete *center*.

PRINCIPLE 2: BRAINS HAVE MAPS The brain maintains information about the body's anatomical organization in terms of topographic representations, or **maps**. The brain contains many mapped representations that record and recall the parameter of *where* a stimulus occurs or an effector is to be controlled. For example, the sensory surface of the body is mapped onto the primary somatosensory area of the cerebral cortex (Figure 15.8b) to form a **somatotopic map** (a map of the body projected to a brain area). An analogous but rougher somatotopic map of motor control exists on the surface of the primary motor cortex (Figure 15.8a); stimulation of a part of the motor cortex will elicit movement of the corresponding part of the body.

There are additional sensory and motor maps in other areas of the cerebral cortex, as well as in many noncerebral brain structures. The visual system, for example, exhibits a point-to-point correspondence between areas in the visual field in the outside world and areas in the retina, which we discussed in Chapter 14. This geometric orienta-

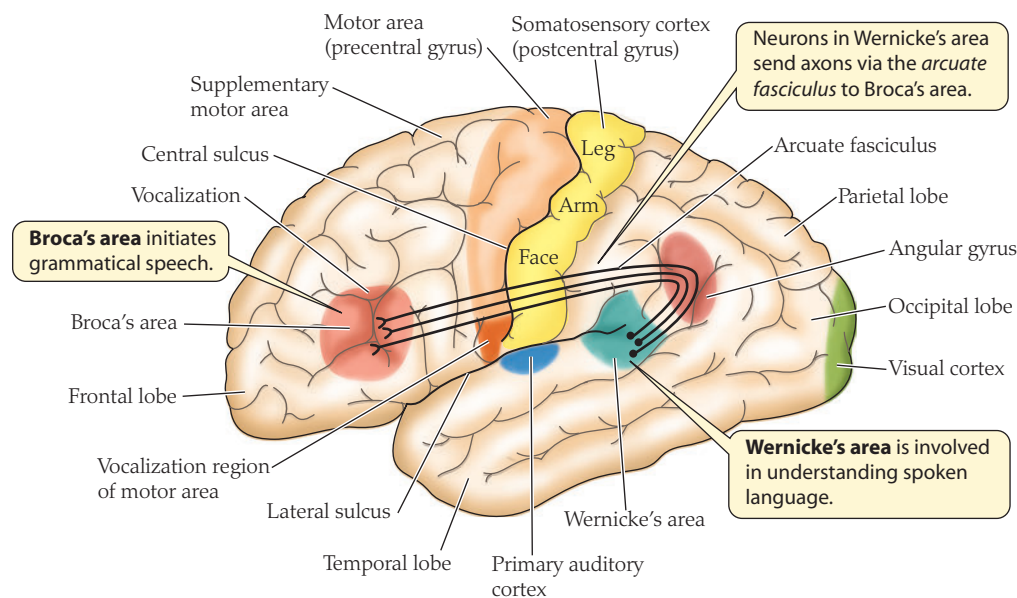

FIGURE 15.6 Localization of function in the human brain This surface view of the left cerebral hemisphere shows primary sensory areas (visual cortex, green; primary auditory cortex, blue; somatosensory cortex, yellow); motor areas (orange); and areas involved in language. Note that although the functions are rather localized, circuits interconnect several areas, as shown for spoken language.

FIGURE 15.7 Functional neuroimaging demonstrates localization of function in the human cerebral cortex Functional magnetic resonance imaging (fMRI) shows increased activity of particular brain areas. This fMRI sectional image of a brain (seen from above; left is anterior) shows increased neural activity during a visual stimulus. The neural activity (measured as increased flow of oxygenated blood and shown in red) increases in the lateral geniculate nucleus of the thalamus (middle) and the primary visual cortex (posterior). (See Figure 14.32 for a diagrammatic view of this pathway and Box 15.2 for a discussion of fMRI as an imaging method.) (From Chen et al. 1999.)

tion is preserved in visual pathways, so that the retinal map of the world is projected to each of the major visual centers in the brain. However, maps in the brain are by no means universal; many areas of the mammalian brain lack topographic organization.

PRINCIPLE 3: SIZE MATTERS In general, the bigger the brain area, the more neurons are present in it, and the more complex the integration that occurs there. Thus mammalian brains, with tens of billions of neurons, perform more complex integration than do insect brains with tens of thousands of neurons. By the same token, the massive enlargement of the cerebral cortex in the course of mammalian evolution (as a result of the developmental proliferation of greatly increased numbers of neurons) attests to major increases in processing capability of mammalian, and especially primate, brains. Primate brains are not “more evolved” than the brains of fish and amphibians, because fish and amphibians have had as long a time to evolve and can be considered to be as well adapted to their ecological niches as primates are. Nevertheless, the great expansion of cerebral cortex in primates has allowed types of neural function (e.g., language, culture) not found in brains with fewer neurons.

PRINCIPLE 4: VERTEBRATE BRAIN EVOLUTION HAS INVOLVED REPEATED EXPANSION OF FOREBRAIN AREAS The hindbrains of fish and amphibians are similar in structure to the corresponding regions in mammalian brains, but birds and mammals have evolved more complex forebrain structures, most notably the mammalian cerebral cortex, as noted previously. According to most evolutionary neurobiologists, many different vertebrate lineages underwent evolutionary expansion of their brains, expanding and reorganizing preexisting components of the forebrain in the process. Mammals reorganized the dorsal pallium into a neocortex, which underwent expansion in several lineages, notably primates. Forebrain expansions in fish and birds have involved different homologies. The “new” forebrain structures are thus not completely new, but rather represent expansions and elaborations of preexisting structures. They may subsume some of the functions of the more posterior structures of the midbrain and hindbrain, but they

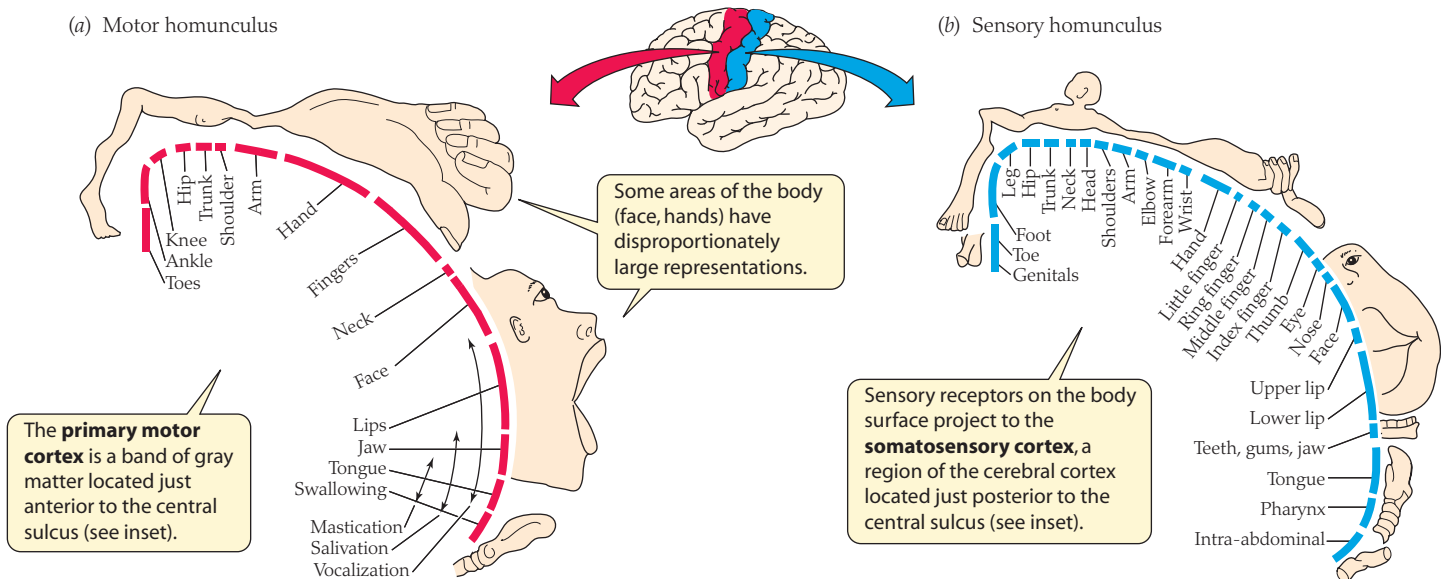

FIGURE 15.8 Maps in the human brain In what is called a somatotopic map, parts of the body are mapped onto the cerebral cortex in a way that preserves their anatomical position on the body. (a) Neurons in the primary motor cortex control movements of parts of the body, and are loosely organized as a somatotopic map that is less detailed than

that of the somatosensory cortex. (b) Sensory receptor locations are mapped somatotopically onto the somatosensory cortex. A drawing of the body projected onto the brain is called a *homunculus*, meaning “little person.” Note the disproportionate size of the cortical areas devoted to the face and hands.

BOX 15.2 FUNCTIONAL MAGNETIC RESONANCE IMAGING Scott A. Huettel

Functional magnetic resonance imaging (fMRI) is a method for detecting the functional activity of different areas of the brain. The use of fMRI has grown dramatically over the past two decades and is now the dominant research method in cognitive neuroscience. Each year, several thousand articles are published that use fMRI to study topics as basic as the structure of memory and as complex as the foundations of moral cognition. What accounts for this remarkable growth? What

information does fMRI provide, and how does that information lead to inferences about brain function? What new directions will fMRI researchers pursue in the coming years, as scientists make new discoveries both about the technique itself and about the functional organization of the brain? **Box Extension 15.2** describes the development of the fMRI technique and its current and potential future uses.

do not replace these “older” structures, which persist with less apparent change. The addition of forebrain structures leads to the popular description that humans have an anterior, telencephalic “mammalian brain” and an older “reptilian brain,” consisting of the deeper structures of the midbrain and hindbrain.

PRINCIPLE 5: NEURAL CIRCUITS ARE PLASTIC We tend to think of the synaptic connections between neurons as “hardwired”—rather fixed and unchanging—but there is abundant evidence that this is not the case. Instead, as we discussed in Chapter 13, synapses are *plastic*: They change with development, maturation, and experience such as learning. Noting a difference between short-term memory and long-term memory will clarify this point: *Short-term memory*, memory of events of the last minutes to hours, can be disrupted by a concussion or by electroconvulsive shock. *Long-term memories*, in contrast, are not lost after a concussion, because they are thought to be stored more permanently as changes in the “wiring”—changes in the strengths of synaptic interconnections of neurons. This storage of long-term memory may be an example of how neural connections are plastic, or subject to change in strength and effectiveness.

We know also that synaptic connections are plastic during development of the nervous system; they are made and broken as an animal’s brain matures, and they are subject to competition between neuron endings for synaptic sites on a postsynaptic target cell (see Box 13.1). Scientists believe that plasticity in development may have mechanisms similar to the plasticity associated with learning and memory that we explored in Chapter 13.

Moreover, there is abundant evidence that new neurons develop throughout life in the nervous systems of both vertebrates and invertebrates. An ongoing proliferation of new neurons has long been accepted for invertebrates and lower vertebrates, and more recent studies clearly demonstrate neuronal proliferation in some parts of adult mammalian nervous systems. Evidence that new neurons proliferate and differentiate throughout life has fueled widespread interest in the use of transplants of undifferentiated stem cells in an attempt to counteract neuron losses in neurodegenerative diseases such as Parkinson’s disease and Alzheimer’s disease.

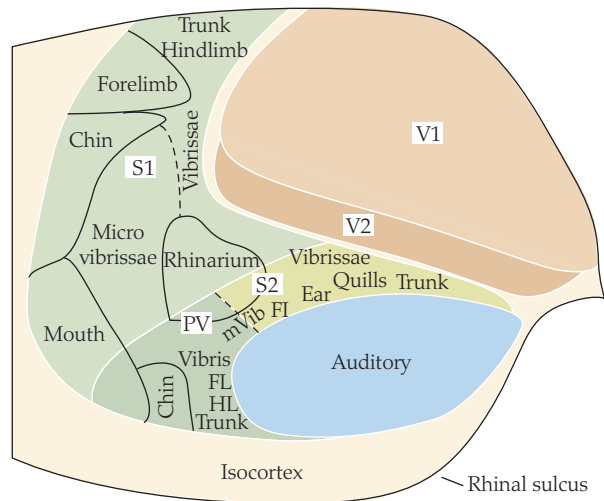

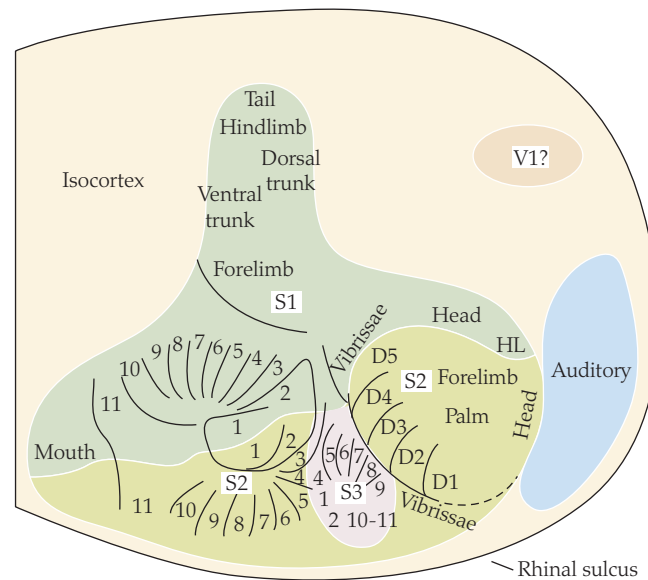

STAR-NOSED MOLES EXEMPLIFY THESE PRINCIPLES OF FUNCTIONAL ORGANIZATION The star-nosed mole with which we opened this chapter provides a clear example of these organiza-

tional principles. **Figure 15.9a,b** shows side views of the cerebral cortex of an African hedgehog (*Atelerix albiventris*) and a star-nosed mole. The hedgehog brain (Figure 15.9a) shows a localization of cerebral cortical function typical of small and relatively unspecialized mammals, with large areas devoted to visual and auditory functions, a primary somatosensory area (S1), and two smaller somatosensory areas (S2, PV) below it. The cerebral cortex of the star-nosed mole (Figure 15.9b) has impressive differences in size of the cortical representations. Both brains demonstrate localization of function (like Figure 15.7), with particular areas performing particular functions, and both brains show somatotopic maps, with particular areas of the body projecting to particular places in the brain (as shown in Figure 15.8). The size differences in the brain representations of the star-nosed mole reflect the unimportance of vision and the importance of somatosensory functions, particularly of the “star,” which has three somatosensory representations that together occupy more area than that devoted to the rest of the body (**Figure 15.9c**). Finally, the star-nosed mole shows evidence of plasticity in development of the brain; a few moles develop with 12 rather than 11 rays in the star, and developing sensory neurons from the “extra” ray induce a corresponding extra cortical representation to which they indirectly project!

The peripheral nervous system has somatic and autonomic divisions that control different parts of the body

As noted previously, physiologists recognize two primary divisions of the vertebrate PNS: the *somatic* and the *autonomic* nervous systems (see Figure 15.4). Here we focus on the properties of these two divisions. We start with a relatively brief discussion of the somatic nervous system. Thereafter, most of this section is devoted to the autonomic nervous system.

Because the somatic nervous system is the part of the PNS that controls the skeletal (striated) muscles, it controls the muscles of locomotion and other body movements, speech, and breathing. Thus it controls most observable behavior. In addition to its motor elements, the somatic nervous system also includes the somatic sensory receptors for touch, hearing, vision, taste, olfaction, and so forth. We have examined aspects of the somatic nervous system in earlier chapters and in the first pages of this chapter. Here we consider only its overall organization.

(a) African hedgehog (*A. albiventris*)(b) Star-nosed mole (*C. cristata*)

(c) Cortical magnification in star-nosed mole

**FIGURE 15.9 Maps in the brain differ for different animal groups**

Side views of the cerebral cortex of an African hedgehog and a star-nosed mole. (a) The hedgehog brain shows a localization of cerebral cortical function typical of small and relatively unspecialized mammals, with large areas devoted to visual (V1, V2) and auditory functions, a primary somatosensory area (S1), and two smaller somatosensory areas (S2, PV) below it. (b) The cerebral cortex of the star-nosed mole exhibits differences in area of cortical representation, reflecting the animal's unusual sensory capacities. The visual area (V1?) is greatly reduced, in accordance with the fossorial mole's greatly diminished visual function. The auditory area is displaced posteriorly, and the somatosensory areas are expanded, especially the ventral ones. The three sets of radiating lines numbered 1–11 indicate three areas that represent the star nose. (c) Depicted here is the disproportionately large representation of the star nose and of the digging forelimb in the star-nosed mole. (After Catania 2005 and 1999.)

Somatic motor and sensory neurons exit and enter the CNS in the cranial and spinal nerves (as do autonomic neurons, discussed next). Mammals have 12 pairs of *cranial nerves*, rather specialized in function, that are numbered 1 to 12 using Roman numerals. Some of the cranial nerves are associated with the major sense organs of the head (I, olfactory; II, optic; VIII, auditory). Other cranial nerves have principally motor functions, or have mixed sensory and motor functions. The vagus nerve (X) innervates the larynx and some other somatic components, while also being a major component of the autonomic nervous system.

The spinal nerves are arranged segmentally, with one pair of spinal nerves per vertebra along the spinal column. These nerves include both sensory and motor somatic neurons. The sensory neurons enter the spinal cord in the dorsal roots of the spinal nerves; the cell bodies of those neurons are located in **dorsal root ganglia**, enlargements of the dorsal roots outside the spinal cord (see Figure 15.3b). The ventral roots of the spinal nerves (see Figure 15.3b) contain axons of the somatic motor neurons that innervate the skeletal muscles. They also contain autonomic neurons that innervate autonomic ganglia. An important property of the somatic nervous system is that somatic motor neurons directly synapse on muscle fibers, without synapsing on other neurons after leaving the

CNS (Figure 15.10a). (This is in basic contrast to motor neurons of the autonomic nervous system, as we discuss below.)

The autonomic nervous system has three divisions

The vertebrate autonomic nervous system is usually defined as if it were a motor system—the division of the PNS that controls the autonomic effectors. However, the autonomic nervous system also includes sensory neurons that convey afferent signals from internal organs to the CNS. Many invertebrate animals have nervous system divisions that control visceral functions. These divisions are sometimes described as *autonomic* by analogy to vertebrate autonomic nervous systems. The autonomic effectors that are controlled at least partly by the vertebrate autonomic nervous system include the following:

- Smooth muscles throughout the body, such as those in the gut wall, blood vessels, eyes (iris muscles), urinary bladder, hair follicles, spleen, airways of the lungs, and penis.
- Many exocrine glands, such as sweat glands, tear glands, and the exocrine portion of the pancreas. (**Exocrine glands** discharge secretions into the environment or into internal body cavities, in contrast to endocrine glands, which secrete into the blood or other body fluids.)

(a) Somatic nervous system

(b) Autonomic nervous system

FIGURE 15.10 The organization of the mammalian somatic and autonomic nervous systems, including examples of effector organs (a) Skeletal muscle is under somatic control. Each motor neuron extends from the CNS to the effector it controls. (b) The heart is under autonomic control, via chains of two neurons with a synapse in a peripheral ganglion. Sympathetic ganglia are typically close to the spinal cord; parasympathetic ganglia are typically near target organs. Preganglionic autonomic neurons secrete the neurotransmitter acetylcholine (ACh); postganglionic sympathetic neurons secrete norepinephrine, and postganglionic parasympathetic neurons secrete ACh. The enteric nervous system (not shown) has some connection to the CNS but is largely restricted to the gut. The enteric nervous system employs a great diversity of neurotransmitters.

- A few endocrine glands, notably the adrenal medullary glands (called chromaffin tissue in some vertebrates) that secrete epinephrine (adrenaline).
- Acid-secreting cells of the stomach.
- The pacemaker region and other parts of the heart.
- The brown adipose tissue of mammals (a heat-producing tissue).
- The swim bladders and integumentary chromatophores (color-change cells) of fish.

The vertebrate autonomic nervous system is usually considered to consist of three divisions—*sympathetic*, *parasympathetic*, and *enteric*—first described by John Langley (1852–1925). Langley based his classification on anatomy, not function. Therefore, his divisions are not always distinctly different in function. Today his scheme is considered valid for mammals. It is often used for nonmammalian vertebrates also, although its application to these other groups remains debatable.

The **sympathetic** and **parasympathetic divisions** in mammals, by definition, functionally link the CNS with autonomic effectors. The two divisions characteristically have opposing effects on the autonomic effectors, so that sympathetic actions are said to mediate “fight-or-flight” responses, whereas parasympathetic actions mediate “rest-and-digest” functions (see page 409). The **enteric division**, in contrast, is largely contained in the walls of the gut, although it has some connection with the CNS.

ANATOMY OF THE SYMPATHETIC AND PARASYMPATHETIC DIVISIONS A key attribute of the sympathetic and parasympathetic divisions is that they have motor pathways in which signals exit the CNS and control autonomic effectors. These motor pathways are characterized by a *peripheral synapse*—that is, an “extra” synapse interposed between the CNS and the ultimate synaptic ending on effector tissue (Figure 15.10b). This peripheral synapse

is a characteristic of the sympathetic and parasympathetic divisions of all vertebrates, so autonomic motor signals in both divisions traverse a two-neuron relay to reach their effectors from the CNS.

The peripheral synapses between the first and second neurons in the sympathetic and parasympathetic divisions are located within clusters of neuronal cell bodies called **autonomic ganglia**. The neurons that extend from the CNS to the ganglia are termed **preganglionic neurons**, whereas those extending from the ganglia to the effectors are termed **postganglionic neurons**. The mammalian sympathetic and parasympathetic divisions differ in the positions of the ganglia. In the parasympathetic division, the ganglia are located mostly at or near the effectors, so preganglionic parasympathetic neurons are long and postganglionic parasympathetic neurons are short (see Figure 15.10b). In contrast, sympathetic ganglia are located mostly near the spinal cord, so preganglionic sympathetic neurons are short, and postganglionic sympathetic neurons are long.

The mammalian sympathetic and parasympathetic divisions also differ in that motor neurons of the two divisions exit the CNS in nerves associated with different regions of the CNS (Figure 15.11). Parasympathetic preganglionic neurons exit the CNS from two regions: cranial and sacral. For this reason, the parasympathetic division is sometimes called the *craniosacral* division. The cranial group of nerves consists of four of the pairs of cranial nerves: the oculomotor (III), facial (VII), glossopharyngeal (IX), and vagus (X) nerves. The sacral group of nerves emerges from the posterior part of the spine.

The preganglionic neurons of the sympathetic division exit the CNS in nerves of the thoracic and lumbar regions of the spine (see Figure 15.11). For this reason, the sympathetic division is also called the *thoracolumbar* division. Most of the nerves terminate in sympathetic ganglia immediately lateral to the spine. These **para-vertebral ganglia** occur segmentally (at regularly repeating intervals) along the length of the spine and are interconnected by peripheral

FIGURE 15.11 Parasympathetic and sympathetic divisions of the autonomic nervous system provide dual innervation of most visceral autonomic effectors. Parasympathetic nerves and ganglia are shown on the right and sympathetic nerves and ganglia on the left, but both have paired right and left sides.

longitudinal nerve connectives, forming a **sympathetic chain** on each side of the vertebral column. In contrast to this general pattern, some preganglionic sympathetic neurons terminate in ganglia more distant from the spine, as in the coeliac ganglion (solar plexus). Some directly innervate the medullary tissue of the adrenal glands (see Chapter 16).

FUNCTION OF THE SYMPATHETIC AND PARASYMPATHETIC DIVISIONS

The postganglionic neurons of the parasympathetic and sympathetic divisions release different chemical neurotransmitter substances at their synapses with effector cells. Parasympathetic postganglionic neurons typically release acetylcholine and thus are termed **cholinergic**. Most sympathetic postganglionic neurons release mainly catecholamines—chiefly norepinephrine (noradrenaline) in mammals—and thus are called **adrenergic** (or noradrenergic).

Autonomic effectors may be innervated by one or both of the sympathetic and parasympathetic divisions. In mammals many smooth muscles of blood vessels and the piloerector (hair-erecting) muscles of the hair follicles receive only sympathetic innervation. Many other effectors, in contrast, receive both sympathetic and parasympathetic innervation (see Figure 15.11). The responses elicited by the two divisions in such cases usually oppose each other. For instance, the pacemaker region of the heart (cells that initiate the heartbeat) is innervated by both divisions. Parasympathetic postganglionic neurons, which secrete acetylcholine as their neurotransmitter, decrease the heart rate. In contrast, sympathetic postganglionic neurons, which secrete norepinephrine, increase heart rate. (Receptors for these neurotransmitters are listed in Table 13.2.)

The parasympathetic and sympathetic divisions play functional roles that reflect their tendency to act in opposition, and demonstrate the integrative actions of autonomic control (Table 15.2). The parasympathetic division (especially its cranial part) tends to promote processes that restore body reserves of energy (e.g., stimulating digestion). In contrast, the sympathetic division promotes mobilizing body energy reserves (e.g., promoting blood flow to muscles) and inhibits some processes that restore reserves; it is particularly activated in the face of stress, and it readies the body to meet stress. Direct sympathetic innervation mediates most of the effects listed for the sympathetic division in Table 15.2, but the sympathetic nervous system also stimulates the medullary tissue of the adrenal glands to secrete epinephrine (adrenaline) and norepinephrine, which act hormonally to complement sympathetic action on effectors. Circumstances that might provoke strong, concerted activation of the sympathetic division include vigorous exertion, pain, threats to safety, and exposure to physical extremes such as severe heat or cold. It is through their integrative and opposed actions that the sympathetic division has been said to prepare an individual for “fight-or-flight,” whereas the parasympathetic division is said to promote “rest-and-digest” functions.

TABLE 15.2 Major actions of sympathetic and parasympathetic divisions in vertebrates

Process	Parasympathetic effect	Sympathetic effect
Digestion: gastrointestinal secretion and motility	Stimulates	Inhibits
Heartbeat	Slows	Increases rate and force
Blood vessels	Usually dilates (when present)	Constricts vessels to kidneys and gut; dilates vessels to skeletal muscles
Blood pressure	Decreases	Increases
Lung passages	Constricts	Dilates
Secretion of epinephrine and norepinephrine by adrenal medullary glands	—	Stimulates

THE ENTERIC NERVOUS SYSTEM CONTROLS THE GUT The enteric division of the autonomic nervous system consists of elaborate networks of neurons located entirely within the walls of the gut. It has been likened to the nerve nets of Cnidaria (see Box 15.1) with a relatively diffuse structural organization and pattern of synaptic interactions among gut sensory neurons, interneurons, and motor neurons. The enteric division controls peristalsis, segmentation, and other patterns of contraction of the smooth muscles of the gut wall that serve to move digested materials through the gut. The enteric nervous system’s function is largely autonomous of CNS control, although the CNS can modulate enteric neurons and synapses via sympathetic and parasympathetic nerves.

The enteric nervous system contains large numbers of neurons: about 200 to 600 million in humans. This is far more neurons than in other peripheral organs and probably exceeds the number of neurons in the spinal cord! Recent evidence shows that about 90% of the visceral fibers in the parasympathetic vagus nerve carry information from the gut to the brain, rather than from brain to gut. This finding, as well as the large number of enteric neurons, suggests that the enteric nervous system plays other roles in addition to moving material through the gut.

SUMMARY The Vertebrate Nervous System: A Guide to the General Organizational Features of Nervous Systems

- The CNS of vertebrates consists of the brain and spinal cord. Cranial and spinal nerves emanate from the CNS to form the peripheral nervous system (PNS). The brain is divided into a forebrain, midbrain, and hindbrain; the forebrain is enlarged in birds and especially in mammals.
- Vertebrate brain functions are somewhat localized. However, brain functions are also somewhat distributed, involving circuits rather than centers.
- Many vertebrate brain regions preserve the orderly spatial arrangements of the corresponding external world, for example, as somatotopic maps of body sensory input and motor output.

- Brains change with development, experience, and learning and memory. Understanding the structural and synaptic bases of these changes is a major challenge to investigators.
- The PNS of vertebrates has a somatic division that controls skeletal muscle and an autonomic division that controls effectors associated with internal organs. The autonomic nervous system is divided into sympathetic and parasympathetic divisions, which usually have opposite physiological effects, and the enteric division, which controls gut contraction and other aspects of digestive tract physiology.

Biological Clocks

Animals (and other organisms) possess endogenous physiological timing mechanisms termed **biological clocks** that rhythmically modulate the functioning of cells, tissues, and organs. Biological clocks endow an animal with an intrinsic **temporal organization**, a timed pattern of change in physiology or behavior that is independent from a change in environment (see Chapter 1, pages 14–16, for discussion of temporal frameworks in animal physiology). Biological clocks are typically operations of the nervous system, controlling physiological and behavioral processes via nervous and neuroendocrine output. Characteristically, the physiological state of an animal is endogenously different at different times of day, or in different seasons of the year. One such change is the sleep–wake cycle, discussed in **Box 15.3**.

Biological clocks orchestrate daily and seasonal changes, controlling and integrating the changes in physiological states. **Figure 15.12** shows the daily variation in several physiological functions in a 24-year-old man. These data are from one of the earliest studies designed to test whether humans have endogenous, physiological mechanisms for keeping track of time. The man was placed in living quarters that were entirely isolated from the outside world. He had no clocks in his environment and was unable to distinguish between day and night. Thus he slept, ate, and urinated without any environmental cues. Three dramatic conclusions can be reached by study of these results. First, the man continued to exhibit regular cycles in all the variables studied. Second, he tended to exhibit internal synchronization of his cycles: On any one day, he tended to have the highest rectal temperature and to excrete the most during the block of time when he was principally awake. Finally, however, he did not stay synchronized with the outside world: Relative to clock time in the outside world, his cycles became later and later as the days went by, so that—for example—after 13 days, he elected to be awake after midnight rather than before midnight (outside world time).

Put loosely, the man in Figure 15.12 was able to keep track of time endogenously, but his internal biological clock was not able to stay precisely synchronized with outside time, so that his rhythm was said to be *free-running* (see below). As we will see, these properties are very general among animals.

Organisms have endogenous rhythms

A *rhythm* is a regular, cyclical variation in function. Rhythms that continue in the absence of environmental information

about time, such as those of the man in Figure 15.12, are termed **endogenous rhythms**. The first organisms in which endogenous rhythms were demonstrated were certain plants that raise their leaves during some times of day and lower them at others.³ In 1729, the Frenchman M. de Mairan reported that these plants continue to raise and lower their leaves in approximately a daily rhythm even when they are kept in constant darkness and at constant temperature. That is, their rhythm of leaf movements is intrinsic or endogenous: It continues in more or less a daily pattern *even when the plants are denied environmental sources of information about the time of day*. Experiments of a similar nature have since been performed on many plant and animal systems, and daily

³In our discussion of rhythms and biological clocks, we will consistently use the words *day* and *daily* to refer to the 24-hour day, not just to hours of daylight.

FIGURE 15.12 Daily rhythm of several physiological functions in a human A young man lived by himself in an apartment without clocks, telephones, windows, or other avenues whereby he could know the time of day in the outside world. He could turn the lights on and off, prepare food, go to bed, urinate, and engage in other processes of daily living, but his timing of those activities was based entirely on his endogenous, physiological sense of time. This graph shows his patterns of variation in five remotely monitored functions during his first 15 days of life without knowledge of external time. (After Wever 1979.)

BOX 15.3 SLEEP David S. Garbe

Why animals sleep continues to be one of the most elusive and mysterious questions in biology. Sleep, nonetheless, is found widely among animals—from relatively simple phyla such as worms (e.g., *Caenorhabditis elegans*) to higher-order groups such as humans—suggesting that sleep is a required, evolutionarily conserved behavior. Yet from certain perspectives, sleep could be considered disadvantageous to an organism's overall survival and fitness because while animals are sleeping, they are not immediately able to eat, mate, or protect themselves from predation. Still we as humans sleep for approximately one-third of our entire

lives. Most scientists conclude that there must be an overriding benefit of sleep that compensates for the lack of interaction with the surrounding environment. In fact, sleep is crucial for survival. Long-term sleep deprivation is lethal to rodents and fruit flies (*Drosophila melanogaster*). Moreover, disturbances in sleep and its regulation are associated with several chronic human disease states, including insulin resistance and diabetes, fatal familial insomnia, shift-work disorder, certain neurodegenerative diseases, and major depressive disorder.

Box Extension 15.3 discusses functions of sleep and mechanisms of its regulation.

Rhesus macaque (*Macaca mulatta*)

rhythms in many types of function in many types of organisms have been shown to persist in constant laboratory environments.

The **period** of a rhythm is the amount of time between a particular part of the rhythm in one cycle (one day) and that same part in the next cycle. Typically the period is measured as the time between the start of one day's episode of activity and the start of the next day's. For example, in the case of Mairan's plants, the period could be measured as the time between the start of leaf raising on one day and the start of leaf raising on the next.

An endogenous rhythm that has a period of about a day is termed a **circadian rhythm** (*circa*, "about"; *dies*, "a day"). Not all daily rhythms prove to be endogenous when tested. Only those that are endogenous—that can persist in the absence of environmental information about the time of day—are properly termed circadian. Circadian rhythms appear to occur in all eukaryotes and some prokaryotes. Thus a capacity for endogenous rhythmicity is believed to be an ancient feature of life. **Table 15.3** lists some examples of the known endogenous circadian rhythms.

Under normal conditions in a state of nature, circadian rhythms are tightly coupled to environmental cues such as a daily light–dark cycle. **Figure 15.13a** shows the locomotor activity and metabolic rate of a chaffinch (*Fringilla* sp.) initially kept on a normal light–dark cycle. In diurnal species such as a chaffinch, locomotor activity, metabolic rate, and many other physiological variables increase during the day, usually starting near dawn. Two rhythms are said to be **in phase** if they occur synchronously.

Thus, for a chaffinch exposed to a normal light–dark cycle, as you can see from **Figure 15.13a**, both locomotor activity and metabolic rate are in phase with the light–dark cycle.

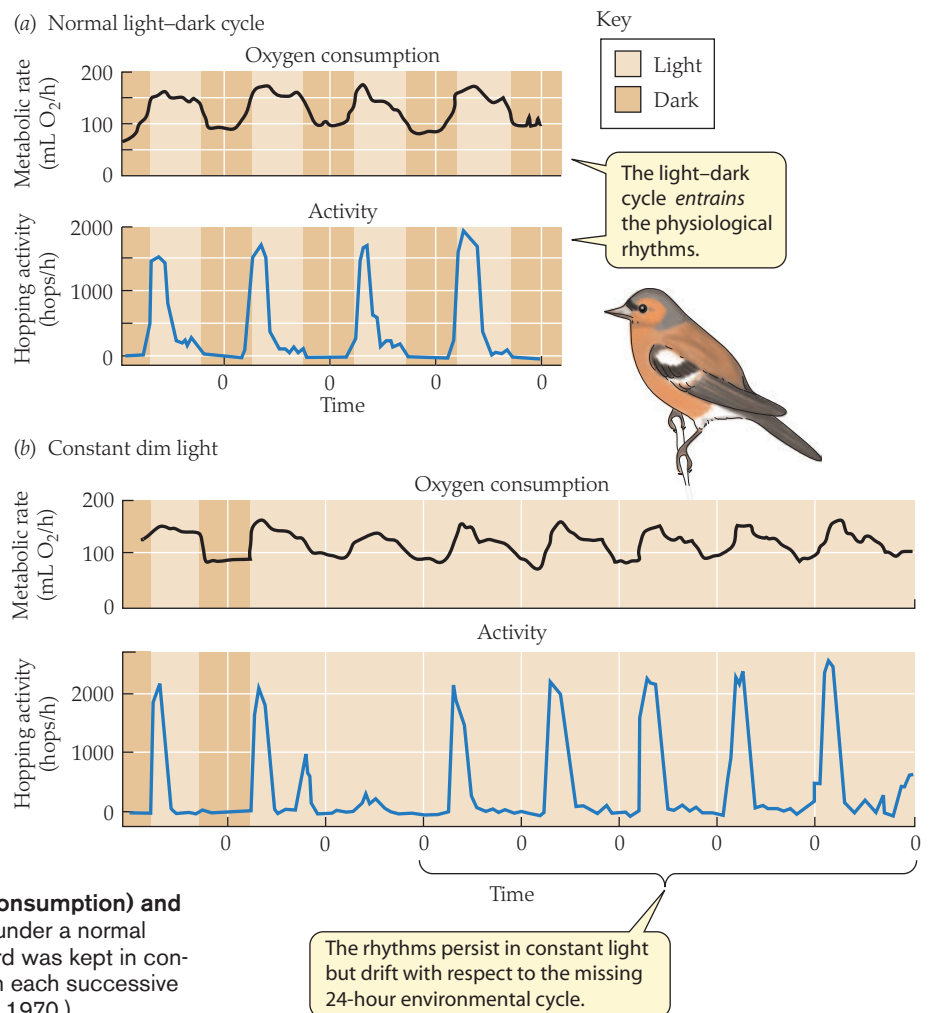

FIGURE 15.13 Circadian rhythm of metabolic rate (O_2 consumption) and motor activity for a chaffinch (a) The bird was initially kept under a normal light–dark cycle, which entrained the rhythm. (b) Later the bird was kept in constant light. Note that the free-running rhythm started earlier in each successive 24-h period. Zero on the x axis denotes midnight. (After Pohl 1970.)

TABLE 15.3 Some processes that show circadian rhythmicity in animals and other eukaryotes

Locomotor activity in many vertebrates and invertebrates
Sleep–wake cycles in many animals
Metabolic rate in many animals
Variations of body temperature (including torpor) in birds and mammals
Urine output and drinking in mammals
Adrenocortical hormone secretion and epidermal mitosis in mammals
Integumentary color change in fish and crabs
Oviposition, mating, and emergence of adults from pupae in insects
Female pheromone release and male pheromone sensitivity in insects
Mating in <i>Paramecium</i>
Bioluminescence and photosynthetic capacity in dinoflagellate algae

To test whether a daily rhythm is an endogenous circadian rhythm, an experimenter must remove the environmental timing information. In the case of the chaffinch, this means removing the light–dark cycle. When a chaffinch is exposed to constant, dim light (Figure 15.13b), both its locomotor rhythm and rhythm of oxygen consumption persist—demonstrating that they are endogenous rhythms—but the rhythms fail to remain synchronized with the time dawn would have come each day. Instead, under these conditions, the period of each rhythm is a little shorter than a day—about 23 hours (h)—meaning that with each passing 24-h day, activity starts earlier and earlier relative to the time dawn would have come. When environmental cues are absent, the biological rhythm that persists is said to **free-run** or to be a **free-running rhythm**. Like the chaffinch and like the man in Figure 15.12, most organisms have rhythms with free-running periods that are circadian—close to but not exactly equal to 24 h.

The difference between a free-running rhythm and one that is synchronized to environmental cues is easier to see if the records of activity on successive days are stacked one below the last, to make a chart called an *actogram*. Figure 15.14 shows the activity rhythms of two nocturnal flying squirrels (*Glaucomys volans*) for 23 consecutive days stacked in this way: One squirrel was studied in a normal light–dark cycle and the other squirrel was studied in constant darkness. The light–dark cycle (when present) synchronizes the activity rhythm of a flying squirrel, bringing it into phase, so that the onsets of activity periods are lined up at the same time each day, as seen in Figure 15.14a. However, when a squirrel is placed in constant darkness and has no environmental information about the time of day, the squirrel’s endogenous rhythm of activity persists, but because the period of the endogenous circadian rhythm is not precisely 24 h, the free-running rhythm drifts in its timing (see Figure 15.14b). Specifically, in this case the period of the free-running rhythm is *more* than 24 h, and therefore the activity interval drifts to occur later and later each day.

The process by which a biological rhythm is brought into phase with an environmental rhythm is called **entrainment**. During this process, the biological rhythm is said to become *entrained* by environmental cues, as illustrated in Figure 15.14a. An environmental cue that is capable of entraining (setting the phase) of a biological rhythm

is called a **phasing factor** or **zeitgeber** (a term adopted from German and meaning “time-giver”). In nature, the onset of darkness each night cues the activity of nocturnal flying squirrels—not so much directly as indirectly—by resetting the biological clock that generates the circadian rhythm (see below). The squirrels do not wait in total ignorance each day to see when darkness will arrive. Rather, they have an endogenous sense of the time of day, and the onset of darkness simply serves as a cue that maintains a *precise* 24-h rhythm in a system that, in itself, would maintain an *approximate* 24-h rhythm.

Several types of environmental stimuli serve as phasing factors for circadian rhythms. Daily cycles of light intensity entrain the great majority of rhythms. In addition, rhythms can be entrained by cycles of temperature, sound, food availability, social interaction, or other parameters.

Biological clocks generate endogenous rhythms

A *biological clock* is a physiological mechanism that times an endogenous rhythm. This statement does not explain the mechanism by which the clock works; it merely presents the logical necessity of the existence of such a mechanism. Most (but not all) biological clocks are located in the animal’s nervous system, as might be expected for their control functions. In examples such as those discussed above, when we speak of entraining a circadian rhythm to a light–dark cycle, it is really the biological clock that is entrained. The endogenous rhythm is the output of the clock. In essence, the clock controls effectors that allow investigators to see what the clock is doing.

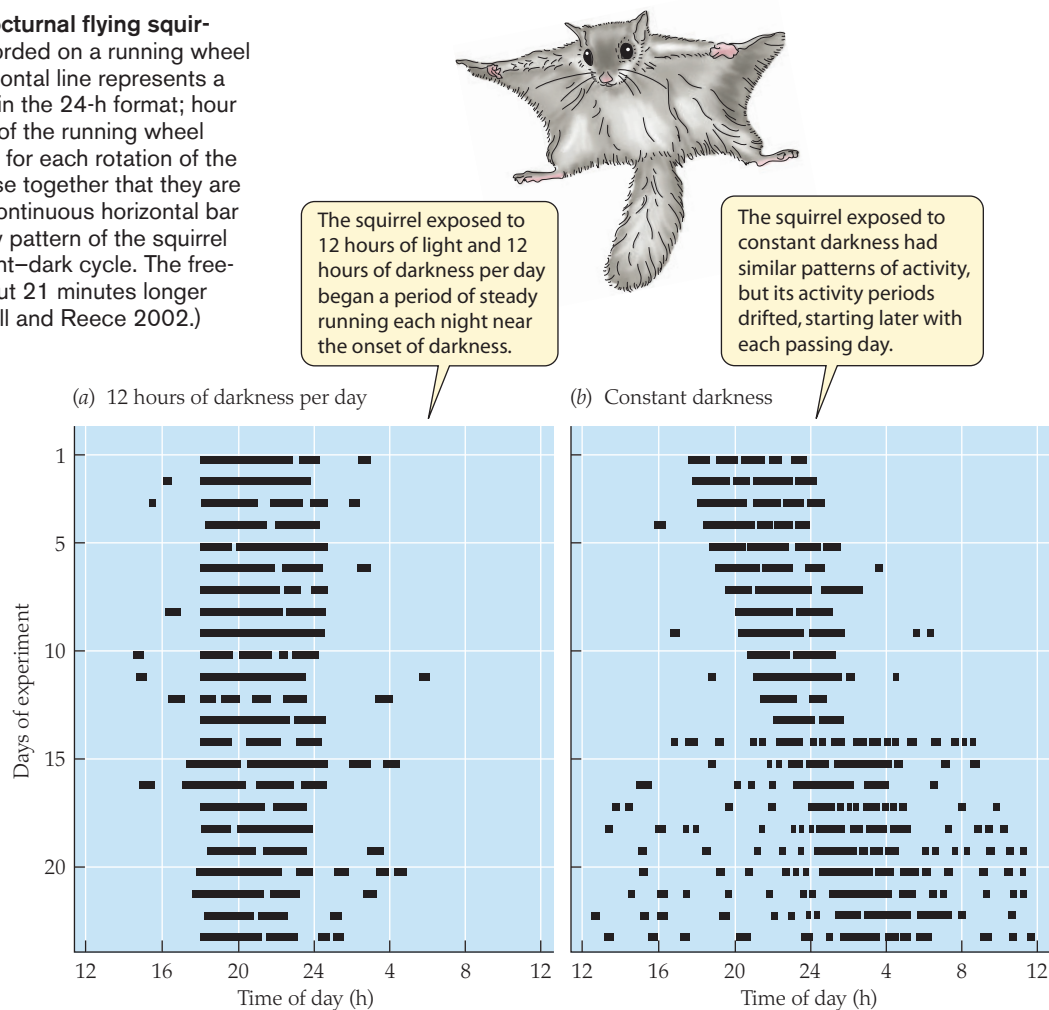

Often a biological clock is localized in a discrete region of the nervous system. For example, the biological clock controlling circadian rhythms in vertebrates is located in the suprachiasmatic nucleus of the brain (discussed later in this chapter). In insects and molluscs, the eyes—or structures closely associated with the eyes—often act as the principal circadian control centers or pacemakers. If the optic lobes of the brain are transplanted from one cockroach to another, for example, the recipient takes on the rhythms of the donor!

Control by biological clocks has adaptive advantages

The major adaptive advantage of biological clocks is that they are predictive: They enable an animal to anticipate and prepare for regular environmental changes. Biological clocks exert *feed-forward control* over effectors, in contrast to homeostatic feedback control (see Box 10.2). Feed-forward control, by definition, initiates changes in physiological systems, rather than correcting for changes after they happen. An animal that is strictly dependent on external cues must wait until the cues appear to trigger or stimulate a response. An animal with an internal clock, however, can anticipate when a physiological or behavioral action will be necessary and can initiate it unbidden.

Circadian clocks permit timing of processes during periods of the 24-h day when environmental cues about time are vague or unreliable. For instance, consider a nocturnal animal that emerges from its nest each evening at dusk, spends the night in feeding and other activities, and retires to its nest each dawn. If it has a circadian clock, it can entrain the clock to the daily environmental cycle defined by dawn and dusk, cues that are obvious and reliable. Then the clock can time the animal’s activities accurately throughout the dark of night, when environmental sources of time information are less obvious and less reliable.

FIGURE 15.14 Activity rhythms of two nocturnal flying squirrels (*Glaucomys volans*) Activity was recorded on a running wheel over a period of 23 days at 20°C. Each horizontal line represents a 24-h day. Times on the x axis are expressed in the 24-h format; hour 12 is noon and hour 24 is midnight. Turning of the running wheel activated a pen to record a short vertical line for each rotation of the wheel; these vertical blips are usually so close together that they are fused and give the appearance of a heavy, continuous horizontal bar during periods of steady running. The activity pattern of the squirrel in (a) was entrained by the environmental light–dark cycle. The free-running rhythm of the squirrel in (b) was about 21 minutes longer than 24 h. (After P. J. DeCoursey in Campbell and Reece 2002.)

Circadian clocks also enable animals to measure changes in **photoperiod**, the number of hours of daylight in a 24-h day. Many animals depend on changes in photoperiod over the course of the year for timing annual events in their life cycles. For example, the long photoperiods of spring may be used as a cue for reproduction or migration.

Finally, circadian clocks enable some animals to use the sun to determine the compass direction, for example in migration. Consider the fact that, if you see the sun on the horizon, you know the direction is west only if you know the time is afternoon. Similarly, certain animals can determine compass directions from the position of the sun, but only if they know the time of day. In these animals, circadian clocks provide the time-of-day information necessary to use the sun as a compass. Homing pigeons orienting relative to the sun, for example, will orient at wrong compass directions if their circadian clocks have been abnormally shifted (see Chapter 18, page 491).

Endogenous clocks correlate with natural history and compensate for temperature

Free-running circadian rhythms of animals have periods that are longer or shorter than 24 h, as we have seen. For many animals the period is correlated with natural history. Whereas nocturnal animals often have periods of free-running rhythm that are longer

than 24 h (and that thus drift later and later each day, as Figure 15.14b illustrates), many diurnal animals have periods shorter than 24 h. However, there are many exceptions. Moreover, experimenters have found that the period of an animal's free-running rhythm is also affected by the level of constant illumination under which the rhythm is measured. The way in which light pulses or light–dark cycles entrain a circadian rhythm also differs somewhat for diurnal and for nocturnal animals.

One remarkable feature of the clocks controlling circadian rhythms is that their timing is relatively insensitive to tissue temperature. Although some clocks can be entrained by temperature changes, the free-running period of the clock itself does not speed up or slow down much with changes in cellular temperature. As seen in Chapter 10 (pages 235–236), the rates of most metabolic processes are quite sensitive to body temperature; heart rate, breathing rate, and metabolic rate, for example, are likely to double or triple if the body temperature of an animal is raised by 10°C. In sharp contrast, the frequencies of free-running circadian rhythms typically increase by less than 5% when body temperature is elevated by 10°C.

A biological clock would obviously be of little use if it were highly sensitive to temperature; imagine the chaos if our wristwatches were to double their rate when warmed by 10°C! The low thermal sensitivity of biological clocks is therefore adaptive. Given, however, that the primary timing mechanisms of these clocks operate on a

cellular level, how do the clocks manage to be so immune to the thermal effects that so strongly influence most metabolic processes? This is a major unsolved question in circadian physiology.

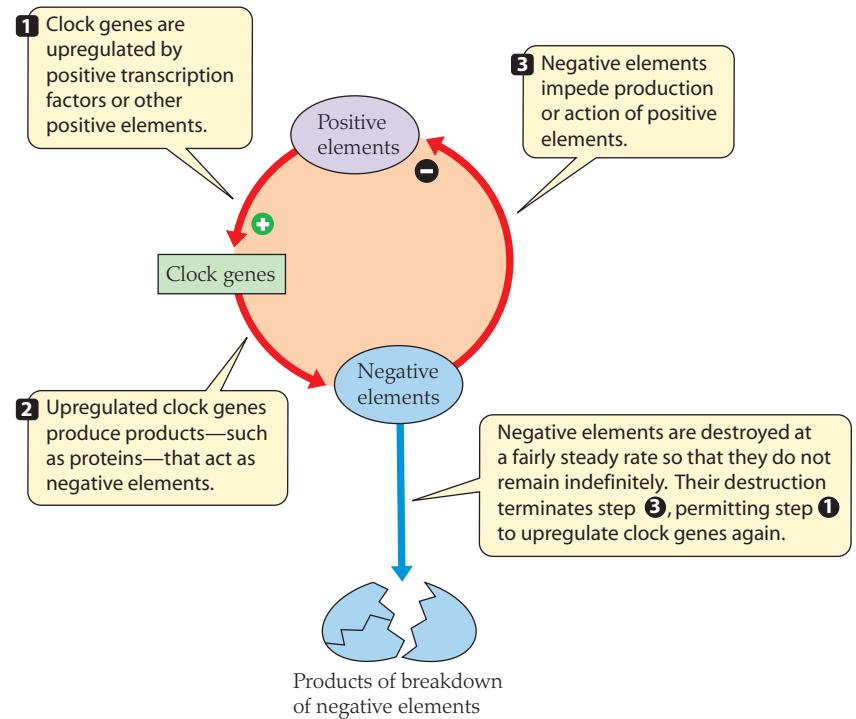

Clock mechanisms are based on rhythms of gene expression

How biological clocks *work* has remained one of the great mysteries of physiology until recently, when new molecular studies of genetic mutants have provided revolutionary insights. Investigators have identified mutations that modify or disrupt clock function in the fruit fly *Drosophila melanogaster*, hamsters, mice, and other model organisms. For example, a mutation in golden hamsters (*Mesocricetus auratus*) causes the activity rhythm of the animals to exhibit an exceptionally short (20-h) free-running period. By determining the biochemical consequences of such mutations, investigators have identified many of the key components of clock mechanisms.

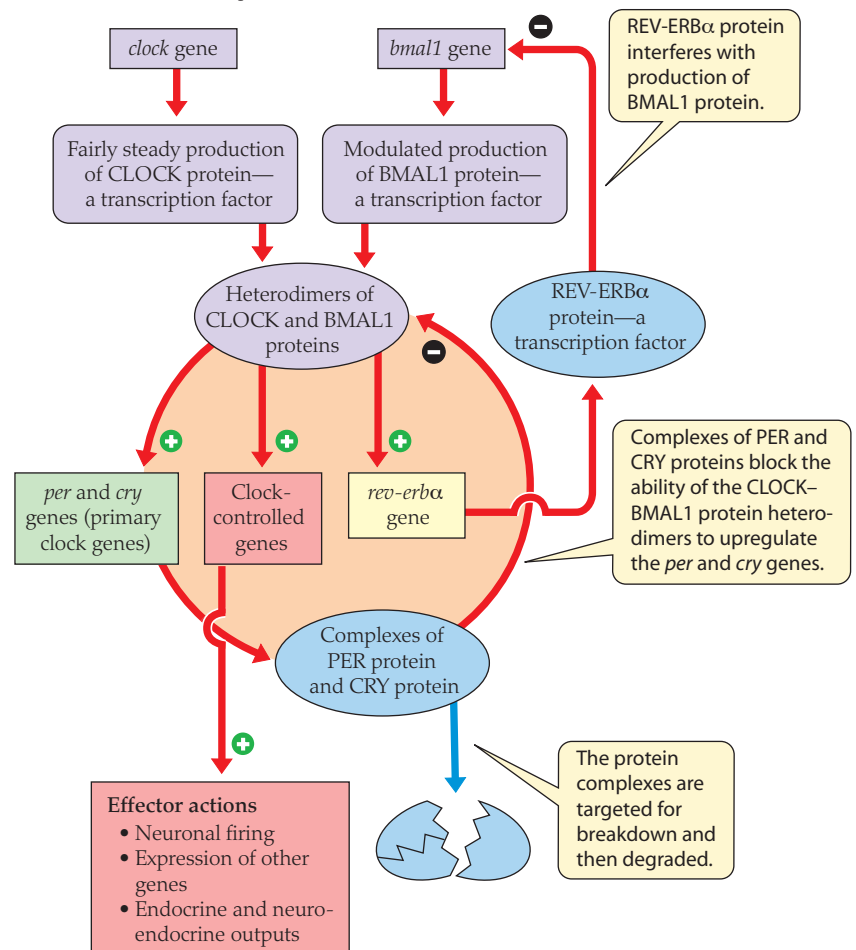

The timekeeping mechanism in a cell typically depends on a rhythmic alternation between enhanced and inhibited expression of key *clock genes* that are broadly homologous among phyla. As diagrammed in steps 1 and 2 in Figure 15.15a, enhanced expression of a clock gene (increased transcription and translation) leads to increased levels of the protein coded by the gene. The protein, however, is a negative factor for expression of the gene. That is, as shown in step 3, the protein eventually suppresses, directly or indirectly, the expression of its own gene; a common action of the protein, for example, is to interfere with the action of transcription factors that promote the gene's expression. Such a mechanism can cycle back and forth between two states of gene expression in much the same way that a pendulum swings between two extremes of position, permitting accurate timekeeping. The details of the timekeeping mechanism vary from one group

FIGURE 15.15 Cellular mechanisms of circadian time-keeping Circadian timekeeping mechanisms—circadian oscillators—exist within the confines of single cells. They depend on the linked, alternating upregulation and downregulation of *clock genes*, to produce proteins that regulate gene expression. A significant aspect not shown here is that mRNAs must cross from the cell nucleus to the cell cytoplasm to be translated, and the proteins thereby produced must cross from the cytoplasm to the nucleus to regulate genes. The dynamics of nuclear–cytoplasmic exchange are thus important elements of the clock mechanism. Protein phosphorylation (not shown) regulates both the rate of translocation and the rate of destruction of the clock proteins. (a) A universal model of a circadian timekeeping mechanism, thought to apply to all organisms. (b) Some of the details of the mechanism in neurons of the mammalian suprachiasmatic nuclei. CLOCK and BMAL1 are the primary positive elements, promoting *per* and *cry* genes as well as clock-controlled genes that govern the effector actions of the rhythm. Complexes of PER and CRY proteins are primary negative elements, blocking upregulation of the *per* and *cry* genes and, in a secondary cycle, also blocking upregulation of the *rev-erba* gene to de-repress the *bmal1* gene (by reducing production of REV-ERB α protein, which itself represses the *bmal1* gene). These primary and secondary cycles are modulated and stabilized by a wide array of other clock-modifying genes, as demonstrated by genome-wide screens. (After Bell-Pedersen et al. 2005.)

(a) A universal model of the mechanism of biological timekeeping

(b) Some aspects of the timekeeping mechanism in neurons of the mammalian suprachiasmatic nuclei

of organisms to another and are proving often to be exceedingly complex. **Figure 15.15b** shows the core elements of the timekeeping mechanism that exists in neurons of the suprachiasmatic nuclei in mammals. A mechanism of this sort is often called a **circadian oscillator** because timekeeping is achieved by oscillation between two states of gene expression.

The loci of biological clock functions vary among animals

Animals exhibit circadian organization throughout their bodies: Many tissues are capable of acting as circadian clocks. Typically, however, one tissue (or more) acts as a *master clock* that entrains, or imposes its rhythm on, all the other tissues. The entrainment ensures that arrays of tissues and organs ordinarily exhibit synchronous rhythms.

In mammals, the master circadian clock resides in the paired **suprachiasmatic nuclei** of the hypothalamic region of the diencephalon. Each *suprachiasmatic nucleus* (SCN) is just dorsal to the optic nerve at the optic chiasm (**Figure 15.16a**). Neurons in the SCN express a rhythmic circadian activity of clock genes (**Figure 15.16b**). A stunning experiment demonstrated the primacy of the SCN. Researchers destroyed the paired suprachiasmatic nuclei in a group of genetically normal hamsters. Later they implanted

in each hamster paired SCNs taken from a mutant hamster that exhibits an unusual, 20-h free-running activity period. Although the genetically normal hamsters exhibited normal free-running activity rhythms before destruction of their SCNs, they did not show circadian rhythms of activity when they lacked SCNs. **Figure 15.16c** illustrates this loss of circadian rhythmicity after SCN destruction. After the hamsters received replacement SCNs, they once again exhibited circadian rhythms, but the free-running period of the rhythms was the unusual, short period characteristic of the mutant donor hamsters.

Individual neurons in the SCN are independently rhythmic when maintained in tissue culture. Communication between neurons in the SCN, as well as between the SCN and the rest of the body, remains inadequately understood; ventral and dorsal SCN neurons differ in neurotransmitters, intrinsic rhythmicity, and connections with other brain areas. Neural connections from the eyes in mammals provide information to the SCN about the daily light–dark cycle in the environment. Interestingly, the light sensors responsible for this entrainment are specialized photosensitive ganglion cells that employ the photopigment *melanopsin*, rather than the (rhodopsin-based) rod and cone photoreceptors of the rest of the visual system.

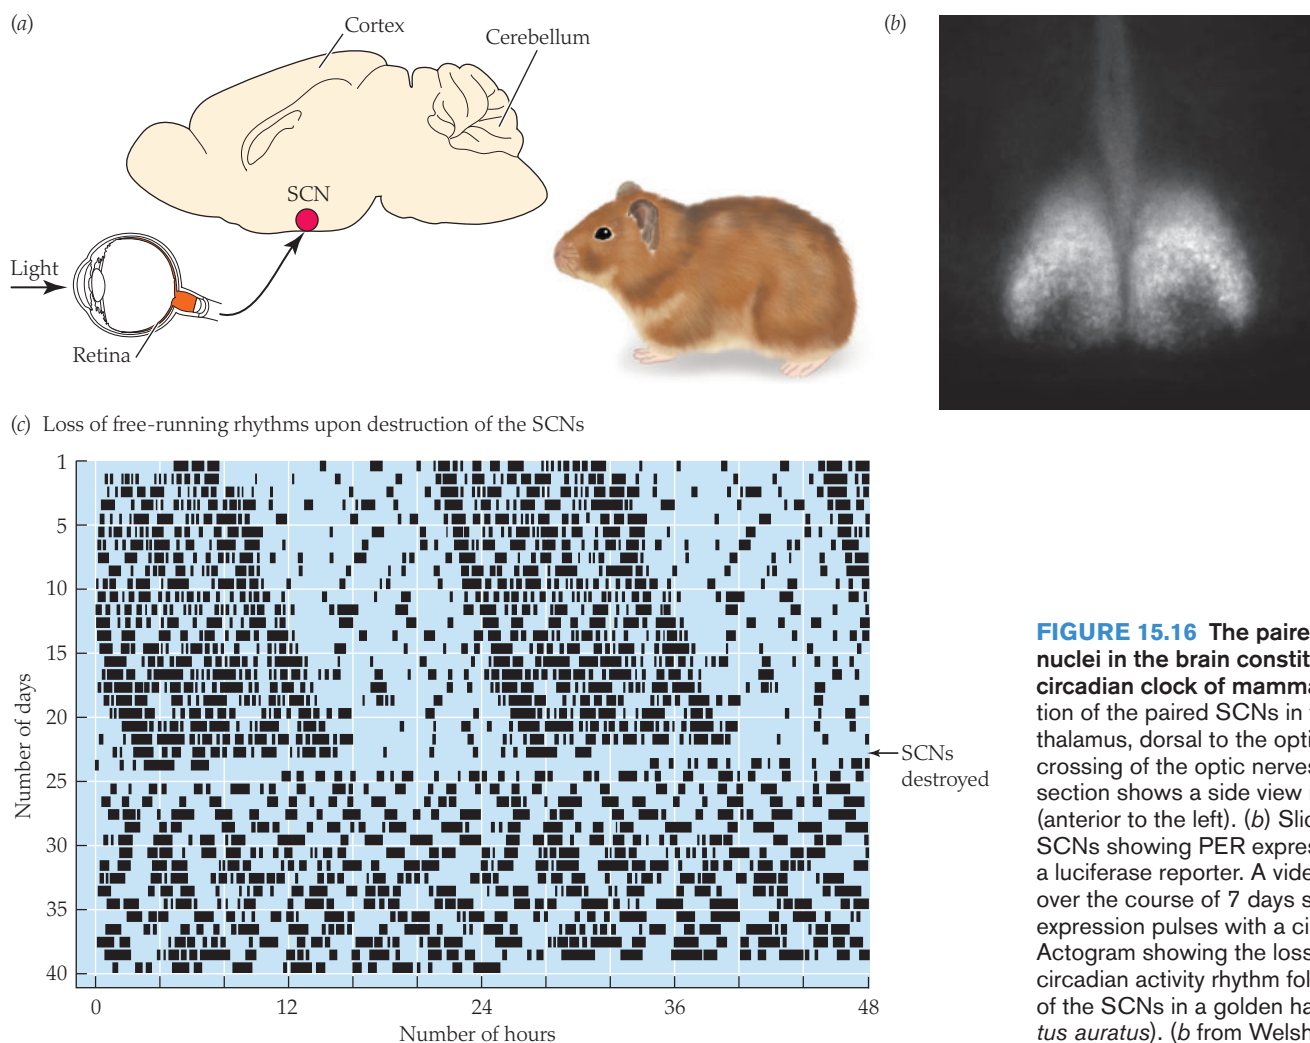

FIGURE 15.16 The paired suprachiasmatic nuclei in the brain constitute the major circadian clock of mammals (a) The location of the paired SCNs in the ventral hypothalamus, dorsal to the optic chiasm (the crossing of the optic nerves). The sagittal section shows a side view near the midline (anterior to the left). (b) Slice of the paired SCNs showing PER expression visualized with a luciferase reporter. A video of the SCN slice over the course of 7 days shows that PER expression pulses with a circadian rhythm. (c) Actogram showing the loss of a free-running circadian activity rhythm following destruction of the SCNs in a golden hamster (*Mesocricetus auratus*). (b from Welsh et al. 2010).

The SCN is not the only anatomical location of circadian control in mammals, although it is the principal control center and the best understood. The retinas are also endogenously rhythmic; however, they do not seem to exert substantial direct control over other tissues. Sometimes certain circadian rhythms in addition to the retinal rhythms persist in mammals after SCN inactivation, pointing to additional clocks. For example, liver cells can maintain a circadian rhythm that can be entrained by feeding. Such peripheral clocks are probably controlled (entrained) by the SCN in normal circumstances.

One important output of the SCN clock controls the pineal gland. The **pineal gland** is a small, unpaired gland that forms embryologically as an evagination of the roof of the brain and is found in virtually all vertebrates. Its principal hormonal secretion is **melatonin**, a compound synthesized from the amino acid tryptophan. In mammals, according to current evidence, the pineal gland is not independently rhythmic; it secretes melatonin in a circadian rhythm because of circadian control from the SCN. Pineal melatonin is secreted at night in mammals (both diurnal and nocturnal) and in virtually all other vertebrates. Thus melatonin is sometimes called the *darkness hormone*. Pineal melatonin is also of great importance in controlling many seasonal rhythms, such as reproduction.

The pineal physiology of nonmammalian vertebrates often differs from that of mammals in two important ways. First, the nonmammalian pineal gland may be endogenously rhythmic and thus can act as a primary circadian control center. Second, the pineal gland is often light-sensitive and acts as a “third eye,” providing extraocular information on the environmental day–night cycle (light may reach the pineal gland through the skull). Interaction between the SCN and the pineal gland in the control of circadian rhythms in nonmammalian vertebrates is complex, diverse, and not well understood. The retinas in nonmammalian vertebrates are endogenously rhythmic, but as in mammals, the retinas seem not to serve as circadian control centers for the rest of the body.

Studies of transcription profiling in various tissues of different animals show that there are daily rhythms of transcription of hundreds of genes (see Chapter 3, page 78–80). In many cases the circadian nature of these daily rhythms has not yet been demonstrated, but it is likely that they result from the output of the circadian clock in the SCN, either directly or via entrainment of other local circadian clocks.

Circannual and circatidal clocks: Some endogenous clocks time annual or tidal rhythms

Daily rhythms have been the most-studied of all biological rhythms, and so we have emphasized them in our discussion of biological clocks. However, animals exhibit rhythmic physiological and behavioral variations that operate on other timescales as well. Annual rhythms of reproduction, migration, fat accumulation, dormancy, and so on are well-known examples. Animals living along the seashore often display rhythms synchronized with the tides, which usually rise and fall every 12.4 h (half a lunar day). For instance, fiddler crabs (*Uca* spp.) that scavenge for food on the sand or mud exposed by low tide become rhythmically more active at each time of low tide.

Some, but not all, annual and tidal rhythms are endogenous: They persist even when animals are placed in a laboratory environment where they are denied environmental information about the time of year or the time of the tidal cycle. Typically the periods of the free-running endogenous rhythms are only *approximately* a year or a tidal cycle in length. Thus the endogenous rhythms are termed **circannual** or **circatidal**.

Under natural conditions, of course, certain environmental parameters vary in phase with the annual or tidal cycle. The endogenous circannual and circatidal rhythms of animals become entrained, so in nature the biological rhythms are kept in phase with the actual seasons and tides. For instance, the annual cycle of photoperiod length (long days in summer, short days in winter) is the phasing factor for certain circannual rhythms; and features of ebbing and flowing tidal water, such as mechanical agitation, serve as phasing factors for some of the circatidal rhythms. It is not clear whether the endogenous timing mechanisms for circannual and circatidal rhythms depend on circadian oscillators. Arguments have been presented on both sides. As yet, the nature of these timing mechanisms remains unresolved.

Interval, or “hourglass,” timers can time shorter intervals

In addition to circadian oscillators—which rhythmically cycle—animals appear to possess physiological timing mechanisms that permit timing of *parts* of days by functioning like stopwatches or hourglasses. These noncyclic timers are called **interval timers** or **“hourglass” timers**. Once activated on a given day, they measure the passage of time; but like stopwatches, they are noncyclic and must be restarted to operate again. Male pigeons, for example, seem to use an interval timer to determine how long they incubate eggs in a particular stint; they stay on the eggs for a relatively fixed length of time after they start, regardless of the time of day when they start. Recent research locates the neurophysiological sites of the interval timers of birds and mammals in different parts of the brain than the circadian oscillators.

What about the star-nosed mole with which we started this chapter? Moles live underground; star-nosed moles have reduced vision, and other moles are considered blind. Thus, moles might be good candidates as animals for which circadian rhythms are of little adaptive advantage. Yet there is evidence that moles have circadian activity rhythms, and all moles are seasonal breeders that presumably can measure day length. Mole visual systems, despite substantial losses of other visual pathways, have robust connections from the retina to the SCN, with prominent melanopsin-containing retinal ganglion cells (shown to be the neurons that entrain SCN clock cells to light). Thus even in fossorial moles, it appears that circadian clocks and the ability to reset them persist.

SUMMARY Biological Clocks

- A circadian rhythm has a period of about a day. It is an example of an endogenous rhythm, one that does not require sensory information for timing.
- A circadian rhythm of an animal will drift, or free-run, in constant light or darkness, when there are no sensory timing cues. A light–dark cycle entrains the circadian rhythm to exactly 24 h.

- A biological clock is the physiological basis of an animal's ability to time an endogenous rhythm. Biological clocks exert rhythmically changing control, modulating the outputs of the nervous and endocrine systems to prepare an animal for daily changes and seasonal changes. In mammals, the suprachiasmatic nucleus (SCN) of the brain is the principal biological clock for circadian rhythms.
- Animals may possess other timing mechanisms for shorter rhythmic periods (such as circatidal rhythms) or longer periods (such as circannual rhythms) than those of circadian rhythms.

Study Questions

1. How does the physiological control exerted by the nervous system and endocrine system relate to the concept of homeostasis?
2. Compare and contrast the nervous system organization in arthropods and vertebrates. What are their functional similarities and differences?
3. How, in general, is the vertebrate autonomic nervous system organized? Is it redundant to have separate sympathetic and parasympathetic control of many organs?
4. The sympathetic and parasympathetic divisions of the autonomic nervous system employ the same neurotransmitter (acetylcholine) for preganglionic neurons, but different neurotransmitters for postganglionic neurons (norepinephrine for sympathetic, and acetylcholine for parasympathetic; see Figure 15.10). How would it affect autonomic function if the situation were reversed—that is, if the preganglionic neurotransmitters were different and the postganglionic neurotransmitters were the same?
5. What adaptive advantages might centralization and cephalization offer in the evolution of nervous system organization?
6. Mammals have brains that are more complex than those of fish and amphibians, particularly in terms of expansion of the cerebral cortex. Does this increased complexity make mammals more advanced and fish and amphibians more primitive? Why or why not?
7. The paired suprachiasmatic nuclei (SCNs) usually function as the master circadian clock in mammals. In some circumstances the circadian rhythms of animals may become split, with some effectors following one free-running rhythm and some following another. Give two hypotheses of how such a split might happen—one compatible with an SCN always being a master clock and one not.
8. One of the first genes that was determined to control circadian-clock timing is the *per* gene in *Drosophila*. Mutants of this gene have shorter or longer circadian free-running rhythms, as well as shorter or longer periods of a much faster rhythmic courtship song. What does this observation suggest about the relationship between circadian rhythms and shorter, hourglass-timing rhythms?

Endocrine and Neuroendocrine Physiology

The plainfin midshipman (*Porichthys notatus*) is a bottom-dwelling fish that lives off the Pacific coast of North America. Males and females migrate to shallow waters of the intertidal zone to breed during summer nights. The swim bladder of males is larger than that of females, and its sonic muscles produce sounds used to court females. There are two types of males. During the breeding season, type I males build nests and make “singing” calls to attract females to the nest for spawning. After fertilization, the female returns to deeper waters. The type 1 male remains at the nest to court more females and to provide parental care to multiple clutches of embryos until they are free-swimming (~30–40 days). Type II males do not build nests, make courting sounds, or provide parental care. Instead, they sneak opportunities to fertilize eggs released at a nest of a type I male.

The midshipman reproductive cycle is tightly choreographed by sex steroids. In males, the blood level of 11-ketotestosterone rises in March at the beginning of the nesting period and is maintained through July. During this time the sonic muscles of the swim bladder grow, and the testes become filled with sperm. In females, estrogen and testosterone peak in April and are correlated with increased ovarian function and also increased sensitivity of the auditory system to detect the male’s advertisement sounds. Investigators have found that nonreproductive females caught in deep waters during the winter are unresponsive to recordings of advertisement calls played underwater. However, when injected with estrogen or testosterone they are attracted to the speaker just like reproductive females are attracted to the type I male’s nest in the summer. These experiments strongly suggest that steroid hormones promote the increased sensitivity of the female auditory system. These changes improve the plainfin midshipman fish’s reproductive potential by ensuring that a female successfully detects and locates a nesting male in nighttime waters. The reproductive cycle of the plainfin midshipman is but one example of the powerful roles hormones play to influence physiological changes at multiple tissues and organs in order to optimize an animal’s success.

In this chapter we examine the principles of hormonal regulation by focusing on a few well-studied examples. Our goal is to give you the tools to apply these principles in understanding the functions of hormones discussed in future chapters. As we explore endocrine physiology, we will see that hormones play essential and integral roles in maintaining homeostasis by changing physiology and behavior in response to demands imposed by both environmental conditions and stages in an animal’s life history. Because hormones influence a broad range of physiological processes, essentially every cell in an animal participates in some endocrine function, and nearly every hormone participates in more than one physiological process.

The plainfin midshipman fish (*Porichthys notatus*)

Introduction to Endocrine Principles

In Chapter 12 we compared rapid, “addressed” neural control of physiological processes with slow, “broadcast” endocrine control. Chemical signals are used to achieve both types of control. However, in neural control, neurotransmitters released from axon terminals of neurons diffuse short distances to bind to receptor molecules on postsynaptic cells (Figure 16.1a). Their short travel time to discrete sites ensures rapid, pinpointed control. Enzymes or reuptake mechanisms rapidly inactivate most neurotransmitters, so the neural signal is quickly terminated.

By contrast, hormones secreted from endocrine or neuroendocrine cells travel in the blood to distant target cells where they exert their effects (Figure 16.1b,c). Whereas neurotransmitter molecules from an axon terminal typically reach a single postsynaptic cell, hormone molecules carried through the bloodstream can influence large populations of target cells, as long as the target cells express receptor molecules for the hormone. Therefore, transport of hormones over long distances permits widespread responses. These responses are initiated slowly, relative to responses to neural signals, because hormones require travel time to reach target cells. Further, some hormones are synthesized only when the endocrine cell is stimulated to secrete them, and this synthesis takes time. Finally, certain hormones control gene transcription and the synthesis of proteins by target cells, so the responses they initiate are exhibited only after a delay, when protein synthesis is accomplished. Responses to hormones may be brief or last as long as hours or days.

Processes controlled by endocrine systems in both vertebrates and invertebrates include water balance, metabolism, coping with a hostile environment, reproduction, and growth and development. Although researchers have accumulated a great deal of detailed knowledge regarding the functions and roles of hormones in vertebrates, our understanding of the endocrine systems of many invertebrate groups is still highly incomplete. Nevertheless, physiologists have found that the basic principles of endocrine function—our focus in this chapter—apply to both vertebrates and invertebrates.

Defined specifically, a **hormone** is a chemical substance produced and released by nonneural endocrine cells or by neurons; it exerts regulatory influences on the function of other, distant cells reached via the blood; and it is effective at very low concentrations (as little as 10^{-12} M). Hormones released by neurons are often referred to as neurohormones, and the neurons as neuroendocrine or neurosecretory cells. The secretory cells that produce hormones secrete them into the surrounding extracellular fluid, from which they diffuse into capillaries.¹ The secre-

FIGURE 16.1 Chemical signals act over short and long distances within the body (a) A neuron releases neurotransmitter molecules that act on receptor molecules of the postsynaptic cell. (b) A nonneural endocrine cell secretes hormone molecules that enter a capillary (or hemolymph) and are carried throughout the bloodstream. Hormones enter and leave capillaries through spaces between the endothelial cells that make up the capillary wall. (c) A neurosecretory cell secretes hormone like a neuron releases neurotransmitter, and the hormone enters and leaves the blood in the same manner as a hormone from a nonneural endocrine cell. (d) Paracrine and autocrine signals diffuse locally to activate receptors on neighboring cells (paracrine) or on the same cell (autocrine). They do not enter the blood. Figure 16.19 illustrates long-distance chemical signals that act *outside* the body, such as pheromones.

¹In animals with open circulatory systems, the blood and extracellular fluid blend to form hemolymph (see Chapter 24). In these animals, hormones are released directly into, and circulated in, the hemolymph.

tory cells may be organized into discrete organs termed **endocrine glands** (also called *ductless glands* because they lack outflow ducts), or they may be isolated cells or clusters of cells distributed among the cells of other tissues. A table of the major mammalian endocrine and neuroendocrine tissues, their secretions, and their main actions at target tissues can be found in Appendix K.

Some substances are unambiguously hormones, such as thyroid hormones (secreted by the thyroid gland) and gastrin (secreted by G cells in the gastric mucosa of the lower part of the mammalian stomach) (see Chapter 6). Many substances carried in the blood—CO₂, for example—may act as signals but are clearly not hormones. CO₂ is produced by metabolism and signals the respiratory centers of some animals to increase their breathing. However, CO₂ is not released primarily by specialized secretory cells, and it is found continuously in the blood at relatively high concentrations. Not all compounds, however, are so easily categorized. Many chemical signals affect the function of nearby cells located in the same organ or tissue but do not enter the circulatory system. These **autocrine** and **paracrine** substances act in many ways like hormones but are usually categorized separately (Figure 16.1d). Furthermore, the same compound may be used both as a hormone and as another type of chemical signal in the same organism. In mammals, for example, cholecystokinin (CCK) is not only a hormone secreted by cells in the intestine, but also functions as a neurotransmitter or neuromodulator in the central nervous system (CNS). **Intracrine** are another example of signaling molecules. These peptide growth factors or hormones function *within* cells in addition to performing traditional hormonal, paracrine, or autocrine functions. Intracrine are either retained within the cell that synthesized them or internalized from the extracellular space.

Hormones bind to receptor molecules expressed by target cells

Although a hormone circulates past many cells, it interacts only with certain cells, called target cells, that respond to it. A target cell expresses *receptor molecules* that specifically bind the hormone. Consider thyroid hormones, for example. These hormones, secreted by the thyroid gland, exert a wide range of metabolic, structural, and developmental effects on many different tissues (see Appendix K). They have such widespread effects because many different cells of the body possess receptor molecules that recognize thyroid hormones. Typical target cells express thousands of receptor molecules for a particular hormone. In addition, many target cells express separate populations of different types of receptor molecules, so they are capable of responding to more than one hormone. The *sensitivity* of a target cell to a particular hormone depends on the number of functional receptor molecules the target cell expresses for that hormone. The sensitivity of a target cell to a particular hormone can change under different conditions because the number of receptor molecules that recognize that hormone can increase (by upregulation) or decrease (by downregulation). These variations in the types and numbers of receptor molecules expressed by target cells contribute to the immense versatility of hormonal regulation in animals. An additional consideration to keep in mind is that a target cell's response to a particular hormone at any moment in time depends not only on the number of receptor molecules it expresses for that hormone but also on the hormone's concentration in the blood.

Concentrations of hormones in the blood vary

For hormones to serve as physiological regulators, their rates of synthesis and secretion must be controlled. Often neurons or other hormones control these processes. Most endocrine cells synthesize and release some hormone all the time, but the rate of release is variable, depending on mechanisms of control. In general, the higher the rate at which a hormone is secreted, the higher its concentration in the blood, and the greater its effect on target cells. Because hormone molecules secreted into the blood are enzymatically degraded at their targets or by organs (such as the liver and kidneys in vertebrates), they do not circulate indefinitely. The blood concentration of a hormone represents a balance between the *rate of addition* of hormone to the blood (by secretion) and the *rate of removal* of hormone from the blood (by metabolic destruction and excretion). Hormone concentration depends primarily on the rate of addition to the blood, because the rate of removal is relatively constant. A hormone's half-life—the time required to reduce the concentration by one-half—indicates its rate of removal from the blood and thus the duration of its activity.

Some hormones may be converted to a more active form after secretion by a process termed **peripheral activation**. For example, thyroid hormone is secreted mainly as a four-iodine compound also known as tetraiodothyronine, or T₄. After T₄ is secreted, target and other tissues enzymatically remove one iodine to form triiodothyronine, or T₃, which is more physiologically active than T₄.

Most hormones fall into three chemical classes

Table 16.1 summarizes the characteristics of the following three chemical classes of hormones:

1. **Steroid hormones** are synthesized from cholesterol (Figure 16.2). In vertebrates, the gonads and the adrenal cortex secrete steroid hormones, as do the skin and, in pregnant mammals, the placenta. The molting hormones of arthropods (e.g., ecdysone) are also steroids. Steroid hormones are lipid-soluble, so they can pass through cell membranes to reach receptor molecules located inside their target cells. In some cells, lipid-soluble hormones (e.g., estrogen) are transported across the membrane. One transporter of these hormones is *megalyn*, an integral protein receptor molecule of the target cell membrane that brings lipid-soluble hormones (often complexed with carrier molecules) into the cell by endocytosis.
2. **Peptide and protein hormones** are structured from chains of amino acids (Figure 16.3). In vertebrates, they include antidiuretic hormones, insulin, and growth hormone. Examples of peptide and protein hormones in invertebrates include the gamete-shedding hormone of sea stars and the diuretic hormones of insects. Peptide and protein hormones vary enormously in molecular size, from tripeptides (consisting of just 3 amino acid residues, such as thyrotropin-releasing hormone) to proteins containing nearly 200 amino acids (such as growth hormone). Often hormones consisting of assemblages of amino acids are simply called *peptide hormones* (blurring the size distinction), and we will usually follow that practice. Peptide hormones are soluble in aqueous solutions.

FIGURE 16.2 Steroid hormones are derived from cholesterol. Steroidogenesis begins with the formation of pregnenolone. Different steroid-secreting cells possess different enzymes that modify pregnenolone to produce specific steroid hormones. The skin cells that produce inactive vitamin D are an exception: They do not cleave the side chain to form pregnenolone.

3. Amine hormones are modified amino acids (Figure 16.4). **Melatonin**, secreted by the vertebrate pineal gland (see Chapter 15), is derived from tryptophan, whereas the **catecholamines** and **iodothyronines** are derived from tyrosine. *Catecholamines* are found widely as synaptic transmitter substances in both invertebrates and vertebrates. However, three catecholamines also serve as hormones in vertebrates: epinephrine (also called adrenaline), norepinephrine (noradrenaline), and dopamine. *Iodothyronines*, the thyroid hormones, are found

only in vertebrates. They are synthesized by the thyroid gland and have the unique property of being rich in iodine. Whereas melatonin and the catecholamines are soluble in water, the iodothyronines are soluble in lipids.

Lipid-soluble hormones as well as many water-soluble hormones are transported in the blood bound to water-soluble *carrier proteins* (see Table 16.1, "Transport"). Carrier proteins bind to hormone molecules reversibly and noncovalently, with varying degrees of affinity. Free and bound forms of the hormone are in

(a) **Gonadotropin-releasing hormone (GnRH)**

pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH₂

Mammalian GnRH is a decapeptide (10 amino acids).

(b) **Insulin**

A chain: Gly-Ile-Val-Glu-Gln-Cys-Cys-Thr-Ser-Ile-Cys-Ser-Leu-Tyr-Gln-Leu-Glu-Asn-Tyr-Cys-Asn

B chain: Phe-Val-Asn-Gln-His-Leu-Cys-Gly-Ser-His-Leu-Val-Glu-Ala-Leu-Tyr-Leu-Val-Cys-Gly-Glu-Arg-Gly-Phe-Phe-Tyr-Thr-Pro-Lys-Thr

Human insulin consists of two chains of amino acids connected and stabilized by disulfide bridges.

FIGURE 16.3 Peptide and protein hormones consist of assemblages of amino acids. (a) The amino acids on both ends of GnRH are modified by posttranslational modification. Therefore pGlu at the N terminal of the peptide is a modified form of glutamic acid, and glycine at the opposite end has undergone C-terminal amidation. (b) The A chain of human insulin consists of 21 amino acids, and the B chain consists of 30.

TABLE 16.1 Peptide, steroid, and amine hormones of vertebrates

Property	Peptides	Steroids	Amine hormones		
			Catecholamines	Thyroid hormones	Melatonin
Site of secretion	Most sites in Appendix K, except adrenal cortex and medulla, thyroid and pineal glands, and skin	Adrenal cortex, gonads, skin, and (in pregnant mammals) placenta	Adrenal medulla	Thyroid gland	Pineal gland
Structure	Chains of amino acids	Derived from cholesterol	Derived from tyrosine	Derived from tyrosine and iodine	Derived from tryptophan
Solubility	Water-soluble	Lipid-soluble	Water-soluble	Lipid-soluble	Water-soluble
Synthesis and storage	Synthesized at rough ER; processed in Golgi apparatus; stored in vesicles in advance of use	Synthesized on demand in intracellular compartments; not stored	Synthesized in cytoplasm and stored in vesicles ("chromaffin granules")	Made prior to use and stored in a colloid island within the gland	Synthesized in the cytoplasm and stored in vesicles
Secretion	Exocytosis	Simple diffusion through cell membrane	Exocytosis	Simple diffusion through cell membrane	Exocytosis
Transport	Dissolved in plasma; some bound to carrier proteins	Bound to carrier proteins	Dissolved in plasma	Bound to carrier proteins	Dissolved in plasma
Half-life	Minutes	Hours	Seconds to minutes	Days	Minutes
Location of receptor molecules	Surface of target cell membrane	Cytoplasm or nucleus (some steroids bind to cell-surface receptors)	Surface of target cell membrane	Nucleus	Surface of target cell membrane
Action at target cell	Activate second-messenger systems or alter membrane channels	Alter gene expression; activated genes initiate transcription and translation	Activate second-messenger systems	Alter gene expression; activated genes initiate transcription and translation	Activates second-messenger systems
Response of target cell	Change activity of preexisting proteins, some of which may induce new protein synthesis	Synthesize new proteins; some may change activity of preexisting proteins	Change activity of preexisting proteins	Synthesize new proteins	Changes activity of preexisting proteins

equilibrium in the blood. Only the free form of the hormone is physiologically active. The equilibrium between free and bound forms is shifted in the vicinity of target cells. When some of the free hormone molecules bind to receptor molecules of a target tissue, some bound hormone molecules unbind from the carrier proteins, and the equilibrium in the blood is maintained. Thus carrier proteins provide a reservoir of bound hormone that can be drawn upon. Carrier proteins also protect hormones from rapid inactivation and excretion and thus extend their half-lives. In humans, the half-life of the steroid hormone cortisol is 60 to 90 minutes (min), and that of thyroxine is several days. In contrast, peptide hormones have half-lives in the range of a few minutes. To maintain a steady level of a peptide hormone in the blood for a period longer than a few minutes, the endocrine cells must continue to secrete it. The water-soluble catecholamine epinephrine has a half-life of no more than 1 to 2 min!

Hormone molecules exert their effects by producing biochemical changes in target cells

To initiate changes in target cells, hormones first bind to specific receptor molecules. Some hormones bind to intracellular receptors and others to cell-surface receptors. Three types of receptor molecules are important in mediating hormone actions: intracellular receptors, G protein-coupled membrane receptors, and enzyme-linked membrane receptors (see pages 58–61).

Lipid-soluble hormones (steroids and iodothyronines) bind to intracellular receptors. Because they are lipid-soluble, these hormones enter target cells by diffusing through the lipid bilayer of the cell membrane (see Figure 2.27) or carried bound to a lipoprotein molecule. Their receptors are located either in the cytoplasm or in the nucleus. When the hormone molecule binds to the receptor molecule, it forms a hormone-receptor complex that acts as a transcription factor that interacts with the target

FIGURE 16.4 Amine hormones are derived from amino acids

Catecholamine-secreting cells use biochemical pathways beginning with tyrosine to produce dopamine, norepinephrine, and epinephrine. The level of expression of specific enzymes in a catecholamine-secreting cell determines which catecholamine is produced in greatest abundance.

cell's DNA to alter gene expression. By turning processes of transcription and translation on or off, the hormone directly influences the synthesis of proteins by the target cell. New proteins, which can be enzymes or structural proteins, carry out the target cell's physiological response. Because the production of new proteins requires time, there is a delay (ranging from many minutes to hours) between the hormone's binding to the intracellular receptor and the target cell's response. Once the proteins are synthesized, the response lasts until they are degraded. In addition, we now know that certain target cells of some steroid hormones, such as aldosterone, estrogen, and certain glucocorticoids, express *cell-surface* receptors for those hormones. When steroid hormones bind to receptors on the cell membrane, they do not exert their effects by genomic means, but instead function like water-soluble hormones, exerting rapid effects commonly called *non-genomic* effects.

The water-soluble peptide and catecholamine hormones do not diffuse into cells. Their receptor molecules are located in the cell membrane and have external hormone-binding sites. These receptors typically mediate hormone actions by altering membrane permeability or by activating an intracellular second-messenger system by way of a G protein. Figures 2.29 and 2.30 illustrate the important roles played by second messengers such as cAMP, cGMP, Ca²⁺ ions, and phosphoinositides in transducing the hormonal signal into a robust response of the target cell. A few peptide hormones, such as insulin and growth hormone, bind to enzyme-linked membrane receptors. Peptide hormones exert their effects primarily by changing the activities of existing proteins, although some may also alter gene activities. Target

cells can change their physiology quickly by using preexisting proteins, so their responses to these hormones can be measured within minutes.

SUMMARY Introduction to Endocrine Principles

- Hormone molecules are synthesized, stored, and released by nonneural endocrine cells or neurons, travel through the circulating blood, exert their effects on target tissues, and are metabolically destroyed or excreted from the body.
- The magnitude of a hormone's effect depends on both the abundance of receptor molecules with which it can bind and its concentration in the blood. Blood concentration of a hormone depends on a balance between the rate of synthesis and the rate of degradation or excretion. The rate of synthesis and secretion of a particular hormone is often governed by another hormone; some endocrine cells also receive neural input.
- Hormones are usually categorized into three main classes: steroids, peptides and proteins, and amines (melatonin, catecholamines, and iodothyronines). The same chemical messenger may function as a hormone in one context and as a neurotransmitter or neuromodulator in another.
- Hormones are carried in the blood in very low concentrations. Their half-lives vary depending on their chemical class, ranging from seconds to hours or days. Carrier proteins in the blood transport many hormones. Free and bound hormone molecules are in equilibrium in the blood. Only free hormone molecules are able to bind to receptor molecules in or on target cells.

- Both lipid-soluble and water-soluble hormones initiate biochemical changes in their target cells by binding to receptor molecules. Measurable responses to water-soluble and lipid-soluble hormones that bind cell-surface receptor molecules occur with a shorter delay than do responses to lipid-soluble hormones that bind intracellular receptors to initiate genomic actions.

Synthesis, Storage, and Release of Hormones

In this section we compare the cellular mechanisms of synthesis, storage, and secretion of two chemical classes of hormones: peptides and steroids. We use insulin as our primary example of a peptide hormone. Insulin is the vertebrate hormone that lowers the concentration of blood glucose by stimulating cells to take up glucose (as well as amino acids) from the blood. It also promotes the incorporation of food molecules into storage compounds. Insulin is synthesized in endocrine cells in the pancreas. Pancreatic endocrine cells are clustered in the islets of Langerhans, which are embedded in the pancreatic exocrine tissue that secretes digestive enzymes. The islet cells that produce and secrete insulin are called B or β (beta) cells. Insulin follows the pattern typical for the synthesis of most secreted peptides in which a large precursor molecule, a *preprohormone*, is modified by *posttranslational processing* to a *prohormone* and finally a mature hormone.

Peptide hormones are synthesized at ribosomes, stored in vesicles, and secreted on demand

The insulin molecule consists of two peptide chains, designated A and B, connected by disulfide bonds (see Figure 16.3b). Although there is some variation among species in the amino acid sequences of the two chains, the general structure of the molecule, the amino acid sequences of certain regions, and the positions of the disulfide bonds are all highly conserved. The information determining the amino acid sequences of the chains is encoded in the DNA of the cell nucleus. The DNA nucleotide sequence of the insulin gene is *transcribed* into the nucleotide sequence of messenger RNA (mRNA), which leaves the nucleus and interacts with ribosomes of the rough (granular) endoplasmic reticulum (ER). The nucleotide sequence of mRNA is then *translated* to determine the amino acid sequence of the polypeptide, **preproinsulin**, that is synthesized at the ribosomes (Figure 16.5).

The preproinsulin polypeptide consists of four regions, termed P, B, C, and A. Regions A and B become the A and B chains of the insulin molecule; C is the segment connecting these chains and is cleaved away. The P segment functions as a leader or signal sequence to facilitate passage of the polypeptide chain through the membrane of the ER into its lumen; it is enzymatically cleaved from the polypeptide even before synthesis is completed. Without the P segment, the polypeptide is called **proinsulin**. Proinsulin contains sulfhydryl ($-SH$) groups, which are oxidized to the three

FIGURE 16.5 Insulin is synthesized, processed, and packaged like other peptide proteins. Insulin is initially synthesized at ribosomes as an inactive preprohormone and takes its final form through posttranslational processing. ER, endoplasmic reticulum; $-SH$, sulfhydryl group; $S-S$, disulfide bond.

disulfide (—S—S—) bridges (bonds) that fold the molecule. After the disulfide bridges form, the C segment is removed by enzymatic action, leaving the A and B chains linked by the disulfide bonds. These stages of posttranslational processing occur as the proinsulin molecules travel first to the Golgi apparatus in shuttle vesicles and then in secretory vesicles that bud off from the Golgi apparatus. The C fragments are retained in the secretory vesicles and are secreted along with the mature insulin molecules. The C fragment is not physiologically active and is metabolized in the blood. It is clinically relevant, however, because clinicians measure its blood concentration in diabetics to monitor insulin secretion by the β cells.

Whereas preproinsulin is produced and processed by a single type of cell, the pancreatic β cell, other preprohormones are synthesized by different types of cells and processed into different end products for secretion. An example is proopiomelanocortin, the precursor of proopiomelanocortin (POMC). POMC is synthesized by different types of cells, including cells in the anterior pituitary gland, brain, skin, and mammalian placenta. Each type of cell expresses different enzymes to carry out posttranslational processing and so produces different end products. Some types of cells co-secrete more than one end product. For example, adrenocorticotrophic hormone (ACTH) and melanocyte-stimulating hormone (MSH) are produced by different types of cells in the anterior pituitary by enzymatically cleaving POMC at different sites. The enzymes of the ACTH-secreting cells cleave POMC in such a way that another hormone, β -endorphin, is also produced and co-secreted with ACTH. β -Endorphin plays an important role in pain control. Cells of the hypothalamus also process POMC to produce significant amounts of β -endorphin.

Insulin and other secreted peptides are stored in vesicles within the cells that synthesize them. They are secreted by calcium-dependent exocytosis. When blood concentrations of glucose increase, β cells depolarize, causing voltage-gated Ca^{2+} channels to open and allow an influx of Ca^{2+} ions. The rate of insulin secretion is modulated by several factors, the most important of which are the levels of glucose and certain amino acids in the blood. As cells in the body respond to insulin's signal to take up glucose, the blood glucose concentration falls, and the β cells are no longer stimulated to secrete insulin. By this *negative feedback* mechanism, the blood glucose concentration is kept relatively constant. Other factors also stimulate insulin secretion; these factors include parasympathetic stimulation of the islets of Langerhans and gastrointestinal hormones secreted by the digestive tract in the presence of food. Both of these stimuli act before blood glucose levels actually increase and therefore function as *feed-forward* mechanisms. Sympathetic stimulation of the islets of Langerhans inhibits secretion of insulin. Without insulin promoting its uptake into cells, glucose remains available in the blood to provide a source of energy for the sympathetic "fight-or-flight" response.

Steroid hormones are synthesized on demand prior to secretion, and are released into the blood by diffusion

Steroid hormones are synthesized from cholesterol. In vertebrates, some cholesterol is obtained from animal fats in the diet. *Steroidogenic* (steroid-producing) endocrine cells and liver cells also synthesize cholesterol. Because cholesterol is not water-soluble, it circulates in the blood bound to lipoprotein carrier complexes. *Low-density lipoprotein (LDL)* complexes transport cholesterol *to* cells throughout

the body, whereas *high-density lipoprotein (HDL)* complexes carry cholesterol *away from* cells to the liver. Steroidogenic cells express LDL receptor molecules on their cell membranes. When an LDL complex binds to the membrane receptor, the cell engulfs the complex by endocytosis and thereby obtains cholesterol.

In vertebrates, endocrine cells of the gonads, adrenal cortex, skin, and (in mammals) the placenta produce steroid hormones. Once these cells synthesize or take in the cholesterol, enzymes cleave the six-carbon side chain to form pregnenolone (except in skin cells), which then enters one of several possible biochemical pathways (see Figure 16.2). Different types of steroidogenic cells have different sets of enzymes, so that each produces a different major end product. The enzymes necessary for steroid synthesis are contained within intracellular compartments: Those involved in converting cholesterol to pregnenolone are located in the mitochondria, and most of the others are in the smooth ER. Therefore, pregnenolone molecules must travel from the mitochondria to the smooth ER for further enzymatic conversions.

Unlike peptide hormones, steroid hormones are not stockpiled in vesicles prior to secretion. Instead, when the cell is stimulated, they are made from precursors stored in lipid droplets and immediately secreted. Secretion is accomplished by diffusion through the cell membrane. Therefore, whereas the blood concentration of a peptide hormone is determined by the rate of release of preexisting stored hormone, the blood concentration of a steroid hormone is determined by the rate of synthesis—and immediate release—of the hormone.

SUMMARY Synthesis, Storage, and Release of Hormones

- Peptide hormones are synthesized by transcription of DNA, translation, and posttranslational processing. They are stored in vesicles and secreted on demand by exocytosis.
- Steroid hormones are synthesized from cholesterol. Steroidogenic cells use different biochemical pathways and sets of enzymes to produce different steroid hormones. Steroid hormones are synthesized on demand and secreted by diffusion through the cell membrane.

Types of Endocrine Glands and Cells

Although some types of endocrine cells are grouped together into distinct endocrine glands, termed *discrete glands*, others may be scattered within the tissues of organs that are otherwise nonendocrine in function, such as the gastrin- and secretin-secreting cells of the mammalian gut (see page 156). These scattered populations of endocrine cells are termed *diffuse glands*. Discrete and diffuse endocrine glands are ends of a continuous spectrum of tissue organization. Several endocrine tissues, such as the islets of Langerhans in the pancreas, have structural organizations intermediate between discrete and diffuse glands. Studies of endocrine glands in different animals suggest that discrete glands, such as the adrenal glands, may have evolved from more diffuse secretory cells of ancestral animals. This idea is supported by the anatomical differences among adrenal glands of amphibians, birds (avian reptiles), and mammals. The adrenal gland of mammals is a discrete gland that sits adjacent to the kidney. The gland consists of

an inner *medulla* that secretes the catecholamines epinephrine and norepinephrine and an outer *cortex* that secretes several different steroid hormones (see Figure 16.9). In birds, the adrenal gland is also discrete, but the catecholamine-secreting cells are distributed among the steroid-secreting cells rather than being segregated into different regions. In amphibians, the adrenal gland isn't discrete at all. Instead its different cell types form patches on the kidney.

Endocrine cells are commonly divided into two major classes: **epithelial** (also called **nonneural**) **endocrine cells** and **neurosecretory cells**. When cells of these types are organized into discrete glands, the glands are described by the same terminology: **epithelial (nonneural) glands** and **neurosecretory glands**. The endocrine secretions of either type of cell or gland are properly termed hormones, but those of neurosecretory structures are often distinguished by being called **neurohormones** or *neurosecretions*.

The signals that stimulate secretion by nonneural endocrine cells are usually other hormones, although some, such as the islets of Langerhans in the vertebrate pancreas, also receive neural input. By contrast, neurosecretory endocrine cells are always signaled to secrete their neurohormones by synaptic input from typical neurons. Thus neurosecretory cells interface directly with the nervous system. Both neurons and neurosecretory cells typically generate action potentials and release their products by exocytosis. However, neurons release neurotransmitter at a synaptic cleft or gap. Neurosecretory cells release neurohormones into the blood. Through this process they transduce neural signals into endocrine signals. The fundamental similarity between neurons and neurosecretory cells suggests evolutionary continuity between the neural and the endocrine control systems. We do not know, however, whether neurosecretory cells evolved from neurons, or vice versa, or whether both types of cells have a common ancestry.

The cell bodies of neurosecretory cells are located within the CNS, but their axons extend outside the CNS. Neurohormones are synthesized in the cell bodies, transported down the axons, and released at the ends of the axons. The axon terminals are often contained within a **neurohemal organ**, which is an anatomically distinct site for the release of neurohormones. It consists of one or more clusters of axon terminals and a rich supply of blood vessels or other circulatory specializations. Neurohemal organs occur in both vertebrates and invertebrates. The pars nervosa of the posterior pituitary gland is a prominent neurohemal organ in vertebrates (see Figure 16.6). The corpus allatum of insects, discussed later in this chapter, is another prominent example.

SUMMARY Types of Endocrine Glands and Cells

- Endocrine glands may be discrete, diffuse, or intermediate. Many discrete glands appear to have evolved from diffusely distributed cells.
- Epithelial (nonneural) endocrine cells are generally controlled by hormones. (Some, such as the β cells of the pancreas, receive neural input.)
- Neurosecretory cells are always controlled by synaptic input from neurons. Neurons and neurosecretory cells are thought to be related evolutionarily, but their origins are not known.

Control of Endocrine Secretion: The Vertebrate Pituitary Gland

In this section we use the vertebrate pituitary gland as an example to illustrate two major controls of secretion: neural control of secretion by neurosecretory cells and neurosecretory control of secretion by endocrine cells. The principles of control described in this example also apply to other endocrine tissues in both vertebrates and invertebrates. This section will also demonstrate that, although pituitary secretions exert far-reaching effects, the hypothalamus dominates pituitary gland functions. The pituitary gland lies immediately below the hypothalamus and consists of two parts: the **adenohypophysis**, commonly called the **anterior pituitary**, and the **neurohypophysis**, commonly called the **posterior pituitary**. In development, the anterior pituitary forms from a dorsal evagination (outpocketing) of the oral cavity called Rathke's pouch. This completely nonneural tissue pinches off from the oral cavity to associate closely with the posterior pituitary, which is an extension of the hypothalamus.

The posterior pituitary illustrates neural control of neurosecretory cells

The posterior pituitary (neurohypophysis) consists of bundles and terminations of axons that originate in the hypothalamus (Figure 16.6). Hypothalamic neurosecretory cells extend their axons through the *median eminence*, which forms part of the floor of the hypothalamus, along the *infundibular stalk*, and into the *pars nervosa* ("nervous part"), where the axons terminate at a rich network of capillaries. (The posterior pituitary is also called the neural lobe or posterior lobe.)

In most mammals, two peptide hormones are released into the blood in the pars nervosa: vasopressin and oxytocin. **Vasopressin**, also called **antidiuretic hormone (ADH)**, limits the production of urine and also stimulates constriction of arterioles. The functions of **oxytocin** (which is produced in both males and females) include causing contractions of the uterus during birth and ejection of milk by the mammary glands during suckling. Endocrinologists originally believed that the hormones of the pars nervosa were synthesized there. However, starting in the 1930s, research revealed that these hormones are actually synthesized by neurosecretory cells that have their cell bodies within the hypothalamus. In mammals (see Figure 16.6), two paired clusters of cell bodies in the hypothalamus, the **paraventricular nuclei** and **supraoptic nuclei**, are the main sites of production of these two peptides. When the neurosecretory cells are stimulated, they generate action potentials that propagate from the hypothalamus to their axon terminals in the pars nervosa. Here they release hormone by exocytosis into the extracellular fluid near capillaries, and the hormone diffuses into the blood.

The hypothalamus–posterior pituitary connection illustrates one form of control of endocrine function: *neural control of neurosecretory cells*. The neurosecretory cells that produce and secrete vasopressin and oxytocin receive and integrate synaptic input from a host of typical neurons. Vasopressin cells, for example, receive input about blood volume and the osmotic concentration of body fluids. When they receive signals reporting high osmotic concentration and/or low blood volume, they secrete vasopressin, which triggers processes involved in retaining water. Likewise,

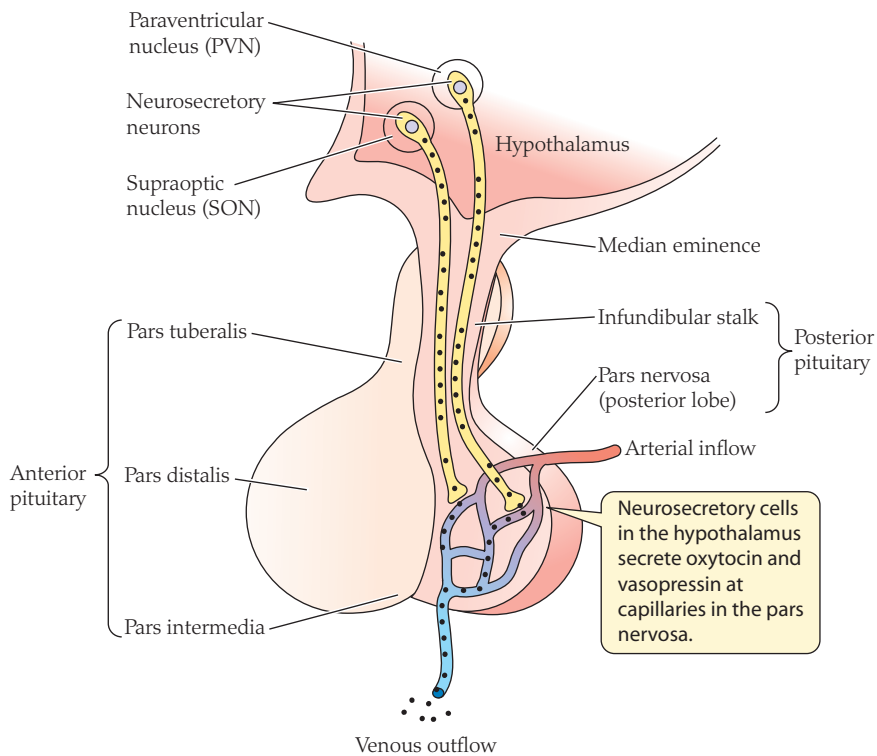

FIGURE 16.6 The posterior pituitary and hypothalamus All vertebrate pituitary glands have two parts, posterior and anterior, but they vary in specific morphology. This diagram and that in Figure 16.7 are based on the structure of the mammalian pituitary gland. The median eminence is a major functional link between the hypothalamus and the pituitary. It includes axons from the SON and PVN to the posterior pituitary and axons from other hypothalamic nuclei to capillaries that coalesce into the portal vessels that carry blood to the anterior pituitary (see Figure 16.7). The pars nervosa of the posterior pituitary contains terminals of axons that extend along the infundibular stalk from cell bodies of neurosecretory cells located in the hypothalamus.

oxytocin cells respond to signals from the mammary glands when suckling occurs or from the cervix of the uterus during labor and birth (see page 479).

Vasopressin and oxytocin, which are very similar in their amino acid sequence (Table 16.2), are considered members of a family of hormones that are probably descended from a single ancestral peptide. They are both nonpeptides (have nine amino acids). In most mammals they differ at only two amino acid sites, yet these structural differences underlie profound differences in function. As shown in Table 16.2, vasopressins and oxytocins in different vertebrate species show additional variations in amino acid composition. For example, whereas most mammals possess arginine vasopressin, nonmammalian vertebrates have arginine vasotocin, a combined vasopressin–oxytocin molecule. There are many other examples of hormone families. For example, insulin is considered the prototype of the insulin family, which includes hormones with structures and genes related to those of insulin. Other members of the insulin family include relaxin, secreted by the ovary and placenta and thought to aid in the birth of viviparous vertebrates, and insulin-like growth factors (IGFs), secreted by the liver and other tissues such as muscle. Investigators analyze both chemical and genetic information about the peptides within families of hormones to learn about their common ancestral origins.

The anterior pituitary illustrates neurosecretory control of endocrine cells

The anterior pituitary (adenohypophysis) is nonneural endocrine tissue (Figure 16.7). It is subdivided into the *pars distalis*, *pars intermedia*, and *pars tuberalis* (see Figure 16.6). The exact positions and relative sizes of these parts vary greatly from one animal group to another, and in some groups not all parts are present. All the hormones of the anterior pituitary are synthesized and secreted by endocrine cells within its tissues. Different specific populations of cells secrete different hormones. All anterior pituitary hormones are peptides, proteins, or glycoproteins (proteins with covalently bound carbohydrate chains).

Anterior pituitary hormones are categorized into two main groups according to their target tissues. The hormones of one group exert their principal effects on nonendocrine tissues. **Growth hormone (GH)**, for example, influences growth and nutrient metabolism in tissues such as fat and muscle. Other hormones of this group are **prolactin** and **melanocyte-stimulating hormone (MSH)**. The second group includes hormones that control other endocrine glands. By convention, hormones that influence the functions of other endocrine glands have the suffix *-tropic* in their names, or are called *tropins*.

Thyroid-stimulating hormone (TSH), for example, is also called *thyrotropin*. This anterior pituitary hormone supports and maintains the tissues of the thyroid gland and also stimulates the gland to secrete thyroid hormones. If a target gland is deprived of

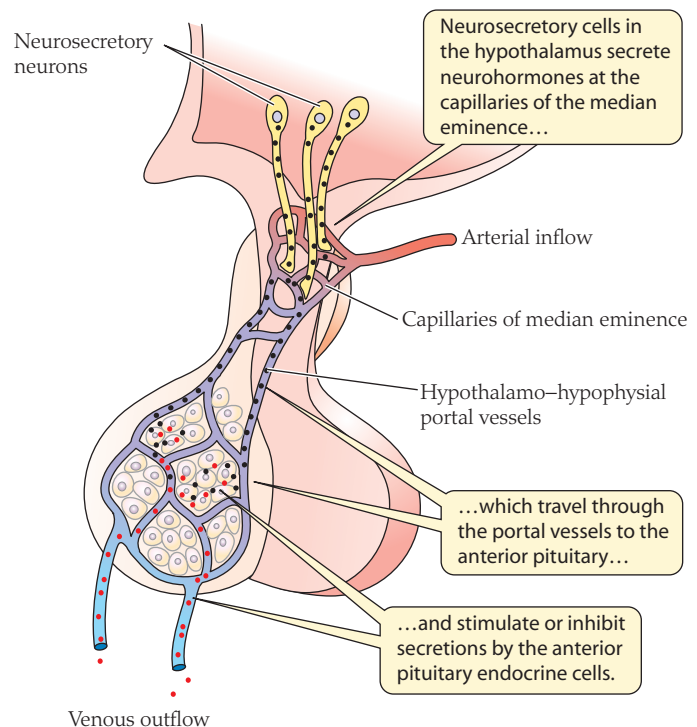

FIGURE 16.7 The anterior pituitary and hypothalamus The anterior pituitary consists of nonneural endocrine cells. Secretion of anterior pituitary hormones is controlled by hypothalamic neurohormones, which are transported in the hypothalamo–hypophysial portal system.

TABLE 16.2 Posterior pituitary nonapeptides found in vertebrates

Common name	Found in	Amino acid site								
		1	2	3	4	5	6	7	8	9
Arginine vasopressin (AVP) (antidiuretic hormone, ADH)	Most mammals	Cys	Tyr	Phe	Gln	Asn	Cys	Pro	Arg	Gly(NH ₂)
Lysine-vasopressin (LVP)	Pig, peccary, hippopotamus	Cys	Tyr	Phe	Gln	Asn	Cys	Pro	Lys	Gly(NH ₂)
Arginine vasotocin (AVT)	Nonmammalian vertebrates	Cys	Tyr	Ile	Gln	Asn	Cys	Pro	Arg	Gly(NH ₂)
Oxytocin	Most mammals	Cys	Tyr	Ile	Gln	Asn	Cys	Pro	Leu	Gly(NH ₂)
Mesotocin	Reptiles (including birds), amphibians, lungfish	Cys	Tyr	Ile	Gln	Asn	Cys	Pro	Ile	Gly(NH ₂)
Isotocin	Most bony fish	Cys	Tyr	Ile	Ser	Asn	Cys	Pro	Ile	Gly(NH ₂)

Note: Green text indicates differences in amino acids among the vasopressins and oxytocin. Mesotocin and isotocin are shown for comparison.

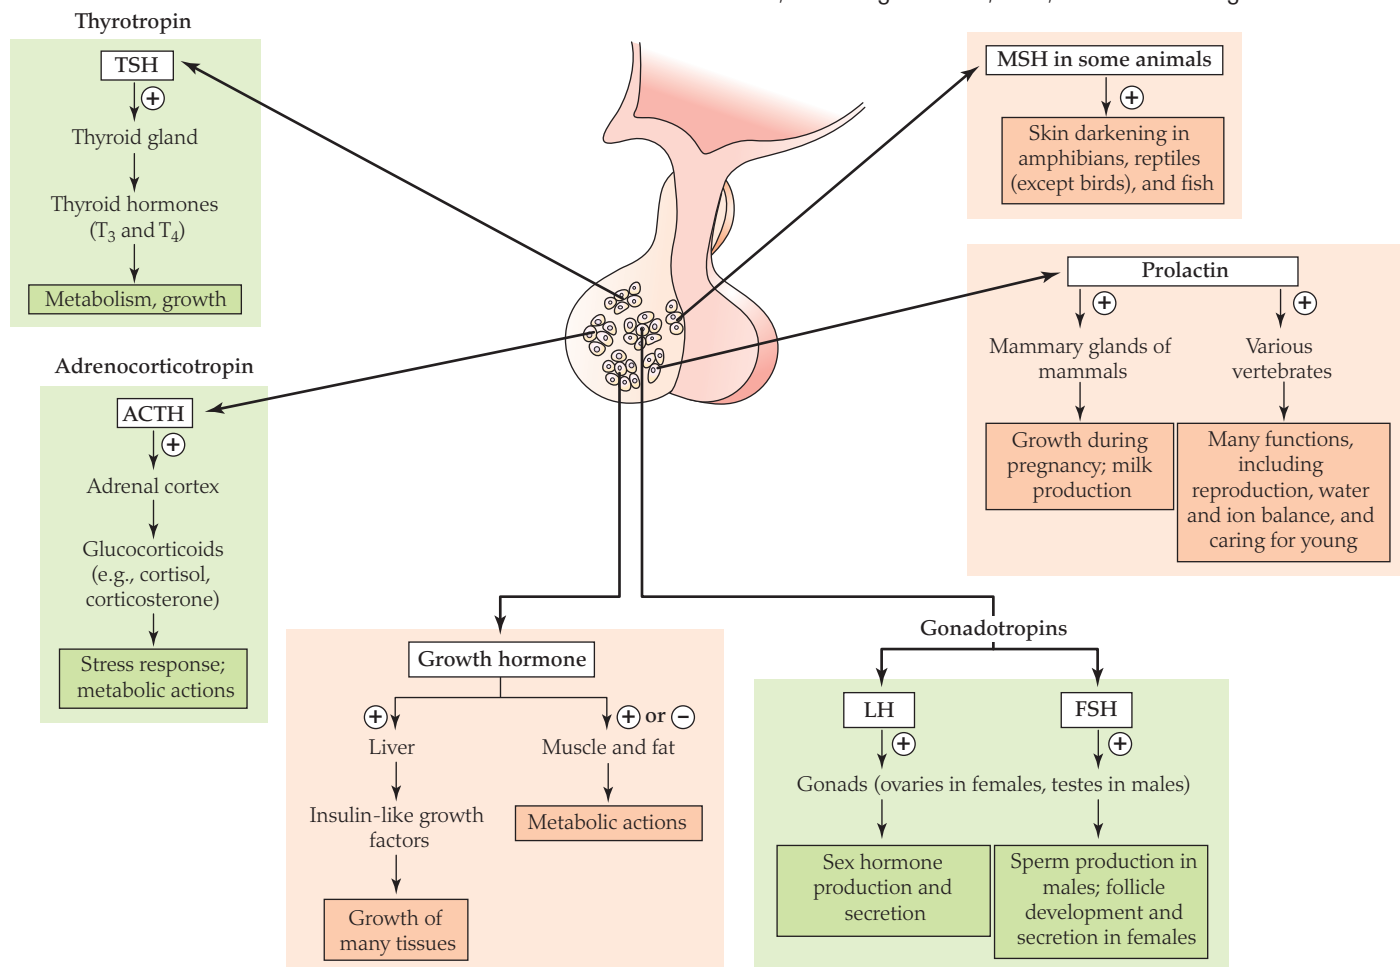

Source: After Bentley 1998.

input from its tropic hormone, the gland not only stops secreting hormone, but also shrivels in size. **Adrenocorticotrophic hormone (ACTH)**, **luteinizing hormone (LH)**, and **follicle-stimulating hormone (FSH)** are also tropic hormones produced by the anterior pituitary. The general functions of the anterior pituitary hormones are listed in Appendix K and **Figure 16.8**.

What kinds of signals control the secretions of the anterior pituitary gland? The answer is, in large part, neurohormones

secreted by neurosecretory cells in the hypothalamus. The anterior pituitary and the hypothalamus are connected by a specific, dedicated vascular pathway (see Figure 16.7). Capillaries of the median

FIGURE 16.8 The anterior pituitary hormones Separate populations of cells in the anterior pituitary secrete different hormones. (+), stimulatory; (-), inhibitory. TSH, thyroid stimulating hormone; ACTH, adrenocorticotrophic hormone; MSH, melanocyte-stimulating hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone.

eminence coalesce into *portal vessels* that travel the short distance along the infundibular stalk to the anterior pituitary; from there they branch to form capillary beds around the endocrine cells of the anterior pituitary. (*Portal vessels* are any vessels that carry blood from one capillary bed to another.) This whole system is termed the **hypothalamo–hypophysial portal system**. The median eminence is a neurohemal organ in which the axons of several populations of hypothalamic neurosecretory cells terminate. These cells produce neurohormones that control the secretions of specific groups of anterior pituitary cells. Some hypothalamic neurohormones stimulate secretion of hormones and are called *releasing hormones* (RHs). Others, called *inhibiting hormones* (IHs), inhibit secretion of anterior pituitary hormones. Each neurohormone is specific in its actions (see Appendix K). Like the anterior pituitary tropic hormones, the RHs are also tropic. They both stimulate secretion by anterior pituitary endocrine cells and maintain their vigor.

The hypothalamic neurosecretory cells secrete their RHs and IHs into the capillaries of the median eminence, and the neurohormones are carried in the portal system to the anterior pituitary, where they exert their effects on their specific target cells (see Figure 16.7). Thus, for example, *thyrotropin-releasing hormone* (TRH) from the hypothalamus stimulates the secretion of TSH in the anterior pituitary, and TSH travels through the general circulation to stimulate release of thyroid hormones from the thyroid gland. The portal system provides a short, direct path for neurohormones to travel quickly, without dilution, from the hypothalamus to the anterior pituitary.

We can think of the hypothalamo–hypophysial portal system as providing an interface between the brain and much of the endocrine system. The posterior pituitary is an extension of the brain. The anterior pituitary—although not part of the brain—is under the control of the brain and regulates the functions of many other tissues, including several endocrine glands. The vertebrate pituitary gland illustrates how the sophisticated integrative capabilities of the CNS influence endocrine function. The CNS receives and integrates input from a multitude of sensory receptors that monitor conditions both within the animal and in its outside environment. Neurons provide synaptic input to neurosecretory cells, which in turn influence the physiology of other cells, including endocrine cells. (In some other glands, such as the islets of Langerhans, we know that neurons that are not part of the hypothalamo–hypophysial system influence endocrine cells directly.)

Neural control of the endocrine system deserves emphasis, but endocrine control of the nervous system is also important. Overall, physiological control is performed by the two systems interacting mutually, not by one unilaterally controlling the other. Many instances of endocrine control of the nervous system are known; examples include the negative feedback effects of secreted hormones on neurosecretory cells (discussed below) and the effects of hormones on neurons that direct stereotyped muscle contractions during metamorphosis in insects (described later in this chapter).

Hormones and neural input modulate endocrine control pathways

When the secretions of one endocrine gland act on another in a sequence, endocrinologists speak of the system as an **axis**. For example, the hypothalamus–anterior pituitary–thyroid axis is an axis that mediates secretion of thyroid hormones. It represents a hormonal sequence from TRH to TSH to thyroid hormones.

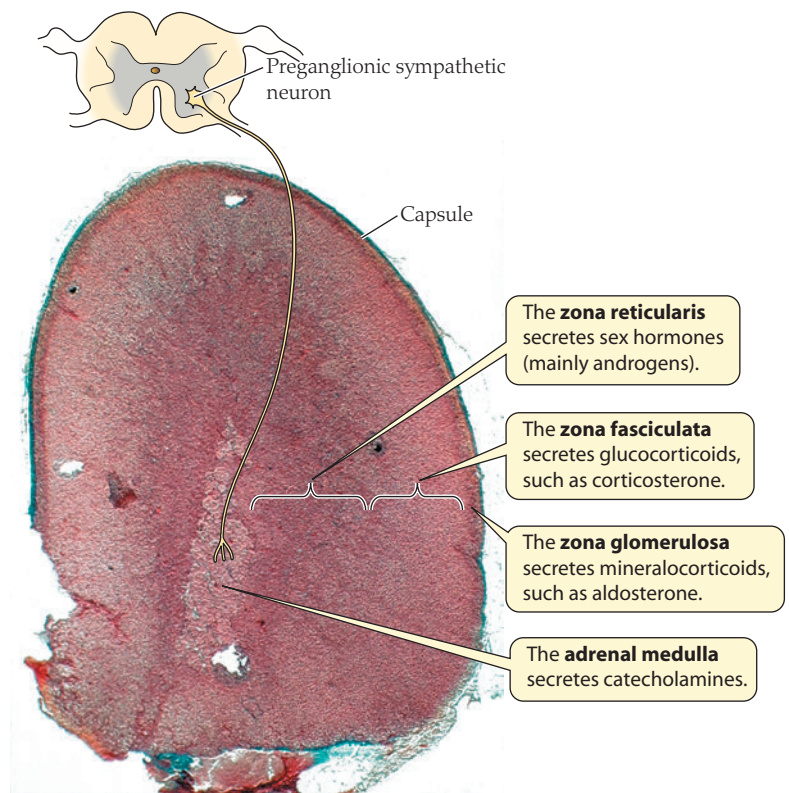

FIGURE 16.9 The adrenal gland consists of an inner medulla and an outer cortex. The different portions characteristic of mammalian adrenal glands are visible in this section of a mouse adrenal gland. The medulla is homologous to a sympathetic ganglion, except that the postganglionic cells do not possess axons. The cortex, which surrounds the medulla, has three distinct layers (the zona reticularis, zona fasciculata, and zona glomerulosa), each specialized to secrete a different category of steroid hormones. (Courtesy of Judith Wopereis, Smith College.)

Similar axes are also found in invertebrates. In this section we use the hypothalamus–pituitary–adrenal cortex (HPA) axis to illustrate how rates of endocrine secretion can be *modulated*, or changed, by hormonal and neural influences.

The adrenal gland (Figure 16.9) secretes several hormones. Here we limit our consideration to the **glucocorticoids** (cortisone, cortisol, and corticosterone), a class of steroid hormones so named because (among other functions) they promote an increase in the blood concentration of glucose (“gluco”) and because they are secreted by the adrenal cortex (“cortico”). Glucocorticoids are central to homeostasis. Their widespread effects include ensuring adequate blood glucose levels, maintaining the responsiveness of blood vessels to stimulation by catecholamines, and limiting inflammation. The main glucocorticoid produced in primates and fish is cortisol, whereas in reptiles (including birds), amphibians, and rodents, it is corticosterone. Stressful or challenging conditions cause increased glucocorticoid secretion. (We consider the mammalian stress response later in this chapter). Glucocorticoid secretion is controlled by the HPA axis. Brain neural activity is integrated by neurons that secrete **corticotropin-releasing hormone (CRH)** into the capillaries of the median eminence. CRH is carried in the portal system to the anterior pituitary, where it stimulates adrenocorticotropic cells to secrete ACTH into capillaries leading to the general circulation.

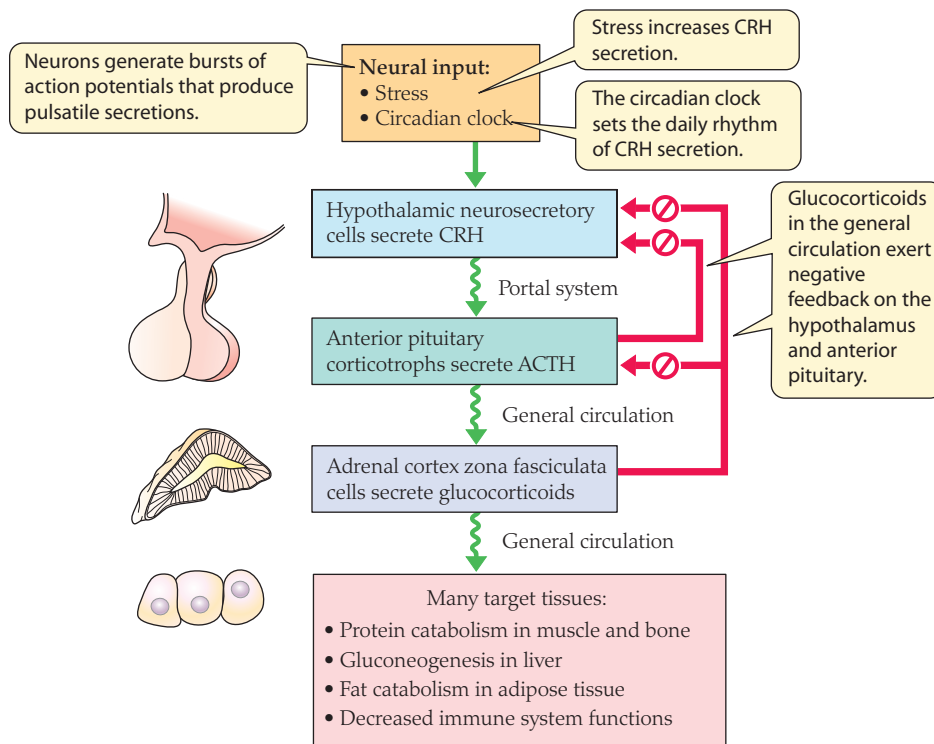

FIGURE 16.10 Hormonal, neural, and feedback mechanisms modulate the action of the HPA axis. Glucocorticoids secreted by the adrenal cortex zona fasciculata exert effects on target tissues and also provide negative feedback to the anterior pituitary and the hypothalamus. CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone.

ACTH is carried to the adrenal cortex, where it stimulates glucocorticoid secretion (Figure 16.10). Glucocorticoids act at different target tissues to influence many physiological processes.

Any stage in this control pathway can be modulated. *Negative feedback* (see Figure 16.10) is the most widespread type of **hormonal modulation**. In negative feedback, a hormone causes changes in its control pathway that tend to suppress its own secretion. In the HPA axis, high glucocorticoid levels tend to suppress secretion of CRH by the hypothalamus and ACTH by the anterior pituitary, and also to reduce the responsiveness of the ACTH cells to CRH. As a result, the pituitary secretes less ACTH, and the adrenal cortex receives less stimulus to secrete glucocorticoids. Mechanisms of negative feedback do not reduce hormone secretion to zero, but instead serve to *stabilize* blood concentrations of hormones. Occasionally, hormonal modulation involves *positive feedback*, such as that resulting in the explosive increase in oxytocin secretion during the process of birth (see page 479).

In addition to feedback mechanisms, other types of hormonal modulation can affect endocrine control pathways. For example, hormones that are ancillary parts of a pathway can alter a target gland's response to a particular hormone. In the HPA pathway, vasopressin (VP) acts together with CRH to increase the secretion of ACTH from the anterior pituitary. Not all VP-secreting neurosecretory cells in the hypothalamus extend their axons to the posterior pituitary. Some terminate their axons on the capillary bed of the median eminence. When released, VP circulates through the portal vessels to the anterior pituitary. By itself VP has little effect on the ACTH-secreting cells. However, when these cells receive signals from both VP and CRH, their secretion is greater than it would be under the influence of CRH alone. This sort of effect, in which one hormone can amplify the effect of another, is called **synergism**.

A hormone can influence the effects of another hormone at the same target tissue in three different ways: by synergism (pro-

ducing an enhanced response such as we have seen with VP and CRH), **permissiveness** (in which the presence of one hormone is *required* for the other to exert an effect), or **antagonism** (in which one hormone opposes the action of another). One example of permissiveness is that of cortisol permitting the catecholamines epinephrine and norepinephrine to cause constriction (narrowing of the diameter) of blood vessels, a function necessary to maintain normal blood pressure. Because cortisol *must* be present for vasoconstriction to occur, basal levels of this glucocorticoid are necessary for homeostatic regulation of blood pressure. Without treatment, humans with a condition called "adrenal insufficiency" (who are unable to secrete adequate amounts of hormones from the adrenal cortex) are at risk of death if they experience a stress, such as a hemorrhage, that requires systemic vasoconstriction.

An example of antagonism is the interaction between insulin and glucagon. We know that insulin secreted from β cells in the islets of Langerhans in the pancreas promotes uptake of glucose from the blood by many different tissues. **Glucagon** is a hormone secreted by A , or α , cells in the islets, and it functions to oppose the action of insulin: It stimulates the release of glucose and fatty acids into the blood. The balanced actions of these two hormones help maintain stable levels of glucose in the blood.¹ In situations, such as stress, in which higher blood concentrations of glucose are required to respond to a crisis, glucagon secretion increases and insulin secretion decreases. Figure 16.11 shows blood glucose levels in dogs given insulin alone or in combination with glucagon and epinephrine. Epinephrine and glucagon are both antagonists of insulin, and they work synergistically to oppose insulin's action.

¹Antagonism, in the context of endocrinology, means that two hormones have opposing actions, but it does not indicate their mechanisms of action. For example, opposing hormones may trigger different biochemical pathways in the target cell, or they may induce downregulation of receptors for the opposing hormone in the target cell.

FIGURE 16.11 Interactions of insulin, glucagon, and epinephrine illustrate synergism and antagonism between hormones. Blood glucose levels were measured in 29 dogs infused with insulin alone or in combination with glucagon and epinephrine. Glucagon and epinephrine both reduce insulin's stimulation of cells to take up glucose from the blood, and they exert a greater effect when they are present together. Error bars show the standard errors. (After Sacca et al. 1979.)

Neural modulation also affects endocrine control pathways. In the HPA axis, neurons reporting increases or decreases in stress provide synaptic input to CRH neurosecretory cells in the hypothalamus (see Figure 16.10). Furthermore, neuronal biological clocks can influence hormone secretion. This is the case in the HPA axis: Blood levels of cortisol regularly rise and fall in a daily rhythm, being highest in the early morning and lowest during the evening. These cyclic changes in secretion are driven by a circadian clock in the brain that sends input to the hypothalamic CRH neurosecretory cells. Changes in lighting and feeding schedules can perturb these diurnal changes in glucocorticoid secretion, and stress can disrupt the diurnal rhythm.

Finally, many hypothalamic and pituitary hormones are secreted *in pulses*, so that there are intermittent brief periods of high hormone concentration in the blood. (When a hormone is continuously present, target cells typically downregulate their receptor molecules for that hormone; it is thought that one advantage of pulsatile release is that it prevents this *desensitization* of target cells.) Synaptic input to the neurosecretory cells governs the pulsatile release of hypothalamic hormones, which in turn causes pulsatile output of pituitary hormones. The amplitude of a pulse of hormone (i.e., the amount of hormone released during a pulse) can vary. For example, the CRH neurons secrete pulses of hormone two or three times per hour. The amplitude of each pulse increases in the early morning in diurnal species (and early evening in nocturnal species) according to input from the circadian clock. It also increases when neural activity signals the

presence of one or more stressors. Ultimately, the *combination* of neural modulation and hormonal modulation determines the minute-to-minute blood levels of hormones.

SUMMARY Control of Endocrine Systems: The Vertebrate Pituitary Gland

- The vertebrate pituitary gland consists of the adenohypophysis (anterior pituitary) and the neurohypophysis (posterior pituitary). Posterior pituitary hormones (vasopressin and oxytocin) are secreted in response to neural activity. Secretions of anterior pituitary hormones are controlled by releasing hormones (RHs) and inhibiting hormones (IHs) from the hypothalamus, which are transported to the anterior pituitary through the hypothalamo–hypophysial portal system.
- The rate of hormone secretion is influenced by a combination of hormonal modulation (such as feedback mechanisms, synergism, permissiveness, and antagonism) and neural modulation (such as sensory input and clock mechanisms). Neural activity also governs the pulsatile release of hormones.

The Mammalian Stress Response

In this section we use the mammalian stress response (Figure 16.12) to illustrate and integrate several of the principles of endocrinology discussed in previous sections. The stress response is an adaptation that allows an animal to respond immediately in a generalized way to a threatening or challenging situation. Stressors experienced by animals include being wounded, being exposed to thermal extremes (birds and mammals) or other hostile environmental conditions, being forced to exercise vigorously, and experiencing troublesome social conditions or high levels of emotion. We tend to think of stressors as negative challenges to survival, but in some instances they may heighten experiences in a positive way. In humans, and perhaps other animals as well, stressors over which an individual perceives a sense of control can be rewarding. For example, seeking novel situations generates stress but also facilitates intellectual and emotional growth. Interestingly, feeding and sexual activity—both essential behaviors for biological success—also stimulate the stress system.

During the stress response, heart and breathing rates increase, cognition and alertness are sharpened, metabolic processes release stored energy, oxygen and nutrients are directed to the CNS and to those sites in the body that are stressed the most, and feeding and reproduction are curtailed. All of these changes serve to ensure survival in an acute crisis. Different stressors differentially turn on different components of the stress response; however, any one stressor that is sufficiently potent will turn on a generalized stress syndrome. When the stressor is no longer present, feedback mechanisms ensure that the stress response is turned off. In the classic example of a zebra chased by a lion, the threat is clear, the physiological response is swift, and the episode has a finite end. However, if a stressor (physical or emotional) persists for long periods, physiological responses that are adaptive in the short term become damaging in the long term.

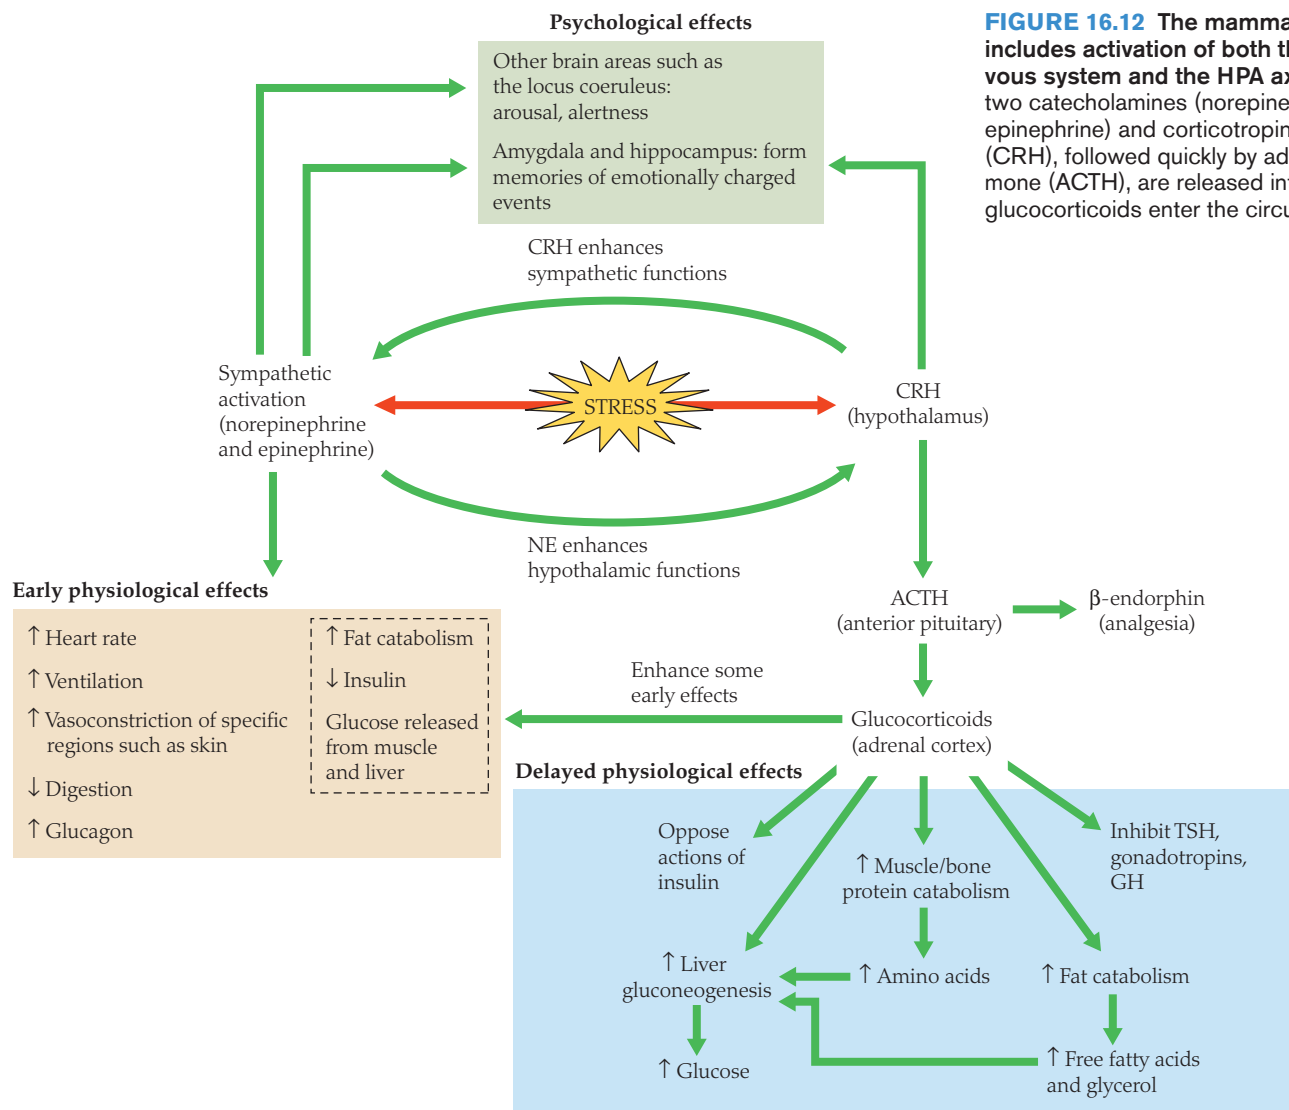

FIGURE 16.12 The mammalian stress response includes activation of both the sympathetic nervous system and the HPA axis. Within seconds, two catecholamines (norepinephrine [NE] and epinephrine) and corticotropin-releasing hormone (CRH), followed quickly by adrenocorticotropic hormone (ACTH), are released into the circulation. The glucocorticoids enter the circulation later.

The autonomic nervous system and HPA axis coordinate the stress response to an acute threat

The rat detects the cat and runs. Within seconds of the threat, the rat's sympathetic nervous system releases catecholamines (epinephrine and norepinephrine) from sympathetic nerve terminals and the adrenal medulla, and hypothalamic neurosecretory cells release CRH into the hypothalamo–hypophysial portal system. A few seconds later, the anterior pituitary secretes ACTH. Thus two output systems, the sympathetic “fight-or-flight” system and the HPA axis, together mount the response to a stressor. Their functions are not independent, but intermingled. For example, in addition to its role as a neurohormone that stimulates ACTH secretion, CRH also acts as a neurotransmitter in other areas of the brain, where it stimulates the sympathetic nervous system. Researchers uncovered this additional role of CRH by injecting it into the brain ventricles of dogs and rats whose pituitary glands had been removed. These animals secreted no ACTH, because the ACTH-secreting cells were gone. However, injected CRH caused increases in blood concentrations of catecholamines and associated increases in blood pressure and heart rate. Experiments such as these reveal that one of the functions of CRH is

to link the sympathetic and adrenocortical branches of the stress response. CRH also acts as a neurotransmitter or neuromodulator in the amygdala and hippocampus (which function together to form memories of emotionally charged events).

The two output branches of the stress response are also linked by norepinephrine. The CRH neurosecretory cells in the hypothalamus receive noradrenergic synaptic input from several different nuclei of the brain. Some of these nuclei are innervated by neurons using CRH as their neurotransmitter, so that reciprocal interactions are possible. Like CRH, norepinephrine also provides input to the amygdala and hippocampus. Although researchers understand many CRH and norepinephrine connections in the brain, they do not know what neurocircuitry upstream of these pathways actually turns on the stress response.

The stress response includes two phases (see Figure 16.12). First, within less than 1 min, the catecholamines (epinephrine and norepinephrine)² trigger increases in heart and respiration rates, blood pressure, and other sympathetic responses. These changes

²Catecholamines act quickly because they are stored in vesicles ready for release, and because, as we saw earlier in this chapter, their target cells respond through second-messenger systems that use preexisting proteins.

provide increased blood flow to the skeletal muscles and heart, as well as increased air flow into and out of the lungs as the bronchial airways increase in diameter. Blood vessels to the skin constrict, diverting blood from sites of possible injury. Digestive functions are suppressed. Arousal of the CNS and alertness are promoted. Epinephrine stimulates the release of glucose into the blood by triggering the breakdown of glycogen stored in the liver (see Figure 2.29) and muscles, and it also stimulates the release of fatty acids from lipid stores. Epinephrine in the blood and norepinephrine from sympathetic nerve terminals both inhibit insulin secretion and stimulate glucagon secretion from the islets of Langerhans. Ordinarily, increased glucose in the blood would stimulate insulin secretion, which would promote the uptake of glucose from the blood by all tissues except brain and exercising skeletal muscle. By inhibiting insulin secretion and stimulating glucagon secretion, the catecholamines ensure plentiful levels of glucose in the blood to fuel physical exertion and maintain brain function.

Additional synergies occur during the first phase of the stress response. For example, epinephrine (in addition to CRH) appears to stimulate the secretion of ACTH, and ACTH may do more than stimulate glucocorticoid secretion. ACTH is known to facilitate learning, and it may contribute to an animal's preparedness in responding to a similar stressor in the future. Finally, ACTH is produced by cleaving of a prohormone, POMC, and can be co-secreted along with other fragments of POMC, including β -endorphin. The latter substance (also produced by POMC cells in the hypothalamus) is an endogenous opiate and may contribute to *analgesia*; that is, it may decrease the animal's perception of pain.

In the second phase of the stress response (see Figure 16.12), glucocorticoids are secreted by the adrenal cortex. The full effects of glucocorticoids on target tissues can be detected about 1 hour after the stress response is initiated.³ Glucocorticoids reinforce the actions of the sympathetic nervous system and have additional metabolic effects that facilitate the release of usable sources of energy into the bloodstream. They stimulate the catabolism of protein in muscle and (at high levels) bone, and they stimulate the liver to use the released amino acids to produce glucose in a process called *gluconeogenesis*. The liver cells release this newly formed glucose into the blood. Like epinephrine and norepinephrine, glucocorticoids oppose the action of insulin and ensure fuel availability. Glucocorticoids also stimulate catabolism of fats so that fatty acids can be used as an alternative energy source by all tissues except the brain (which uses only glucose in the short term but can use ketoacids made from fatty acids in the liver during starvation). The metabolic actions of glucocorticoids, coordinated with those of the catecholamines, ensure glucose availability to the brain in the face of required physical exertion and possible enforced fasting (for example, while hiding from a predator or recovering from a wound). The amino acids released by protein catabolism are also available for tissue repair.

In addition to their important metabolic effects, glucocorticoids increase their permissive effect on vasoconstriction stimulated by the catecholamines, as we saw earlier. They also inhibit the secretion of gonadotropins (FSH and LH), thyrotropin (TSH),

³The effects of glucocorticoids take longer to appear because these steroid molecules must be produced from precursors prior to secretion. Once secreted, they typically exert genomic effects in their target cells, which then synthesize new proteins.

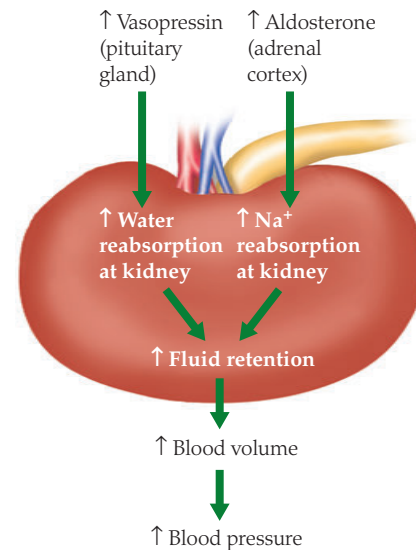

FIGURE 16.13 The regulation of blood volume after blood loss. Vasopressin and aldosterone exert effects at the kidney to conserve fluid and thereby help to maintain adequate blood volume and blood pressure.

and growth hormone (GH) from the anterior pituitary. Assuming the chase is short, and, for example, the rat pops into its burrow before the cat seizes it, the inhibitory effects of glucocorticoids on reproduction and growth are minimal. Safe in its burrow, the rat experiences diminished sympathetic neural responses, and the glucocorticoid molecules in its general circulation feed back negatively on the CRH and ACTH cells of the HPA axis. Thus the glucocorticoids themselves modulate the stress response. With decreased ACTH in the circulation, the adrenal cortex secretes decreased amounts of glucocorticoids, and concentrations in the blood return to basal levels.

If an animal experiences a severe wound and loses blood, several mechanisms are called into play to correct the loss of blood volume (Figure 16.13). Blood volume directly affects blood pressure, and blood pressure is necessary to ensure adequate delivery of oxygen and nutrients to the brain and other essential organs. Catecholamines released by the already activated sympathetic nervous system stimulate the heart and blood vessels to maintain blood pressure. Vasopressin released from the posterior pituitary stimulates the nephrons in the kidney to retain water, and aldosterone secreted by cells in the zona glomerulosa of the adrenal cortex acts at the nephrons to retain sodium, which exerts an osmotic holding effect on water. The combined actions of these hormones are aimed at conserving fluid volume, which translates to adequate blood volume and blood pressure. These ideas are further explored later in this chapter (see pages 439–442) and Figures 16.16 and 16.17).

The HPA axis modulates the immune system

Although glucocorticoids modulate the stress response by negative feedback on the hypothalamic CRH cells, they also regulate functions of the immune system (Figure 16.14). The *immune system* works to prevent the invasion of foreign pathogens and to search out and destroy those that sneak through natural barriers. It neutralizes toxins and disposes of dead, damaged, and

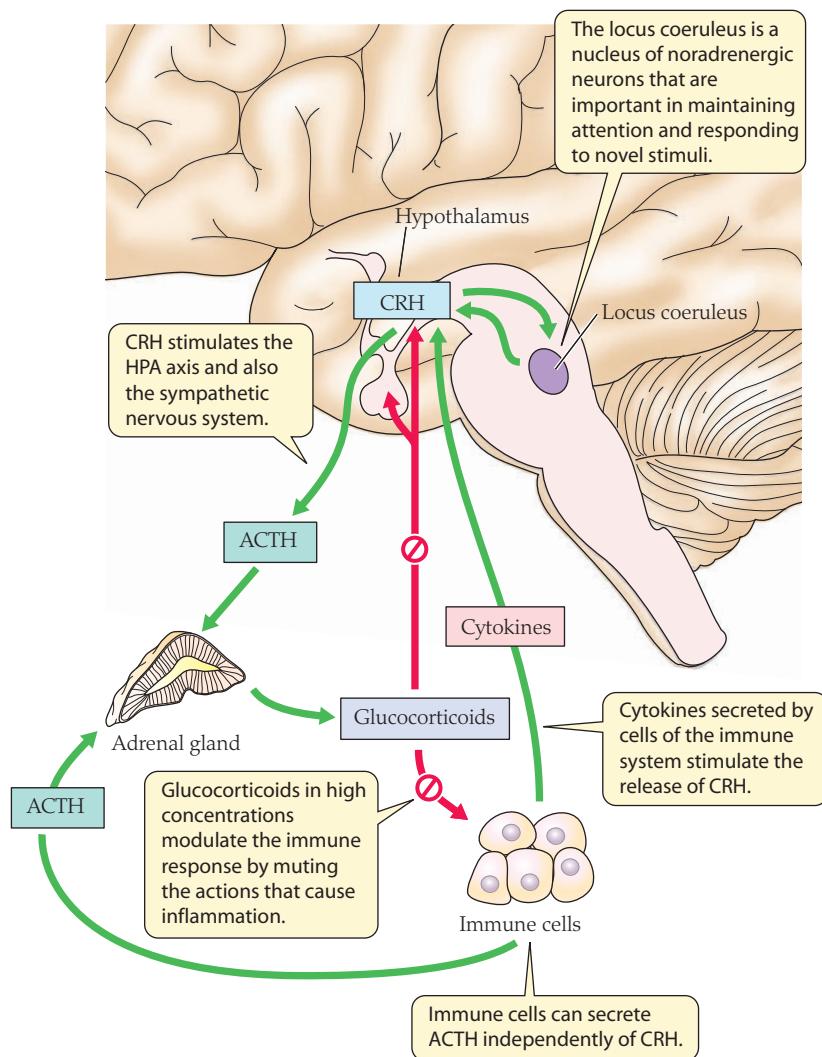

FIGURE 16.14 The central nervous system and the immune system interact during the stress response CRH, corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone.

abnormal cells. During the early phases of the stress response, the catecholamines and glucocorticoids (still at low concentrations) stimulate the immune system. Stimulating the immune system ensures that a wounded animal barely escaping a predator, for example, doesn't succumb to bacterial infection from the wound. The immune response often causes inflammation in response to infection or a wound. At higher concentrations (in later stages of the stress response and during recovery), glucocorticoids have anti-inflammatory effects and thus keep the immune system from overreacting and damaging healthy cells and tissues.⁴ Researchers now know that a web of chemical pathways allows communication among the nervous, endocrine, and immune systems. These three systems interact continuously to maintain homeostasis as an animal navigates its daily life.

⁴Physicians often prescribe glucocorticoids such as cortisone to fight excessive inflammation. This treatment can be helpful in the short term. However, recent evidence suggests that glucocorticoids may be proinflammatory in the CNS after injury (e.g., after a stroke), and their use in these circumstances may be contraindicated.

When certain cells of the immune system detect bacterial or viral pathogens or tumor cells, they release **cytokines**, which are chemical messengers. Like other chemical messengers, different cytokines bind with specific receptor molecules on target cells to communicate specific excitatory or inhibitory messages. In the stress response, certain cytokines travel in the blood to the hypothalamus, where they stimulate CRH neurosecretory cells. This chemical connection directly informs the CNS that the animal has detected an invading stressor. Using cytokines to turn on the stress response accomplishes two goals. First, the physiological responses of the HPA axis, such as the mobilization of energy stores, help the animal fight infection. Second, the glucocorticoids (at high concentrations) inhibit the production of agents that cause inflammation (such as prostaglandins). By muting inflammation, they modulate (keep in check) the immune response.

Studies on experimental animals have indicated, on a whole-organism scale, a relationship between the stress response and inflammatory disease. For example, if the HPA axis of normal rats is disrupted by removing their pituitary glands, they become susceptible to inflammation. Some genetic strains of rats have also shown this association. The Lewis strain of rat, for example, has an impaired HPA axis and secretes little CRH in response to stress; this strain of rats is highly susceptible to inflammatory and autoimmune disease. Injecting glucocorticoids into these animals improves their resistance to inflammation. Conversely, the Fischer strain of rat has an HPA axis that responds excessively to stress; it is highly resistant to inflammatory disease, presumably because it secretes high levels of glucocorticoids.

The intricacies of communication among the nervous, endocrine, and immune systems are not limited to cytokines interacting with the CNS. Some cells of the immune system can also stimulate glucocorticoid secretion without involving the CNS. In the presence of pathogens, these cells synthesize the hormone ACTH and secrete it into the blood. This ACTH acts at the adrenal cortex in the same way it would have had it been secreted by cells in the anterior pituitary. This single example provides only a glimpse of the interrelatedness of the three systems. We have seen that cells of the immune system secrete hormones, that cells in the nervous system have receptors for cytokine signals produced by immune cells, and that hormones affect the functions of both the nervous system and the immune system. The field of *neuroimmunomodulation* is ripe for future investigations, which have the potential to reveal the mechanisms underlying "mind-body interactions."

Chronic stress causes deleterious effects

Acute stressors are of short duration, and the resulting stress responses are also brief. All of the components of the stress response, as we have seen, contribute positively to the survival of a rat getting away unscathed from a cat, or a gazelle narrowly escaping with a bleeding gash inflicted by the jaws of a hyena. However, the stress response can be maladaptive when it is induced in animals exposed to stressors for long periods, or exposed repeatedly to stressors such as those related to social rank in dominance hierarchies or to "psychological" stressors.

Researchers and clinicians suspect that continuously constricted blood vessels and retention of salt and fluid when no blood is lost contribute to hypertension (high blood pressure) and other cardiovascular maladies. Prolonged exposure to glucocorticoids also gives rise to other pathological conditions. The catabolic actions of glucocorticoids cause muscle wasting and bone thinning. Their suppression of immune-system functions causes susceptibility to infections and disease. Chronic activation of the HPA axis suppresses reproductive functions, a phenomenon seen in highly trained athletes (both male and female), ballet dancers, starving animals, and persons with anorexia nervosa. High levels of glucocorticoids have also been implicated in causing atrophy of dendrites of neurons in the hippocampus, and even shrinkage of the hippocampus itself. Thus continuous or repeated bouts of stress can potentially damage a part of the brain that is especially important in forming memories of emotionally charged events. Because of their far-reaching effects, stress and anxiety are subjects of intense ongoing research.

Plasma glucocorticoid concentrations show seasonal variations

Much of our understanding of the stress response has been gained from experiments using laboratory animals. However, increasing numbers of investigators are now paying attention to the roles of the stress response, and glucocorticoids in particular, in wild animals in their natural environments. We know that blood concentrations of glucocorticoids vary normally according to a circadian rhythm, and studies reveal that many amphibians, mammals, and reptiles (including birds) also show seasonal changes in glucocorticoid concentrations. In many (but not all) of these animals, glucocorticoids are highest during the breeding season. Investigators have proposed that glucocorticoids may be secreted maximally during periods of the year when energy demands are highest, or when they are necessary to support physiological processes associated with season-specific behaviors, or when they are needed to prime vascular, immune, cognitive, and metabolic systems in anticipation of events that occur during specific seasons. (These events could include breeding, disease, predation, and severe weather.) The roles of glucocorticoids in different species and the effects of different stressors on the physiology of animals in their natural environments are topics of active inquiry. An understanding of animals' abilities to respond to the challenges of environmental changes and extremes, including those imposed by human factors, will be important in developing successful conservation, environmental, and animal husbandry programs.

SUMMARY The Mammalian Stress Response

- The stress response is a generalized constellation of physiological changes aimed at ensuring survival when an animal is exposed to real or perceived hostile or challenging conditions.
- The major physiological actions in the stress response include mobilizing stored energy and inhibiting energy storage; enhancing cardiovascular and respiratory functions; increasing alertness and cognition; inhibiting feeding, digestion, and reproduction; and modulating immune function. If an animal experiences loss of blood, hormones are secreted that promote the retention of water and solutes.

- The same effects of the stress response that are essential for survival of an animal exposed to an acute stressor can be deleterious during periods of prolonged stress.
- Wild animals in their natural environments experience seasonal variations in blood concentrations of glucocorticoids.

Endocrine Control of Nutrient Metabolism in Mammals

This is the first of three sections that address endocrine controls of three essential mammalian physiological processes. We begin with endocrine controls of nutrient metabolism and follow with considerations of salt and water balance and calcium metabolism. Animals acquire nutrients—carbohydrates, lipids, and proteins—when they eat, but many animals do not eat continuously. Still, their cells need nutrients all the time. Moreover, their cells may require the three major classes of nutrients in very different proportions than are found in digested foods. Thus, to provide continuous and appropriate nutrients to all tissues, nutrient metabolism requires not only feeding but also management of storage, mobilization, and molecular interconversions of nutrients. [Table 16.3](#) lists several hormones that influence nutrient metabolism. Two main hormones, insulin and glucagon, play major roles in nutrient metabolism.

Insulin regulates short-term changes in nutrient availability

Many mammals go through bouts of feeding separated by several hours of not feeding. To prevent alternations of feast and famine at the cellular level, mechanisms are set in motion that favor storage of nutrient molecules immediately after a meal and mobilization of nutrients from storage depots as the hours pass until the next meal. Insulin is the most important hormone involved in managing short-term fluctuations of nutrient availability.

During digestion, several factors—including rising concentrations of glucose and amino acids in the blood, gastrointestinal hormones, and parasympathetic activity—stimulate the β cells in the pancreatic islets of Langerhans to increase their secretion of insulin. Insulin is the dominant hormone in the blood during the fed state. It favors the *storage* of all three major classes of nutrients. It promotes the uptake of glucose, fatty acids, and amino acids from the blood into tissues, especially muscle and fat. In the case of glucose, for example, insulin binds to its receptor molecule on a target cell and triggers a series of signal transduction events that lead to the incorporation of specific glucose transporter molecules (called GLUT-4 transporters) into the membrane of the target cell. The GLUT-4 transporters allow the target cell to take up glucose by facilitated diffusion. The brain and liver, however, do not depend on insulin to stimulate the uptake of glucose. Instead, they both have constitutive glucose transporter molecules that permit them to take up glucose continuously. Interestingly, skeletal muscles in the process of exercising do not depend on insulin for glucose uptake either. Although resting skeletal muscles require insulin to promote incorporation of GLUT-4 transporters into their cell membranes, the contractions of exercising muscles stimulate insulin-independent incorporation of GLUT-4 transporters into the membrane.

TABLE 16.3 Hormones involved in mammalian nutrient metabolism

Hormone (source)	Main stimulus for secretion	Major actions on nutrient metabolism
Insulin (β cells of the endocrine pancreas)	High blood glucose; high blood amino acids; gastrointestinal hormones; parasympathetic stimulation	Increases glucose uptake from the blood by resting skeletal muscle cells and fat cells (hypoglycemic effect); promotes formation of glycogen (glycogenesis) from glucose in muscle and liver; stimulates fat cells to synthesize triglycerides from glucose; promotes the use of glucose in ATP production; increases uptake of free fatty acids and triglyceride synthesis by fat cells; inhibits breakdown of triglycerides; increases uptake of amino acids by muscle and liver, promotes protein synthesis, and inhibits protein degradation; inhibits gluconeogenesis
Glucagon (α cells of the endocrine pancreas)	Low blood glucose; high blood amino acids; sympathetic stimulation	Increases blood glucose levels by stimulating glycogenolysis and gluconeogenesis in liver cells (hyperglycemic effect); promotes breakdown of triglycerides to increase blood levels of free fatty acids and glycerol; inhibits triglyceride synthesis
Epinephrine (adrenal medulla)	Sympathetic stimulation during stress and exercise	Increases blood glucose levels by promoting glycogenolysis in both liver and muscle cells; often promotes triglyceride degradation to increase blood levels of free fatty acids and glycerol; inhibits insulin release and antagonizes glucose uptake by cells; stimulates glucagon and ACTH secretion
Glucocorticoids (zona fasciculata of adrenal cortex)	Stress	Enhance the actions of glucagon and catecholamines; increase blood glucose levels by antagonizing cellular glucose uptake and promoting glycogenolysis and gluconeogenesis; promote degradation of triglycerides to form free fatty acids and glycerol; promote degradation of proteins to form free amino acids
Thyroid hormones (thyroid gland)	Secreted continuously; increased by TRH and TSH, which are influenced by exposure to cold in human newborns (but not adults) and other animals	Promote oxidation of nutrients (raise metabolic rate); enhance effects of catecholamines on metabolism; stimulate growth hormone secretion and enhance the effects of growth hormone on synthesis of new proteins
Growth hormone (anterior pituitary gland)	Secreted continuously with a circadian rhythm; increased by GHRH (influenced by stress, exercise, hypoglycemia); inhibited by somatostatin	Promotes protein synthesis and growth; increases uptake of amino acids by liver and muscle; enhances breakdown of triglycerides to increase blood levels of free fatty acids; antagonizes glucose uptake by muscles
Androgens (gonads and adrenal cortex)	Secreted continuously from puberty onward	Promote protein synthesis and growth of muscle

Because insulin causes a decrease in blood glucose levels, it is said to exert a *hypoglycemic effect*. Insulin also sets in motion events that stimulate enzymes that synthesize nutrient storage molecules: glycogen from glucose, triglycerides (lipids) from fatty acids or glucose, and proteins from amino acids. At the same time insulin promotes the formation of these large molecules, it inhibits the enzymes that break them down.

Insulin secretion decreases as digestion comes to an end, and the ebbing of insulin levels in the blood is often the only endocrine change necessary for a shift to net *mobilization* of nutrients from stores. As insulin declines, breakdown of stored glycogen and lipids begins, and glucose and fatty acids are released into the blood. The overall pattern of insulin secretion—high levels in the fed state and low levels in the unfed state—provides negative feedback that tends to *stabilize blood concentrations of nutrients*.

Figure 16.15a shows the average rise and decline in plasma levels of insulin for several people after a high-carbohydrate meal. With increased glucose in the blood, insulin secretion increases; as blood glucose levels decline, so do blood levels of insulin. The spike in blood glucose following the meal shows that blood nutrient concentrations are not completely stable. However, concentrations remain far more stable than they would without the negative feedback mediated by insulin. No other hormone

in the body can lower blood glucose levels. This point is made dramatically clear by people with *diabetes mellitus*, who secrete abnormally low amounts of insulin or who have diminished tissue responsiveness to insulin. After a high-carbohydrate meal, individuals with untreated diabetes experience far higher blood glucose concentrations than those without diabetes. In fact, the blood glucose levels of diabetics become so high that their kidneys are unable to recover all the glucose filtered from the blood in the process of urine formation (see Chapter 29), and glucose is excreted in their urine and wasted. Chronic high levels of glucose cause damage to the eyes, kidneys, blood vessels, and nervous system.

Given its importance, it is not surprising that insulin secretion and the sensitivity of the body's cells to it are influenced by several other hormones over the long term. For example, adiponectin (secreted by adipose tissue) increases cell sensitivity to insulin, and osteocalcin (secreted by osteoblast cells of bone) both promotes insulin secretion and increases cell sensitivity to it.

Glucagon works together with insulin to ensure stable levels of glucose in the blood

Glucagon is a peptide hormone secreted by the α cells of the pancreatic islets. The main stimuli for its release are low levels of glucose in the blood, sympathetic stimulation of the α cells,

(a) High-carbohydrate meal

(b) High-protein meal

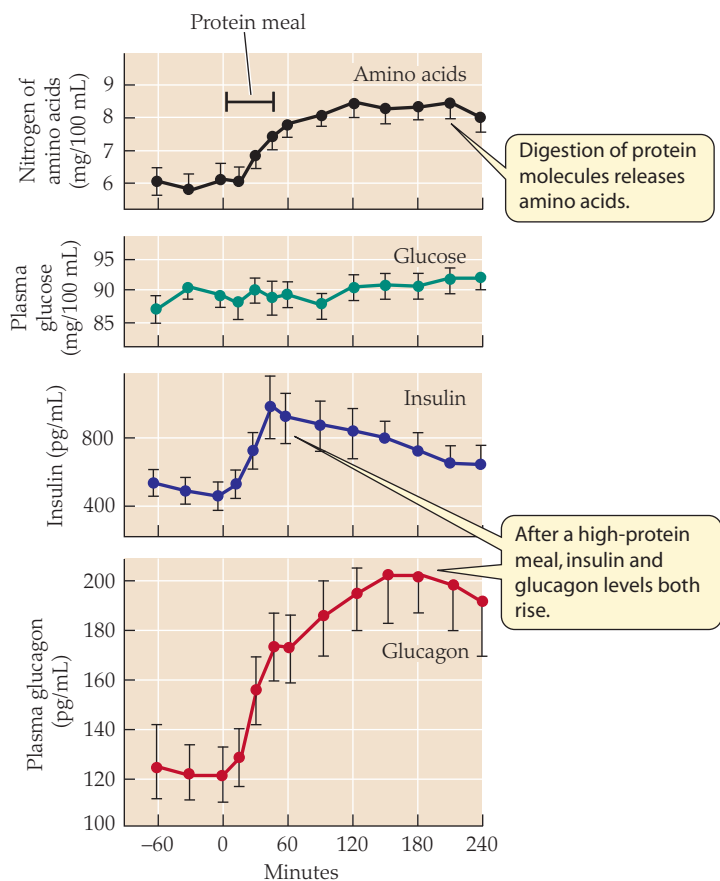

FIGURE 16.15 Hormone and nutrient levels in the blood of healthy human subjects before and after a meal (a) Levels for 11 subjects who consumed a high-carbohydrate meal of white bread and boiled spaghetti, corn, rice, and potatoes. (b) Levels for 14 subjects who consumed a high-protein meal of boiled lean beef. Error bars show the

standard errors. The experimenters used different scales on the y axes to emphasize the changes in hormone levels. Thus the rise in insulin is notably smaller in (b) than in (a), and the rise of glucagon is more robust in (b) than its decline in (a). (After Müller et al. 1970.)

and high levels of amino acids in the blood. Its main effect is to increase the production of glucose and its release into the blood. Because it causes blood glucose levels to rise, glucagon is said to exert a *hyperglycemic effect*, the opposite of insulin's hypoglycemic effect. Glucagon stimulates cells in the liver to break down glycogen in a process called *glycogenolysis* and to release the resulting glucose into the blood. Glucagon also exerts effects opposite to those of insulin with regard to fats. It inhibits triglyceride (lipid) synthesis and stimulates adipose (fat) cells to break down triglycerides into fatty acids and glycerol and release these products into the blood. In addition, glucagon stimulates *gluconeogenesis* in liver cells. In gluconeogenesis, new glucose molecules are formed from noncarbohydrate molecules, mainly amino acids and glycerol obtained from the breakdown of triglyceride molecules. Proteins and fats are both mobilized from body tissues at low insulin levels. Thus amino acids from protein breakdown and glycerol from fat breakdown become available for gluconeogenesis in liver cells.

As blood glucose levels rise, glucagon secretion tends to decrease by negative feedback. Consequently, from meal to meal, both insulin and glucagon contribute to stable blood glucose levels. Under conditions of stress (and exercise), however, sympathetic stimulation causes secretion of epinephrine from the adrenal medulla as well as increased synaptic input to the α cells. Epi-

nephrine has the dual effect of stimulating the α cells to secrete glucagon and inhibiting the β cells from secreting insulin. This arrangement ensures increased glucose availability without hindrance from insulin.

Glucagon is secreted when blood levels of glucose and fatty acids are low, a condition typical of the unfed state. However, the rate of glucagon secretion is not increased by low levels of amino acids. Instead, glucagon secretion increases when blood levels of amino acids are *high*. Therefore, although glucagon is the dominant hormone during the unfed state, it is often secreted during the fed state, depending on the nutrient composition of a meal. When a high-carbohydrate meal is consumed by healthy human subjects, blood levels of glucose rise, insulin secretion increases, and glucagon secretion decreases (see Figure 16.15a). Under these conditions, the low levels of glucagon reinforce the actions of insulin. After a high-protein meal, however, *both* insulin and glucagon rise (Figure 16.15b). The rise in insulin promotes the incorporation of absorbed amino acids into body proteins. The rise in glucagon under these circumstances has an adaptive advantage because a high-protein meal in itself supplies little glucose, yet the brain's preferred energy source is glucose. Increased glucagon ensures an output of glucose from liver glycogen stores even in the face of high insulin levels.

The interactions between insulin and glucagon in managing the appropriate use and storage of foodstuffs are key to maintaining nutrient homeostasis. We have seen that absorbed nutrients, gastrointestinal hormones, and sympathetic and parasympathetic inputs act at the α and β cells of the islets of Langerhans to influence secretion of glucagon and insulin. As a final consideration, we need to remember that the brain (especially the hypothalamus) continually integrates afferent information provided by secreted hormones and nutrients themselves. The brain receives information about short-term energy availability from the presence of nutrients such as glucose and free fatty acids in the blood. It receives information about long-term energy stores from the presence of circulating hormones such as leptin, which is secreted by adipose cells. Brain neural activity transduces these inputs into efferent signals that coordinate glucose production by the liver, insulin and glucagon secretion in the pancreas, and glucose uptake by muscle cells. Ongoing research continues to clarify and enhance our understanding of the broad, integrative framework involved in regulating body fat stores and blood glucose levels. These research efforts may reveal possibilities for treatment of obesity and diabetes, two major public-health concerns.

Other hormones contribute to the regulation of nutrient metabolism

Other hormones that exert their own unique regulatory roles also influence nutrient metabolism. For example, both growth hormone and glucocorticoids act *synergistically* with epinephrine to enhance epinephrine's effect on lipid breakdown. Other hormones play an essential *permissive* role in nutrient metabolism. Background levels of glucocorticoids, for example, are essential for preventing levels of blood glucose from plummeting during fasting and other stresses. Not only do glucocorticoids stimulate glucose formation, but they are also required for glucagon and epinephrine to exert their effects.

Several hormones play key roles in the growth of young animals. Growth hormone, thyroid hormones, and androgens are important because they promote the formation of proteins. For example, the presence of testicular androgens—principally testosterone—during puberty brings about the greater muscular development that occurs in boys as compared with girls. These hormones also work together synergistically to enhance each other's effects. Thyroxine, for example, enhances the effects of growth hormone in young animals.

Hormones also alter nutrient metabolism during exercise and fasting. Both circumstances require mobilization of metabolic fuels from stores. During both, insulin secretion declines. Without insulin's effects, glycogen breakdown, lipid breakdown, protein breakdown, and gluconeogenesis all occur at heightened rates. Glucagon secretion rises during both exercise and fasting and stimulates glycogenolysis and gluconeogenesis in liver cells. Other hormones may also play a role, but exercise and fasting do not necessarily elicit the same hormonal responses. For example, epinephrine secretion increases during exercise but does not consistently increase during fasting. Furthermore, prolonged fasting, but not exercise, often leads to a decline in thyroid hormone levels; this decline serves to lower metabolic demands and conserve fuels.

SUMMARY Endocrine Control of Nutrient Metabolism in Mammals

- Insulin is secreted when nutrient molecules are abundant in the blood. It exerts a hypoglycemic effect by promoting uptake and storage of nutrients and inhibiting degradation of glycogen, lipids, and proteins. In the absence of insulin, nutrient molecules are mobilized to enter the blood from storage sites.
- Glucagon is secreted when blood glucose levels are low. It exerts a hyperglycemic effect by stimulating the breakdown of glycogen (glycogenolysis), the breakdown of triglyceride molecules, and the formation of glucose from noncarbohydrate sources (gluconeogenesis).
- Growth hormone, glucocorticoids, epinephrine, thyroid hormones, and androgens typically play permissive and synergistic roles in nutrient metabolism.

Endocrine Control of Salt and Water Balance in Vertebrates

We devote the last part of this book (Chapters 27–30) to the strategies animals use to maintain salt and water balance in a variety of environments. In this section we explore the endocrine controls employed by vertebrates to maintain appropriate body fluid volume and appropriate concentrations of salts. Salts dissociate into ions in solution and therefore are also referred to as electrolytes. (Physiologists often use *salt* and *electrolyte* interchangeably.) Because dissolved particles exert osmotic pressure that holds water, they have a direct effect on fluid volume in the animal. Furthermore, fluid volume has a direct effect on arterial blood pressure, which is essential for ensuring delivery of respiratory gases and nutrients to cells and removal of metabolic by-products (see Chapter 25). Therefore, the hormones involved in salt and water balance have far-reaching effects. The dominant salt in the extracellular fluid is NaCl, which dissociates into Na^+ and Cl^- ions. The main hormones involved in salt and water balance affect the movements of Na^+ and water. Cl^- typically follows Na^+ passively.

Antidiuretic hormones conserve water

Earlier in this chapter we discussed vasopressin—also called antidiuretic hormone (ADH)—which is a nonpeptide produced by neuroendocrine cell bodies in the hypothalamus and released from their axon terminals in the posterior pituitary gland. This hormone acts to conserve water by preventing the production of a large volume of urine. All major classes of vertebrates produce hormones with antidiuretic action. Most mammals use *arginine vasopressin* (AVP), but some pigs and their relatives use *lysine vasopressin* (LVP), and nonmammalian vertebrates use the closely related *arginine vasotocin* (AVT) (see Table 16.2). In all vertebrates, the target tissue of these hormones is the nephron of the kidney. Antidiuretic hormones stimulate the reabsorption of water from the lumen of the nephron. This means that instead of being excreted in the urine, water is returned to the extracellular fluid.

The action of AVP has been studied extensively in mammals. Its effect is to stimulate the incorporation of specific **aquaporin** (AQP, water channel) molecules (see Chapter 5; page 121) into the

FIGURE 16.16 An antidiuretic hormone functions to conserve water Arginine vasopressin (AVP) stimulates the incorporation of aquaporin 2 (AQP-2) into the apical membranes of epithelial cells in the collecting duct of the nephron, resulting in the return of water to the extracellular fluid. The water undergoes osmosis into nearby capillaries and is carried out of the kidney in the bloodstream.

membranes of epithelial cells in the collecting duct of the nephron (Figure 16.16). Different types of aquaporins exist permanently in various regions of the nephron. However, AQP-2 molecules are present in the apical membranes (those facing the lumen) of the cells of the collecting duct only when vasopressin is present. The epithelial cells of the tubules of the nephron are connected by *tight junctions*, which prevent movement of substances, including water, between cells. Thus water in the lumen of the tubule is destined for excretion unless it can pass through the epithelial cells back into the interstitial fluid and plasma. Receptor molecules for AVP are located on the basal side of the cells. When AVP is secreted from the posterior pituitary, it travels in the general blood circulation to the kidneys and binds to these receptors. Through second-messenger systems, AVP stimulates the movement of AQP-2 molecules from intracellular storage vesicles to the apical membrane facing the lumen. Experiments show that when exposed to AVP, the epithelial cells begin to increase their permeability to water within 1 min, and reach peak permeability in about 40 min. Water moves out of the lumen osmotically. It passes into the epithelial cell and out the basal end of the cell through a different type of AQP channel (aquaporin-3) that is always present and open.

When the extracellular fluid has a high osmotic concentration or the extracellular fluid volume is low, neurons in the CNS stimulate the AVP neuroendocrine cells in the hypothalamus to secrete AVP. In the presence of AVP, AQP-2 channels are incorporated into the apical membranes of the epithelial cells, allowing reabsorption of water. When the extracellular fluid has a low osmotic concentration or the extracellular fluid volume is large, the AVP neuroendocrine cells do not secrete AVP. In the absence of AVP, the AQP-2 channels are taken back into the cells' cytoplasm, and none (or very few) are present in the apical membranes. Therefore, water is not reabsorbed—no matter what the osmotic gradient. The water is excreted because it cannot escape the lumen.

The renin-angiotensin-aldosterone system conserves sodium

Aldosterone is a steroid hormone (see Figure 16.2) produced and secreted by the zona glomerulosa of the adrenal cortex. It is called a *mineralocorticoid* because it contributes to the balance of minerals—mainly sodium and potassium—in the body. The main target tissues of aldosterone are epithelial cells located in the late distal tubule and early collecting duct of the nephron (Figure 16.17). The effect of aldosterone is to increase the ability of these cells to reabsorb Na^+ (take it out of the lumen and return it to the interstitial fluid and plasma).⁵ In addition, aldosterone stimulates the release of K^+ into the lumen (for excretion). When aldosterone is

secreted, it enters its target cells, binds to cytoplasmic receptors in the cells, and stimulates them to synthesize new $\text{Na}^+-\text{K}^+-\text{ATPase}$ pumps and Na^+ and K^+ channels for incorporation into the cell membrane. The pumps are incorporated into the basal membrane and the channels into the apical membrane of the epithelial cells.

The $\text{Na}^+-\text{K}^+-\text{ATPase}$ pumps actively transport K^+ into the epithelial cell and Na^+ out of the cell. The pumps set up concentration gradients so that K^+ diffuses through its channels on the apical membrane from a high concentration in the cytoplasm to a low concentration in the lumen of the tubule (to be excreted). Na^+ diffuses along its concentration gradient in the opposite direction. It passes through Na^+ channels from the lumen into the cell (where the Na^+ concentration is low) and is then pumped from the basal side of the cell into the extracellular fluid (to be retained in the body).

⁵Aldosterone also has other target tissues, including the urinary bladder (amphibians, reptiles other than birds, and mammals), sweat glands (mammals), salt glands (reptiles, including birds), salivary glands (mammals), and intestine (mammals, birds, and amphibians). At all of these target tissues, its effect is to retain Na^+ in the body.

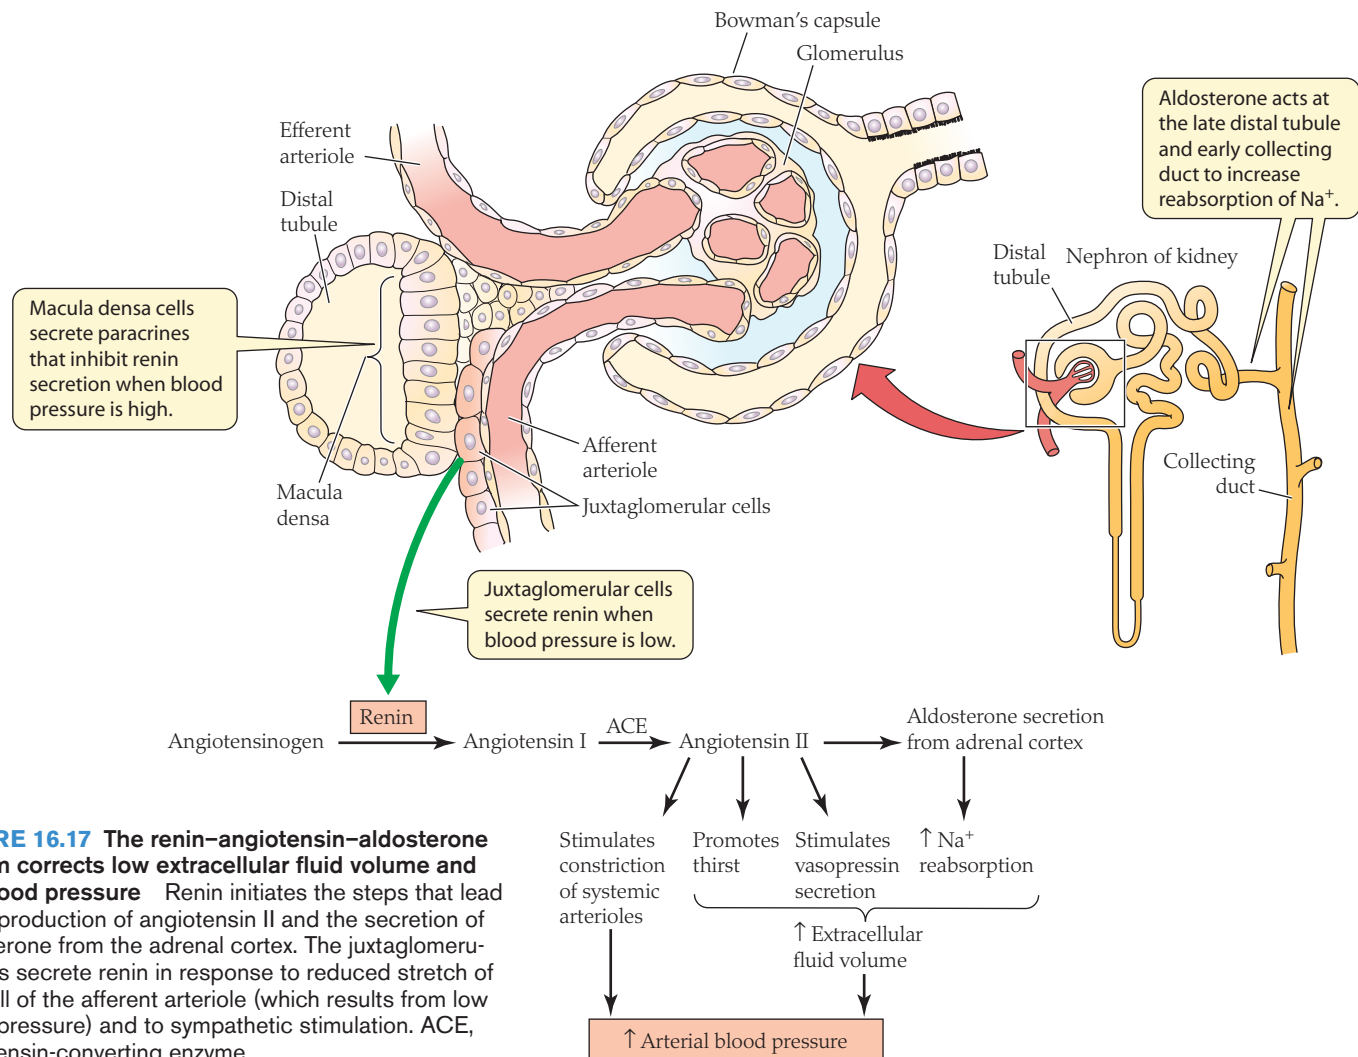

FIGURE 16.17 The renin–angiotensin–aldosterone system corrects low extracellular fluid volume and low blood pressure. Renin initiates the steps that lead to the production of angiotensin II and the secretion of aldosterone from the adrenal cortex. The juxtaglomerular cells secrete renin in response to reduced stretch of the wall of the afferent arteriole (which results from low blood pressure) and to sympathetic stimulation. ACE, angiotensin-converting enzyme.

Aldosterone is secreted under conditions of low arterial blood pressure. One way to correct low blood pressure is to increase the extracellular fluid volume (or preserve it, in the case of blood loss). Na^+ (and Cl^-) within the extracellular fluid exerts an osmotic “hold” on water. This effect, combined with increased reabsorption of water, increases the volume of the extracellular fluid and therefore increases arterial blood pressure.

An intricate sequence of events and substances leads to the secretion of aldosterone and the correction of low blood pressure. When low blood pressure is detected, specialized cells in the kidney secrete a substance called **renin**. These cells, called **juxtaglomerular cells** (JG cells) or granular cells, are modified smooth muscle cells located in the walls of the arterioles leading to the glomerulus (afferent arterioles) of the nephron (see Figure 16.17). The JG cells are sensitive to stretch. When they are stretched *less* (as in the case of low blood pressure), they increase their secretion of renin. The JG cells are also innervated by sympathetic nerve fibers and receive sympathetic stimulation to secrete renin when blood pressure is low. Finally, renin secretion is regulated by paracrines from the *macula densa*, a group of specialized cells that monitor fluid and solute flow through the distal tubule. When blood pressure is low, the macula densa cells reduce their paracrine-mediated inhibition of the JG cells. Mammals, reptiles (including birds), amphibians, and bony

and cartilaginous fish all have juxtaglomerular cells that secrete renin. Its actions have been studied most thoroughly in mammals.

Renin is the first substance in a chain that leads to the secretion of aldosterone (see Figure 16.17). Renin is secreted into the blood and, in mammals, has a half-life of about 20 min. It interacts enzymatically with a large protein called **angiotensinogen**, which is produced by the liver and is continuously present in the blood. Renin cleaves a peptide bond of angiotensinogen to produce a 10–amino acid peptide called **angiotensin I**. Angiotensin I itself does not have a physiological effect. Circulating in the blood, angiotensin I encounters a membrane-bound enzyme called **angiotensin-converting enzyme (ACE)**, which is produced by the endothelial cells of the blood vessels. ACE cleaves two amino acids from angiotensin I to make the eight–amino acid peptide hormone **angiotensin II**. Angiotensin II stimulates the secretion of aldosterone from the adrenal cortex. In addition, angiotensin II causes constriction of systemic arterioles, stimulates secretion of vasopressin, and promotes thirst and drinking. All of these actions contribute to raising the extracellular fluid volume and therefore raising arterial blood pressure.

Interestingly, the toxin of the Brazilian pit viper *Bothrops jararaca* kills by causing a catastrophic drop in blood pressure. A component in the toxin specifically blocks the action of ACE and therefore halts production of angiotensin II and secretion of aldosterone.

Knowing this physiology, researchers at the pharmaceutical firm Bristol-Myers Squibb studied the molecular structure of the most active component in the venom, which gave them an understanding of the structure of the active site of ACE. They then designed a drug that interacts specifically with the active site and prevents its enzymatic action. This drug, captopril, was the first “ACE-inhibitor” drug used to treat hypertension (high blood pressure).

Atrial natriuretic peptide promotes excretion of sodium and water

Atrial natriuretic peptide (ANP) is produced by specialized muscle cells in the atria of the heart and is secreted when the heart muscle cells are stretched. High arterial blood pressure and large amounts of sodium, which lead to expanded extracellular fluid volume, stimulate ANP secretion. ANP has been identified in most vertebrates. It acts on the distal parts of nephrons to inhibit the reabsorption of Na^+ and increase its excretion. ANP also inhibits the secretion of vasopressin, renin, and aldosterone, thereby counteracting the hormones that conserve water and Na^+ . Finally, ANP increases the rate of blood filtration in the nephrons, which causes more fluid to be excreted. Consequently, by its many effects, ANP produces a reduction in the extracellular fluid volume and corrects conditions of high arterial blood pressure. The mechanisms by which ANP exerts these actions are not yet understood and are being actively investigated. ANP has also been found to stimulate the excretion of Na^+ from the gills of bony fish.

SUMMARY Endocrine Control of Salt and Water Balance in Vertebrates

- Hormones continuously regulate the balance of salt and water in vertebrates.
- Vasopressins are peptide neurohormones that stimulate the conservation of water.
- Aldosterone is a steroid hormone that stimulates the conservation of Na^+ . It is part of the renin–angiotensin–aldosterone system that is set in motion under conditions of low arterial blood pressure.
- Atrial natriuretic peptide (ANP) exerts many different actions, all of which stimulate the excretion of Na^+ and water.

Endocrine Control of Calcium Metabolism in Mammals

Calcium is finely regulated in both the extracellular and intracellular fluids. We know that the intracellular Ca^{2+} concentration is kept very low ($<10^{-7} M$) so that transient influxes of Ca^{2+} from intracellular organelles or the extracellular fluid will trigger cellular responses such as muscle contraction or exocytosis. The extracellular concentration of Ca^{2+} is higher than that in the cytoplasm (~ 1.2 millimolar $[mM]$), but it too is maintained within very narrow limits. Low levels of Ca^{2+} cause hyperexcitability of nerve and muscle membranes, which can produce muscle twitches and sensations of tingling and numbness. High levels of Ca^{2+} cause reduced excitability that produces hyporeflexia (slower reflexes) and lethargy. Three hormones—*parathyroid hormone (PTH)*, active vitamin D (*1,25-dihydroxycholecalciferol* or

1,25[OH] $_2$ D $_3$), and *calcitonin*—acting at bone, the intestine, and the kidney regulate the extracellular Ca^{2+} concentration (Figure 16.18). The total amount of calcium in the blood plasma includes that bound to proteins (mainly albumin), complexed with anions such as phosphate, sulfate, and citrate, and free as ionized Ca^{2+} . Only free Ca^{2+} (about half the total calcium) is biologically active.

Parathyroid hormone increases Ca^{2+} in the blood

In mammals, PTH is secreted by *chief cells* of the parathyroid glands. The paired parathyroid glands are located on the thyroid gland, on either side of the pharynx. PTH is an 84–amino acid peptide hormone. Like other peptide hormones, PTH is produced initially as a prohormone that is modified to its mature form by posttranslational processing. The chief cells produce PTH continuously and secrete it by exocytosis. Their rate of secretion depends on the concentration of Ca^{2+} in the extracellular fluid, increasing when extracellular Ca^{2+} is low and decreasing when it is high. The chief cells possess a G protein–coupled receptor (see Figure 2.30), the Ca-sensing receptor (CaSR), on their cell membrane that acts via the amplifier enzyme phospholipase C to *inhibit* the secretion of PTH. Thus, less PTH is secreted when extracellular Ca^{2+} is high. When extracellular Ca^{2+} is low, the inhibition is lifted and more PTH is secreted.

PTH binds to several different target tissues to cause an increase in extracellular Ca^{2+} . It exerts its effect at all targets by binding to cell-surface membrane receptors, activating the amplifier enzyme adenylyl cyclase, and increasing the second messenger cAMP (see Figure 2.30). In bone, PTH acts synergistically with active vitamin D to cause bone resorption (breakdown), a process that releases both Ca^{2+} and phosphate into the extracellular fluid. In the kidney, PTH stimulates certain cells of the nephron to reabsorb Ca^{2+} , and other cells to excrete phosphate anions. This combined effect ensures that reabsorbed Ca^{2+} does not complex with phosphate but instead remains free and biologically active, neatly sidestepping the potential problem raised by the release of both Ca and phosphate during bone resorption. Finally, PTH stimulates certain cells of nephrons to convert inactive vitamin D to its active form. One action of active vitamin D is to promote Ca^{2+} absorption from the intestine.

Active vitamin D increases Ca^{2+} and phosphate in the blood

The inactive form of vitamin D (cholecalciferol, also called vitamin D_3) is produced in skin cells by the action of UV light; it is also obtained from the diet and from vitamin supplements. Cholecalciferol circulates to the liver, where it is converted to 25-hydroxycholecalciferol, and then to the kidney, where enzymatic actions in cells of the nephron convert it to its active form, $1,25(\text{OH})_2\text{D}_3$. All of these forms of vitamin D are circulated in the blood plasma bound to carrier proteins. Both low extracellular Ca^{2+} and PTH stimulate conversion of vitamin D_3 to its active form. This steroid hormone targets three main types of cells: epithelial cells of the small intestine, osteoblasts of bone, and cells in the kidney nephron (see Figure 16.18). At the intestinal epithelium, $1,25(\text{OH})_2\text{D}_3$ exerts its action through gene transcription that leads to the synthesis of an intracellular calcium-binding protein, *calbindin*. Calbindin facilitates absorption of Ca^{2+} from the intestinal lumen into the blood. When calcium-containing nutrients are digested, Ca^{2+} ions diffuse from

FIGURE 16.18 Parathyroid hormone (PTH), active vitamin D, and calcitonin finely regulate Ca^{2+} in the extracellular fluid Negative-feedback mechanisms modulate these hormones' rates of secretion. The text explains that these hormones also regulate extracellular phosphate. (a) When extracellular Ca^{2+} is low, secretion of PTH and active vitamin D increases. These hormones act at target tissues to increase extracellular Ca^{2+} . (b) When extracellular Ca^{2+} is high, calcitonin secretion increases, and secretion of PTH and active vitamin D decreases. Calcitonin acts at its target tissues to decrease extracellular Ca^{2+} .

the small intestine lumen into the epithelial cell down their electrochemical gradient. Upon entering the cell, they bind to calbindin. The binding of free Ca^{2+} to calbindin maintains the concentration gradient for more free Ca^{2+} to enter the cell. Ca^{2+} -ATPase pumps actively transport Ca^{2+} out of the cell and into the extracellular fluid, where it enters capillaries. Thus, $1,25(\text{OH})_2\text{D}_3$ promotes absorption of Ca^{2+} through the synthesis and function of calbindin. Another action of $1,25(\text{OH})_2\text{D}_3$ is to act synergistically with PTH to release Ca^{2+} and phosphate from bone. Both hormones target bone-forming cells called *osteoblasts*, but the peptide PTH binds to a membrane receptor, and $1,25(\text{OH})_2\text{D}_3$ binds to an intracellular receptor. Through separate actions, the two hormones lead to the production and release of cytokines from the osteoblasts. The cytokines are paracrine signals that trigger the differentiation and activation of *osteoclasts*. Active osteoclasts break down bone (resorb it) and, in the process, liberate Ca^{2+} and phosphate ions. Finally, $1,25(\text{OH})_2\text{D}_3$ stimulates the reabsorption of both Ca^{2+} and phosphate ions at the kidney nephron. However, the actions of PTH on regulating these ions at the nephron appear to be much more robust than those of $1,25(\text{OH})_2\text{D}_3$.

Calcitonin opposes bone resorption and decreases Ca^{2+} and phosphate in the blood

Calcitonin is a 32-amino acid peptide hormone secreted by *C* (*clear*) cells in the thyroid gland in mammals (see Figure 16.18b). *C* cells possess a G protein-coupled membrane calcium-sensing receptor similar to that in PTH-secreting cells. However, whereas high extracellular Ca^{2+} *inhibits* the release of PTH, it *stimulates* the release of calcitonin. Calcitonin acts directly at the osteoclasts to inhibit bone resorption and the release of Ca^{2+} and phosphate ions. Despite laboratory experiments that have shown these cellular effects, observations in humans strongly suggest that calcitonin does not affect in any measurable way the functions of osteoclasts in the skeletons of adult humans. For example, removing the thyroid gland (the source of calcitonin) while sparing the parathyroid glands

has no effect on bone metabolism. However, in other mammals (and perhaps also in humans), calcitonin plays an important role in preventing bone resorption in pregnant and lactating females. It thereby protects the maternal skeleton and diverts dietary calcium to the fetus or lactating neonate. At the kidney nephron, calcitonin facilitates the excretion of both Ca^{2+} and phosphate.

Calcitonin is used clinically to treat diseases such as osteoporosis and Paget's disease (a disease characterized by overactive osteoclasts that weaken the bones by excessive resorption). Interestingly, the calcitonin used to treat humans comes from fish, salmon in particular. Fish also regulate Ca^{2+} in the extracellular fluid within narrow limits, and they use calcitonin to inhibit the resorption of Ca^{2+} from bone. Salmon calcitonin has a similar, but not identical, amino acid structure to that of the mammalian hormone. It is favored for therapeutic use because it binds to the same receptor molecule on target cells as mammalian calcitonin does, but it binds more tightly and is degraded more slowly (that is, it has a longer half-life).

SUMMARY Endocrine Control of Calcium Metabolism in Mammals

- Three hormones finely regulate the extracellular concentration of calcium ions in mammals: parathyroid hormone (PTH), active vitamin D (1,25-dihydroxycholecalciferol, or $1,25[\text{OH}]_2\text{D}_3$), and calcitonin.
- The peptide PTH is secreted by chief cells of the parathyroid glands when extracellular Ca^{2+} is low. PTH stimulates cells in the nephron of the kidney to reabsorb Ca^{2+} and excrete phosphate and also to increase the conversion of inactive vitamin D to active vitamin D. In concert with active vitamin D, PTH stimulates bone resorption. These functions all contribute to increased Ca^{2+} in the extracellular fluid.
- Active vitamin D is formed when extracellular Ca^{2+} is low. It is a steroid and binds to intracellular receptors to influence gene transcription in its target tissues. It promotes absorption of dietary Ca^{2+} across the intestinal epithelium, the resorption of bone, and the reabsorption of both Ca^{2+} and phosphate in the nephron. Its actions increase Ca^{2+} and phosphate in the extracellular fluid.
- The peptide calcitonin targets osteoclasts in bone to inhibit bone resorption. At the kidney nephron, calcitonin increases the excretion of calcium and phosphate ions. These actions decrease calcium and phosphate in the extracellular fluid.

Endocrine Principles in Review

In the examples so far described in this chapter, we have seen the far-reaching and complex interrelationships between the endocrine system and other systems within the organism. In future chapters, we present comparable examples of hormonal regulation that are woven into the tapestry of overall homeostasis. Five prevailing patterns of hormonal control appear repeatedly:

1. The control of any single system likely involves more than one hormone. For example, fluid balance requires not only hormones that control water release or conservation, but also other hormones that control solute concentrations in body fluids.
2. A hormone that affects the functions of one system probably affects other systems as well. For example, a hormone that controls conservation or release of water will directly affect blood pressure.
3. Hormones may interact with each other synergistically, permissively, or antagonistically.
4. Most endocrine controls are inextricably associated with neural controls. We also know that the immune system interacts with the endocrine and nervous systems in some arenas; future research will probably reveal that all three systems are more intimately related than we now understand.
5. Many molecules that function as hormones in one context function as different types of chemical signals in different contexts. Vasopressin and oxytocin, for example, serve as neurotransmitters—not as hormones—in the CNS. To illustrate their neurotransmitter function, we describe in [Box 16.1](#) the influence of oxytocin and vasopressin on male–female bonds in certain voles.

This list of five patterns of hormonal control gives an overview, but it is possible to make further generalizations about the complexity of endocrine function. [Table 16.4](#) presents several specific ideas to keep in mind when considering endocrine function. In the next sections, we consider several different types of chemical signals.

Chemical Signals along a Distance Continuum

In this and preceding chapters, we have seen that cells communicate with one another by a variety of mechanisms. Based on the distances involved, mechanisms of communication between cells can be broadly grouped into six main categories ([Figure 16.19](#)):

1. *Gap junctions* (see page 329) are formed by connexon protein channels between adjacent cells. When these channels are open, they allow ions and other small molecules to diffuse directly from one cell to the next.
2. *Cell adhesion molecules (CAMs)* on the external surface of cell membranes play important roles in signaling between adjacent cells involved in embryonic development, wound repair, and cellular growth and differentiation.
3. *Neurotransmitters* (see Chapter 13) are released by presynaptic neurons in response to electrical signals. They diffuse across a narrow synaptic gap to interact with receptor molecules on a postsynaptic cell, which may be a neuron, muscle cell, or endocrine cell.
4. *Paracrines* and *autocrines* diffuse relatively short distances to influence cells in the local environment—including themselves, in the case of autocrines.
5. *Hormones* and *neurohormones* are specialized for long-distance communication within the animal. (From our study of the stress response, we know that *cytokines* also communicate across long distances; however, they function locally as well.)

BOX 16.1 CAN MATING CAUSE TRUE COMMITMENT?

The peptides arginine vasopressin (AVP) and oxytocin serve as hormones when released into the blood from the posterior pituitary gland. These same peptides serve as neurotransmitters when released by neurons in the CNS. Although many of the functions of AVP and oxytocin in the CNS are not yet understood, elegant studies of two different species of rodents, the prairie vole (*Microtus ochrogaster*) and the montane vole (*Microtus montanus*), have shown that these two peptides participate in the control of behaviors related to monogamy and social attachment.

The prairie vole is one of very few species of mammals that are monogamous. These animals form pair bonds in the process of mating. Over a 24-h period, a pair will engage in 15 to 30 bouts of copulation, after which they undergo a transition in behavior. They show preference for each other's company, the male develops aggressive behaviors toward other males (which he did not show before mating), and both parents care for their young even several weeks after weaning. By contrast, montane voles do not form pair bonds after mating, they breed promiscuously, and the males do not help care for the young; in fact, even the females abandon their young 2 or 3 weeks after birth. These predictable behaviors can be demonstrated in the laboratory, and investigators have studied them using a variety of behavioral, physiological, and anatomical experimental paradigms.

Groundbreaking experiments showed that if oxytocin (but not AVP) is injected into the

cerebral ventricles of the brain of an unmated female prairie vole, she will form a pair bond with a male without mating at all. Conversely, if an antagonist to oxytocin is administered by injection into the cerebral ventricles of a female before mating, she will not form a pair bond with the male, even though mating went ahead normally. Interestingly, oxytocin does not affect males in the same way. Instead, injection of AVP into the cerebral ventricles of an unmated male prairie vole elicits mate preference and aggressive behavior toward other males. The development of these behaviors is blocked if an antagonist to AVP is injected into the male prairie vole prior to mating.

In further experiments, researchers used labeling techniques to identify the distributions of postsynaptic receptors for oxytocin and AVP in the brains of the two types of voles. The monogamous prairie voles showed high densities of oxytocin receptors in the nucleus accumbens and high densities of AVP receptors in the ventral pallidum. The promiscuous montane voles did not show receptors in either of these areas, although they showed labeled receptors for AVP and oxytocin in other regions of the brain. The nucleus accumbens and the ventral pallidum are parts of the brain's reward circuitry, which is associated with reinforcement and conditioning (the same parts of the brain thought to be involved in cocaine or nicotine addiction). A current hypothesis to explain why prairie voles are monogamous is that mating stimulates the release of oxytocin and vasopressin. These peptides, in turn, ac-

A monogamous mammal The prairie vole (*Microtus ochrogaster*) forms a pair bond with its mate.

tivate the reward circuits, which reinforce the formation of pair bonds. Montane voles lack receptors for oxytocin and AVP in these brain areas, so they receive no reinforcement for pair-bond formation. Ongoing studies of these two species of voles are aimed at developing a broad understanding of the neurobiological and genetic factors that underlie social bond formation in other animals, including humans.

FIGURE 16.19 Chemical messengers act over short, intermediate, and long distances

TABLE 16.4 Generalizations about the complexity of endocrine and neuroendocrine function

Feature	Examples
Some endocrine organs are specialized for a single function: to secrete hormones.	The exclusive function of the thyroid gland is to secrete hormones. The exclusive function of the anterior pituitary gland is to secrete hormones.
Some organs secrete hormones and also perform other functions.	The testes secrete testosterone and also produce sperm cells. The pancreas secretes hormones from specific endocrine cells (insulin from β , glucagon from α , and somatostatin from δ cells) and also secretes digestive enzymes from exocrine structures.
A single endocrine organ may secrete more than one hormone, and different control mechanisms may control their secretion.	The anterior pituitary gland consists of discrete populations of endocrine cells, each of which secretes a specific hormone. Secretion is controlled by hypothalamic RHs and IHs. The adrenal cortex secretes glucocorticoids and mineralocorticoids under the control of hormones. The adrenal medulla secretes epinephrine and norepinephrine in response to synaptic input from preganglionic fibers of the sympathetic nervous system.
More than one tissue may secrete the same hormone.	Both the pancreas and the hypothalamus secrete the hormone somatostatin (also called GHIH at the hypothalamus). Both the anterior pituitary and certain immune system cells secrete ACTH.
A single hormone may affect the functions of more than one target cell, and the actions of the target cells may produce different outcomes.	Glucocorticoids stimulate protein degradation in muscle, triglyceride degradation in adipose tissue, and gluconeogenesis in the liver. Oxytocin causes contraction of the uterine smooth muscle during birth and milk ejection from the mammary gland during suckling.
Secretion rates of hormones may vary over time in a cyclic pattern.	Glucocorticoid secretion varies on a diurnal cycle (influenced by the circadian clock). Secretion of estrogen and progesterone varies over the estrous or menstrual cycles of female mammals.
A single target cell may express receptor molecules for, and therefore respond to, more than one hormone.	Liver cells respond to insulin by taking up glucose and converting it into glycogen for storage (glycogenesis). The same liver cells respond to glucagon by breaking down glycogen (glycogenolysis), diminishing glycogen synthesis, and producing glucose from noncarbohydrate molecules (gluconeogenesis).
A single endocrine or neuroendocrine cell may secrete more than one hormone.	Because of the particular enzymes it uses in posttranslational processing, a POMC-expressing endocrine cell of the anterior pituitary secretes ACTH, β -endorphin, and other fragments. Some cells in the hypothalamus co-secrete AVP and CRH.
The same molecule may be a hormone in some contexts or a different type of chemical signal in others.	CRH is a neurohormone released into the hypothalamo–hypophysial portal system and a neurotransmitter at other sites in the CNS. Norepinephrine is a hormone when released into the blood from the adrenal medulla and a neurotransmitter when released from postganglionic fibers of the sympathetic nervous system. Although the chemical nature of the signaling molecule remains the same, the nature of the response is determined by the mechanisms set in motion upon binding to the receptor molecule.
Hormones may interact with each other synergistically, permissively, or antagonistically.	Glucagon, epinephrine, and glucocorticoids interact synergistically to increase glucose levels in the blood. Insulin and glucagon exert antagonistic effects that influence glucose concentration in the blood: Insulin decreases glucose in the blood, whereas glucagon increases it. Glucocorticoids are necessary to permit the catecholamines to cause contraction of smooth muscle cells in the walls of small blood vessels.

6. Finally, some chemical signals act outside the animal. For example, animals of the same species communicate with **pheromones**, whereas animals detect **kairomones** to obtain chemical information about members of a different species. Chemical signals that act outside the body on members of the same or different species are also called *ectocrines*.

Having previously considered most of these classes of intercellular communication, we will now briefly turn our attention to the local chemical messengers—paracrines and autocrines—and the external chemical messengers—pheromones and kairomones.

Paracrines and autocrines are local chemical signals distributed by diffusion

Examples of locally acting chemical messengers are *neuromodulators*, *cytokines*, and *eicosanoids*. *Neuromodulators* may be released

from synaptic nerve terminals along with neurotransmitters and—like transmitters—bind to specific receptor sites typically on postsynaptic cells. They tend to exert their effects more slowly and for a longer duration than do neurotransmitters. One way in which neuromodulators modify the postsynaptic response to a neurotransmitter is by changing the conductances of specific membrane channels. Like paracrines in general, neuromodulators can diffuse from their site of release and influence the responsiveness of not only their immediate postsynaptic cell but also nearby cells that have appropriate receptor sites. Because of their long-term influences and their ability to affect a population of neighboring cells, neuromodulators have the potential to modify the functions of entire neuronal circuits. Neuromodulators may also be released by postsynaptic cells to influence the activity of the neurons from which they receive presynaptic input (**Box 16.2**).

BOX 16.2 HORMONES AND NEUROMODULATORS INFLUENCE BEHAVIOR

Mating behavior of the rough-skinned newt *Taricha granulosa* provides an elegant example of a neuromodulator acting in concert with a steroid hormone. The neuromodulator is an endocannabinoid (an endogenously produced marijuana-like substance), and the hormone is the steroid stress hormone corticosterone. During mating the male newt clasps the female in a posture called *amplexus*. The pair may maintain this posture for hours. However, should the animals be exposed to a stressor (for example, the approach of a predator), they rapidly disengage. Injecting corticosterone into a mating male can inhibit clasping within minutes—much too short a time for corticosterone to exert an effect through genomic action. Recent studies show that corticosterone in this system does not enter its target cell to bind with intracellular receptors. Instead, it binds to membrane receptor molecules to produce a rapid response by nongenomic processes. The target cells are neurons in the hindbrain that control clasping behavior. Corticosterone stimulates these target neurons to produce endocannabinoid. Once produced and released, the endocan-

nabinoid acts as a paracrine neuromodulator that influences the activity of presynaptic neurons to the neuron that controls clasping. It inhibits the release of excitatory presynaptic transmitter and/or stimulates the release of inhibitory transmitter, and thereby reduces the probability of action potential generation by the cell that produced it—the neuron that stimulates clasping behavior. Faced with a stressor, the ability to uncouple quickly, become watchful, and escape if necessary provides an adaptive advantage to the newts.

Corticosterone's binding to a membrane receptor molecule ensures a rapid response. Ongoing studies in many vertebrates, including mammals, have shown that endocannabinoids modulate many physiological processes governed by endocrine axes that originate in the hypothalamus. The example of mating in newts illustrates the intimate and complex relationships between endocrine and neural systems in defining, and refining, behavior and ultimately the success of an animal.

Cytokines are peptides or proteins secreted by many different types of cells. They are made on demand when required to play a regulatory role. Acting locally as paracrines, cytokines control cell development and differentiation as well as the immune response. Cytokines involved in the immune response may also travel long distances in the blood, just like hormones do. Because of the medical importance of cytokines, our greatest knowledge of them comes from studies of mammals. A particularly well known large group of cytokines is the *interleukins*. Interleukin 2, for example, is a cytokine that enhances the activity of cytotoxic (killer) T cells in the immune response. Different cytokines control the process of *angiogenesis* (the development of new blood vessels). Angiogenesis is important in the growing animal and also in wound healing, in rebuilding the uterine lining following menstruation, and in increasing the vascular supply to cardiac and skeletal muscle during endurance training by athletes (see Chapter 21).

Eicosanoids are lipid-derived paracrine molecules involved in inflammation and allergic responses. All eicosanoids are produced from arachidonic acid, a fatty acid constituent of the phospholipids in cell membranes. There are two main classes of eicosanoids: leukotrienes and prostanoids. Leukotrienes are secreted by certain white blood cells and cause constriction of the airways in the lungs, making it difficult to breathe during asthma attacks and the life-threatening allergic reaction called anaphylaxis. The prostanoids include thromboxanes and prostaglandins. Thromboxanes cause constriction of blood vessels and aggregation of platelets, two important processes necessary for clot formation when a blood vessel is damaged. The prostaglandins are found in many dif-

ferent tissues and are involved in pain, inflammation, fever, and numerous other functions.

These few examples of local chemical messengers show only a small sample of the exquisite variety of intercellular signaling mechanisms found in the animal kingdom. Animals use diverse classes of molecules as chemical messengers, they employ enzymes to modify the specificities of signaling molecules, and they use the same molecule in different contexts as a different type of chemical messenger. An interesting example is the gas nitric oxide (NO), which functions as a neurotransmitter and possibly as a neuromodulator. NO also functions as a paracrine to regulate the diameter of small blood vessels (see Chapter 25; page 659). It is synthesized by the endothelial cells that form the inner lining of blood vessels and diffuses into the adjacent smooth muscle cells in the wall of the vessel. It causes the smooth muscle cells to relax and the vessel to dilate.

Pheromones and kairomones are used as chemical signals between animals

Pheromones are chemical signals that act between members of the same species. They are produced within the animal and then released into the environment. In many animals, they convey information that signals social status (for example, sex or dominance), sexual readiness, food trails, and alarm, and they elicit behaviors that are typically stereotyped and not modified by experience. Pursuing a potential mate, mating behavior, and aggressive behavior to protect a territory are often set in motion by pheromones. Physiological functions, such as the onset of puberty and estrous cycling, are also influenced by pheromones.

Many vertebrates detect pheromones with a sensory structure called the *vomerinasal organ* (VNO) (see Chapter 14). In several amphibians and reptiles, the VNO is the major olfactory organ—that is, the VNO detects both general odors and pheromones. For example, the Komodo dragon (*Varanus komodoensis*) specializes in eating carrion. This large lizard follows the scent of a recently dead animal by repeatedly sampling the air with its tongue and then touching the tongue to the roof of its mouth, where there are openings to the VNO. Interestingly, the male rough-skinned newt described in Box 16.2 rubs his mental (chin) gland on the snout of the female during mating. It is proposed that the gland generates courtship pheromones that reach the female's VNO through the nasal passages and make her receptive to mating. Many mammals, such as rodents, use the VNO to detect pheromones exclusively. Early experiments showed that surgically ablating the VNO resulted in impaired behaviors: Males would neither defend their territories nor mount females; females would not adopt the lordosis position for mating, and they seldom became pregnant. Recent studies in mice using both surgical ablation experiments and knockout animals that lack functional VNO neurons suggest that both mate preference and sexual behavior are controlled by pheromones. Invertebrates also use pheromones, which they detect with a variety of chemosensory structures. The sensory apparatus used by male silkworm moths to detect *bombykol*, the powerful sex-attractant pheromone released by females, is described in Chapter 14.

The molecular structures of most pheromones are not known, but those that have been identified vary widely. Bombykol is a fat-derived alcohol; aphrodisin, the pheromone in the vaginal secretions of female hamsters, is a protein. The pheromone in the saliva of boars is a steroid; if a female pig detects this pheromone, she will stand motionless in the lordosis position.

Whereas pheromones released into the environment convey information between members of the *same* species, other categories of chemicals released by animals give information (unintentionally) to members of *different* species. *Kairomones* are chemicals produced by animals of one species that are released into the environment—not for the purpose of communicating, but in the process of accomplishing some other function. Members of a second, detecting species exploit these kairomones in a way that benefits them but may be a detriment to the members of the releasing species. Kairomones elicit both behavioral and physiological responses. For example, one species may release a kairomone that reveals its location to a potential predator and elicits foraging behavior in the predator. Or a predator may release a kairomone that informs potential prey of its presence. Such an enemy-avoidance kairomone allows the prey to respond defensively. For example, water fleas of the genus *Daphnia* detect kairomones released by predatory fly larvae in the surrounding water; they respond by developing spines and “helmets” that may protect them from the predators.

Additional interspecies chemical signals include *allomones* and *synomones*. Allomones are released by a species for its own advantage, such as a predator emitting a chemical that attracts prey. Synomones are released by members of one species that provide information advantageous to both its own species and also to the members of a different species; for example, both species could benefit from avoiding a toxic plant. As researchers learn more about the physiological processes triggered by intraspecific and interspecific informational chemicals, we can look forward

to enlarging our understanding of physiology in the context of ensuring survival and reproductive success in the natural world.

SUMMARY Chemical Signals Along a Distance Continuum

- Chemical signals fall along a “distance spectrum” ranging from molecules that signal between individual cells and over short distances, to hormones and neurohormones that travel long distances in the blood, to chemical signals released by animals into the environment. Receptor molecules of target cells in tissues or sense organs detect these signals to trigger a functional response.
- Locally acting paracrines and autocrines include neuromodulators, cytokines, eicosanoids, and the gas NO.
- Pheromones are chemical signals released into the environment that convey information to animals of the same species. Kairomones, allomones, and synomones are chemicals released into the environment that convey information between members of different species.

Insect Metamorphosis

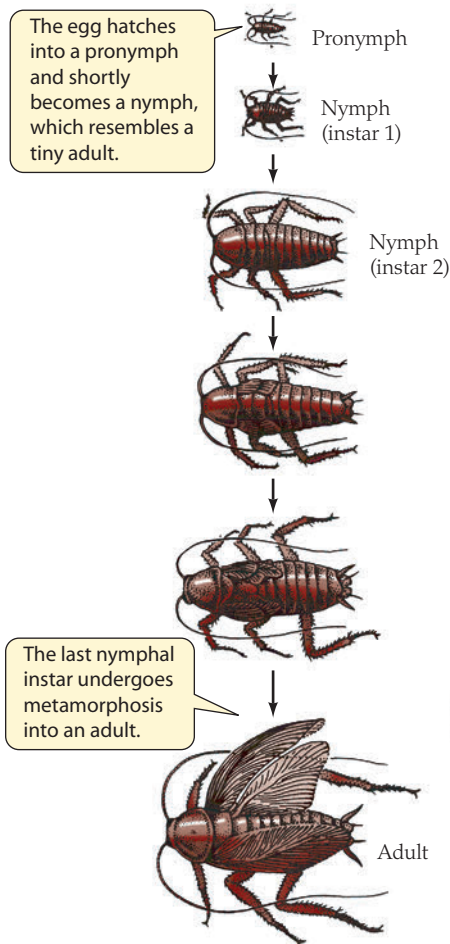

In this section we explore the hormones that control metamorphosis in insects. It is important to keep in mind that hormones play as varied and extensive roles in invertebrates as they do in vertebrates. Color changes, spawning, metamorphosis, water balance, nutrient metabolism, growth, maturation, and death are just a few of the functions controlled by hormones in invertebrates. We have chosen insect metamorphosis as our example because it demonstrates that the same principles of endocrine function found in vertebrates also apply to invertebrates. In addition, because insects have great agricultural, medical, and forensic importance, their natural history and physiology have been studied extensively (Box 16.3).

Insects have separate sexes. They engage in courtship behavior that leads to sperm being deposited and stored in the female reproductive tract. Fertilization does not take place at the time of mating. It occurs later, usually just before the female lays her eggs. After various periods, depending on the species and environmental conditions, the eggs hatch. From hatching onward, insects undergo a complex developmental journey to reach sexual maturity. The life cycles of most insects involve changes in the form of the animal at different stages. In other words, insects go through **metamorphosis** (*meta*, “change”; *morph*, “structure or form”). Although insects and vertebrates are evolutionarily divergent, we will find that their endocrine systems have independently evolved many similar features.

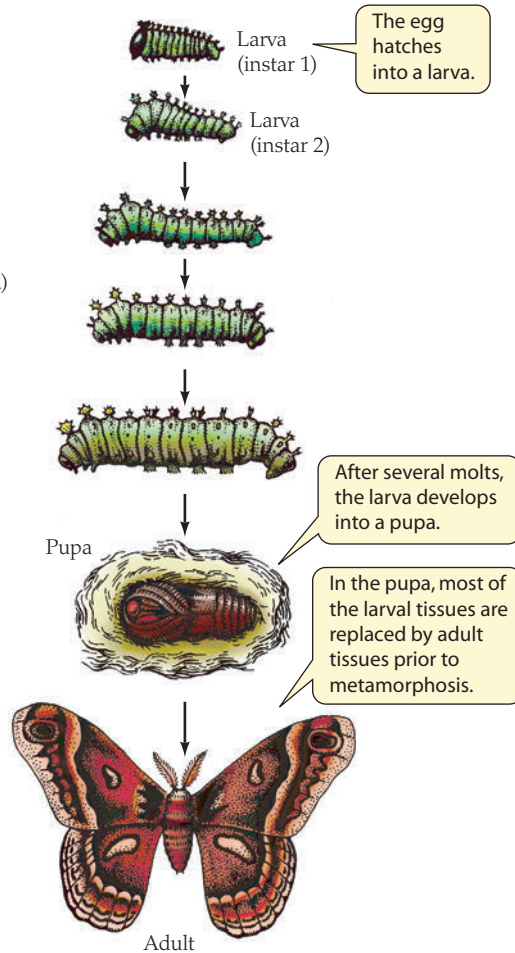

Insect metamorphosis may be gradual or dramatic

There are two main types of metamorphosis (Figure 16.20). Insects such as bugs, grasshoppers, and cockroaches go through gradual metamorphosis and are referred to as hemimetabolous (*hemi*, “partial or gradual”; *metabolous*, “change”). In hemimetabolous insects, the immature (juvenile) forms, called *nymphs*, resemble the adult, except that they are smaller and have only immature wings and genital structures. Animals such as flies, beetles, butterflies, and moths go through dramatic metamorphosis and are referred to as holometabolous (*holo*, “complete”).

(a) Hemimetabolous development

(b) Holometabolous development

**FIGURE 16.20 Two types of metamorphosis**

Most insects go through either hemimetabolous or holometabolous development. (a) Cockroaches go through gradual or partial (hemimetabolous) metamorphosis. (b) Moths go through complete (holometabolous) metamorphosis.

In holometabolous insects, the *larva* becomes a *pupa* and then metamorphoses into an adult. The larva and pupa look completely different from the adult.

In hemimetabolous development, the egg hatches into a nymph, which goes through several **molts**, or **ecdyses** (see Figure 16.20a). With each molt, epidermal cells underlying the cuticle (exoskeleton) synthesize a new cuticle, the old cuticle is shed (a process called *ecdysis*), and the new cuticle is expanded while it is still soft and pliable. To expand it, the animal takes air into the foregut and “puffs itself up.” The swallowed air applies pressure on the hemolymph (blood) and forces it into narrow lanes. The increased pressure inside the body helps fill out or unfurl external structures. Once expanded, the new cuticle hardens. The larger cuticle provides room for internal structures to grow before the next molt. The periods between molts are called **instars**. Hemimetabolous nymphs go through four to eight instars; each species has a characteristic number. The last nymphal

BOX 16.3 INSECTS IN FORENSICS AND MEDICINE

Certain insects, such as the blowflies, feed and lay their eggs only on *necrotic* (dead) tissue. This characteristic has been employed by forensic scientists as one method to determine the time of death of bodies found under suspicious circumstances. Studies of many different insects have revealed a progression of species that occupy a corpse. The blowflies (bluebottles and greenbottles) arrive first and lay their eggs in moist regions. The eggs hatch, and maggots (larvae) develop and feed on the tissues. Flesh flies soon are drawn by olfactory cues to the decomposing flesh, and they too lay eggs that develop into maggots. Maggots of blowflies and flesh flies go through three larval instars. Depending on how long the cadaver is left to decompose, the maggots may pupate and metamorphose into adults. The presence of pupal cases gives clues to investigators about time elapsed since death.

As the maggots feed, beetles arrive to feed on both the corpse and the maggots. Wasps and other flies follow in progression. After several months, mites, along with skin and hide beetles, and finally clothes moths, explore the dried remains. Forensic entomologists collect pupal cases, excrement, and other evidence of the animals that roved the cadaver. They take into account environmental conditions (such as temperature and humidity), the species of insects on a corpse, and the details of the life cycle of each and “work backward” in time to estimate when death occurred. Insects can also give clues about the site of death. Because some insects have a very narrow range of habitats, a species of insect found on a corpse out the insect’s range indicates that the body was moved.

The larvae of some of the same insects that are attracted to corpses also feed on the necrotic tissues of wounds of living people. During the American Civil War, surgeons

recorded that wounds of soldiers with maggots on them were cleaner and healed more quickly than wounds not visited by maggots. These days, physicians usually clean wounds by *surgical debridement*, using instruments to scrape away dead tissue so that living tissue can grow in the healing process. However, they also use maggots of blowflies to debride wounds that are especially resistant to healing. Once or twice a week, blowfly larvae are applied to the surface of wounds at a density of five to eight larvae per square centimeter. The larvae are voracious feeders, but they do not eat living tissue. They seek out every bit of necrotic tissue in the wound, so they succeed in doing a far better job of cleaning than surgical instruments can do. Larvae applied to wounds must be sterile. The eggs laid by adult blowflies are soaked in solutions of Lysol or Clorox and then kept in sterile culture dishes until they hatch into sterile larvae.

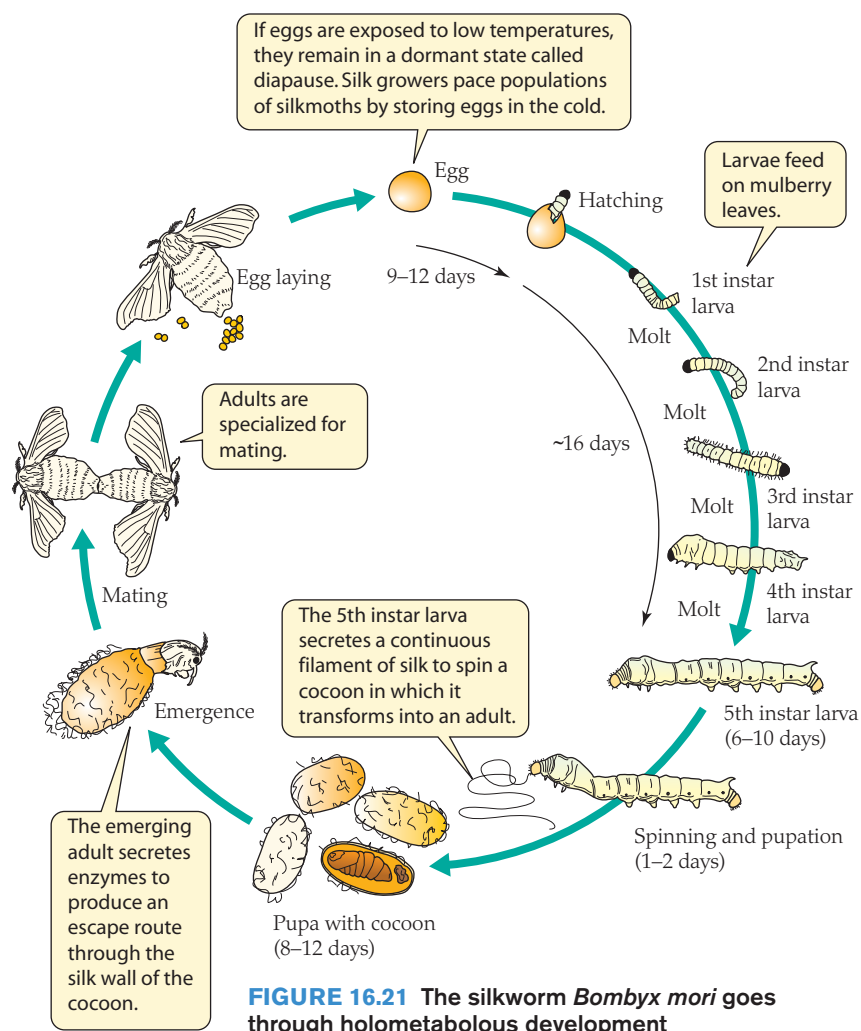

FIGURE 16.21 The silkworm *Bombyx mori* goes through holometabolous development

instar undergoes metamorphosis into the adult. Adults have complete wings and are sexually mature. Adults do not grow or undergo additional molts.

In holometabolous development, the egg hatches into a *larva* (see Figure 16.20*b*). Depending on the species, larvae are referred to as grubs, caterpillars, or maggots. Like hemimetabolous nymphs, holometabolous larvae go through several molts and expand the new cuticle. With each molt, the animal increases in size. The larvae of holometabolous insects are the forms that usually cause crop damage. After several molts, holometabolous larvae enter a stage called the **pupa**, in which most of the larval tissues are destroyed and replaced by adult tissues. The pupa has a much thicker cuticle than the larva or adult. The pupa then metamorphoses into an adult. Adults are specialized for reproduction. In some species, such as the silkworm moth, the adult may not even feed. The holometabolous life cycle of the domesticated silkworm moth *Bombyx mori* is shown in Figure 16.21.

Hormones and neurohormones control insect metamorphosis

Three main hormones control insect metamorphosis: prothoracicotropic hormone (PTTH, a small protein), ecdysone (a steroid), and juvenile hormone (JH, a *terpene*, which is a fatty acid derivative). The chemical structures of JH and 20-hydroxyecdysone—the active

form of ecdysone—are shown in Figure 16.22. Although the specific mechanisms of metamorphosis differ from species to species, investigators have shown that these three hormones typically function together. Several additional hormones play important roles in ecdysis (molting) and metamorphosis. Bursicon is a protein secreted by neurosecretory cells in the CNS. It stimulates the darkening (tanning) and hardening (by cross-linking of protein molecules) of the newly produced cuticle. Eclosion hormone (EH), corazonin, pre-ecdysis triggering hormone (PETH), and ecdysis triggering hormone (ETH) are important in initiating the signals that control stereotyped movements during ecdysis. All of these hormones are peptides. EH and corazonin are secreted by neuroendocrine cells in the brain. PETH and ETH are secreted by Inka cells located on the *tracheae*, the branched tubes of the respiratory system of insects that extend from openings in the body wall (see page 612). Figure 16.23 illustrates the main neural and endocrine structures involved in insect metamorphosis, and Table 16.5 summarizes the endocrine and neuroendocrine secretions.

In both hemimetabolous and holometabolous insects, the molting process begins in the *brain*, where neuroendocrine cells produce the neurohormone PTTH. Like neuroendocrine cells in vertebrates, these cells receive synaptic input, integrate synaptic information, and generate action potentials that trigger hormone secretion by exocytosis. Figure 16.24 shows PTTH neuroendocrine cells in the brain of a moth. Their axons extend to a pair of structures closely associated with the brain, the **corpora allata** (singular *corpus allatum*). In some insects, the PTTH axons may also terminate in the corpora cardiaca. The axon terminals secrete PTTH from these structures into the hemolymph. Ecdysis is triggered by a variety of signals, all mediated ultimately by the nervous system. Day length, temperature, crowding, and certain behaviors are known to set the molting process in motion. Neurons

FIGURE 16.22 Juvenile hormone (JH) and 20-hydroxyecdysone are both lipid-soluble hormones

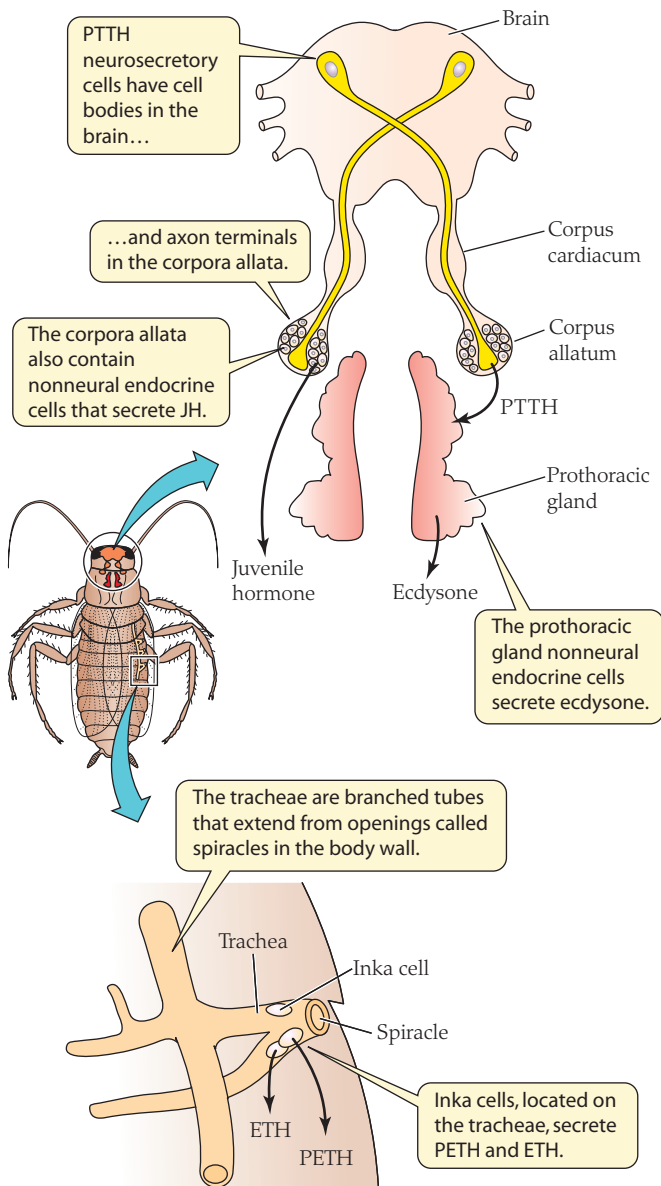

FIGURE 16.23 Endocrine and neuroendocrine structures involved in the control of insect metamorphosis Ecdysone (molting hormone), JH, PETH, and ETH are all secreted by nonneural endocrine cells. PTTH is secreted by neurons with cell bodies in the brain and secretory axon terminals in the corpora allata. In some insects, the PTTH axons may terminate in the corpora cardiaca.

that detect these factors send excitatory synaptic signals to the PTTH cells in the brain to stimulate secretion.

The PTTH is carried in the hemolymph to the thorax, where it stimulates the **prothoracic glands** to secrete ecdysone. Ecdysone is a prohormone that is converted by peripheral activation to **20-hydroxyecdysone** by several different tissues in the body. The major target tissue of 20-hydroxyecdysone is the epidermis, which lies just below the cuticle. 20-Hydroxyecdysone, also called β -ecdysone or *molting hormone*, stimulates the epidermis to secrete enzymes that digest away the old cuticle and synthesize a new one.

JH maintains juvenile (immature) characteristics in the developing animal. This hormone is released from nonneural endocrine cells in the corpora allata. Thus each corpus allatum

FIGURE 16.24 Neuroendocrine cells secrete PTTH Four PTTH-secreting cells in the brain of the moth *Manduca sexta* were stained with an immunofluorescent dye. The axons cross at the midline and extend to the corpora allata on the opposite side, where they form highly branched terminals. The width of the brain is about 1.5 mm. (Courtesy of Walter Bollenbacher; from O'Brien et al. 1988.)

is both a site for neurosecretory release of PTTH (a neurohemal organ) and a nonneural endocrine gland that secretes JH. When 20-hydroxyecdysone acts on the epidermis and the hemolymph level of JH is high, the insect will molt into another, larger juvenile form—a larger larva (in holometabolous insects) or nymph (in hemimetabolous insects). The corpora allata become inactive during the last larval or nymphal instar. Therefore, when ecdysone is secreted to initiate the next molt, there is little or no JH present. When 20-hydroxyecdysone is secreted in the presence of very low hemolymph levels of JH, the epidermis will produce adult or pupal structures. The nymph of a hemimetabolous insect will develop into an adult, and the larva of a holometabolous insect will develop into a pupa. In holometabolous insects, ecdysone is secreted again (and converted to 20-hydroxyecdysone) at the end of pupation. Because no JH is present, 20-hydroxyecdysone triggers metamorphosis into the adult form.

How do 20-hydroxyecdysone and JH exert their effects on target cells? Both hormones are soluble in lipids. Both pass through the cell membrane and bind with intracellular receptors in their target cells. The hormone–receptor complexes activate or inhibit the transcription of specific genes. Insects have *larval genes*, *pupal genes* (in holometabolous forms), and *adult genes*. As the animal goes through its life cycle, appropriate combinations of 20-hydroxyecdysone and JH control expression of these genes. The proteins encoded by specific genes influence the functions of the target cells.

In the laboratory, it is possible to remove the corpora allata surgically and thus remove the source of JH. When this procedure is carried out on early instars, instead of molting into another juvenile form, the experimental animals metamorphose into tiny, sterile adults. Or the converse experiment can be done: Last-instar larvae or nymphs can be treated with additional JH, either by implanting donor corpora allata from earlier-stage instars or by applying JH to the animal's surface. These experimental animals do not

TABLE 16.5 Major hormones and neurohormones that control insect metamorphosis

Hormone	Type of molecule	Type of signal	Site of secretion	Major target tissue	Action
Prothoracicotropic hormone (PTTH)	Protein (~5000 molecular weight)	Neuroendocrine	Brain, with axon terminals extending to corpora allata	Prothoracic glands	Initiates molting (ecdysis) by stimulating release of ecdysone from prothoracic glands
Ecdysone (molting hormone)	Steroid	Endocrine	Prothoracic glands in larva/nymph; ovary in adult	Epidermis in larva/nymph; fat body in adult	When activated to 20-hydroxyecdysone, promotes cellular mechanisms to digest old cuticle and synthesize new one; stimulates production of yolk proteins in adult
Juvenile hormone (JH)	Terpene (fatty acid derivative)	Endocrine	Corpora allata	Epidermis in larva/nymph; ovary in adult	Opposes formation of adult structures and promotes formation of larval/nymphal structures; functions as a gonadotropin in adult
Corazonin	Peptide	Neuroendocrine	Brain	Inka cells	Promotes PETH and ETH secretion from Inka cells
Ecdysis hormone (EH)	Peptide	Neuroendocrine	Brain	Inka cells, possibly others	Promotes PETH and ETH secretion from Inka cells
Pre-ecdysis triggering hormone (PETH)	Peptide	Endocrine	Inka cells of tracheae	Neuronal circuits in brain	Coordinates motor programs to prepare for shedding the cuticle
Ecdysis triggering hormone (ETH)	Peptide	Endocrine	Inka cells of tracheae	Neuronal circuits in brain	Coordinates final motor programs for escaping from old cuticle
Bursicon	Large protein (~35,000 molecular weight)	Neuroendocrine	Brain and nerve cord	Cuticle and epidermis	Tans and hardens new cuticle

Sources: After Randall et al. 2002; Žitňan et al. 2003; and Žitňan et al. 2007.

metamorphose into adults, but instead molt into giant extra-instar larvae or nymphs. Silk growers have used this phenomenon to their advantage. The larvae of the domesticated silkworm *Bombyx mori* spin silk filaments to make their cocoons. Spraying late-instar larvae with an analog of JH prevents them from pupating, so they molt instead into extra-instar larvae. When these larger larvae pupate, they spin more silk to make larger cocoons. Using this technique, silk growers can obtain a 10–20% increase in usable silk filaments.

Juvenile hormone and its analogs have also been found useful in certain kinds of pest control. For example, the JH analog methoprene is added to storm-water catch basins to control certain mosquito species known to be vectors of West Nile and dengue viruses. Catch basins are parts of drainage systems that hold water for various periods of time and provide areas for mosquitoes to breed. Methoprene added to the water mimics JH and prevents the emergence of adult animals. Preventing a large proportion of an insect population from reaching sexual maturity reduces its reproductive capability and overall impact. Methoprene has been proven effective in controlling insect pests in their adult stage, such as mosquitoes, fleas, and biting flies. Because the larvae of many insects cause severe damage to agricultural crops, researchers would like to find a way to antagonize (instead of mimic) JH. A JH antagonist that induced larvae to metamorphose early into adults would curtail their voracious feeding stages. So far, however, effective JH antagonists for broad-scale use have not been identified.

EH, corazonin, PETH, and ETH are also essential for the progress of an insect through its life cycle. Every time the insect molts, it must break out of its old cuticle. Escaping the last nymphal cuticle (in hemimetabolous insects) or the pupal case (in holometabolous insects) is critical if the new adults are to survive and reproduce; indeed, all previous stages in the life cycle are aimed at this goal. Insects employ motor behaviors to shed their old cuticles. Holometabolous larvae, for example, generate very precise muscular movements. Before actually shedding the old cuticle (which has been previously digested away from the epidermis under the direction of 20-hydroxyecdysone), the animal performs *pre-ecdysis behavior* lasting about 1 h. In pre-ecdysis, contractions of the body-wall musculature begin on the dorsal side of each segment and proceed toward the ventral side. These motions loosen and split the old cuticle. *Ecdysis behavior*, in which the old cuticle is actually shed, takes about 10 min. It involves peristaltic waves of contractions starting from the posterior end and moving anteriorly. Similar behavioral sequences are required for ecdysis at the end of each instar in both holometabolous and hemimetabolous insects.

How are the skeletal muscles of the body wall signaled to contract? Current data indicate that the Inka cells located on tracheae secrete PETH and ETH. These peptides stimulate neuronal circuits in the CNS that control motor programs for coordinated muscle contractions. PETH and ETH are released prior to every

molt in both holometabolous and hemimetabolous insects.⁶ How are the Inka cells signaled to secrete PETH and ETH? EH and corazonin, both neuropeptide hormones secreted by the brain, are known to promote Inka cell secretions. Thus neural activity and neuroendocrine and endocrine functions are all essential for coordinating the physiological processes leading to ecdysis.

After metamorphosis, the adult is poised for reproduction. For reproduction to succeed, the corpora allata, which became inactive and stopped secreting JH before the final molt, must begin to secrete JH again in the adult. JH functions as a gonadotropin in adults to support the production of fertile eggs and sperm. (Recently, peptide molecules isolated from ovaries, oviducts, and brains of insects have also been shown to influence gonadal function in insects. These molecules are subjects of active inquiry.) In addition, JH stimulates the production of pheromones required for mating. Ecdysone is also produced in the adult—not by the prothoracic glands, but by the ovaries. JH, functioning now as a gonadotropin, causes its secretion. Ecdysone, converted to 20-hydroxyecdysone, stimulates the fat body, an organ that performs functions similar to those of the vertebrate liver, to produce yolk proteins, which are transported to the ovary for incorporation into eggs. With adults now capable of producing gametes and releasing chemical signals that attract mates, the insect life cycle is ready to be repeated.

⁶At each molt, ecdysone, through its genomic actions, stimulates PETH/ETH secretion by Inka cells and increased expression of ETH receptors on their target neurons in the brain.

SUMMARY Insect Metamorphosis

- Insect metamorphosis illustrates the convergent evolution of endocrine and neuroendocrine functions between vertebrates and invertebrates.
- Insects change form in the course of their life cycles. Hemimetabolous insects go through gradual metamorphosis, and holometabolous insects go through complete metamorphosis.
- Environmental and behavioral signals mediated by the nervous system initiate molting by providing synaptic input to the PTH neuroendocrine cells in the brain. These cells secrete PTH, which stimulates secretion of ecdysone from the prothoracic glands. Ecdysone is converted to 20-hydroxyecdysone by peripheral activation.
- 20-Hydroxyecdysone stimulates the epidermis to secrete enzymes required for the molting process. At each molt, the epidermis lays down a new cuticle beneath the old one.
- Under the control of PETH and ETH, the insect performs stereotyped pre-ecdysis and ecdysis movements in order to shed the old cuticle.
- JH, secreted by nonneural endocrine cells in the corpora allata, prevents metamorphosis into the adult form. The relative amounts of JH and 20-hydroxyecdysone in the hemolymph determine whether the epidermis will produce juvenile, pupal, or adult structures.
- In adults, JH functions as a gonadotropin, stimulates the production of sex-attractant pheromones, and stimulates the secretion of ecdysone, which promotes incorporation of yolk into eggs.

Study Questions

1. Explain why the effects of steroid hormones are seen after a longer delay than the effects of peptide hormones.
2. Construct a table to compare the hormones involved in water and salt balance. Include the site of secretion and molecular structure of each hormone, the principal stimuli that cause its secretion, its effect on target cells, and other information you consider important.
3. Insulin secretion is essential in metabolism. What type of molecule is insulin? What structure secretes it? What factors control its secretion? What is/are its target tissue(s)? What effect(s) does it exert?
4. Compare and contrast the functions and modes of action of the following pairs of hormones: insulin and glucagon; active vitamin D and parathyroid hormone; adrenocorticotrophic hormone (ACTH) and cortisol.
5. Compare and contrast the structure and functions of hypothalamic neurosecretory neurons that send their axons to the posterior pituitary gland with those of hypothalamic neurosecretory neurons that have axons terminating on the capillary network of the median eminence.
6. List the similarities and differences between prothoracicotrophic hormone (PTTH) and ecdysone. Consider the structural and functional characteristics of both molecules.
7. In patients receiving cortisone drug therapy, adrenocorticotrophic hormone (ACTH) secretion decreases, and the adrenal glands shrink. Using your knowledge of the HPA axis, feedback mechanisms, and the tropic functions of hormones, explain why patients experience these changes.
8. Using your knowledge of the stress response, explain why the physiological changes of the stress response are important to survival in the short term and deleterious when they persist over long periods.
9. Define/describe negative feedback in endocrine controls and explain its physiological significance.
10. Discuss antagonism, permissiveness, and synergism in the context of hormone interactions.

Reproduction

“Mad as a March hare” is a 500-year-old expression—referenced often in literature and film, from Sir Thomas More (1529) to Lewis Carroll (1865) to *Dr. Strangelove* (1964)—that refers to one of the most visible of all mammalian reproductive behaviors. The species of hare that likely gave rise to the expression (*Lepus europaeus*) was introduced to the British Isles from continental Europe at the time of the Roman Empire. In Britain, the animals begin each year in February or March to “box” with each other in broad daylight. Boxing hares stand straight upright, kicking and batting each other with their forelegs. They also dash and leap in other forms of “madness.” *Harebrained* refers to people who behave like them. Several other species of hares and rabbits are known to box as well. At least in the two or three species that have been studied, boxing is primarily an interaction between females and males in which the females—being at a stage not receptive to mating—repel male advances. Boxing mirrors the reproductive biology of the hares and rabbits in two ways. First, being seasonal, it reflects the seasonality of reproduction. Second, it emphasizes that animals often need to be in a specialized state of receptivity for mating to take place.

Rabbits and hares are classed as **induced ovulators** because in them, **ovulation**—the release of mature eggs from the ovaries of a female—is induced by, and dependent on, stimuli generated by the actual act of copulation. Whenever animals of any sort engage in sexual reproduction, one of the key requirements for success is *synchronization* that ensures that competent eggs meet competent sperm. The achievement of this essential condition is particularly straightforward in the induced ovulators. In them, because copulation itself is the stimulus for mature eggs to be shed from the ovaries into the female reproductive tract, eggs remain in the ovaries until sperm are provided, and then the eggs move from the ovaries to the reproductive tract to meet the sperm. One might expect fertilization of virtually 100% of ovulated eggs under such circumstances, and in rabbits that is the outcome. Despite these advantages, induced ovulation occurs in only a minority of mammal species. Most mammals—indeed most animals of all kinds—are classed as **spontaneous ovulators** because ovulation results from processes endogenous to the female, more or less independent of mating.

In addition to rabbits and hares, the induced ovulators include certain cats, shrews, and camelids. Humans, most rodents,¹ dogs, and farm animals such as cows and sheep are spontaneous ovulators.

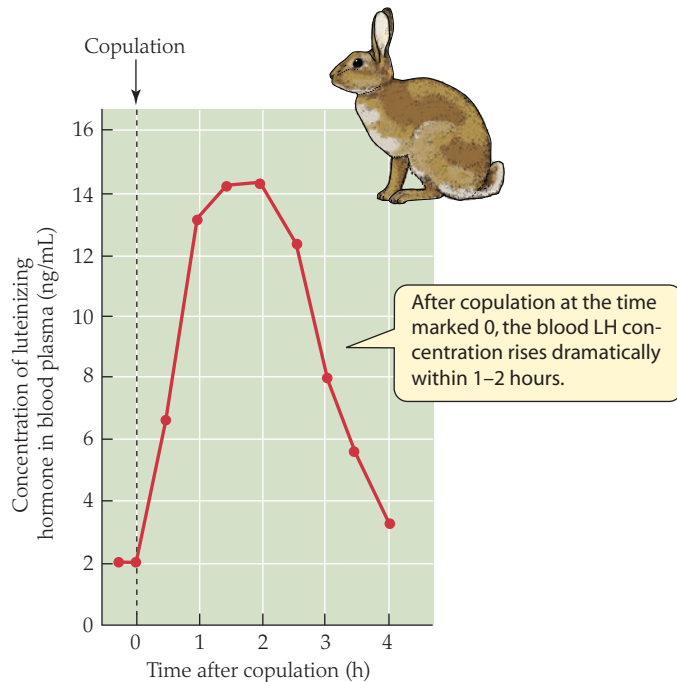

When physiologists study reproduction, they investigate the mechanisms by which induced and spontaneous ovulation occur. They also investigate many other aspects. Reproduction is a stunningly extended process when one considers all the steps required for one generation of adults to beget another generation of adults, and physiologists study many of the steps. To set the stage for identifying all the aspects of

¹Rabbits and hares are not rodents; they are lagomorphs.

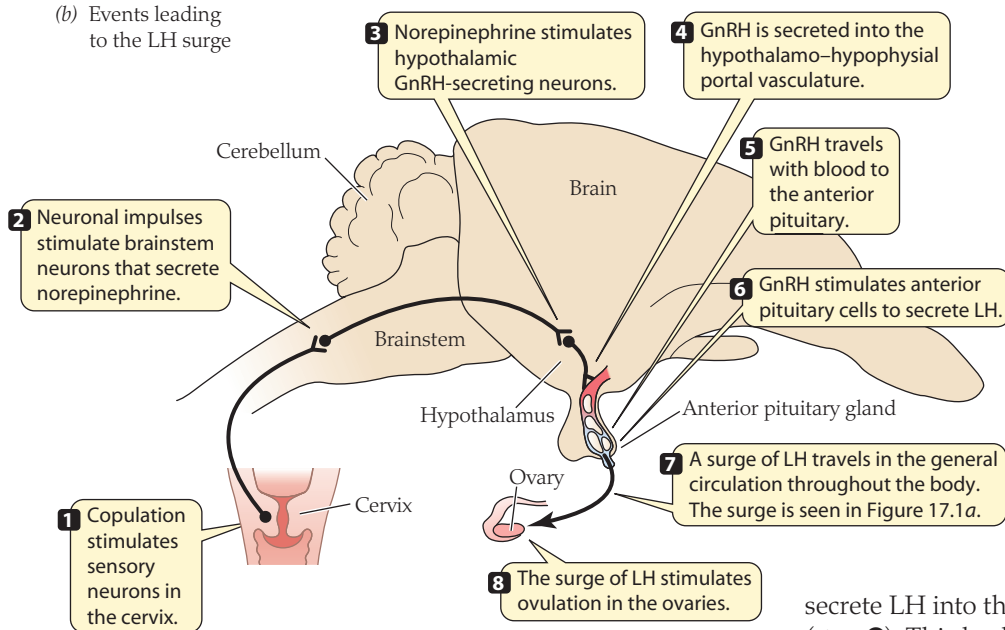

Boxing is a captivating prelude to the mating season in some hares and rabbits The antics of boxing hares in the month of March were the inspiration for Lewis Carroll's invention of the March Hare in *Alice in Wonderland*.

(a) The LH surge in female rabbits

(b) Events leading to the LH surge

reproduction studied by physiologists, let's focus further on our opening example to develop more background. Of all the rabbits and hares, the best understood species is the European rabbit (*Oryctolagus cuniculus*), which not only exists in the wild but also has been domesticated as the "laboratory rabbit" used extensively in research. As we now look further at the reproductive biology of rabbits and hares, we will use information on the European rabbit. Other rabbits and hares are believed in general to be similar.

The endocrine system typically plays a key role in the coordination of reproduction throughout the animal kingdom. Exemplifying

FIGURE 17.1 The physiology of induced ovulation in female rabbits

(a) The surge in the concentration of luteinizing hormone (LH) in the blood plasma following copulation. Data are averages for nine animals. (b) Major steps leading to ovulation following copulation. A sequence of this sort is often described as a *neuroendocrine reflex* because both neural and endocrine steps are involved in bringing about a stereotyped outcome in response to a specific stimulus. For greater detail on the hypothalamo–hypophysial portal vasculature, see Figure 16.7. GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone. (a after Tsou et al. 1977.)

this point, the endocrine system plays a pivotal role in the coordination of copulation and ovulation in rabbits and other induced ovulators. When a female rabbit copulates, a surge of the peptide hormone **luteinizing hormone (LH)**—secreted by her pituitary gland—occurs soon afterward (Figure 17.1a). This **LH surge** is responsible for inducing the release of eggs from her ovaries.

Copulation initiates a *sequence* of neuronal, neuroendocrine, and endocrine events that culminate in the LH surge (Figure 17.1b). First (step 1 in the figure), the copulatory act provides sensory inputs (e.g., physical stimulation of the cervix) that are relayed by neuronal pathways to the brain. These neuronal signals, according to recent

research, then (step 2) stimulate increased secretion of the neurotransmitter norepinephrine (NE) into the hypothalamus of the brain by neurons whose cell bodies are located in the brainstem; genes involved in NE synthesis have been shown by genomic studies to exhibit increased transcription (heightened mRNA synthesis) in the brainstem neurons within 20–40 min after a female rabbit mates. Within an hour after copulation (steps 3 and 4), neurosecretory cells in the hypothalamus, stimulated by NE, initiate a massive increase in secretion of gonadotropin-releasing hormone (GnRH; see Figure 16.3) into the blood in the hypothalamo–hypophysial portal system (see Figure 16.7). The GnRH is carried by blood flow in the portal system (step 5) to the anterior pituitary gland and stimulates cells in the anterior pituitary to

secrete LH into the general circulation at a greatly increased rate (step 6). This leads to a dramatic rise in the concentration of LH in the blood: the LH surge (step 7).

Eggs released from the ovaries in response to the LH surge (step 8 in Figure 17.1b) arrive in the oviducts (the passageways to the uterus; see Figure 17.8b) about 10 h after copulation. Sperm have also arrived there by then, and fertilization occurs there.

As already suggested, the events we have described cannot occur at just any time of year in rabbits that are living in the natural environment. Instead, wild rabbits in places such as northern Europe exhibit a strongly seasonal cycle of reproductive competence, being ready to reproduce only during the warmer months of the year. In male rabbits, the testes regress each autumn; by winter, they cease sperm production and are only a third or a half of their

summer size. Following the winter solstice in late December, however—in a context of ever-increasing hours of daylight per day as time passes—the testes regrow, under photoperiodic control, and ultimately reestablish full sperm production, a process termed **testicular recrudescence**. The rabbit version of “March madness” then begins. Female rabbits—as is true of females in most species of mammals (although not humans)—are attracted to males and will mate with them only at highly circumscribed times when the females are in a specialized state of reproductive receptivity termed **estrus**² or “heat” (see page 468). Periods of estrus cease to occur in the winter months. They resume, however, at the same time of year as the males regain testicular function.

Estrus—a change of behavior—is induced by effects of **estrogens** on the brain; estrogens are a class of steroid hormones (see Figure 16.2). The estrogens are secreted by the ovaries at times when mature eggs are present: an example of an elegant synchronization mechanism. Because of this mechanism, a female rabbit enters estrus only when she has mature eggs. Then, when she mates, the act of copulation itself induces the release of the mature eggs so they can be fertilized.

A property of rabbits and hares that tends to seem strange to human eyes is that their nursing is very brief. A mother rabbit, after she gives birth, typically covers her young in a nest and departs except for a single 3-minute nursing visit each day. Youngsters must obtain all their daily food in that brief interval. Natural historians believe, without firm evidence, that leaving the young alone for most of the time is a way to protect them from predators by making them as inconspicuous as possible. The same strategy is employed by many African antelopes in the days immediately following birth.

One vital challenge that nestling rabbits must meet is to orient quickly to their mother’s teats during the short interval she visits them each day. Recent research has revealed that a pheromone emitted by the mother is crucial for this task. A **pheromone** is a chemical compound (or mix of compounds) emitted into the environment by one individual of a species that elicits specific behavioral responses from other individuals of the same species (see page 445). The pheromone employed in rabbit nursing is apparently secreted by each nipple onto the skin surface of the nipple, where it coats the skin and gets into the milk. Young are guided to the nipple by their attraction to the pheromone. Pheromones are also commonly employed in reproduction in other ways. In animals ranging from crabs and insects to mammals, for example, adult males of many species are attracted to adult females by pheromones the females emit (see page 448).

What Aspects of Reproduction Do Physiologists Study?

With the background we have developed, we are now in a good position to identify the aspects of reproduction studied by physiologists. Reproduction is, of course, essential for each species. Because of its essential nature, it is studied by ecologists, evolutionary biologists, geneticists, and developmental biologists. Within the rich context created by these varied perspectives, physiologists focus on roughly a half dozen aspects of reproduction, which are illustrated by our

introductory discussion of rabbits and hares. **Figure 17.2** provides additional illustrations.

The aspects of reproduction that physiologists emphasize are:

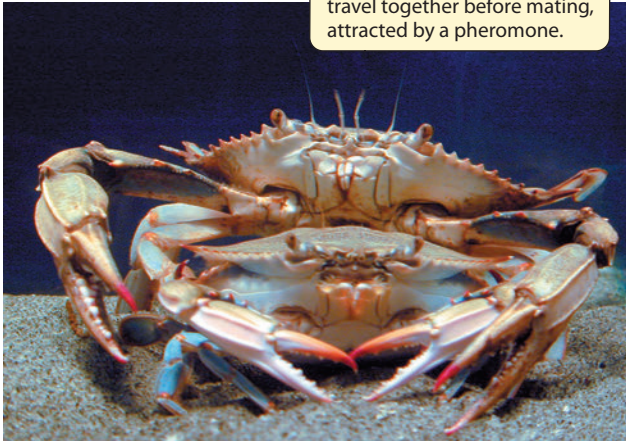

- *Mechanisms of mate association.* Potential mates need to find each other and communicate sexual readiness. Physiologists study the signaling and sensory processes that mediate these activities, including pheromones and behaviors such as estrus.
- *Control of the annual cycle of reproduction.* Most animal species reproduce at particular times of the year. Physiologists study the mechanisms by which reproduction is coordinated with the annual environmental cycle as well as the mechanisms responsible for seasonal changes in structure and function.
- *Mechanisms of function of the reproductive cells and organs.* Physiologists study how eggs are made, how erections occur, how sperm cells are sustained and sometimes transformed after being discharged from a male, how milk is synthesized, how nutrients are exchanged in placentas, and the mechanisms of all the other activities of reproductive organs and cells.
- *Coordination of the reproductive organs by neural, endocrine, and neuroendocrine mechanisms.* Physiologists study how an animal’s reproductive organs are coordinated and controlled during an episode of reproductive activity. Endocrine coordination is often preeminent, making *reproductive endocrinology* a major theme.
- *Delivery of resources to offspring by parents.* Parents sometimes transfer large quantities of resources to their offspring by prenatal processes (e.g., by synthesizing egg yolk) or postnatal ones (e.g., by bringing food items to young or nursing them with milk). **Offspring provisioning** is a general term that refers to these processes. Physiologists study the implications of provisioning for the energy and nutrient budgets of parents and offspring, and they study the mechanisms of offspring provisioning.
- *Physiology of the young.* Offspring face distinctive physiological challenges because they are small, immature, and often live in types of environments different from those of their parents. As discussed in Chapter 4, physiologists study the distinctive functional attributes of the young at each stage of development—and the maturation process itself—emphasizing that reproduction is successful only if the young succeed in meeting each challenge they face so that they survive to attain sexual maturity.

Our focus in this chapter will be on *sexual* reproduction. In some types of animals, asexual mechanisms of reproduction are also important. For instance, an individual reef coral is a colony of genetically identical hydra-like polyps produced asexually by budding; the way the coral grows is that its existing polyps put out extensions of tissue that develop directly into additional polyps. **Parthenogenesis**—the development of an egg without fertilization—is another type of asexual reproduction that occurs in some animals, such as certain fish and insects. Asexual reproduction has thus far received far less attention from physiologists than sexual reproduction.

²The noun is spelled *estrus*, but the adjective is spelled *estrous*. Thus it is correct to speak of “estrus” and of “estrous cycles.”

(a) Mate association

Male and female blue crabs travel together before mating, attracted by a pheromone.

(b) The annual reproductive cycle

Male elk grow massive new antlers each summer prior to seeking mates. Antler growth is under control of photoperiod and, probably, a biological clock—and mediated by melatonin and testosterone.

(d) Reproductive coordination and control

After sperm are ejaculated by a male mammal, they must transform biochemically to be able to swim fast and fertilize efficiently.

(c) Reproductive mechanisms

Follicle bulging on surface of ovary

An ovarian follicle—the structure that nurtures an egg in the mammalian ovary—secretes estrogens that prepare the female for pregnancy and, in some species, induce estrus.

(e) Provisioning of offspring

Parent terns expend their own metabolic energy to catch food to provision their young.

(f) Distinctive physiology of young

Gills

The young stage of a damselfly—unlike the terrestrial adult—lives under water, lacks functional wings, and breathes with gills.

FIGURE 17.2 The aspects of reproduction studied by physiologists

(a) Female blue crabs (*Callinectes sapidus*) can mate only when they have just molted. Male and female crabs travel together for days prior to mating so the male will be present when the female molts. (b) In the Rocky Mountain elk (*Cervus elaphus*) shown (also called red deer), antler growth—a remarkable form of annual regeneration—is strongly controlled by photoperiod. Evidence from related species suggests that photoperiod entrains an endogenous quasi-annual (circannual) biological clock. (c) Human sperm (shown) and other mammalian sperm are poorly effective at fertilizing eggs when first ejaculated. They must undergo a process termed **capacitation** (discussed later in this chapter) in the female reproductive tract to be able to fertilize efficiently. Capacitation involves biochemical restructuring of sperm membranes and all other sperm parts.

(d) In a mammalian ovary (such as the human ovary shown), each egg, as discussed later in this chapter, is nurtured by a follicle. Follicles enlarge, bulge out on the ovarian surface (seen here), and become endocrine structures as they mature. Through its hormonal secretions, a follicle helps prepare a female's body to nurture the egg that will be released when the follicle ruptures. (e) Terns, such as this common tern (*Sterna hirundo*), catch fish by diving from above into fish schools. They feed whole fish to their offspring. (f) Damselflies are insects that start life as aquatic nymphs and later metamorphose into terrestrial adults. Shown here is an aquatic nymph of the blue-tailed damselfly (*Ischnura elegans*). The gills are external. When a nymph metamorphoses into a terrestrial adult, its wings emerge fully formed from the wing primordia, which are visible on the dorsal side of the nymph shown.

Reproduce Once or More Than Once?— Semelparity versus Iteroparity

One of the most important reproductive attributes of a species is the number of times that individuals are physiologically capable of reproducing. When each individual is physiologically programmed to reproduce at only a single time in its life, the condition is described as **semelparity**, and the species is said to be **semelparous**.

The four sexually reproducing animals featured in **Figure 17.3** represent some of the best-studied examples of semelparity. The marine polychaete worm that is pictured (see **Figure 17.3a**) lives for several years, burrowing in bottom sediments, before it initiates reproduction.³ At that point, an individual metamorphoses into a specialized reproductive form called an **epitoke**, which has a distinctive external appearance and accumulates large numbers of sperm or eggs in its coelomic cavity. Eventually, male epitokes swim up into the water and release all of their sperm at the entrances of burrows occupied by females, which release eggs. Both sexes then undergo programmed death (phenoptosis). A neurohormone secreted by the brain is believed to control the transition to sexual maturity. This neurohormone inhibits sexual maturation and is secreted during

³Details of life history often differ among populations of a single species. Details mentioned in this paragraph and the next are for representative populations of each species.

most of the life of an individual. When secretion stops late in life, partly because of photoperiodic controls, the animal is doomed, but before it dies it transitions to the epitoke form and produces mature gametes. Probably, endocrine or neuroendocrine controls are paramount in orchestrating the single act of reproduction in other semelparous animals as well.

The other three species pictured in **Figure 17.3** also reproduce just once. Adult males of the octopus shown (see **Figure 17.3b**) place packets of sperm in the reproductive tracts of adult females during mating. Each female subsequently lays about 250,000 fertilized eggs over a period of a month. She then stops searching for food for herself and guards the eggs for 1–2 months, until they hatch. Guarding the eggs is her final achievement because she dies soon after her eggs hatch. Males also die at about the same time.

Semelparity is common among insects, among which the mayflies provide the most dramatic examples. Mayflies spend most of their lives in streams as aquatic, sexually immature nymphs. With the last molt of their exoskeleton, when the individuals of some species are already more than a year old, they emerge from the water as flying adults (see **Figure 17.3c**), often in fabulously large swarms. These adults cannot feed because they lack mouthparts. They live for only a few minutes, a few hours, or at most a few days (depending on the species), during which they mate and lay eggs.

Sockeye salmon (see **Figure 17.3d**), after growing to adulthood over a period of 1–4 years in the Pacific Ocean, migrate up riv-

(a) Nereid worm (*Nereis virens*)

(b) Octopus

(c) Mayfly

(d) Sockeye salmon

FIGURE 17.3 These semelparous species are physiologically programmed to reproduce during only a single period of time in their lives. Individuals die after a single bout of reproduction. (a) The marine polychaete annelid worm *Nereis virens*. (b) The octopus *Octopus vulgaris*. (c) The mayfly *Ephemera danica*. Shown here is the adult stage. Mayflies spend most of their lives as aquatic, water-breathing nymphs. (d) A breeding male sockeye salmon (*Oncorhynchus nerka*). These fish do not feed after they start their upriver migration to spawning areas. They develop hook-shaped jaws that they can no longer close but that are useful in mating competition with other males. They also develop humped backs and brilliant red coloration. Other species of Pacific salmon (genus *Oncorhynchus*) are also semelparous, although the Atlantic salmon (*Salmo salar*) is iteroparous.

ers—sometimes hundreds of miles—before spawning. Both sexes stop feeding as soon as they enter the rivers from the sea. They then must obtain energy to power their upriver migration entirely by catabolizing their own body substance, particularly fat. After reaching their destination, they spawn and die.

Semelparity is exceedingly rare in mammals but not unknown. Males of certain antechinuses (“marsupial mice”) of Australia die abruptly after just one reproductive opportunity (Box 17.1).

An important feature of semelparous species is that the vigor of parental individuals can be sacrificed to an unusually large extent to provide resources for offspring. This is true because the parental individuals have no future reproductive potential after their single bout of reproduction. The parents often catabolize unusually large portions of their own tissues to provide energy and nutrients for gamete synthesis and breeding. Pacific salmon illustrate this well; by the time they spawn, they are often capable of little else because of the profound extent to which they have depleted their body resources.

Most species of animals are **iteroparous**, meaning that individuals are physiologically capable of two or more separate periods of reproductive activity during their lives (i.e., multiple *iterations* of reproduction). In many species, for example, individuals reproduce at least once per year for as many years as they live. Individuals of iteroparous species (unlike semelparous ones) undergo reproductive *cycles*. These cycles are known often to be principally under endocrine and neuroendocrine control, whether ovulation is induced or spontaneous. We have already seen this in discussing rabbits and hares: Ovarian estrogens control when a female will enter estrus, and after she mates, GnRH—a brain neurosecretion—and LH—a pituitary hormone—control her ovulation (see Figure 17.1b). Later in this chapter, we will look in even greater detail at the endocrine and neuroendocrine controls of reproductive cycles in iteroparous species.

BOX 17.1 SEMELPARITY IN A MAMMAL

Males of the brown antechinus (*Antechinus stuartii*)—a species of small Australian marsupial, sometimes loosely called a “marsupial mouse”—lead lives governed by pressures to reproduce. Only dominant males succeed in mating with females. Therefore, to be ensured of impregnating a female and passing his genes on to another generation, a male must achieve dominance.

Photoperiod, acting via the pineal gland and its hormone melatonin, causes a precise synchronization of the reproductive cycles of these animals. All the males in a particular population become sexually mature at the same time. For several weeks after becoming sexually mature, males engage in intense fights with other males in an effort to become dominant and succeed in mating.

In about 2 months, after all the females are pregnant, all the males, whether or not they have mated, become sterile and begin to die. Studies show that the immune systems of the males are suppressed, and microorganisms and parasites invade these already stressed animals. In the laboratory, male *Antechinus* live far longer than in the wild, but just like in the wild, they become sterile after the mating period. Their testes fill with connective tissue and no longer produce sperm or hormones.

The question of parental investment in offspring is far more complex in iteroparous animals than in semelparous ones. This is so because when iteroparous parental individuals produce offspring in any one period of reproductive activity, they remain able to produce more offspring in the future. Consider a species in which a female produces 10 offspring per year and has an expected reproductive life span of 10 years. After a female has reproduced for her first time, she has produced only 10 of her possible lifetime total of 100 offspring. To produce the other 90, her own life and health must be preserved. Thus, as she provides resources to her first set of offspring, we expect her in general to refrain from doing so to an extent that would put her own life at risk.

Based on life-history theory, the parents’ likely life span in natural populations is expected to be an important determinant of parental investment in offspring in iteroparous species. Among related species, parents faced with a high probability of early death are predicted to make a greater sacrifice of their own resources for the sake of their young than are parents with long future life expectancy.

Eggs, Provisioning, and Parental Care

Small, lightly provisioned eggs that hatch into small, immature, and lightly provisioned offspring probably represent the primitive condition in animals. Eggs of this sort are common in modern aquatic species, and in many cases the numbers of these small eggs are enormous. A single female sea urchin, for example, may spew 1 million, or even 20 million, small eggs into the sea in one reproductive event. A single 1-meter-long Atlantic codfish (*Gadus morhua*) releases about 3 million eggs each time she spawns, and if she can live long enough to reach a size of 1.3 m, she will release 9 million eggs at each spawning. One can reason that a female has a certain total amount of yolk that she is able to invest in her eggs in a reproductive cycle. Animals like the urchins and cod essentially divide this total into millions of tiny pieces. Millions of eggs can therefore be produced. However, each egg is provisioned with only a tiny bit of yolk, and offspring run out of provisions quickly. Offspring, therefore, must feed themselves soon after hatching, or die.

An important aspect of reproductive diversification is that many animals have evolved strategies of delivering increased quantities of provisions to each offspring. The deposition of more yolk in each egg is perhaps the simplest means of increasing provisions. Many sharks and rays illustrate this phenomenon dramatically, as seen in the species of dogfish shark in Figure 17.4, in which the amount of yolk per egg is enormous.⁴ With so much yolk going to each egg, only a few eggs can be produced; a 1-meter-long dogfish shark produces fewer than 20 eggs in a single reproductive event, in sharp contrast to a cod of similar length, which produces 3 million eggs. The advantage of increased provisioning is that yolk-rich eggs—compared with yolk-poor ones—tend to yield bigger, more mature offspring that are more likely to survive. Per generation, 1% of shark eggs can be expected to survive to adulthood, whereas survivorship of cod eggs is often 0.00001%. In addition to sharks and rays, other animals noted for producing eggs that contain relatively large amounts of yolk include birds, turtles, lizards, and other nonavian reptiles—and some invertebrates, such as squid.

⁴Yolk is the only means of provisioning in the species shown.

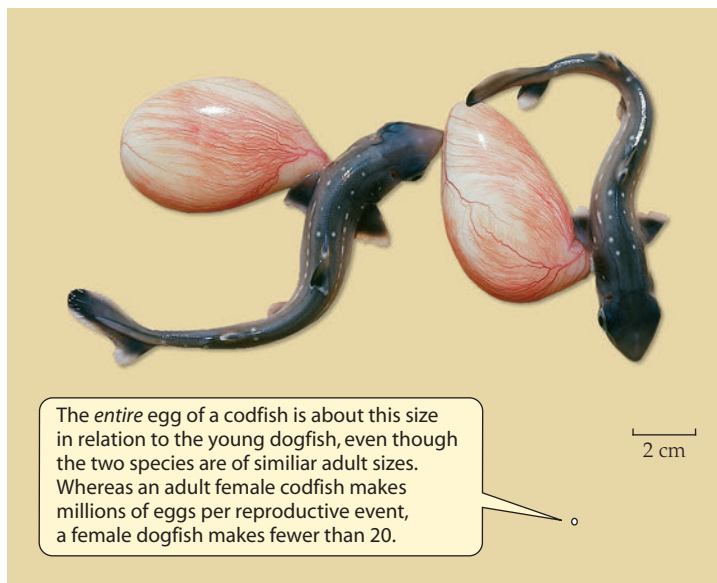

FIGURE 17.4 Abundant provisioning of offspring with yolk in a species of dogfish shark (*Squalus acanthias*) In this species, after eggs are fully formed, they are retained in the reproductive tract of the mother while the young undergo their initial development. During this developmental phase, the young live off the yolk provided to each egg when the egg was formed; they receive no further nutritional assistance from their mother. The youngsters pictured here have already used more than half their yolk to grow to the stage shown. Note that the sac containing the yolk of each individual is profusely vascularized by the individual's circulatory system; nutrient molecules are mobilized from the yolk by blood flow through the yolk-sac blood vessels. An egg of a codfish is shown at about the same scale for comparison.

Thinking in evolutionary terms, we see that animals that provision their offspring with egg yolk have faced a trade-off. For any given total parental investment, they can produce lots of yolk-poor eggs that have little individual chance of survival, or they can produce small numbers of yolk-rich eggs that have a far greater individual chance of survival. In cases in which related species have diverged and followed both of these evolutionary paths, biologists often cannot offer a full explanation.

There are other mechanisms of providing lots of provisions to each offspring besides producing yolk-rich eggs. These additional provisioning mechanisms—which are sometimes combined with yolk provisioning—can be classed as *prenatal* or *postnatal*.

Speaking of *prenatal* provisioning by means other than yolk deposition, one mechanism is the transfer of nutrients from the bloodstream of the mother to the bloodstream of each developing offspring. This, of course, is what placental mammals do; the placenta is a structure specialized to facilitate such nutrient transfer, as discussed further later in this chapter. Such nutrient transfer also occurs in placenta-like structures in some other vertebrates, including certain lizards, requiem sharks, and hammerhead sharks. A second mechanism of prenatal provisioning is for the mother to produce eggs that do not develop to maturity on their own but instead serve as food for the offspring that develop.⁵ Some snails, including the large whelks of the Atlantic seaboard of the United States, provide examples. These snails deposit multiple eggs in

⁵The eggs that are eaten are sometimes “programmed” to be used in this way, as by being infertile and therefore incapable of development, but in general the process of determining which eggs serve for food is not understood. In invertebrate examples, the eggs that are eaten are called *nurse* eggs.

capsules; inside each capsule, only a few individuals develop fully, and those individuals feed on the other eggs prior to hatching from the capsule. Similarly, within litters of great white, mako, and porbeagle sharks—which develop in their mother's reproductive tract—some individuals eat others.

Considering *postnatal* provisioning, lactation in mammals represents one example. Postnatal provisioning also occurs when parents gather food for their young, as when birds feed fish or insects to their offspring (see Figure 17.2e). Similarly, certain wasps lay their eggs on prey that will serve as food for the offspring that hatch from the eggs.

A vital point to reemphasize about provisioning of all sorts is that, while aiding offspring, it imposes costs on parents. Reproducing parents must eat sufficiently, above and beyond their own needs, to provide the yolk or other materials they donate to their offspring. Of all animals, mammals and birds provide the greatest provisions per offspring to their young. Consequently, while young mammals and birds start life with particularly abundant resources, their parents face exceptional reproductive costs per offspring.

External or Internal Fertilization?

Fertilization is usually external in aquatic animals that make small, lightly provisioned eggs. Females release the eggs into the water, and males release sperm into the water in the same vicinity. Sometimes, as in certain fish, the males are quite meticulous in matching the spatial pattern of their sperm output to the spatial distribution of the eggs.

Internal fertilization is required under several circumstances. One such circumstance is when fully formed eggs are encased in shells or capsules that sperm cannot penetrate. For example, eggs laid on land—such as those of birds and lizards—typically are defended against desiccation by shells or capsules that sperm could not penetrate. Skate eggs also are enclosed in thick defensive capsules. In such cases, fertilization of the eggs must occur in the female reproductive tract prior to the time that the shells or capsules are added. Fertilization must also be internal if offspring are to undergo their early development in the reproductive tract of the mother. Internal fertilization is therefore required for placental or placenta-like provisioning.⁶

Internal fertilization has evolved multiple times independently. Not surprisingly, therefore, it occurs by multiple means. In mammals, a penis inserted into the female reproductive tract squirts a fluid containing sperm into the tract. In most birds, there is no penis; instead, sperm are transferred when a male and female press their cloacal apertures together. In many invertebrates and in sharks and rays, sperm are transferred in physically discrete packets (*spermatophores*). These packets may be grasped by transfer appendages that place them in the female reproductive tract (e.g., in crabs and octopuses);

⁶When offspring develop in the reproductive tract of their mother, they exit their mother as small animals—a phenomenon called *viviparity*—instead of exiting as eggs (*oviparity*). Several types of provisioning can occur in cases of viviparity. Sometimes, as exemplified by the dogfish in Figure 17.4, offspring that develop in the reproductive tract of their mother are nourished entirely by egg yolk. This condition has been termed *yolk sac viviparity* or *ovoviviparity*. When, as happens in certain sharks, certain young provision themselves by eating other young while in their mother's reproductive tract, the condition is termed *cannibal viviparity*. Also, of course, nutrients may be transferred from the mother's blood to the offspring's blood across a placenta or placenta-like structure (occasionally called *placental viviparity*).

alternatively, they may be washed into the reproductive tract by water currents, as when a male shark inserts a modified pelvic fin (clasper) and washes sperm packets down a groove in the fin.

The Environment as a Player in Reproduction

The environment of reproducing animals typically exerts major influences on the reproductive process and outcome. Three aspects of the immediate environment—its nutritional, social, and physical aspects—are crucial.

The *nutritional environment* can exert both obvious and subtle effects. Among the obvious, reproductive success is threatened if the amounts of food available are inadequate. Food shortages are legendary for sometimes decimating offspring, thereby nullifying the reproductive efforts of parents. For example, the eggs of most fish are so lightly provisioned that when larvae emerge from the eggs, they soon confront urgent needs for food, and many instances are known in which virtually 100% of larvae have starved because food organisms were not available in close synchrony with hatching. Nutritional effects are often more subtle. Even when offspring live, if food and nutrients are not fully adequate in quantity and quality, reproduction can be impaired in multiple ways. As discussed in Chapter 4, for example, young mice and rats of both sexes reach puberty much later than usual when they are fed inadequately. A parallel phenomenon likely occurs in people; girls in subsistence cultures are often 2–3 years older at menarche (first ovulation) than girls in well-fed cultures. Endocrinologists have established that malnutrition in female mammals of reproductive age can halt the secretion of gonadotropins and thereby stop the maturation of eggs in the ovaries (see Chapter 16).

Turning to the *social environment*, the most obvious social requirement for reproduction is that males and females find each other and achieve states of mutual sexual readiness. More intricate social processes are often important as well. Male elk (*Cervus elaphus*; see Figure 17.2b) in Scotland—where they are called red deer—for example, rarely father offspring before they are 5 years old, even though they are *physiologically* able to do so by 2 years of age. The social challenges they face in relating to other males account for the difference; a male must be big and experienced enough to dominate other males before he will gain access to females. In some species of dragonflies and coral-reef fish, as well as mammals, males need to control territories to have ready access to females; males without territories have relatively little opportunity to mate.

The third key aspect of the environment is the *physical environment*, including day length, temperature, and sometimes other physical factors. Reproduction is often cued by physical environmental factors.

Photoperiod—the number of hours of daylight per 24-h day—is an attribute of the physical environment of great significance for reproduction in both invertebrates and vertebrates at temperate latitudes. Because photoperiod varies in a mathematically exacting way with the time of year, it provides unambiguous information on the timing of the seasons. An important general statement is that animals commonly synchronize their reproduction with the seasons by use of photoperiodic information. By comparison with this simple statement, however, the physiological mechanisms that have evolved to achieve this synchronization are almost bewilderingly complex. Several mechanisms have evolved, and the

mechanisms used can differ not only among major animal groups but also among related species or even populations within a species.

In mammals two basic mechanisms exist for using photoperiod. Some species (e.g., sheep, sika deer, some ground squirrels, and European hamsters [*Cricetus cricetus*]) orchestrate events in their annual reproductive cycles by use of internal circannual timing mechanisms that endogenously time events for an entire year in each cycle. In these species, information on the prevailing photoperiod in the environment is used to entrain (adjust) the internal clocks so they are synchronized with annual events in the outside world. Most species, by contrast, do not use endogenous circannual timing mechanisms. Instead, they continually adjust their reproductive physiology to correspond to the immediately prevailing photoperiod in their environment. For example, many mice—using long photoperiods as an indicator of spring and summer—remain in a state of reproductive readiness for as long as the photoperiod is long; thus, they stay in a state of readiness indefinitely if artificially provided with unending long-photoperiod days. However, in keeping with their immediate responsiveness to prevailing photoperiod, they promptly start to downregulate their reproductive readiness if switched to short-photoperiod days. A common phenomenon seen in species of this type—a phenomenon that modifies their relation to photoperiod—is *refractoriness*, a type of noncyclic endogenous timing process. Refractoriness refers to an animal's becoming unresponsive to a photoperiod after being exposed to it for an extended length of time (e.g., several months). Several species, for example, if exposed continually to short-photoperiod days, eventually cease responding to the short photoperiod and begin to exhibit the reproductive readiness they display on long photoperiods. Regardless of the mechanisms species use to control their reproductive state by sensing photoperiod, the typical outcome in the natural world is that reproduction is synchronized with the seasons by use of photoperiodic information.

In mammals, and also in some other vertebrates, the hormone *melatonin*—secreted by the pineal gland—participates as an endocrine signal in the photoperiodic control of reproduction. Melatonin is secreted at night. Melatonin secretion is thus inversely related to photoperiod, decreasing as the number of hours of light per day increases (see page 388[2E]). Melatonin does not act on target tissues simply by increasing its effect as its concentration rises, as some hormones do. Instead, the pattern of melatonin secretion is best thought of as a *code* that encodes the photoperiod. Tissues interpret melatonin signals in ways that give them accurate information on photoperiod as they modulate their functions.

Environmental temperature is another important attribute of the physical environment. Like photoperiod, it also is often employed as a cue for reproduction in temperate climates. A common pattern is for animals to enter a state of reproductive readiness in synchrony with photoperiodic cues and then mate or spawn when they experience warm temperatures; in such cases, temperature “fine tunes” the timing determined by photoperiod. Along seacoasts, animals are believed often to use tidal cues, or possibly direct lunar cues, to time their reproduction.

In deserts and some other environments, favorable conditions for reproduction occur unpredictably rather than in dependable cycles. To time their reproduction, animals in such environments may not use cyclic cues such as photoperiod but instead respond to the immediate presence of essential resources. Rainfall is often the principal cue to reproduce in desert animals (see Box 21.1).

The physical environment is important in ways besides cueing reproduction. In sea turtles and many other nonavian reptiles, for example, nest temperature determines whether eggs develop into males or females—a phenomenon known as **temperature-dependent sex determination**. An effect that is far more widespread is that environmental temperature typically influences how rapidly offspring grow and reach reproductive maturity. For instance, among animals in which body temperature matches environmental temperature, the rate of maturation of the young is often greater in warm environments than in cold ones because elevated tissue temperatures speed biochemical processes.

The Timing of Reproductive Cycles

For animals that live in environments with regular seasonal cycles, the reproductive cycle is nearly always timed to coordinate with the seasonal cycle in at least certain ways. In some species of this sort, individual steps in the reproductive process are rigidly linked to each other. Therefore, although reproduction is coordinated with the environment, the individual steps in the reproductive process cannot be separately coordinated: Mating leads promptly to fertilization, fertilization leads promptly to embryonic development, and development adheres to a relatively rigid schedule, culminating in hatching or birth at a relatively fixed time after fertilization. Humans illustrate this sort of sequencing in an especially inflexible way.

Many animal species, however, have evolved mechanisms of decoupling successive steps in the reproductive process, so that the time that elapses between one step and the next is flexible. Such mechanisms increase options for certain steps to be coordinated with environmental conditions independently of other steps.

Sperm storage permits flexible timing between copulation and fertilization

Sperm storage in the female reproductive tract is a common mechanism that provides for flexible timing between one major step of the reproductive cycle—copulation—and the next—fertilization. Female blue crabs (*Callinectes sapidus*; see Figure 17.2a) provide a dramatic illustration. They are typically able to copulate for only a few hours in their lives: the hours that elapse between the time they shed their next-to-last exoskeleton and the time their final exoskeleton starts to get hard. After this brief period when they can mate, however, they may mate and fertilize new masses of eggs for a year or more because of the storage of viable sperm in their reproductive tract. A female crab that copulates in the autumn of one year, for example, may use the sperm from that mating to produce a new batch of fertilized eggs in the spring of the next year. Queen honeybees store sperm for years, and certain bats do so for over half a year. Sperm storage occurs also in certain other crustaceans and insects, and in certain sharks, salamanders, turtles, snakes, and birds.

Embryonic diapause permits flexible timing between fertilization and the completion of embryonic development

Embryonic diapause—a programmed state of arrested or profoundly slowed embryonic development—occurs in many sorts of animals and serves to decouple fertilization and the full development of embryos. In cases of embryonic diapause, embryos start to develop but then stop for a while before continuing. The length of the pe-

riod of arrested development is typically flexible. Thus embryonic diapause permits adjustment of the time between fertilization and completion of embryonic development. Mechanisms of embryonic diapause have evolved independently many times. Because of this, the mechanisms often differ greatly in morphological and biochemical detail from one animal group to another.

Among invertebrates, embryonic diapause occurs in certain crustaceans and mites, plus a wide variety of insects. The eggs laid by silkworm moths (*Bombyx*) provide a particularly well understood example. For a silkworm-moth mother that herself developed under certain conditions, egg diapause is deterministic: The eggs the mother lays—following copulation and fertilization—are programmed to undergo a complete arrest of development (cessation of mitosis) when they reach the gastrula stage of their embryonic maturation. Programming of this developmental arrest occurs while the eggs are still forming in the mother's ovaries; this programming is mediated by a peptide neurohormone (*diapause hormone*) that is secreted by cells in the mother's subesophageal ganglion and that acts on the eggs during their formation via a G protein-coupled receptor. Diapausing eggs are laid in the autumn. After such eggs have entered their programmed developmental arrest, for them to emerge from their arrested state, they must be exposed for about 2 months to a low temperature (e.g., 5°C or lower).⁷ The low temperature terminates ("breaks") the diapause; consequently, development resumes soon after the cold exposure. In natural habitats, these interacting processes—the programmed appearance of diapause and the need for extended cold exposure to terminate it—ensure that fertilized eggs laid in the autumn do not erroneously complete development and hatch prior to winter. Instead, the eggs wait until winter has passed to hatch (Figure 17.5a; see also Figure 16.18).

Among vertebrates, embryonic diapause occurs in certain fish, turtles, birds, and both marsupial and placental mammals. It is usually called **delayed implantation** in placental mammals because the arrest of embryonic development occurs when an embryo is at the blastocyst stage of its maturation, prior to implantation of the embryo in the uterine wall at the start of the placental stage.

Delayed implantation in some species of mammals is classed as *obligate* because it is a feature of all pregnancies. Its role in such cases is typically to match the length of the reproductive cycle to the length of the calendar year. Antarctic fur seals (*Arctocephalus gazella*) illustrate delayed implantation in this role (Figure 17.5b). A female fur seal goes into estrus and mates in the days immediately after she gives birth during the early summer. If she conceives a new offspring, she cannot afford to give birth to it either much earlier or much later than early summer in the following year. If she were to give birth earlier—in the Antarctic spring—her newborn could immediately experience overwhelming cold. If she were to give birth later, her newborn could have too short a period of summer to mature before its first winter. In fact, the average time that elapses between the day a female copulates and the day she gives birth is almost exactly 365 days! Placental development requires only about 250 days, however. The time from copulation to birth is adjusted to be 365 days by delayed implantation. After an egg is fertilized and develops to the blastocyst stage, it goes into developmental arrest (in the uterus) for 3–4 months. It stays in this arrested state

⁷If diapausing eggs are not exposed to cold, they eventually resume development, but not for a very long time—a year or longer.

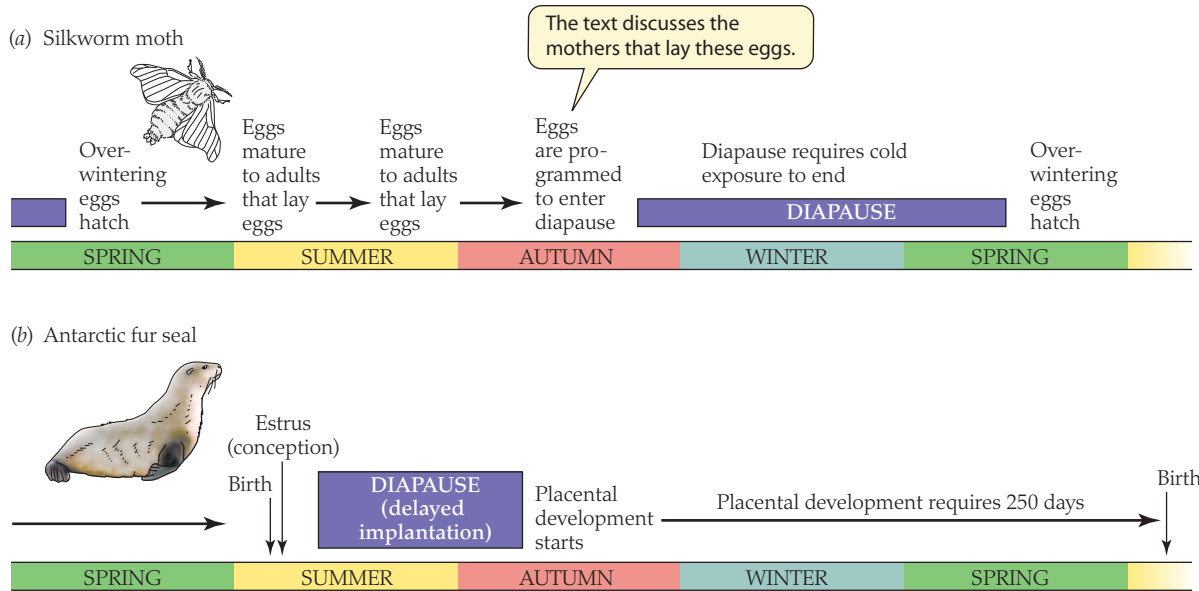

FIGURE 17.5 Embryonic diapause is employed by both of these animals to synchronize reproductive events advantageously with seasonal environmental conditions (a) Female silkworm moths (*Bombyx*) that lay eggs in the autumn produce diapausing eggs that arrest their development and stay arrested until they have had a long period of cold exposure, ensuring they do not hatch until spring. (b) In Antarctic fur seals (*Arctocephalus gazella*), placental development lasts only about 250 days. Diapause—here called delayed implantation—is employed to ensure that placental development does not start until an advantageous birthing season is only 250 days in the future. (There are many varieties of silkworm moths, which differ in details of their life cycles. Shown here is the life cycle of the type termed *multivoltine*. In the fur seal diagram, “placental development” is used as a shorthand to refer to the period between implantation and birth.)

for long enough that when, finally, it resumes development and implants (under photoperiodic control), 250 days remain before the proper birthing moment.

Delayed implantation is classed as *facultative* in species of mammals in which it can either occur or fail to occur in any particular pregnancy. White-footed mice (*Peromyscus leucopus*), which are abundant in many North American forests, exemplify facultative delayed implantation. Their time between conception and birth can be as short as 23 days or as long as 37 days (a >50% difference)! Facultative delayed implantation is responsible for this variation. In 23-day gestations, no delay of implantation occurs; 23 days, in other words, is the period required for development to be completed without interruptions. Delayed implantation can occur, however, and can be of variable length. A 5-day delay results in a 28-day gestation. A 10-day delay causes a 33-day gestation. Patterns of this sort are common in rodents. Detailed studies of laboratory mice have started to unravel the complex physiology and hormonal controls involved. In those mice, in the midst of a delay, not only is the embryo’s development arrested, but also the uterine wall is unresponsive to the embryo’s presence (although ultimately the uterus must accept implantation of the embryo). The arrested state can be ended by a pulse of estrogen secreted by the ovaries. The estrogen brings the uterus into a receptive state, and the uterus then secretes a uterine hormone, catecholesterone, which activates the embryo. After this cross-talk between the uterus and embryo, implantation soon occurs, and the embryo completes intrauterine development.

Facultative delayed implantation often functions in rodents in a coordinated way with *postpartum estrus*, another physiological process that affects the timing of reproduction. In species that exhibit **postpartum estrus**, a female becomes receptive to mating—and is capable of conceiving—in the immediate aftermath of giving birth (*postpartum*, “following parturition”). If a female mouse or rat successfully mates during postpartum estrus, she goes through a period of nurturing two litters of young at once: While one litter grows in the nest, a second simultaneously grows in her uterus! This process gives the animals great reproductive potential but can be very demanding on the mother. In small mammals in general, lactation is the most expensive phase of the reproductive cycle for the mother, and it becomes especially expensive as her nestling young, growing larger and larger, approach weaning. Often, as is true in the white-footed mice we discussed in the last paragraph, the length of time required for an uninterrupted gestation (23 days in the white-footed mouse) is almost the same as that required for nestlings to mature from birth to weaning (21 days). Therefore, the litter developing in the uterus can have grown to full prenatal size—placing its greatest prenatal demands on the mother—at the very time that lactation is most expensive for her. Facultative delayed implantation is used to prevent this stressful coincidence by offsetting the development of the two litters. When white-footed mice *without nestlings* conceive litters, they exhibit no delay of implantation; gestation is 23 days. However, when they conceive in a postpartum estrus and thus *have nestlings*, they often exhibit a delay of implantation of a week or longer. Consequently, the intrauterine young are still at a relatively early stage of development when the nestling young reach weaning age and are most demanding.

Postpartum estrus is not limited to rodents. It occurs also in many true seals, sea lions, and fur seals, as we have seen. Horses and zebras, some kangaroos, and rabbits and hares also exhibit it.

The timing of reproductive events is often rigorously controlled in seasonal environments

In iteroparous animals occupying seasonal environments, cycles of reproduction are commonly timed in ways that correlate favorably with the seasonal cycle of environmental conditions, as al-

ready emphasized. Seasonal breeders have evolved mechanisms by which they use environmental cues to regulate the hormones that control their reproductive cycles so that the timing of major processes such as mating, birth, or weaning tends to be optimized relative to seasonal conditions. The most well known and common manifestation of this phenomenon, in aquatic as well as terrestrial species, is that animals of many species produce offspring in the spring, when algal or plant productivity is exceptionally high, providing an abundant food base for parents and offspring.

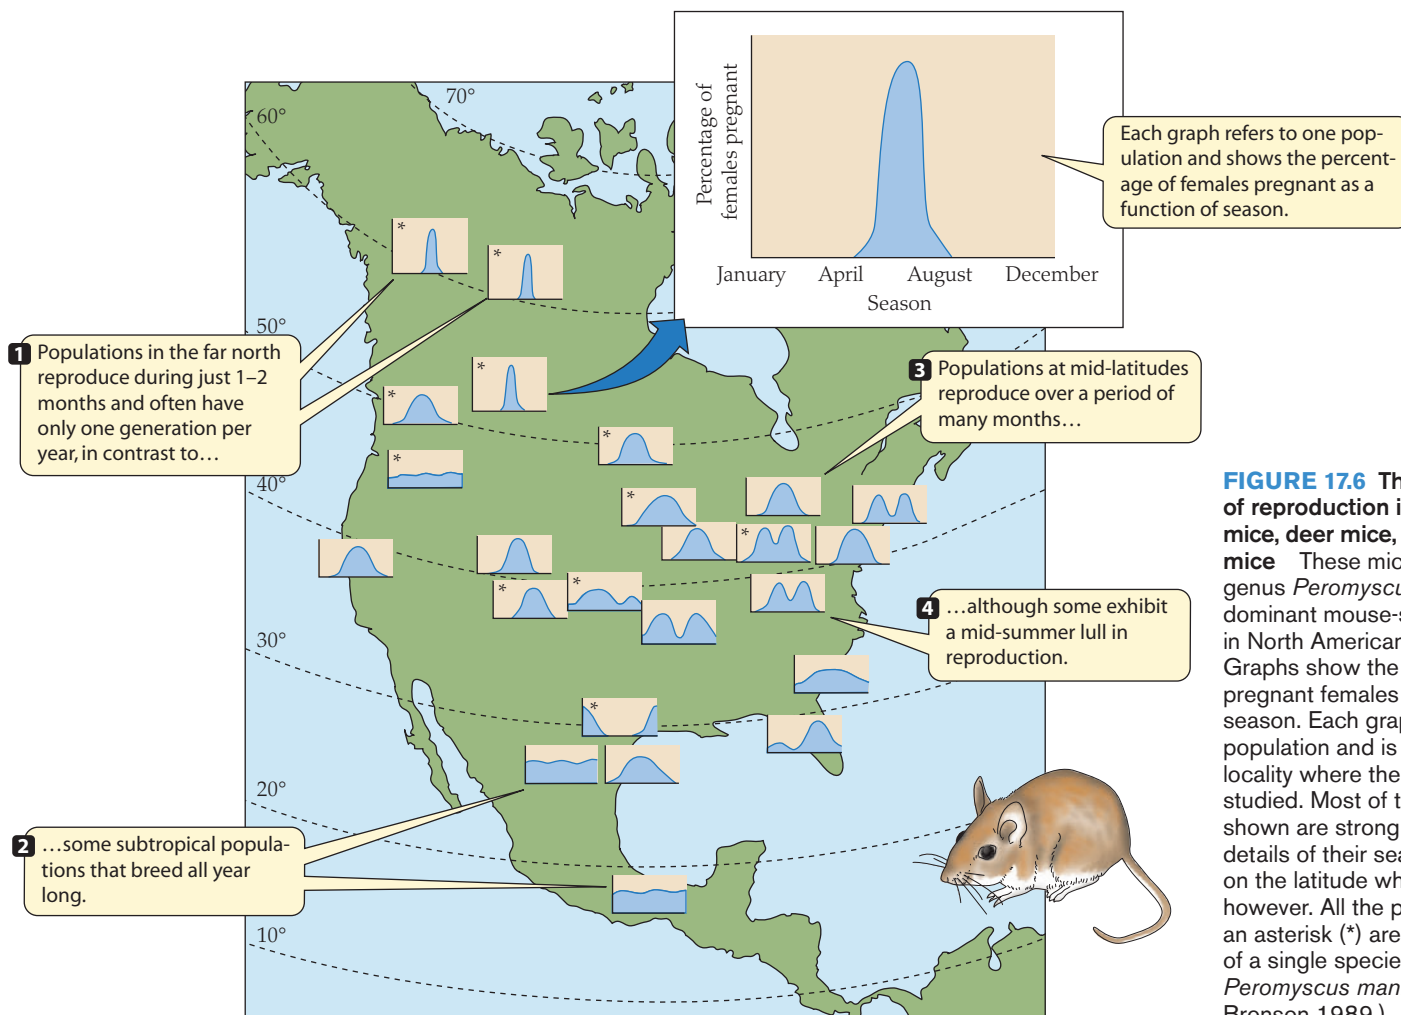

The most dramatic examples of reproductive seasonality are provided by animal species in which iteroparous individuals reproduce just once per year, at a highly restricted and defined time. The palolo worms of the tropical South Pacific (*Palola viridis*) must rank as the most extraordinary of such animals. Individual palolo worms spend their lives burrowing within the coral reefs. Once a year, the posterior end of each individual transforms into a reproductive entity—a type of epitoke (see page 429[2e])—filled with eggs or sperm. All of these epitokes simultaneously detach from the parent worms, swarm to the sea surface within a span of 30 min, and release their gametes at the time of the third quarter of the moon in October or November! This spectacular process is the single mating event of the year, and individuals do not reproduce again until a year later. The moon phase seems to function in this case as a synchronization factor; when all indi-

viduals spawn at the third quarter of the moon, they are assured of spawning together.⁸

Several species of foxes and wolves also breed a single time per year. In their own way, they seem as extraordinary as the palolo worms. A female red fox (*Vulpes vulpes*), for example, enters estrus for only a single 1- to 6-day interval—and ovulates just once—in a year. Even if she fails to conceive or loses her young, she next enters estrus and ovulates a full year later. Mammals of this sort are called *monestrous* (“one estrus”). Many species of birds that breed at temperate latitudes also reproduce just once a year; they produce a single clutch of eggs in the spring (usually employing photoperiod and temperature as timing cues), and even if that clutch fails, they do not produce a second.

Most iteroparous species, while exhibiting distinct reproductive seasonality, have broader reproductive seasons. This is true of white-footed mice and the closely related deer mice, which illustrate patterns of seasonality that are common in small- and medium-sized mammals. They go through multiple mating cycles per year everywhere they live, but the total length of their reproductive season varies regularly with latitude, being short at high latitudes where favorable summer conditions do not last long, but longer at mid-latitudes (Figure 17.6). Whatever the length of the reproduc-

⁸The details of the palolo description given here are for a population in Samoa that has been carefully studied.

tive season, females that are not pregnant or lactating exhibit an endogenously timed **estrous cycle** during the reproductive season, whereby they enter estrus and spontaneously ovulate every 6 days. The mice are described as *polyestrous* because of having more than one estrus per year. When a female becomes pregnant, her estrous cycle stops, but when she gives birth several weeks later, she exhibits a postpartum estrus and can immediately become pregnant again, as we have discussed. Male mice in the reproductive season produce sperm constantly. Physiological programming—which synchronizes reproduction with environmental photoperiod—accounts for the seasonality of reproduction. Under short-day conditions (much as we saw earlier in rabbits and hares), females cease their cycles of estrus and ovulation, and in males the testes regress to small size (by apoptosis), cease sperm production, and are withdrawn into the abdomen.⁹

For the mice, one important consequence of the latitudinal variation in length of the reproductive season is that the number of generations per year varies with latitude. Newborns become sexually mature in less than 2 months. Therefore, if the reproductive season lasts 6 months or more, youngsters can readily have offspring or even grand-offspring in the same year as their birth. In contrast, only a single generation per year is likely at high latitudes where the reproductive season is short.

Some of the themes evident in the mice are so common that they can be seen even in other small- and medium-sized animals as distantly related as insects. One of the well-studied migratory locusts, *Locusta migratoria*, for example, also exhibits distinct latitudinal trends in the seasonality of reproduction (migratory locusts are discussed further in Chapter 4). Whereas only one generation is completed at cold, high latitudes, two generations may be completed at mid-latitudes, and even three or four generations at still warmer latitudes. Adult females lay multiple batches of eggs before dying. The eggs are programmed to develop promptly into new individuals if the mother has experienced long days, but the eggs are programmed to enter embryonic diapause if the mother has experienced short days. The short days of autumn lead all the mothers in a population to lay diapausing eggs, and the population therefore experiences a hiatus in its reproductive output. Winter cold is required to terminate the diapause. Thus the population regains its reproductive potential only the next spring, when the diapausing eggs—which have overwintered—resume development and mature into the next year's first adults. Just as in the mice, reproduction is physiologically programmed to cease in winter.¹⁰

Insects as a group, in fact, make extremely common use of programmed quiescent stages to synchronize their reproductive cycles to the annual seasonal cycle. In many species, the larva, pupa, or adult—instead of the egg—is the stage that enters programmed quiescence (the quiescence is then called *larval*, *pupal*, or *adult diapause*). Regardless of the stage, programmed quiescence typically acts to interrupt the progress of the life cycle at a stressful time of year.

Large-bodied mammals face distinctive and intriguing challenges to synchronize their reproductive cycles with the annual seasonal cycle. This is true because they have intrinsically long

gestation periods that often last a large fraction of a year but not exactly a year (see Figure 1.8). To see the challenge, consider a hypothetical mammal with an 8-month gestation. If two adults mate in the late spring or summer—a fine time for them—their offspring will be born in the dead of winter unless a winter birth is prevented by some sort of reproductive specialization.

One option for large-bodied mammals to achieve synchronization of their reproductive cycle and the seasonal cycle is the one we have already discussed: delayed implantation (see Figure 17.5b). Sheep, goats, deer, and primates have never evolved delayed implantation, however, and thus cannot employ that option. The option that some such species in temperate latitudes employ is **short-day breeding**. These species resemble most temperate-zone mammals in that they have distinct periods of the year when they are physiologically ready and unready to reproduce. Unlike most temperate-zone mammals, however, they come into reproductive readiness when the photoperiod (hours of light per day) is short or decreasing, rather than long or increasing. Scottish sheep provide the classic example.¹¹ In the spring, the males have small testes and little blood testosterone. Days start to shorten following the summer solstice (about June 21), and as the photoperiod declines, male sheep begin by late summer to exhibit increased testis size and elevated testosterone concentration. Mating occurs between early October and mid-December. With a gestation of about 5 months, the young are born between March and May, when spring conditions prevail. Besides delayed implantation and short-day breeding, a third option for synchronizing the reproductive cycle and seasonal cycle in large mammals is more difficult to document but may in fact be employed by zebras and horses. That option is the specialized evolution of a 12-month placental gestation. The plains zebra has a gestation (without delayed implantation) of almost exactly 12 months, and the wild (Przewalski) horse has a gestation of 11.5 months.

Some large mammals are distinctive among all iteroparous animals in that they are unable to reproduce every year when all the requirements of both prenatal and postnatal development are taken into account. African elephants provide an extreme example. They have a gestation of 22 months—the longest known—and nurse for 3 years. The average time between births is 6–7 years. Some of the large whales have gestations of 1–1.5 years and give birth only every 2–3 years.

SUMMARY The Timing of Reproductive Cycles

- In iteroparous animals that live in environments with regular seasonal cycles, the reproductive cycle is nearly always timed to coordinate with the seasonal cycle of environmental conditions, in at least certain ways. Photoperiod and environmental temperature are the most commonly used environmental cues employed to achieve this coordination. The most dramatic aspect of the coordination is that individuals or populations often become physiologically incapable of reproducing during the most unfavorable time of year (winter).

⁹Individuals in a single population vary substantially in how rigidly they respond to short days by entering a nonreproductive state.

¹⁰The details of the locust description given here are from studies of Japanese populations.

¹¹As discussed earlier, sheep have an endogenous circannual rhythm that controls annual reproductive events. The rhythm is entrained to photoperiod in the prevailing environment in such a way that reproductive readiness is enhanced as photoperiod decreases.

- Sperm storage and embryonic diapause are commonly employed mechanisms that permit certain steps in the reproductive process to be coordinated relatively independently of other steps. Sperm storage uncouples the times of mating and fertilization. Embryonic diapause uncouples the times of fertilization and completion of embryonic development.
- Embryonic diapause in placental mammals is called delayed implantation. It may be obligate or facultative. Obligate delayed implantation is typically employed to create down time so as to adjust the total length of the reproductive cycle to be about 365 days. Facultative delayed implantation in small mammals is typically used to create offsets in developmental timing between litters that a mother is simultaneously nurturing in her uterus and nursing.
- Among small- and medium-sized iteroparous species, a minority reproduce just once per year at highly circumscribed times (e.g., palolo worms, red foxes, some birds). Most go through two or more reproductive cycles per year; among these, there tend to be more cycles per year at mild, low latitudes than at cold, high latitudes because the season that is favorable for reproduction is longer at the mild, low latitudes.
- Large-bodied mammals with gestation periods that are lengthy, yet shorter than 12 months, often employ delayed implantation or short-day breeding to ensure that their young are born at a favorable time of year. The mammals of largest size, such as elephants and large whales, require more than a single year to complete a reproductive cycle.

Sex Change

One of the most intriguing phenomena in animal reproductive biology is that in some species, individuals can change sex during their lifetimes. Teleost fish, gastropod molluscs, and marine annelid worms are the three groups in which this phenomenon is best known. Fertilization is typically external in the species involved; their sex change, therefore, does not require a wholesale alteration of sexual anatomy, such as exchanging a penis for a vagina, or vice versa. However, an individual that has been producing sperm starts to produce eggs instead, or one that has been producing eggs makes sperm. Often, behavior, body coloration, and other secondary sexual characteristics change as well (Figure 17.7).

The formal name for sex change is **sequential hermaphroditism**. A *hermaphrodite* is an individual that produces both eggs and sperm in its lifetime. A *sequential* hermaphrodite produces eggs at one time and sperm at a different time, rather than both together. A sex-changing species is **protandrous**—meaning “man first”—if individuals start as males and later turn into females (*proto*, “first in time”; *andros*, “man”). A species is **protogynous** if individuals start as females and later become males. In some species, an individual can switch back and forth between the two sexes more than once.

Biologists think that sex change has evolved in cases in which *lifetime reproductive output* is maximized by changing sex. Fish species in which males control harems of females provide an instructive illustration. To control a harem, a male must be large so he can ward off other males. If individuals are physiologically and morphologically able to adopt either sex, we can reason that an individual will do best in terms of leaving offspring if it starts its reproductive life as a female; when young and small, it would

be unable to control a harem, and thus would be unable to breed in a consistent way if it were male. When the individual grows large enough to control a harem, however, it will do best in terms of leaving offspring if it is male because then it will be able to mate with many other individuals (an entire harem) rather than being just one female in a crowd of many females. These concepts are believed to explain why many harem-forming species of coral-reef fish have evolved to be protogynous sequential hermaphrodites rather than adopting a single lifelong sex.

Although the physiological regulation of sex change in sequential hermaphrodites is not well known, the endocrine basis of sex change is starting to become clear in some of the protogynous harem-forming fish. Sex steroids, such as estrogens, and some other hormones, such as arginine vasotocin (AVT), are involved. In bluehead wrasse (see Figure 17.7), for example, when a female individual has the opportunity to become the dominant male, she undergoes a very rapid fourfold increase in hypothalamic transcription of mRNA for AVT, and the consequent increase in AVT seems to account for a sharp increase in her expression of male sexual behavior.

(a) Female

(b) Male

FIGURE 17.7 Sex change: A bluehead wrasse (*Thalassoma bifasciatum*) when female and, later, when male Individuals of this species of coral-reef fish are often protogynous sequential hermaphrodites. In this case, an individual starts life as a female (a) but later becomes male (b) if the opportunity arises. (a courtesy of Aaron M. Florn.)

Reproductive Endocrinology of Placental Mammals

Endocrinology is the preeminent topic in the physiological study of reproduction. For exploring reproductive endocrinology in depth, humans and other mammals provide excellent illustrations for several reasons. First, mammalian reproductive endocrinology is the best understood in the animal kingdom and often serves as a model for studies of other animals. Also, of course, we are intrinsically interested in our own reproductive endocrinology, and knowledge of it has important applications, as in contraception. In this section, although our principal focus is on endocrinology—particularly human endocrinology—we will also integrate information on other topics, such as morphology and gamete production, that are essential for a full appreciation of the endocrinology. Most species of mammals are spontaneous ovulators, and in discussing endocrinology in this section, we assume spontaneous ovulation unless stated otherwise.

Females ovulate periodically and exhibit menstrual or estrous cycles

According to the prevailing view of most investigators, female mammals produce all the egg cells—oocytes—they will ever have during their fetal life. A female's total number of egg cells—a crucial factor for her fertility—is thus defined at birth. Recent studies on mice have suggested, to the contrary, that additional egg cells may be produced after birth and into adulthood from germline stem cells; this evidence is still being evaluated. In the fetal ovaries, diploid germ cells called **oogonia** divide repeatedly by mitosis to produce many oogonia. Each of these oogonia undergoes the very first stage of meiosis—during which its chromosomes replicate (see Appendix H)—during fetal life or shortly afterward. The cells are then called **primary oocytes**. Thereafter, the cells remain as primary oocytes, without completing the first meiotic division, until they are ovulated following a female's attainment of reproductive maturity at puberty.

After a female reaches sexual maturity, one or a few of the primary oocytes in her ovaries mature and undergo ovulation—release from the ovaries—during each of her ovulation cycles. Because all the primary oocytes are formed during fetal life, some must remain in the ovaries, awaiting ovulation, for many years in long-lived mammals. Oocytes of elephants and some whales, for example, may remain viable for 60 years! An individual primary oocyte completes its first meiotic division at the time it is ovulated. It will complete its second meiotic division only if it is fertilized.

In most species of mammals that display spontaneous ovulation, females ovulate in cycles until they become pregnant (at which time the pregnancy interrupts the ovulation cycles). Primates such as humans, gorillas, and chimpanzees menstruate in each cycle that does not result in pregnancy; that is, after pregnancy has failed to occur, they shed the uterine lining as a blood-tinged discharge from the vagina. Their cycles are thus called *menstrual cycles*. In other species of mammals, females do not menstruate. Instead, the principal outward manifestation of their ovulation cycles is that they go into estrus (heat) in approximate synchrony with ovulation. As mentioned previously, their cycles are termed *estrous cycles*, and during estrus they use behaviors and other signals, such as pheromones, to indicate that they are sexually receptive. Estrus

lasts, depending on the species, for a few hours to a few days during each cycle. Menstrual and estrous cycles, as indicated, are named for their outward manifestations: menstruation and estrus. An important fact to recognize is that these outward manifestations occur at dramatically different points in the underlying physiological cycles. Whereas estrus occurs at the same time as ovulation, menstruation occurs long after ovulation, when the uterine lining is being shed following a failure of pregnancy to be achieved.

Ovulation occurs in response to a surge of luteinizing hormone (LH) released from the anterior pituitary gland in species of mammals that are spontaneous ovulators, as well as in ones that are induced ovulators. You will recall that in induced ovulators, copulation itself sets in motion the chain of events that culminates in the LH surge (see Figure 17.1). In spontaneous ovulators, the LH surge is produced endogenously in the female (independent of copulation) by a series of interacting endocrine and neuroendocrine events over the course of the menstrual or estrous cycle.

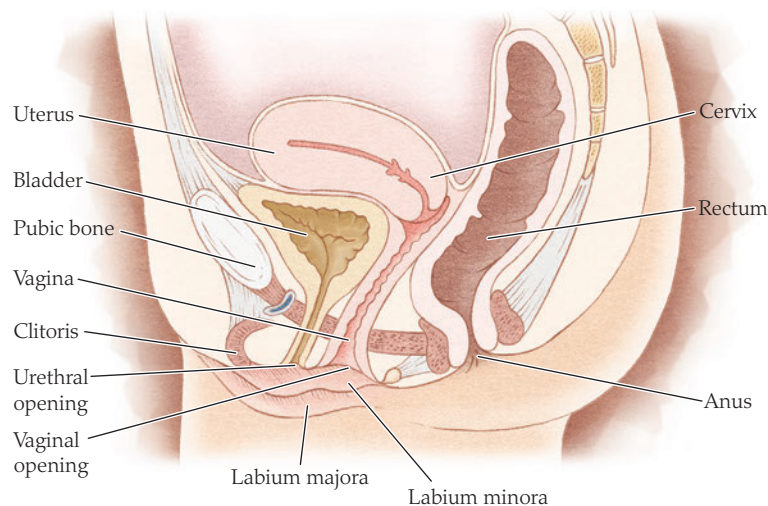

The status of the uterus is modulated during each menstrual or estrous cycle. The inner lining of the uterus is prepared for pregnancy in coordination with ovulation. If pregnancy fails to occur, the lining regresses and then is prepared again in the next menstrual or estrous cycle.

We will use the human menstrual cycle as our common thread in describing the endocrine controls of these processes, while also noting parallel aspects of estrous cycles. In preparation for a full discussion of the human menstrual cycle, we first need to look at the cellular and morphological changes that occur in the ovaries and uterus. **Figure 17.8** shows the anatomy of the human female reproductive system. **Figure 17.9** displays many of the major morphological and endocrinological events in the human menstrual cycle. In Figure 17.9, all four parts (*a–d*) are plotted in relation to a single time axis, shown at the bottom. The beginning of the first day of menstruation is arbitrarily considered to be “day 0” on that axis, and the axis covers 28 days, the average length of a menstrual cycle.¹² As we discuss the cellular and morphological changes in the ovaries and uterus, we will focus on parts (*b*) and (*d*) of the figure. Later, we will consider all four parts of Figure 17.9 together as we integrate all of the events that occur in the menstrual cycle.

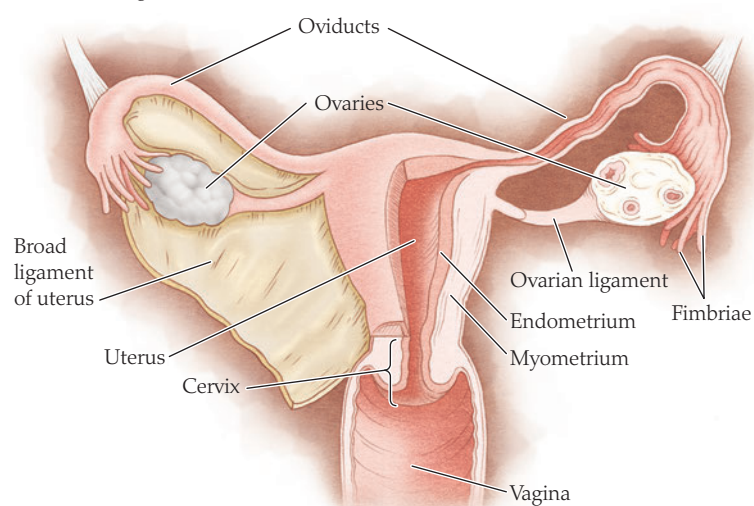

EVENTS IN THE OVARIES Soon after a female is born, each primary oocyte in her ovaries becomes enclosed by a single layer of somatic cells. An oocyte and its layer of somatic cells are then together called a **primordial follicle**. After a female has reached reproductive maturity, a subset of her primordial follicles is recruited to mature further during each menstrual or estrous cycle—a process termed **folliculogenesis**. The part of the menstrual or estrous cycle during which follicles mature is known as the **follicular phase** of the cycle.

Early in the follicular phase, the somatic cells enclosing each recruited primordial follicle become more cuboidal and come to be known as **granulosa cells**. This marks the transformation of the follicle to a **primary follicle**. As further maturation occurs, the primary oocyte increases in size and secretes around itself a noncellular layer of glycoproteins, the **zona pellucida**. In addition, the granulosa cells increase in number and form multiple layers. The next step is maturation into a **secondary follicle** (see Figure

¹²Normal human menstrual cycles are 21–42 days long, and normal menstrual periods last 2–8 days.

(b) Internal organs (frontal view)

(c) Ovary

17.8c). In this process, a fluid-filled cavity, the *antrum*, opens up within the layers of granulosa cells. Moreover, connective tissue at the outer margin of the granulosa cells differentiates into a layer of **theca cells**.¹³

Although many follicles begin to mature in the ovaries at the start of each follicular phase, only some of the follicles attain full

¹³ Although maturation to the secondary follicle stage requires follicle-stimulating hormone (FSH) and LH, development to the primary follicle stage is not believed to require hormonal support and therefore can occur without FSH and LH.

FIGURE 17.8 The human female reproductive system The female reproductive system includes (a) the external genitalia and (a, b) the internal organs. The external genitalia are collectively called the *vulva* and consist of the *labia majora*, *labia minora*, and *clitoris*. The oviducts are sometimes called *fallopian tubes*. (c) An ovary, showing the developmental stages of follicles and corpora lutea. Each ovary is about 2–4 cm long. At any one time, it contains follicles and corpora lutea in various stages of development. In this diagram, the earliest stages are shown at the upper left, and successively more mature stages are depicted in order in a clockwise loop. This arrangement is for pedagogical purposes only, however: All the stages can in fact be found throughout the ovary.

maturity. In species that ordinarily give birth to a single offspring, such as humans, just one *dominant follicle* matures fully in most menstrual or estrous cycles. That follicle grows to be especially large by mitotic proliferation of its granulosa and theca cells and expansion of the fluid-filled antrum. Ultimately, when the follicular phase of the cycle ends with the LH surge, the oocyte of this dominant follicle will complete its first meiotic division (a division that began when the female was a fetus in her mother's uterus); one of the daughter cells produced by this division will receive almost all the cytoplasm and will become the **secondary oocyte** that will be fertilized if mating is successful (see Appendix H). When the follicle is fully developed, it is known as a **mature, Graafian, or preovulatory follicle**. It becomes positioned just under the outer epithelium of the ovary and bulges outward into the space surrounding the ovary (see Figure 17.2d). In humans, whereas a late primary follicle is only about 0.02 cm in diameter, a fully mature follicle is 1.5–2.0 cm in diameter! All the other follicles that initiated maturation at the start of the follicular phase—that is, all those except the single dominant one—degenerate by a process of programmed cell death termed **atresia**.¹⁴ In species of mammals that normally give birth to litters of multiple offspring, atresia also occurs, but multiple follicles develop to full maturity and undergo ovulation.

During the maturation of a follicle, two-way communication between the oocyte and the granulosa cells coordinates the follicle's development. The oocyte and its nearest granulosa cells make cytoplasmic connections across the zona pellucida by means of gap junctions. Both types of cells also secrete paracrine agents. The granulosa cells provide signals and nutrients that support the oocyte's development and influence which oocyte genes are expressed. The oocyte, in turn, paces follicular development and sends signals that stimulate granulosa proliferation.

When the LH surge activates the process of ovulation, enzymes secreted by the fully mature follicle break down the thin layer of overlying ovarian epithelium and the juxtaposed follicular wall. Antral fluid pours out of the ruptured follicle into the space surrounding the ovary, carrying with it the oocyte surrounded by the zona pellucida and attached granulosa cells (see Figure 17.8c).

Fertilization of an ovulated oocyte, if it occurs, normally takes place in the oviducts (also called the fallopian tubes). Each ovary is positioned near the opening of an oviduct (see Figure 17.8b), and oocytes released from the ovary are swept into the opening, as by ciliary action.

¹⁴ A human female has 200,000–400,000 primary oocytes in her ovaries at the time of puberty. Over her lifetime, only about 400 of these oocytes will mature and be ovulated. The rest will be lost through the atresia that occurs in each menstrual cycle.

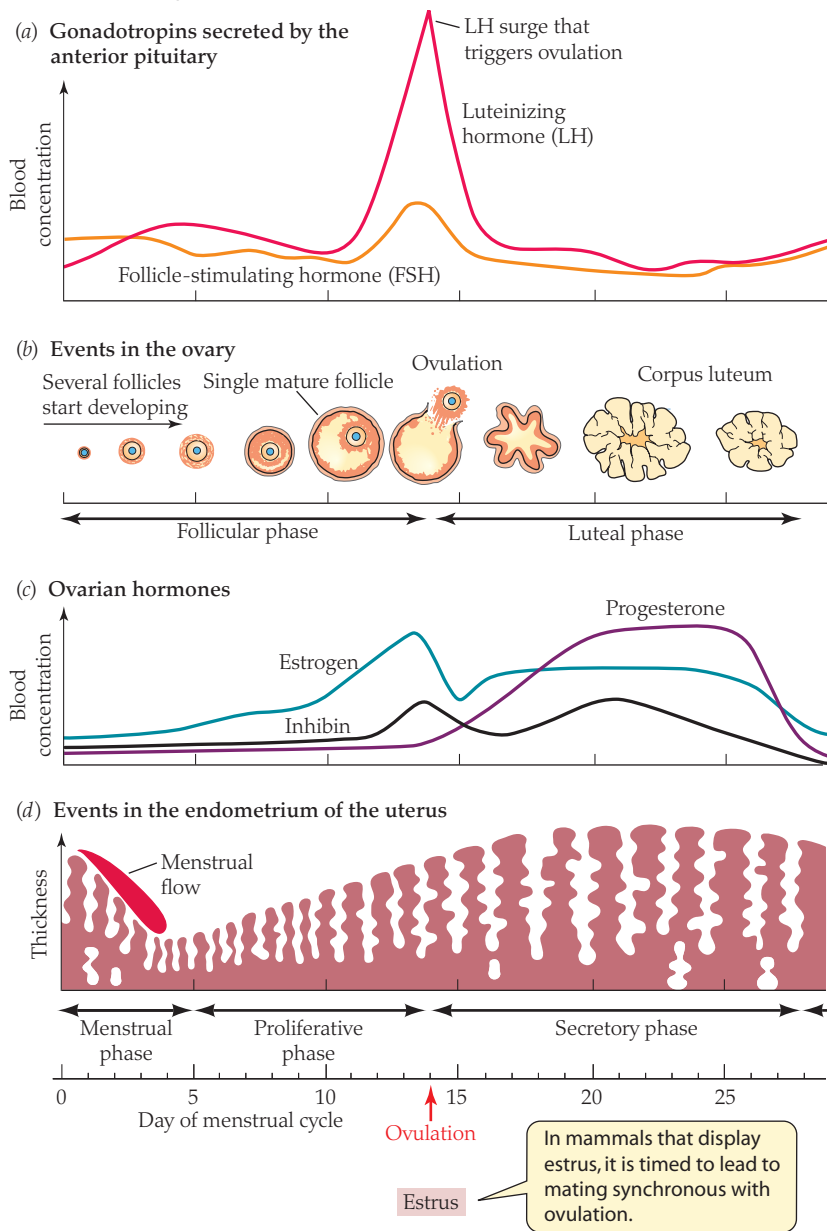

FIGURE 17.9 A synoptic view of events in the human female reproductive cycle The blood concentrations of (a) anterior pituitary hormones and (c) ovarian hormones vary in relation to cellular changes in (b) the ovaries and (d) the uterus in a highly orchestrated way. All four parts of this figure are plotted in relation to a single time axis (at the bottom), with the first day of menstruation considered to be “day 0.” In mammals with estrous cycles, events are basically similar, although there are many differences of detail. In such animals, as shown at the bottom of the figure, estrus (heat) is coordinated to occur synchronously with ovulation; this coordination is achieved by effects of estrogen (see part c) and other hormones on brain function. Estrus lasts from a few hours to a few days, depending on the type of mammal, whereas ovulation occurs at a single point in time. Note that menstruation and estrus—the outward manifestations of menstrual and estrous cycles—occur at dramatically different times of the underlying physiological cycle; menstruation occurs roughly halfway between one ovulation and the next, whereas estrus occurs when ovulation occurs.

In the ovary, ovulation marks the end of the follicular phase and the start of the **luteal phase**. The cells of the ruptured mature follicle within the ovary reorganize through proliferation, vascularization, and other processes to form a structure called the **corpus luteum** (plural

corpora lutea) (see Figure 17.8c). If the oocyte in the oviduct is not fertilized, the corpus luteum—known as a **corpus luteum of the cycle**—secretes hormones for a finite time and then degenerates. In humans a corpus luteum of the cycle functions for about 10 days and then starts to regress; in the average cycle, the luteal phase ends on day 28, when the corpus luteum stops functioning entirely. If fertilization occurs, the corpus luteum—known as a **corpus luteum of pregnancy**—grows even further and continues to secrete hormones that are essential for establishing and maintaining pregnancy. In some types of mammals, such as many rodents, the luteal phase is highly attenuated because the corpus luteum of the cycle is very short-lived.

As already suggested, both follicles and corpora lutea are endocrine structures. In fact, when we speak of “ovarian hormones,” we are really speaking of secretions of the follicles and corpora lutea.

EVENTS IN THE UTERUS The glandular, epithelial lining of the uterus, known as the **endometrium** (see Figure 17.8b), cyclically prepares for pregnancy, and then, if pregnancy fails to occur, reverts to an unprepared state (see Figure 17.9d), as already mentioned. In mammals with menstrual cycles—namely, humans and some other primates—the endometrium sloughs off during menstruation and then regrows as the uterus prepares again for pregnancy. In species of mammals with estrous cycles, the endometrium is not sloughed off but is simply resorbed.

The ways in which the phases of the uterine cycle in humans relate to the phases of the ovarian cycle are seen in Figure 17.9 (compare parts *b* and *d*). The **menstrual phase** of the uterine cycle, lasting about 5 days, is the part when sloughing occurs. It is followed by the **proliferative phase**, during which the endometrium undergoes rapid thickening—from about 1 mm thick to 3–5 mm thick—and redevelops glands and circulatory vascularization. These uterine phases occur simultaneously with the follicular phase in the ovaries. The uterine proliferative phase is synchronized to reach completion approximately when ovulation occurs. The uterus then enters its **secretory phase**, which overlaps with the ovarian luteal phase. In the secretory phase, the endometrium matures to the point that it is fully ready to accept implantation of an embryo and provide the embryo with nutritive support during its early postimplantation development. Implantation occurs about midway through the secretory phase if the egg that is ovulated is fertilized.

ENDOCRINE CONTROL OF THE FOLLICULAR PHASE Menstrual and estrous cycles are orchestrated by neurohormones released from the brain and by hormones released from the anterior pituitary gland and ovaries. To understand the human menstrual cycle, we need to follow events occurring over time at four different sites in the body: the hypothalamus, anterior pituitary gland, ovaries, and uterus. Figure 17.9 synthesizes many of the major endocrinological events and shows how they synchronize with cellular and morphological events. For convenience, we divide our discussion into three sections, this one on the follicular phase and the next two on ovulation and the luteal phase.

Two gonadotropic hormones (gonadotropins) secreted by the anterior pituitary gland play major roles in controlling menstrual and estrous cycles: **luteinizing hormone (LH)** and **follicle-stimulating**

hormone (FSH). The secretion of LH and FSH is controlled by **gonadotropin-releasing hormone (GnRH)**, a neurohormone released by GnRH-secreting neuroendocrine cells in the hypothalamus of the brain (see Appendix K), and by hormones—discussed later—secreted by the ovaries. The GnRH-secreting cells—which receive and integrate a variety of neural and neuroendocrine inputs—generate bursts of action potentials roughly every 1.5 h (with some variation depending on the phase of the menstrual or estrous cycle), and these bursts lead to synchronous release of GnRH by means of exocytosis. Accordingly, GnRH is secreted in pulses.¹⁵ The pulses of GnRH are carried by blood flow in the hypothalamo–hypophysial portal system to the anterior pituitary gland (see Figure 16.7). There they stimulate the secretion of LH and FSH in pulses.

The GnRH-secreting neuroendocrine cells in the hypothalamus are influenced by many factors and in many ways serve as the final, integrative communication path for multiple inputs affecting reproductive physiology—inputs that converge on those cells. Malnutrition or stress, for example, can impair GnRH secretion (and therefore reproduction). In seasonal breeders, environmental signals such as photoperiod—integrated by the nervous system—often affect a female’s reproductive status by influencing the pulsatile activity of the GnRH-secreting cells. **Kisspeptin neurons** in the forebrain—relatively recently discovered—play critical roles in the control of the GnRH-secreting cells. Because kisspeptin neurons have receptors for steroid hormones, they can respond to steroid (e.g., estrogen) signals,

¹⁵The rate and amplitude of the pulsed release are important factors in determining the actions of GnRH. The pulsed pattern is in itself highly significant in that artificially induced steady release of GnRH leads, in many circumstances, to strong suppression of LH and FSH secretion (see page xxx in Chapter 16).

and they possibly represent the principal pathway by which the GnRH-secreting neurons are affected by steroid signals. Kisspeptin neurons act on the GnRH-secreting cells by secretion of **kisspeptin**, a peptide that acts—sometimes at exceedingly low concentrations—as an excitatory signal to the GnRH-secreting cells. Although we will discuss kisspeptin neurons chiefly in relation to the menstrual and estrous cycles, they are also critically involved in controlling the early stages of puberty. The recent discovery that kisspeptin neurons help control early puberty is exciting because the mechanism of puberty initiation remains unknown and represents one of the great remaining mysteries in the study of the life cycle.

During the follicular phase of the ovarian cycle, as seen in Figure 17.9a, blood concentrations of LH and FSH remain relatively flat until a few days before ovulation. Then they increase dramatically, peaking at the time of ovulation. As the blood concentrations of LH and FSH rise, both hormones act on the follicles developing in the ovaries. The initial target of LH in each maturing follicle is the layer of theca cells that encloses the follicle. FSH acts on the granulosa cells. These two target tissues, working in concert, result in secretion of the steroid hormone **estrogen** by the follicles (we use the generic term *estrogen* for simplicity, although in fact two or more chemically specific estrogens are produced, the principal one being *estradiol*). As outlined in Figure 17.10, when LH binds to receptors on the cell membranes of the theca cells, those cells are stimulated to produce androgens. The androgens diffuse through the theca cell membranes to the nearby granulosa cells. The binding of FSH to receptors on the cell membranes of the granulosa cells stimulates the action of the enzyme **aromatase**, which converts the androgens into estrogen by a chemical process termed **aromatization** (see Figure 16.2). The granulosa and theca cells “need each other” to synthesize estrogen because only the theca cells can

synthesize the androgens that are the precursors of estrogen, but only the granulosa cells can produce aromatase, which is required to convert androgens to estrogen.

Blood levels of estrogen increase slowly during the early stages of follicular development, then rise dramatically prior to ovulation (see Figure 17.9c). Estrogen itself plays a role in this increase by acting locally as a paracrine/autocrine agent within the ovary. In combination with FSH and growth factors, estrogen stimulates the proliferation of granulosa cells. This is a classic example of *positive feedback* (see Box 1.1) in that estrogen produced by the granulosa cells stimulates mitotic multiplication of the granulosa cells themselves, and then as the cells increase in number, they produce increasing amounts of estrogen, a process that supports their continued proliferation.

The granulosa cells of the developing follicles change in their ability to respond to LH

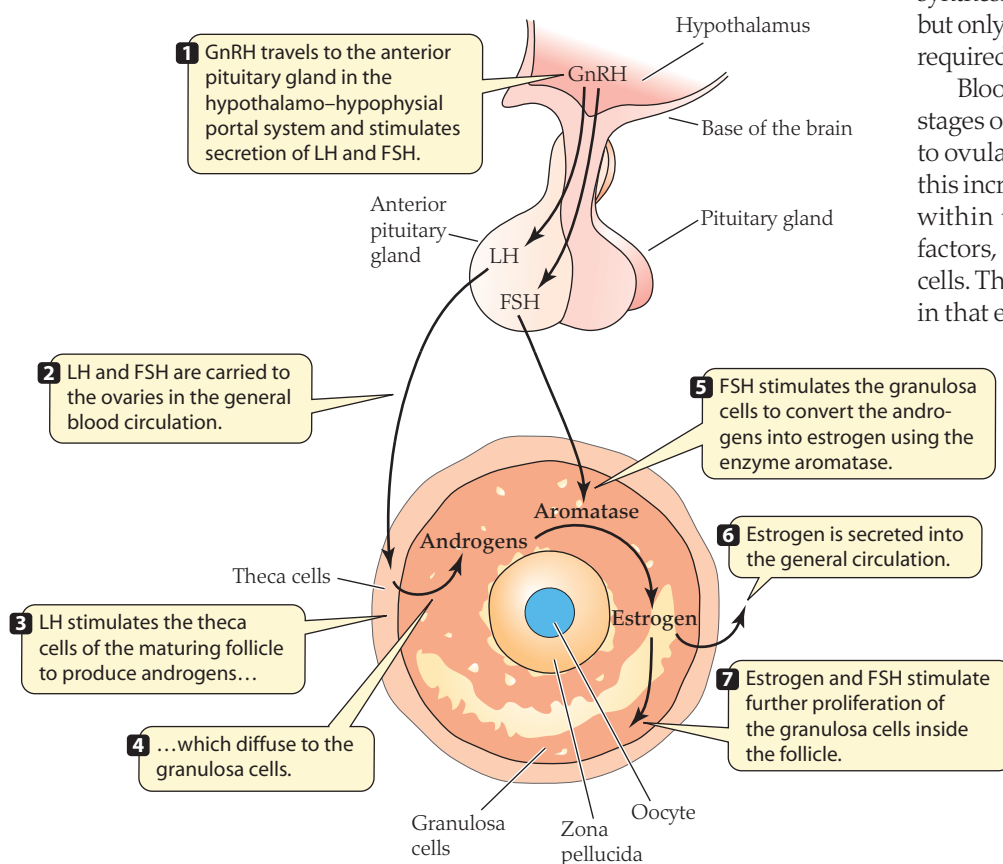

FIGURE 17.10 Hormonal control of estrogen production and secretion by an ovarian follicle

The top of this diagram shows the base of the brain and the pituitary gland (see Figure 16.7b). The bottom shows a maturing follicle in the ovary. Estrogen (principally estradiol) is synthesized and secreted by each such follicle. Estrogen synthesis by a follicle requires both LH and FSH and entails a cooperative function of the theca and granulosa cells.

as they mature. Although they do not possess receptors for LH during the early part of follicular development, the granulosa cells of dominant follicles later produce LH receptors and incorporate them into their cell membranes. The LH receptors of the mature granulosa cells permit these cells to respond to the surge of LH that triggers ovulation.

The estrogen secreted by the follicles affects the anterior pituitary gland and probably the hypothalamus. The effects of estrogen on these structures depend on its concentration in the blood. During early follicular development, when blood estrogen levels are low, estrogen exerts a negative feedback effect that keeps blood levels of LH and FSH low. During late follicular development, however, estrogen (now at a high blood concentration) causes increased secretion of LH and FSH by the gonadotropin-secreting cells in the anterior pituitary, and it also—in most studied species—causes increased GnRH secretion by the GnRH-secreting neuroendocrine cells in the hypothalamus. This effect on GnRH secretion is mediated by kisspeptin neurons; current evidence indicates that high levels of estrogen stimulate kisspeptin neurons to deliver excitatory signals to the GnRH-secreting cells to increase their secretion of GnRH. The increased GnRH secretion, combined with the enhanced secretory capability of the pituitary gonadotropin-secreting cells that respond to GnRH, culminates in a huge output of LH—the LH surge—that triggers ovulation.

In addition to its effect on the anterior pituitary and hypothalamus, estrogen stimulates growth of the endometrium of the uterus by binding with specific receptors in the endometrial cells. Indeed, the rise in blood levels of estrogen during late follicular development in the ovary (see Figure 17.9c) is responsible for the proliferative phase of the uterus (see Figure 17.9d). Among its many effects, estrogen stimulates the endometrial cells to produce receptor molecules for **progesterone**, another steroid hormone, in preparation for events that occur after ovulation.

During the final part of the follicular phase, the granulosa cells of dominant follicles increase their secretion of **inhibin**, a hormone that inhibits FSH secretion from the anterior pituitary. The first section of **Table 17.1** summarizes the cells and hormones that are active during the follicular phase.

ENDOCRINE CONTROL OF OVULATION When the anterior pituitary gland secretes LH in amounts sufficient to produce the surge in blood LH concentration (see Figure 17.9a), the LH exerts multiple effects on the granulosa cells of the dominant follicle (or follicles) that bring about dramatic events within hours. LH causes the granulosa cells to secrete chemical mediators that induce the oocyte to complete its first meiotic division (see Appendix H). LH also causes the granulosa cells to begin secreting progesterone, decrease their secretion of estrogen, and release enzymes and prostaglandins that lead to breakdown of the outer follicular membranes and overlying ovarian epithelium. As the membranes and epithelium rupture, antral fluid and the oocyte are released from the ovary. Finally, LH initiates morphological and biochemical changes in the remaining granulosa cells and theca cells, causing them to transform into a corpus luteum.¹⁶

¹⁶The transformation of the residual follicle into a corpus luteum was named *luteinization* in the early study of endocrinology. This explains why the hormone that promotes the transformation was named *luteinizing hormone*. *Lutein* refers to yellow pigment. A corpus luteum is yellow in some cases, explaining why its formation was called luteinization and why it was given the name “yellow body.”

ENDOCRINE CONTROL OF THE LUTEAL PHASE After the LH surge is over, the newly formed corpus luteum begins to function. At this time the anterior pituitary gland secretes a low level of LH, which maintains the corpus luteum. The corpus luteum secretes progesterone, estrogen, and inhibin, and during the middle of the luteal phase, blood levels of these hormones increase, peaking in association with maximal endometrial thickness (see Figure 17.9c). Progesterone is the major hormone secreted by the corpus luteum and rises to a particularly high blood concentration in the luteal phase. Progesterone and estrogen, acting in concert, exert negative feedback on the anterior pituitary (and probably the hypothalamus) to keep GnRH, LH, and FSH secretions low. Inhibin also suppresses FSH secretion.

In primates, development of new follicles is greatly suppressed during the luteal phase, mediated in part by the low blood levels of LH and FSH that exist during that phase. In some other mammals, folliculogenesis can occur in all phases of the cycle but is reduced during the luteal phase.

The corpus luteum is essential for establishing conditions that permit implantation and pregnancy. Progesterone secreted by the corpus luteum in the luteal phase is especially important in preparing the uterus for implantation. The endometrial lining of the uterus is able to respond to progesterone at this time because of the process noted earlier, that estrogen secreted in the follicular phase stimulated the endometrium to synthesize progesterone receptors. Stimulated by progesterone, the exocrine glands of the endometrium secrete glycogen and enzymes, and additional blood vessels develop in the endometrium. The thickened and secretory endometrium is poised to support implantation and nourishment of an embryo¹⁷ if fertilization occurs. Progesterone also inhibits contractions of smooth muscle cells in the walls of the uterus and oviducts. The second part of Table 17.1 summarizes the hormones that are active during the part of the cycle dominated by the corpus luteum.

In primates (although not all mammals), the cells of the corpus luteum have a limited life span in the absence of pregnancy. If pregnancy occurs, the embryo, in many mammal species, provides a hormonal or paracrine signal that rescues the corpus luteum by preventing its degeneration, as detailed in the discussion of pregnancy. However, if pregnancy does not occur, the luteal cells stop secreting hormones and degenerate. This process is completed within about 14 days after ovulation in humans, as mentioned earlier.

One important effect of the degeneration of the corpus luteum is that it sets the stage for a new cycle of folliculogenesis. Without a functional corpus luteum, blood concentrations of progesterone, estrogen, and inhibin decrease to the low levels that characterize the end of the luteal phase and the start of the follicular phase (see Figure 17.9c). The hypothalamus and anterior pituitary gland are thereby freed of negative feedback, so that secretion of LH and FSH can rise again, initiating another round of follicular development in the ovaries.

Another important effect of the degeneration of the corpus luteum occurs in the uterus: The endometrium—because it is no longer supported by luteal hormones—is resorbed or, in species that menstruate, sloughed off. In mammals that menstruate, the endometrium responds to the loss of luteal hormones by secreting prostaglandins, which initiate deterioration of its superficial

¹⁷A developing mammal starts to be termed an *embryo* at about the time it implants in the endometrium and is considered to be an embryo thereafter. In medical terminology, a human is an *embryo* from implantation to the end of the eighth week of pregnancy, and a *fetus* from the ninth week until birth.

TABLE 17.1 Endocrine and neuroendocrine cells and the major secretions involved in ovarian cycles and pregnancy in female mammals, emphasizing humans

Cells	Hormone	Action
Follicular phase		
Hypothalamic GnRH cells	GnRH	Stimulates secretion of FSH and LH from anterior pituitary cells
Anterior pituitary gonadotropin cells	LH	Stimulates theca cells to secrete androgens during the follicular phase Surge of LH triggers final maturation of the oocyte and ovulation Following ovulation, LH initiates transformation of follicle cells to the corpus luteum
	FSH	Stimulates aromatase action in granulosa cells to convert androgens to estrogen
Theca cells of ovarian follicle	Androgens	Diffuse from theca cells to granulosa cells for conversion to estrogen
Granulosa cells of ovarian follicle	Estrogen (principally estradiol)	Acting together with FSH, stimulates proliferation of granulosa cells At low concentrations, has a negative feedback effect on the anterior pituitary (and possibly the hypothalamus), keeping FSH and LH secretions low At high concentrations, has a positive feedback effect on the anterior pituitary and often the hypothalamus, promoting the LH surge Promotes estrous behavior in species that exhibit estrus Promotes growth of endometrium and development of endometrial progesterone receptors
	Inhibin	Inhibits FSH secretion
Luteal phase		
Corpus luteum cells	Progesterone (the dominant secretion)	Causes endometrium to become secretory; promotes relaxation of uterine and oviduct smooth muscles
	Estrogen	Acting together with progesterone, reduces secretion of FSH and LH from the anterior pituitary; thereby greatly suppresses folliculogenesis in primates and slows folliculogenesis in other mammals
	Inhibin	Inhibits FSH secretion
Pregnancy		
Placental cells	Chorionic gonadotropin	Secreted by embryonic placental cells in primates and horses, in which it rescues the corpus luteum and ensures the maintained function of the corpus luteum
	Progesterone	Opposes stimulatory effect of estrogen on uterine smooth muscle until late in pregnancy Stimulates secretion of prolactin from the anterior pituitary Acting together with estrogen and prolactin, promotes growth of mammary glands
	Estrogen	Acting together with progesterone and prolactin, promotes growth and development of mammary glands Acting together with progesterone, prevents milk secretion by mammary glands Prepares the uterine smooth muscle for parturition by promoting production of oxytocin receptors and synthesis of connexins that form gap junctions between muscle cells Stimulates enzymatic breakdown of cervical collagen fibers, thereby softening the cervix
	Lactogen (chorionic somato-mammotropin)	Alters maternal glucose and fatty acid metabolism to shunt glucose and fatty acids to the fetus; may contribute to development of capacity for lactation

layers. The prostaglandins cause constriction of the uterine blood vessels and contraction of the myometrium, the smooth muscle in the uterine wall. The closing off of the blood supply prevents O₂ and nutrients from reaching the cells in the endometrium, and the cells begin to die. The superficial layers of cells are then lost in menstrual flow, leaving just the thin base of the endometrium to start the next cycle. The uterine blood vessels dilate following their initial constriction. The increased blood flow then causes the walls of weakened capillaries to break, and bleeding occurs. Menstrual flow is thus a mixture of sloughed-off endometrial cells and blood.

Males produce sperm continually during the reproductive season

The anatomy of the human male reproductive system ([Figure 17.11](#)) is typical of the general pattern of organization seen throughout the eutherian mammals. The penis contains the urethra, which allows the passage of urine during urination and semen during ejaculation.

THE TESTES AND PRODUCTION OF SPERM The paired **testes** (testicles), responsible for sperm and hormone production, are contained in the **scrotum**, a sac that suspends the testes outside

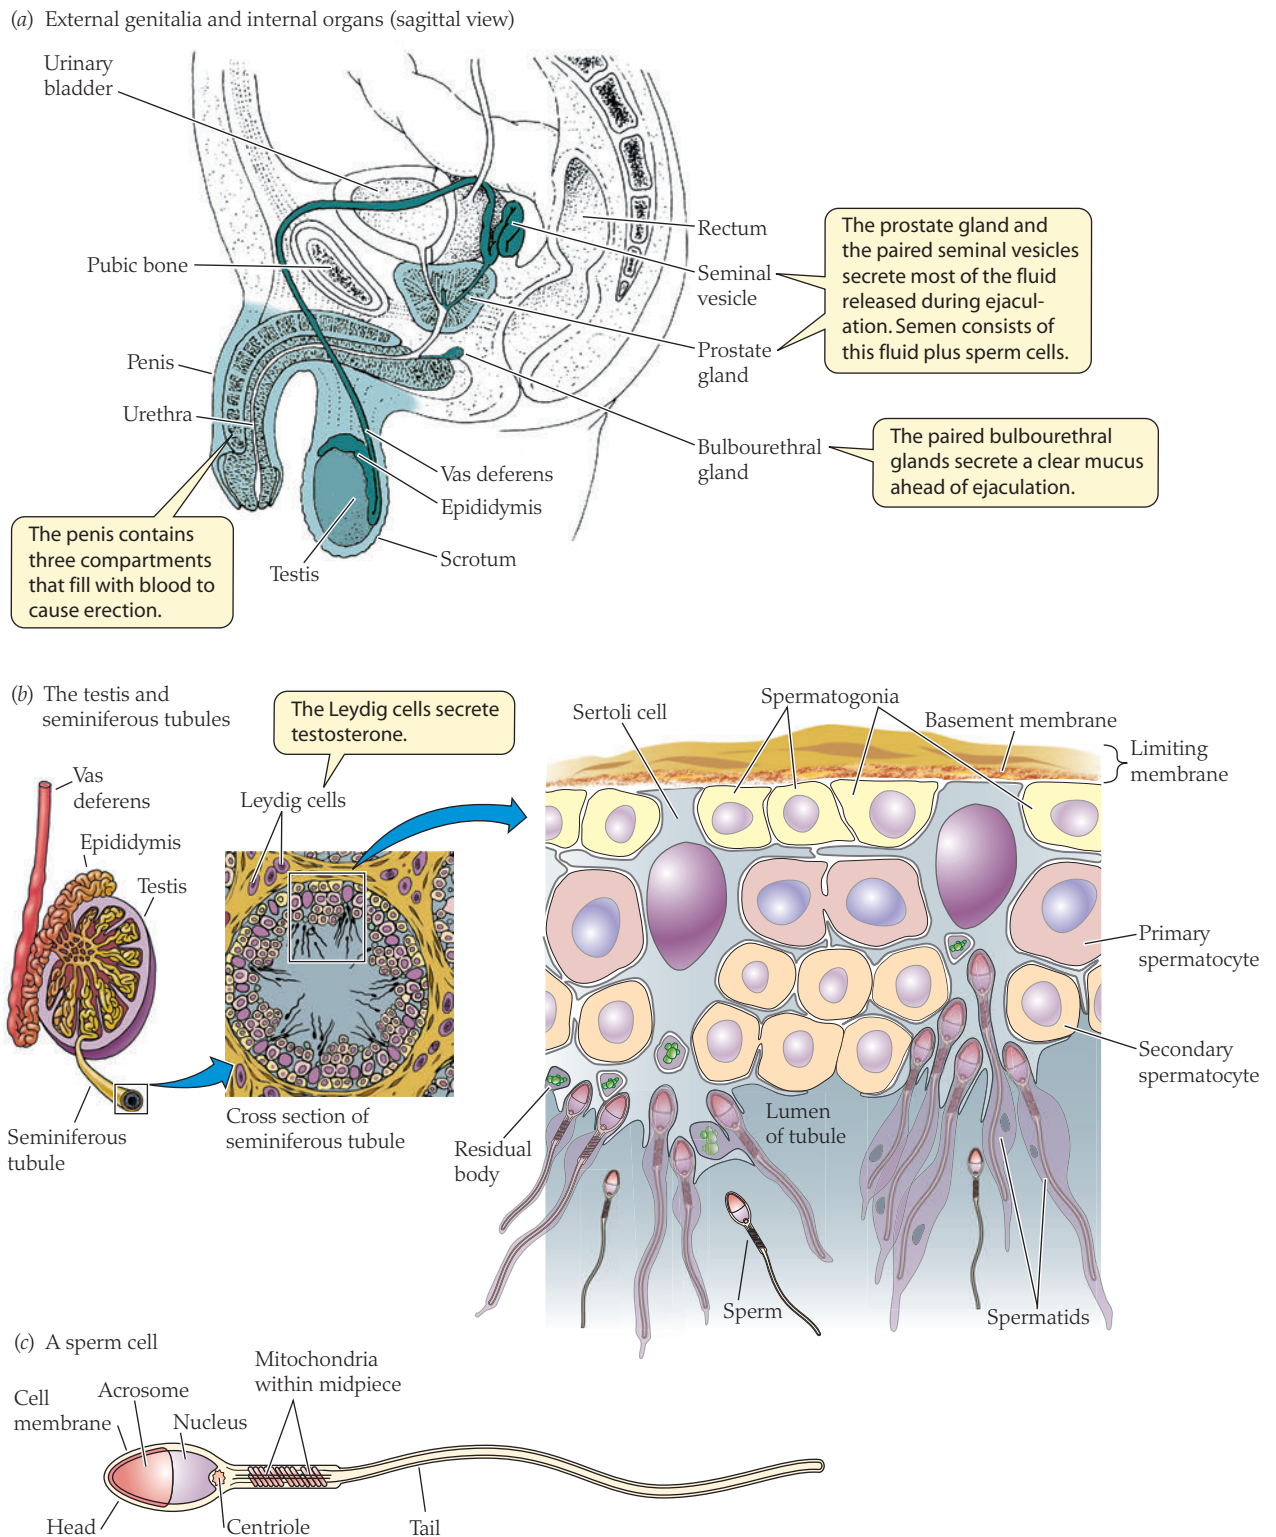

FIGURE 17.11 The human male reproductive system (a) The male reproductive system, colored various shades of blue in this diagram, consists of the external genitalia (penis and scrotum), the testes, ducts such as the vas deferens on each side of the body, and the accessory glands (a single prostate gland, paired seminal vesicles, and paired bulbourethral glands). The urethra is colored white to symbolize that its function is only partly reproductive, inasmuch as it conveys both urine and semen to the outside. (b) Each testis is divided into 200–300 compartments containing coiled seminiferous tubules that are continuous with the epididymis and vas deferens. Each seminiferous tubule, which

is bounded by a basement membrane, consists of a single layer of Sertoli cells interspersed with sperm-producing cells at various stages of development. Leydig cells occur in the connective tissue that fills the spaces between adjacent seminiferous tubules. In the development of sperm, spermatogonia develop into primary spermatocytes, then secondary spermatocytes, then spermatids, and finally sperm. (c) A mature sperm cell possesses a nucleus with a haploid set of chromosomes, a flagellum tail for motility, mitochondria that produce ATP, and an acrosome, which contains enzymes that help the sperm penetrate to the egg during the process leading to fertilization.

the body cavity. Most mammals exhibit this condition. In human males, the testes are normally in the scrotum all the time. In many other species, such as certain mice, the testes are in the scrotum only in the reproductive season, being drawn inside the abdomen at other times. All tissues are susceptible to heat damage if their temperature goes high enough. The testes of most mammals are unusual in that they are damaged by exposure to ordinary abdominal temperature (37°C). The testes need to be about 2°C cooler than that for normal production of viable sperm, and being in the scrotum permits this. Why the testes require a relatively low temperature remains a mystery. The testes are internal in dolphins, whales, and seals but are believed to be kept cooler than most internal tissues in those species by specialized arrays of arteries and veins supplied with blood that has been cooled by flowing through vessels close to the body surface.¹⁸ The testes are also internal in elephants, hyraxes, and elephant shrews, and in those species they might function at abdominal temperature.

Sperm are produced in coiled **seminiferous tubules** (see Figure 17.11*b*). The seminiferous tubules of a testis merge to join a coiled tube, the **epididymis**, located next to the testis within the scrotum. The epididymis becomes continuous with the **vas deferens**, which empties into the urethra. In cross section (see Figure 17.11*b*), one can see that the internal structure of each seminiferous tubule is composed of sperm-producing cells in various stages of development, plus a single layer of critically important somatic cells, the **Sertoli cells**, which support and regulate the production of sperm. The seminiferous tubules account for about 85% of testis volume, and the Sertoli cells account for much of the tissue volume of the seminiferous tubules. Sertoli cells multiply during puberty, but their number in an adult is generally considered to be fixed. Strong correlations exist between the number of Sertoli cells and both testis size and the rate of sperm production. Connective tissue fills the spaces between the seminiferous tubules. **Leydig cells** (also called **interstitial cells**) located in the connective tissue secrete the androgen **testosterone**.

ENDOCRINE CONTROL IN MALES The Leydig cells exhibit a fascinating lifetime pattern of testosterone secretion, which we will discuss using the human male as an example (Figure 17.12). The Leydig cells secrete testosterone in abundance during the first trimester of embryonic life, when the hormone plays a key role in sexual differentiation of the penis, scrotum, seminal vesicles, and other male structures (Box 17.2). By the 12th to 14th week after conception, the form of the genitalia is determined, and soon the Leydig cells become less active for the remainder of uterine life. They then secrete testosterone in abundance following birth. The function of this episode of secretion, which peaks at about 1 month after birth, is uncertain. The Leydig cells then become quiescent, in this case for more than a decade, until puberty starts and blood testosterone rises again. Thereafter, testosterone secretion remains high throughout life, although it declines gradually after middle age.

In adult testes, the production of testosterone is controlled by pituitary gonadotropins, and the production of sperm is controlled

FIGURE 17.12 Testosterone secretion and sperm production during the life span of human males. Note that the time scale is not even. (After Troen and Oshima 1981.)

by both the gonadotropins and testosterone. The brain and pituitary hormones involved are the same as those in females. GnRH is released from the hypothalamus (in pulses), and FSH and LH are secreted from the anterior pituitary gland. The Leydig cells are the target tissue of LH, which binds to receptors on the cell membranes and stimulates the cells to produce and secrete testosterone. The Sertoli cells are the target tissue of FSH and also are influenced by testosterone from the Leydig cells. Both testosterone and FSH, acting indirectly through effects on Sertoli cells, play roles in stimulating spermatogenesis (production of sperm), although the importance of FSH in spermatogenesis varies among species of mammals; whereas testosterone is essential for spermatogenesis, in humans FSH plays more of an augmenting role and is not absolutely required for sperm production (although one or more pituitary agents are required inasmuch as pituitary removal stops spermatogenesis). Besides paracrine substances that promote the proliferation and differentiation of sperm, the Sertoli cells secrete several additional substances, including (1) products that nourish the developing sperm; (2) inhibin, which inhibits FSH secretion from the anterior pituitary; and (3) fluid that fills the lumens of the seminiferous tubules. This fluid contains **androgen-binding protein** that binds testosterone and thereby keeps the hormone at a high concentration within the lumens of the tubules. Table 17.2 summarizes the cells and hormones that are active in male reproduction.

Testosterone secreted into the general circulation is responsible for masculinizing many tissues. At puberty, for example, it promotes growth of the penis and testes, deepening of the voice, and growth of facial hair. It contributes to an adolescent growth spurt in muscle mass in boys and to muscular strength throughout life.

Negative feedback effects of testosterone and inhibin on the anterior pituitary and hypothalamus keep FSH and LH secretions relatively low and steady from day to day in males. This pattern

¹⁸ Countercurrent heat exchange (see page 237[2E]) occurs in these arrays of arteries and veins. The venous blood flowing through the arrays comes from the body surface, where it is cooled. By virtue of the countercurrent exchange, arterial blood flowing toward the testes is efficiently cooled, prior to reaching the testes, by losing heat to the venous blood.

BOX 17.2 SEX DETERMINATION AND DIFFERENTIATION, EMPHASIZING MAMMALS

Animals use a variety of mechanisms to determine the sex of an individual. Sometimes, the sex of an individual is not hardwired by genes, but instead, environmental factors play major roles in sex determination. We have seen two examples earlier in this chapter: sex change based on harem formation or other social factors in certain fish, and determination of sex by the body temperature prevailing during embryonic development in sea turtles and some other nonavian reptiles. In mammals, sex is determined genetically.

The external genital structures of a mammalian embryo are said to be **indifferent** during early development because they have the potential to differentiate into either male or female structures. The indifferent state is illustrated in a 4-week-old human embryo at the top of the figure. As the gonads develop (as discussed in **Box Extension 17.2**), if they are testes, the **genital tubercle** is hormonally signaled to develop into the glans (“head”) of the penis, the **labioscrotal swellings** are signaled to develop into the scrotum, and the other primordia form male structures as well. If the gonads develop into ovaries, all these structures differentiate into female external genitalia. For example, the genital tubercle becomes the glans of the clitoris, and the labioscrotal swellings become the labia majora (see Figure 17.8a).

The gonads are also indifferent early in the development of a mammalian embryo: They can become either testes or ovaries. The indifferent gonads are positioned in the mid-abdomen. The gonads stay there throughout development in females. In males of most species of mammals, the gonads migrate away from their initial position as gestation proceeds, so that at birth they are either in the scrotum (as in humans) or poised to enter the scrotum.

Box Extension 17.2 discusses the sexual differentiation of internal structures at greater length. It also discusses the genetic and endocrine mechanisms that control sexual differentiation.

Differentiation of the external genitalia Colors are used to identify homologous tissues. For example, the tissue labeled yellow is of the same developmental origin in all five drawings. In early development—as typified by a human embryo at 4 weeks of developmental age (seen at the top)—the external genital structures are identical regardless of an individual’s sex. In male embryos (XY), secretion of testosterone by the gonads when they differentiate causes the external genitalia to differentiate to become male in form, starting after the seventh week of gestation in humans. Without testosterone, the genitalia become female in form. The external genitalia can be definitively distinguished as male or female at about the twelfth week of human gestation.

contrasts with the dramatic cycles of anterior pituitary (and ovarian) secretions seen in females (see Figure 17.9). The relatively constant levels of hormones in males sustain continuous production of sperm. Whereas this constancy of hormone concentrations and sperm production prevails throughout the year in adult human males, it prevails only in the reproductive season in seasonal breeders. In the many species of mammals that cease reproduction for part of the year, hormonal changes are instrumental in shutting down and later reactivating sperm production.

ERECTION AND EJACULATION The shaft of the human penis is filled almost entirely by three compartments of spongy tissue that can be expanded with blood. Erection entails inflating these compartments with blood until the penis is stiff. In males of several types of mammals, such as bats and carnivores, the penis contains a bone—the baculum—that helps provide stiffness for copulation.

Nitric oxide (NO), a messenger molecule, is the immediate mediator of erection. Erotic thoughts or physical stimuli lead to release of NO from parasympathetic nerve endings in the penis.

TABLE 17.2 Endocrine and neuroendocrine cells and secretions involved in male reproduction, emphasizing humans

Cells	Hormone	Action
Hypothalamic GnRH cells	GnRH	Stimulates secretion of FSH and LH from anterior pituitary cells
Anterior pituitary cells	LH	Stimulates Leydig cells to secrete testosterone
	FSH	Required for development of, and supports, Sertoli cells; stimulates Sertoli cells to support spermatogenesis but in a secondary role to testosterone
Leydig cells	Testosterone	Required for mitosis and meiosis of spermatogenesis. Stimulates Sertoli cells to support and regulate spermatogenesis. Exerts negative feedback on the anterior pituitary and the hypothalamus Mediates secondary sexual characteristics such as growth of facial hair and muscular strength During early development, mediates sexual differentiation of reproductive organs (see Box 17.2) During early development, mediates sexual differentiation of certain aspects of brain neuroendocrine function and certain other aspects of brain fine structure and function (at least some of these effects are mediated by aromatization products of testosterone)
Sertoli cells ^a	Inhibin	Inhibits FSH secretion

^aSertoli cells also secrete *nonhormonal* products, notably substances that nourish the differentiating sperm, extracellular fluid (including androgen-binding protein) that fills the seminiferous tubules, and paracrine agents.

The NO leads to dilation of blood vessels that permit blood to fill the spongy tissues. Investigators have recently discovered a positive feedback loop for NO. After NO from nerve endings initiates erection, the flux of moving blood causes further release of NO from endothelial cells in blood vessel walls. The positive feedback loop is important because NO is very short-lived and needs to be generated rapidly if its concentration is to be high. NO acts by mediating synthesis of cyclic GMP, a second messenger (see Figure 2.28). Current medications for erectile dysfunction inhibit an enzyme that breaks down cyclic GMP, thereby permitting the second messenger to act longer.

Semen, the fluid expelled from the penis during ejaculation, consists of sperm plus secretions of accessory sex glands. In humans, the most important accessory sex glands (see Figure 17.11*a*) are the prostate gland and seminal vesicles—which provide most of the fluid in semen—and the bulbourethral glands, which secrete a clear mucus ahead of ejaculation. After sperm mature in the testes, they are stored in the epididymis and vas deferens. They are mixed with the accessory-gland fluids as ejaculation occurs. The accessory-gland fluids provide fructose and other energy sources for the sperm; they contain acid–base buffers and other agents that create a suitable environment for the sperm; and they contain messenger compounds such as prostaglandins.

Pregnancy and birth are orchestrated by specialized endocrine controls

Fertilization usually occurs in the upper third of the oviduct, near the ovary. Sperm must travel there through the female reproductive tract to meet the secondary oocyte(s). Whereas millions of sperm enter the female reproductive tract in a single act of mating, very few actually arrive at the oocyte, and only one fuses with it to form the zygote. While sperm are in the female reproductive tract, they go through a process called **capacitation**, which is essential for them to be capable of fertilizing the oocyte (see Figure 17.2*c*). Capacitation enhances the abilities of sperm to swim rapidly and to fuse with the cell membrane of the oocyte. If a female mammal mates with more than one male in a brief period of time, **sperm competition** is said to occur within the female reproductive tract as

the sperm from the two sources vie to fertilize the oocyte. In species of mammals with a routine pattern of synchronous insemination by multiple males, the males tend to have dramatically large testes—which enable them to enter large numbers of sperm into the sperm competition (Figure 17.13).

In the period following ovulation, the oocyte is retained in the upper third of the oviduct because the lumen of the oviduct, owing to effects of estrogen, is constricted sufficiently to block travel toward the uterus. The lumen of the oviduct is not pinched off entirely, however, and therefore the tiny sperm can swim through to reach the oocyte.

The oocyte is enclosed in the zona pellucida and surrounded by granulosa cells when in the oviduct (Figure 17.14*a*). For fertilization

FIGURE 17.13 Testis size depends on mating system in mammals. Species of mammals are placed in two categories: *single-male mating* in which the usual pattern is for one male to copulate with a female during a single mating period and *multiple-male mating* in which the usual pattern is for multiple males to copulate with a female during a single mating period. Because testis size varies in a regular, allometric fashion with body size in all mammals analyzed together, an “expected” testis size can be calculated for each species simply by use of the species’ body size. The y axis shows the actual testis size as a ratio of this expected size. Number of species analyzed is 54 for all mammals, 25 for primates. Error bars show ± 1 standard error. (After Kenagy and Trombulak 1986.)

(a) The oocyte in the oviduct as sperm arrive

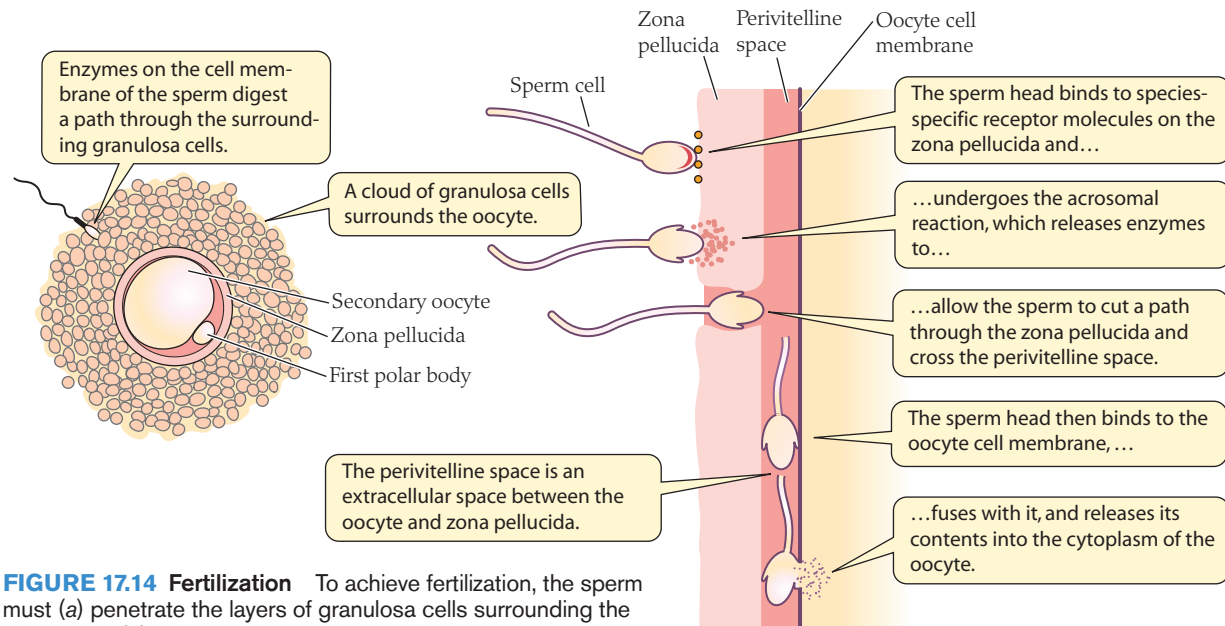

FIGURE 17.14 Fertilization To achieve fertilization, the sperm must (a) penetrate the layers of granulosa cells surrounding the oocyte and (b) both cut a channel through the zona pellucida and fuse with the oocyte cell membrane. In conjunction with the final step shown here, the sperm flagellum (tail) is also taken into the oocyte where it is broken down in the cytoplasm (not shown). (b after Primakoff and Myles 2002.)

to occur, sperm must traverse these structures to reach the cell membrane of the oocyte. The head of a sperm has enzymes on its outer surface that break down the extracellular matrix between granulosa cells, allowing the sperm to penetrate. To breach the zona pellucida (**Figure 17.14b**), a sperm releases enzymes by exocytosis from the acrosome (see **Figure 17.11c**) in its head. The exocytosis of these enzymes, called the **acrosomal reaction**, is triggered only when the sperm head binds to protein molecules, which are species-specific, on the zona pellucida. After its acrosomal reaction is initiated, a sperm cuts a channel through the zona pellucida. The head of the sperm then adheres to the cell membrane of the oocyte. Only a few sperm get this far. The cell membrane of just one of these sperm fuses with the cell membrane of the oocyte, and the cytoplasm of the two gametes become continuous. **Fertilization** refers to this specific event, which results in the formation of a **zygote**.

Two crucial processes quickly follow fertilization. One is a reaction—termed the **cortical reaction**—that blocks more than one sperm from fertilizing the oocyte. The second is completion of meiosis by the oocyte. During the cortical reaction, organelles called **cortical granules** in the fertilized oocyte's peripheral cytoplasm release substances into the extracellular space around the oocyte that alter the cell membrane as well as the zona pellucida. These alterations prevent adhesion or fusion of more than one sperm, ensuring that only one haploid set of paternal chromosomes is admitted to the oocyte. Meanwhile, the oocyte completes the second meiotic division (see **Appendix H**), and thereafter only a single haploid set of maternal chromosomes remains in the oocyte. The two haploid sets of chromosomes join to make the zygote's diploid set of chromosomes.

IMPLANTATION, LUTEAL RESCUE, AND EARLY PREGNANCY **Im-plantation** is the entry of the early embryo into the cellular matrix

of the endometrium, the uterine epithelium. For this process to occur, the newly conceived individual must travel to the uterus. As it does so, mitotic cell divisions take place, and the zygote (the single cell formed by fertilization) matures into a hollow early embryo termed a blastocyst. The trip down the oviduct is relatively slow; in humans, the early embryo arrives in the uterus about 4 days after fertilization took place in the upper third of the oviduct. Travel down the oviduct becomes possible because the rising levels of progesterone secreted by the corpus luteum induce the smooth muscles of the oviduct to relax, so the lumen of the oviduct opens. Once in the uterus, the blastocyst “hatches” from the zona pellucida and remains free (for about 3 days in humans) before implanting.

The blastocyst consists of cells that will ultimately develop into the newborn individual, plus cells collectively termed the **trophoblast** that will not contribute to the new individual but instead help form the placenta. A portion of the outer surface of the blastocyst is specialized to make contact with the endometrium and begin the process of implantation. To enable the blastocyst to bury itself in the nutrient-rich endometrium, enzymes are secreted by trophoblast cells.

Progesterone is required for the endometrium to remain in a highly developed state, rather than being sloughed off or resorbed. The placenta is the principal source of the necessary progesterone after the placenta develops. However, in early pregnancy—the days or weeks immediately following implantation—the corpus luteum is the primary source of progesterone and must continue to secrete it at high levels. The corpus luteum must therefore be rescued so that it does not degenerate, as it would in the absence of pregnancy. In humans, the shift from dependence on the corpus luteum as the primary source of progesterone to dependence on the placenta happens after about 50–70 days (pregnancy lasts about 266 days). The corpus luteum must thus survive for at least 50–70 days rather than atrophying in 14 days, as it does in the absence of pregnancy.

To rescue the corpus luteum, different species use different mechanisms. In primates, an embryonic membrane that participates

FIGURE 17.15 Humans and other primates employ chorionic gonadotropin to rescue the corpus luteum when pregnancy occurs

The data shown here are for humans. During the first part of pregnancy, the hormone chorionic gonadotropin—secreted by the chorion, an embryonic membrane that contributes to formation of the placenta—sustains the life of the corpus luteum, which secretes estrogen and progesterone into the blood. In later pregnancy, the placenta becomes the principal source of estrogen and progesterone and also secretes them into the general circulation.

in the formation of the placenta—the chorion—secretes the hormone **chorionic gonadotropin (CG)**, which rises in blood concentration following fertilization (Figure 17.15) and acts on the corpus luteum to extend the corpus luteum's life. CG is in the same glycoprotein chemical family as LH, and genomic evidence indicates it evolved relatively recently in geologic time—in the common ancestor of the anthropoid primates (monkeys, apes, and humans)—by duplication of a gene for LH and subsequent evolutionary modification of the gene. CG is excreted in the urine and serves as the basis for pregnancy tests; detection of CG in the urine indicates that an embryo has implanted and is developing. Uniquely among nonprimate mammals, horses independently evolved a gonadotropin secreted by the chorion that functions similarly to the primate CG to rescue the corpus luteum. In sheep and cows, the trophoblast cells of the embryo secrete a paracrine substance that prevents uterine cells from producing circulating prostaglandins that would cause the corpus luteum to degenerate. In rodents, the hormone prolactin, released by the anterior pituitary gland, sustains the corpus luteum.

THE PLACENTA At first, the endometrium provides the embryo with sufficient nutrients and other forms of metabolic support. However, as time passes, the implanted embryo interacts with maternal uterine structures to form the **placenta**, a structure in which blood vessels of the maternal and embryonic circulatory systems are so closely juxtaposed that O_2 and other materials can move readily between the bloodstreams of the mother and embryo.¹⁹ Four or five quite-distinct structural types of placentas are known

¹⁹Where we here speak of the “embryo” and the “embryonic” circulation and bloodstream, these would be called the “fetus” and the “fetal” circulation and bloodstream during the later stages of intrauterine development because as noted before, an embryo comes to be called a fetus as it matures.

in various mammals. In all the types, the maternal and embryonic bloodstreams are separated by intervening cellular structures, such as the endothelia of blood capillaries (see Figure 2.6). Consequently, although many substances move readily between the two bloodstreams by diffusion and other transport processes (see Chapter 5), the bloods do not normally mix. The flow of maternal blood through the placenta supplies the embryo with O_2 and nutrients.²⁰ It also removes CO_2 and other metabolic by-products.

In addition to being a nutritive and waste-removal structure, the placenta is also an endocrine structure (see Table 17.1), as already mentioned. The mature placenta secretes estrogen (mostly estriol in humans and many other mammals), progesterone, and other hormones that support physiological functions during pregnancy and prepare the mother's body for birth and lactation. Progesterone is essential for maintaining the endometrium in a highly developed state and for inhibiting contractions of the myometrium (the muscular portion of the uterus). Estrogen (produced through aromatase action from androgens made in other tissues) stimulates growth of the myometrium. Both progesterone and estrogen contribute to preparing the mammary glands (breasts) for lactation.

BIRTH The factor(s) that initiate birth (parturition) remain largely unknown. We know, however, that during the period prior to birth, several physiological changes occur that prepare the mother and fetus (late embryo) for the birth process.

Blood estrogen, present at ever-increasing levels as pregnancy progresses (see Figure 17.15), prepares the myometrium for contractile activity in two important ways. First, estrogen stimulates the myometrial smooth muscle cells to synthesize *connexins*, the protein molecules that join together to make up *gap junctions* (see Figure 2.7). The gap junctions that are formed allow electrical activity to spread from cell to cell in the smooth muscles of the myometrium, so that the entire myometrium can produce highly coordinated contractions. Second, estrogen stimulates the myometrial smooth muscle cells to produce receptors for the hormone **oxytocin**. In some mammals, although probably not humans, **relaxin**—a peptide hormone secreted by corpora lutea—also plays an important role in preparing for birth. Secretion of relaxin during the period leading up to birth induces remodeling and softening of the cervix, the uterine tissue that opens into the vagina; it also facilitates the establishment of flexible, elastic connections between pubic bones. In these ways, relaxin demonstrably eases the exit of fetuses from the uterus, facilitating rapid delivery.

Oxytocin is the principal hormone controlling the forces that produce delivery. It is secreted by hypothalamic neurosecretory cells and released from the posterior pituitary gland at the time of birth, and it stimulates uterine smooth muscle cells to produce and secrete prostaglandins. Both the oxytocin and the prostaglandins strongly stimulate contractile activity by the smooth muscle cells. As birth becomes imminent, forceful contractions spread over the body of the uterus toward the cervix and vagina. The contractions force the fetus against the cervix, thereby stimulating mechanoreceptors there. These conditions set up the positive feedback loop shown in

²⁰Substances such as drugs and alcohol in the maternal blood can also cross the placenta. Some are known to cause physical or behavioral birth defects by disrupting development of the embryo/fetus. When a mother consumes alcohol during pregnancy, for example, her child can suffer a suite of negative effects known as *fetal alcohol syndrome*.

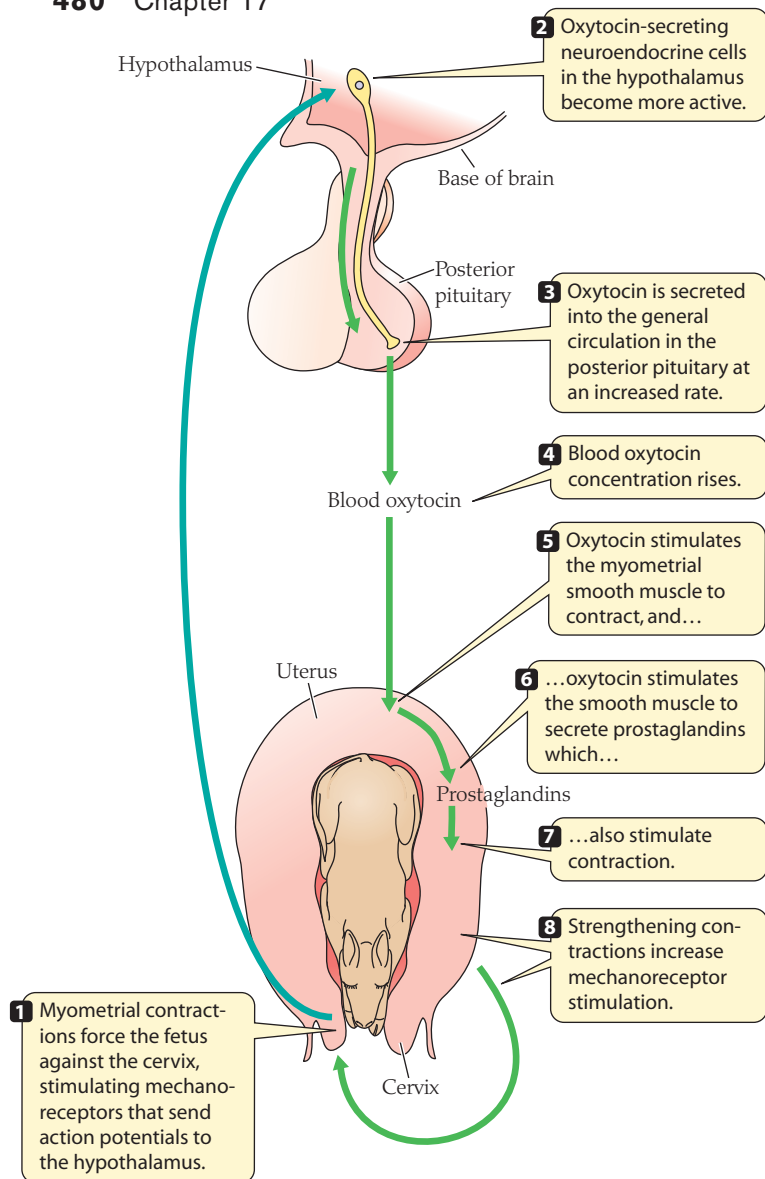

FIGURE 17.16 Positive feedback during birth Oxytocin, prostaglandins, and mechanical stimuli at the cervix participate in a positive feedback loop that progressively forces the cervix to open wide enough to permit the fetus to be born.

Figure 17.16: The mechanoreceptors in the cervix send action potentials to the hypothalamus, where they stimulate neurosecretory cells to secrete oxytocin. Having recently incorporated oxytocin receptors into their cell membranes, the myometrial smooth muscle cells respond to the oxytocin with contractions. With increased contractions forcing the fetus against the cervix, the cervical mechanoreceptors are stimulated even more, and more oxytocin is secreted. As myometrial contractions increase, the cervical opening dilates (widens) to permit passage of the fetus. These events reach a crescendo with delivery. After the fetus is born, the placenta (called the afterbirth) is also delivered. Without the placenta as an endocrine structure, the mother's blood levels of progesterone and estrogen then plummet toward pre-pregnancy levels (see Figure 17.15).

Lactation is governed by neuroendocrine reflexes

A defining characteristic of mammals is that females have mammary glands that provide milk to their newborn young. **Lactation**

is the process of producing and providing milk. It consists of two functionally distinct steps. The first is **milk production** or secretion—in which milk is synthesized by cells of the mammary glands and secreted into cavities within the glands. The second step is **milk ejection** or **let-down**—in which milk is expelled from the cavities of the mammary glands into the mouth of the offspring. Milk—which varies widely among species in its detailed composition—is an essential source of food until the time of weaning for most newborns. Immediately after birth, the mammary glands in many species—prior to secreting milk—secrete fluids termed *colostrums*, which are rich in antibodies and vitamins.

All mammary glands have a similar basic structure, although species vary widely in the size and number of their mammary glands. A mammary gland (Figure 17.17a) consists of many hollow, semi-spherical glandular structures called **alveoli** (singular **alveolus**) connected to milk **ducts**. The secretory epithelial cells of an alveolus synthesize milk and secrete it into the alveolar lumen. Contractile myoepithelial cells surround the alveolar epithelial cells. When the myoepithelial cells contract, they squeeze the alveolus and force milk from the alveolar lumen out via the ducts of the mammary gland.

Lactation is controlled principally by two hormones (Figure 17.17b). In fact, these two hormones control the two steps of lactation. Prolactin secreted from the anterior pituitary gland stimulates *milk secretion* by the alveolar epithelial cells. Oxytocin secreted from the posterior pituitary gland stimulates *milk ejection*. Oxytocin thus has two major reproductive roles: It helps orchestrate uterine contraction during birth, and it stimulates milk ejection.

In females that are not lactating, dopamine—also called prolactin-inhibiting hormone (PIH)—inhibits secretion of prolactin. Dopamine is secreted from neuroendocrine cells in the hypothalamus and carried to the anterior pituitary gland in the hypothalamo–hypophysial portal system. During late pregnancy and lactation, dopamine secretion *decreases*, thereby permitting secretion of prolactin. In addition, thyrotropin-releasing hormone (TRH) stimulates secretion of prolactin.

Oxytocin acts by stimulating the myoepithelial cells surrounding the alveoli to contract. This contraction ejects milk. Milk ejection is essential for the offspring to obtain milk because the simple application of sucking forces to the nipples is inadequate to draw out enough milk.

Suckling by offspring is a potent stimulus for the secretion of both prolactin and oxytocin, as emphasized by Figure 17.17b. The nipples are richly innervated and very sensitive to mechanical stimulation. Suckling triggers mechanosensory signals that are transmitted by neurons to the central nervous system. These neural signals affect hypothalamic dopamine- and TRH-secreting neurons to decrease dopamine secretion and increase TRH secretion—thereby increasing prolactin secretion by the pituitary gland—and they stimulate hypothalamic neuroendocrine cells to secrete oxytocin. These control sequences are often described as being *neuroendocrine reflexes* because they are relatively automatic processes mediated by both neural and endocrine elements.

In many types of mammals, estrus and/or ovulation are suppressed during lactation in response to high levels of prolactin. Such suppression of estrus is called *lactation anestrus*, and the suppression of ovulation is called *lactation anovulation*. Prolactin-mediated suppression of GnRH secretion by the hypothalamic

(a) A mammary gland in a cow udder

(b) Hormonal control of lactation

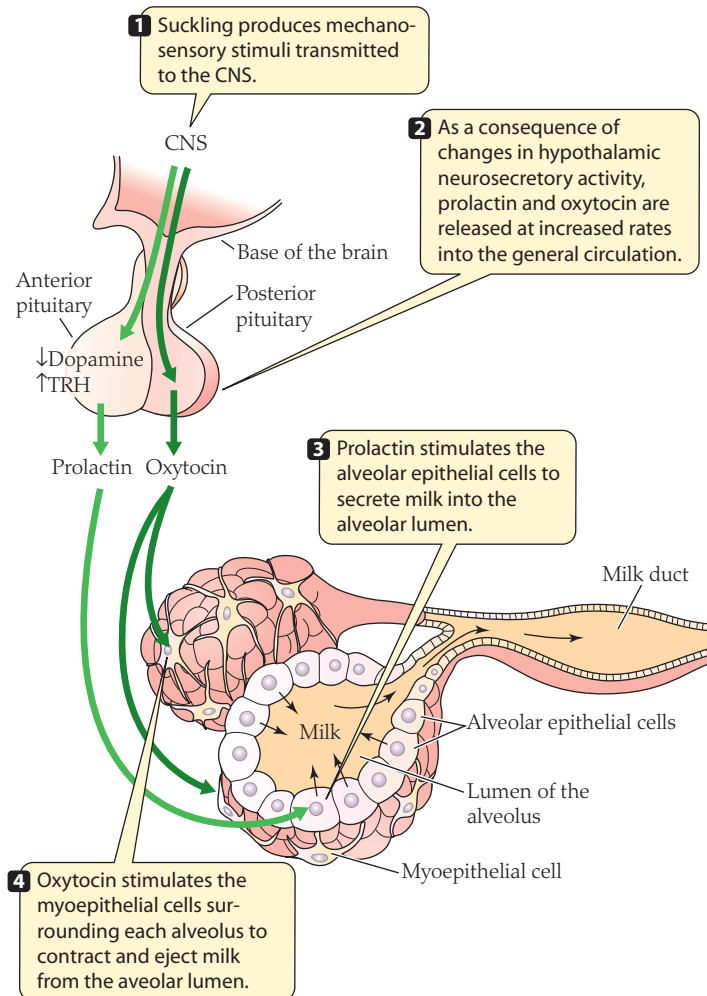

FIGURE 17.17 Mammary glands and lactation (a) The structure of mammary glands as illustrated by the cow udder. Mammary alveoli (singular alveolus) synthesize milk, which exits by ducts. Cisterns, which are not found in humans or several other mammals, collect and store milk. (b) The hormonal control of lactation. Suckling stimulates the secretion of prolactin and oxytocin by the pituitary gland. Prolactin stimulates milk synthesis. Oxytocin stimulates milk ejection. Other neural signals, such as those activated by an infant's cry or a clanking milk bucket in a dairy barn, can stimulate oxytocin (but not prolactin) secretion and promote milk ejection. CNS, central nervous system. TRH, thyrotropin-releasing hormone.

GnRH-secreting cells, leading to reduced FSH and LH secretion, is the primary basis for these phenomena. In human populations that do not use contraceptives, breast-feeding appears to play an

important role in determining spacing between births. Studies of prolactin levels in both !Kung and American mothers show that frequent nursing episodes maintain high blood levels of prolactin, which induce anovulation.

SUMMARY Reproductive Endocrinology of Placental Mammals

- The ovaries produce oocytes and secrete hormones. Oocytes are shed from the ovaries during each estrous or menstrual cycle during the reproductive season. Each cycle has three main ovarian phases: development of follicles (follicular phase), ovulation, and function of the corpus luteum (luteal phase). The uterine endometrium grows thicker prior to ovulation and becomes secretory after ovulation.
- The gonadotropins known as luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—released in response to gonadotropin-releasing hormone (GnRH)—stimulate granulosa cells in ovarian follicles to secrete estrogen (particularly estradiol). Estrogen acts as a paracrine/autocrine agent that stimulates proliferation of granulosa cells. It also acts as a blood-borne hormone that stimulates growth of the uterine endometrium, affects behavior in species with estrus, and feeds back on the anterior pituitary gland and hypothalamus.
- Ovulation is induced by copulation in some species, but is spontaneous in most. A surge in secretion of LH triggers ovulation in either case. In spontaneous ovulators, the surge is a consequence of endogenous interactions of endocrine and neuroendocrine tissues, notably the hypothalamus, anterior pituitary gland, and ovarian follicles. A key part of the process is stimulation of kisspeptin neurons by estrogen, followed by kisspeptin-stimulated secretion of GnRH.
- After ovulation, the cells of each ruptured ovarian follicle reorganize into a corpus luteum, which secretes progesterone, estrogen, and inhibin. These hormones inhibit or decrease folliculogenesis in the ovaries by reducing secretion of LH and FSH from the anterior pituitary. Progesterone supports the secretory state of the uterine endometrium and inhibits contraction of the smooth muscles of the myometrium and oviducts.
- If fertilization does not occur, the corpus luteum degenerates, and uterine endometrial tissue is resorbed or discharged as menstrual flow. If fertilization does occur, the corpus luteum is rescued and continues to function. Its function is essential for maintenance of the uterus and placenta in early pregnancy.
- Fertilization occurs in the oviduct when a secondary oocyte is present and sperm have undergone capacitation. Upon fusion of the two gametes' cell membranes, the oocyte completes meiosis and undergoes the cortical reaction, which blocks fertilization by any additional sperm. The zygote moves down the oviduct to the uterus, developing into a blastocyst, which ultimately implants (possibly following delayed implantation in some species).
- After implantation, the embryonic trophoblast and maternal endometrium form the placenta, a structure in which embryonic and maternal blood vessels closely intermingle, permitting exchange of O_2 , nutrients, and wastes between the two bloodstreams (although not mixing of blood). The placenta secretes hormones, such as progesterone, which are crucial for maintaining the placenta and sustaining pregnancy.

- Birth is accomplished by coordinated contractions of the uterine myometrium (smooth muscle). Birth is facilitated by a positive feedback loop—mediated partly by hypothalamic oxytocin secretion—that causes the contractions to become more and more powerful.
- Milk is produced by alveolar epithelial cells in the mammary glands. Prolactin stimulates milk secretion by the epithelial cells. Oxytocin causes milk ejection (milk let-down) by stimulating the contraction of myoepithelial cells surrounding the alveoli. Suckling increases secretion of both prolactin and oxytocin.
- Males produce sperm continuously during the breeding season. Sperm are produced with the aid of Sertoli cells in the seminiferous tubules in the testes. Leydig cells embedded in connective tissue between the seminiferous tubules secrete testosterone. The functions of the seminiferous tubules and Leydig cells are controlled by continuous secretion of LH and FSH, released in response to GnRH.
- In males, LH stimulates the Leydig cells. Testosterone from the Leydig cells promotes sperm production via effects on the Sertoli cells, sometimes with additive effects exerted by FSH on the Sertoli cells.
- Erection of the penis results from blood flow into spongy tissue, controlled by nitric oxide (NO). The parasympathetic nervous system initiates NO production, but then further NO is released from blood vessel endothelial walls, forming a positive feedback loop. During ejaculation, sperm are mixed with secretions of male accessory glands (principally the prostate gland and paired seminal vesicles in humans) to produce the semen that is emitted.

Study Questions

1. “Breeding like rabbits” is a common expression for having large numbers of offspring. Rabbits are indeed noted for their great reproductive potential. Rabbits exhibit induced ovulation and postpartum estrus. Define these reproductive traits, and explain how they help endow rabbits with their considerable reproductive potential.
2. Suppose you are in charge of a captive breeding program for a species of zoo animal that is similar to humans in its reproductive endocrinology. By study of hormone signals, how could you tell when a female ovulates? If you permit her to mate at that time, how could you later tell from study of hormone signals whether she has conceived? Explain your answers.
3. Estimate the age of a primary oocyte within a dominant follicle in the ovary of a woman on her 18th birthday. Explain your reasoning.
4. Explain the advantages that both insects and mammals can realize from embryonic diapause.
5. Ovulation in mammals occurs in response to a surge of luteinizing hormone (LH), whether it is induced or spontaneous. Compare and contrast the ways the LH surge is generated in induced and spontaneous ovulators.
6. In discussions of feedback in biological systems, negative feedback is typically emphasized, and positive feedback is often treated as an anomaly. In fact, positive feedback is common in reproductive physiology. List two or three examples of positive feedback. Explain how positive feedback functions to advantage in each case. If possible, discuss whether homeostasis is always ideal.

7. Consider a species, such as a lizard, in which females produce sets of eggs with large, heavy quantities of yolk. Suppose you hypothesize that one of the costs of reproduction is that females cannot run as fast or escape predators as well when they are in the process of producing such eggs. Describe a manipulative experiment you could carry out to test your hypothesis, and explain how you would interpret your results. (For an example, see the paper by Miles et al. in the References.)
8. What are the relative advantages and disadvantages of semelparity and iteroparity? In answering, consider iteroparous species that have both short and long expected life spans in their natural environments.
9. Knowing what you do about the feedback effects of testosterone on the anterior pituitary gland, explain the reason that male athletes who take anabolic steroids become temporarily sterile (anabolic steroids are steroids that mimic some actions of testosterone).
10. Aromatase inhibitors are a new generation of drugs used to treat women who have estrogen-sensitive breast cancers (cancers that grow most rapidly when estrogen is present). Explain why aromatase inhibitors are useful in these cases.
11. Prolactin and oxytocin are both involved in lactation. Define, describe, and explain the functional significance of each of these hormones.

Integrating Systems *at Work*: Animal Navigation

This newly hatched marine turtle crawling toward the sea is beginning an astounding migration during which it will spend up to three decades in the Pacific Ocean before returning to its birth site (Malaysia) to breed. In the South Atlantic Ocean, green turtles (*Chelonia mydas*) feed off the coast of Brazil and then migrate eastward across more than 2200 km of open ocean to nest at Ascension Island, an isolated speck of land in the middle of the South Atlantic. In the Northern Hemisphere, loggerhead turtles (*Caretta caretta*) hatch on Florida beaches, swim out to the Gulf Stream, and spend years circulating around the North Atlantic before returning to U.S. waters.

Because it may take an individual sea turtle 30 years to reach sexual maturity, researchers had been uncertain whether the turtles were returning to their *natal* beaches. Accumulated evidence suggests that they do. For example, no sea turtle tagged at Ascension Island has ever been found to nest elsewhere. Moreover, analysis of mitochondrial DNA indicates that green turtles nesting at different sites are genetically distinct, a fact suggesting that gene exchange between different colonies is relatively rare. The reproductive success of sea turtles is based on their finely tuned sense of place. As breeding season arrives, sea turtles move unerringly toward a precise destination, irrespective of their individual positions at sea.

Sea turtles are masters of animal navigation. As physiologists use the term, **navigation** is the act of moving on a particular course, or toward a specific destination, by using sensory cues to determine direction and position. As sea turtles demonstrate, navigational abilities facilitate specialized locomotor behaviors such as migration and homing. **Migration** is the periodic movement of an animal from one region to another. Migratory periods may be prompted by seasonal changes, as is often the case with migratory birds. A migratory cycle, however, may extend over an animal's lifetime, as is true of Pacific salmon (*Oncorhynchus* sp.), which return from the sea to their natal lakes to spawn and die. Whereas migration may involve movements on a global scale, homing is often a more localized behavior. **Homing** is the ability of an animal to find its way repeatedly to a *specific point*, most often its nesting or dwelling place, although some animals, such as honeybees (*Apis mellifera*), use their homing abilities to pinpoint food sources too.

The dividing line between migration and homing is not always clear, and some navigating animals appear to engage both abilities selectively. Homing performance, however, usually declines as the distance from home or a target increases, and an animal's homing abilities may be disrupted completely if it is passively displaced (e.g., blown off course by a storm or deliberately moved by a researcher) from its path of travel.

It's not surprising that animal navigation has been an object of scientific interest to researchers. Lacking maps, compasses, and other human cultural accoutrements, how do navigating animals gather and interpret cues about their position on the planet? Do they possess physiological (sensory) mechanisms unavailable to humans? Is the ability to navigate mainly a result of learning and memory of past experience? And what is the evolutionary importance for the animal of the ability to navigate?

A newly hatched sea turtle begins a lifetime of navigation.

The Adaptive Significance of Animal Navigation

Physiologists presume that navigational abilities evolved because they represent an adaptive advantage to the animals that possess these skills. Before examining how animals navigate, let's consider *why* it may be advantageous for them to do so.

Navigational abilities promote reproductive success

Most (but hardly all) animals reproduce at a time and place that presents the lowest degree of environmental stress to the parents and their offspring. For example, long-distance migrants such as humpback whales (*Megaptera novaeangliae*) spend the summer feeding in the food-rich polar seas of the Northern Hemisphere. In the winter, however, they migrate to more tropical waters to reproduce, often traveling as much as 3200 km. Surprisingly, humpback whales apparently do not eat during the winter breeding season; only one out of 2000 caught in one study had food in the stomach. The winter migration is *not* to areas of high food productivity, but rather to areas of warm water that engender less thermoregulatory stress, especially for the young.

Many animals exhibit *natal philopatry*, the tendency either to stay in the area of their origin or to return to it to reproduce. In many species of migrating birds, such as the wood thrush (*Hylocichla mustelina*), males return every spring to reestablish the same territories each year. In this case, learned familiarity may contribute to the advantage of philopatry, but not in another case. Anadromous fish (i.e., fish that ascend rivers from the sea to breed), such as Pacific salmon, provide the most dramatic example of how animal navigation skills are employed to accomplish this reproductive aim (Figure 18.1).

Several species of salmon (*Oncorhynchus*) hatch in freshwater streams and lakeshores in the North Pacific rim. After spending between 1 and 3 years in downstream waters and lakes as juveniles, they metamorphose into smolts and migrate downstream to the Pacific. The maturing salmon spend a few years in the Alaskan Gyre, a large circulating current that offers plentiful foraging opportunities. The adult salmon of North American species share the gyre with those of Asiatic species. Although the various species feed together, they do not breed in the gyre. Spawning occurs only after adult salmon migrate through the open ocean to their natal river and then, using the imprinted scent of their natal lake or stream, home accurately to it. Here they reproduce once and die.

Presuming that natal philopatry evolved by natural selection, what is its adaptive advantage that has led to such impressive navigation ability in salmon? Probably the most important advantage is that the ability to home to the natal stream returns locally adapted individuals to appropriate environments. Salmon populations are often strongly adapted to local breeding environments, and this

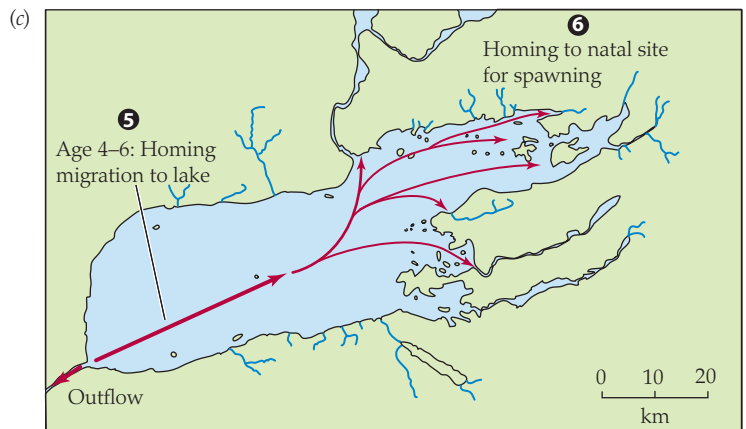

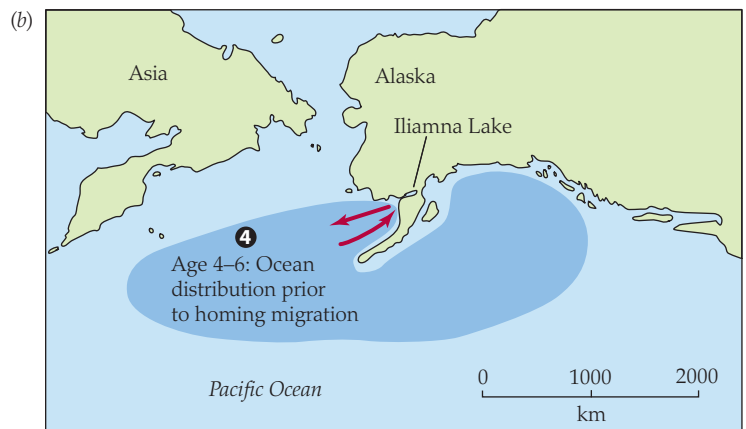

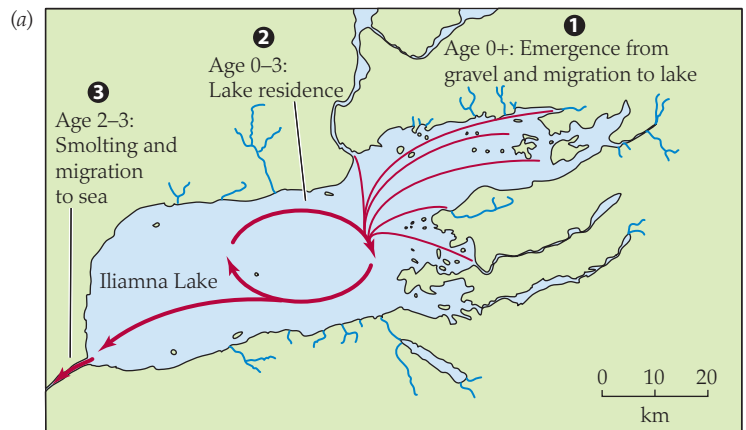

FIGURE 18.1 Salmon life-cycle migration and homing The life cycle of sockeye salmon (*Oncorhynchus nerka*) from Iliamna Lake in Alaska. (a) Newly hatched salmon emerge from gravel of streams and beaches and spend up to 3 years in the lake before transforming to smolts that migrate to the sea. (b) Ocean distribution of maturing salmon prior to their homing migration back to Iliamna Lake. (c) Homing migration back to the lake and to their natal site for spawning. (d) A male in the reproductive phase (left) has red sides, a deep body, and elongated, hooked jaws. (a–c from Dittman and Quinn 1996.)

adaptation reduces the fitness of strays that disperse instead of returning to the natal site.

However, *perfect* site fidelity would be expected to be disadvantageous because conditions change from year to year at a breeding habitat, so there should be some dispersal to adjust to these temporal changes. Salmon populations appear to maximize reproductive fitness by natural selection favoring a balance of a high percentage of return to natal sites and a low percentage of dispersal. By using navigational skills to feed globally but spawn parochially, salmon thus maintain distinct populations that are well adapted to their breeding sites.

Navigational abilities facilitate food acquisition

The examples cited of sea turtles, humpback whales, and Pacific salmon all suggest a common conclusion: The best place to feed isn't always the best place to breed. Using their navigational abilities, migratory animals can position themselves favorably at food sources, accumulating chemical energy until they reach breeding readiness. By spending their summers feeding in polar seas, humpback whales take advantage of mineral-rich upwellings from the ocean floor that support an abundant food chain, as well as long summer days that maximize the time these animals can spend foraging.

Animal navigators also employ homing skills to acquire food. For example, several species of birds store or cache seeds, hiding them and then retrieving them days or months later. Clark's nutcrackers (*Nucifraga columbiana*) and pinyon jays (*Gymnorhinus cyanocephalus*) dig holes in sandy ground and bury seeds. An individual of either species is able to locate thousands of cache sites and also to remember which sites it has already visited and emptied. A single Clark's nutcracker may hide 33,000 seeds in a season at approximately 6600 locations, and it can remember these locations and retrieve the seeds with a degree of success that is nothing less than astonishing.

In another example of using homing skills to acquire food, foraging honeybees may take hours or days to first locate a new source of nectar, but then new workers will appear at the food source within minutes of the first bee's return to the hive. Karl von Frisch (1886–1982) demonstrated that a returning forager performs a "dance" that conveys information to other bees about the direction and distance of the food source (Figure 18.2). The dance consists of looping turns alternating with a straight-line portion in which the signaling bee waggles her abdomen. Typically the dance is performed in the hive, on the vertical surface of a honeycomb, out of view of the sun. The angle between the sun and the food source is translated into an angle between vertical and the waggle component of the dance, so that other workers leaving the hive know the correct direction of the food source. Food location by honeybees certainly requires navigation, but it is somewhat atypical of homing behavior because it involves social cooperation and communication among individuals.

Migrating animals need navigation

For migrating animals, the adaptive value of navigation is difficult to separate from the adaptive value of the migration itself. If migratory movements have evolved by natural selection, they must convey adaptive advantages that outweigh their energetic and informational costs. Sometimes the adaptive advantages of migration are obvious; for example, birds that feed on flying in-

(a) On a horizontal surface

(b) Inside the hive on a vertical surface

FIGURE 18.2 The waggle dance of honeybees conveys information about the direction and distance of a food source. A returning forager that has discovered a nectar source dances either outside the hive on a horizontal surface (a) or inside the hive on a vertical surface (b). Distance is coded by the duration of the waggle run.

sects in temperate summers must go south in the winter (when the insects at temperate latitudes are dormant), unless they hibernate or find a different winter food. Navigation is clearly important in migration, and not only for knowing which way is south. Most seasonal migrants do not just move south in the fall and north in the spring; instead they travel along defined routes to restricted destinations (more restricted for some than others). Therefore, detailed navigation ability of migrants presumably imparts its own selective advantage, one that is separable (at least in principle) from the migratory journey itself.

Navigational Strategies

In the novel *Something about a Soldier*, Mark Harris describes army inductees in World War II riding a train through New Jersey to the unknown destination of their next training camp:

The men ... engaged in quiet conversation ... devoting themselves, in the main, to speculation concerning their destination. In this they were handicapped, lacking, as they did, the near presence of

streets, avenues, schoolhouses, saloons, subway kiosks marked Uptown and Downtown, and other familiar landmarks by which they ordinarily brought themselves into relationship with the compass. They were now moving (they argued) either south or north or west. They dismissed only the possibility that they were traveling east, into the Atlantic Ocean. Jacob [the protagonist of the novel] observed that they ignored compromises or combinations, and he thought, *the fallacy of absolutes*.

Like Harris's army inductees, animals can use a variety of sensory cues to navigate. Accordingly, when researchers speculate about how animals navigate, and test their hypotheses, they need to avoid the *fallacy of absolutes*. A trip can involve several sequences of direction, and navigating its course can likewise involve combinations of mechanisms. While it is navigating, an animal may use several different sensory cues, and it may use them to implement a variety of navigational strategies—in sequence, in a hierarchy, or in simultaneous combinations.

Navigation is a complex instance of animal behavior, involving sensory integration and motor control, as well as learning and memory. Hence, it is often useful to approach this topic by studying the repertoire of behavioral mechanisms that animals exhibit as they navigate rather than to dive immediately into a search for underlying physiological mechanisms or cellular functions. Biologists who study animal behavior recognize five behavioral strategies that animals use to navigate (Table 18.1): *Trail following, piloting, path integration, compass navigation, and map-and-compass navigation*.

It is noteworthy that the names of these strategies have analogies with human navigational techniques. But because some navigating species have sensory abilities and integrative capacities that humans lack, these named strategies may not actually encompass *all* the navigational techniques that animals employ. Moreover, terms such as *compass* and *map* are metaphors when applied to animals; we cannot know how animals actually experience the compasses and maps that their behavior suggests they possess.

Trail following is the most rudimentary form of animal navigation

Most people are familiar with following a trail through a forest or across a field in which each spot of trampled earth follows in a continuous series from start to finish. Similarly, **trail following** is a navigational strategy that is accomplished by detection of an interconnected series of local sensory cues (i.e., cues that are immediately proximate to an animal). Although humans are used to thinking about trails in visual terms, for many navigating species of arthropods, such as ants, a trail may consist solely of olfactory cues.

Trail-laying ants have an abdominal scent gland that is used to lay a *trail pheromone*, a chemical signal that marks a path to a food source. Each ant senses the olfactory profile of its path of travel and, in turn, deposits olfactory markers that it and other members of the colony can use to travel between a nest and the food source. (As we will discuss shortly, other kinds of ants employ different navigational strategies.)

Piloting animals follow a discontinuous series of learned cues

A person who knows that a hot-dog stand is located at the base of a tower, and who heads toward the tower to find the stand, is employing piloting. Using this navigational strategy, **piloting** animals

TABLE 18.1 A classification of strategies in animal navigation

Strategy	Description and source of information
Trail following, route learning	Continuous cues about trail, landmarks
Piloting	Landmarks (discontinuous)
Path integration	Integrated direction and distance information
Compass navigation	Celestial or magnetic cues, learned or genetic
Map-and-compass navigation	Compass cues, landmark- or gradient-based map

Source: After Papi 1992.

follow a discontinuous series of learned landmarks to determine where they are in their path of travel with respect to their destination. (A **landmark** is a discrete, sensed marker of position, usually but not necessarily visual.) The ability to use learned landmarks to navigate means that sensory cues need not be connected in a relatively unbroken series, as is the case with trail following. Moreover, because piloting is learned behavior, most animals that employ this strategy improve their navigational performance with age and experience. Although landmark-based learning such as piloting is considered relatively simple behavior, we will see that it is difficult to distinguish from more behaviorally sophisticated processes, such as map-and-compass navigation, a topic we cover later in the chapter (see page 494).

As our example of the hot-dog stand suggests, animals often use piloting as a strategy to find their way to a specific destination, a fact that Nikolaas Tinbergen (1907–1988) proved in a classic field experiment with digger wasps (*Philanthus triangulum*). Tinbergen placed a ring of pinecones around the entrance of a wasp's burrow. When the wasp emerged, she flew around the entrance for about 6 s before disappearing to hunt for food. Tinbergen established experimentally that the wasp used the pinecones as a local landmark for navigation by shifting the pinecone ring about 30 cm from the entrance while the wasp was away. On returning, the wasp flew to the center of the pinecone ring and was unable to find the nest. If the pinecone ring was moved farther than 1 or 2 m from the nest, the wasp even failed to locate the ring (and the nest). This latter observation suggests that, for the digger wasp, it is primarily the final moments in navigating to a destination that depend on piloting; the wasp uses other sensory cues to return to the correct neighborhood.

Birds that cache seeds also appear to use local landmarks as a primary mechanism in relocating their food. In one experiment, Clark's nutcrackers in an aviary hid pine seeds in an open arena strewn with landmark objects. After the birds had cached the seeds, the array of objects on one side of the arena was displaced by 20 cm, whereas the array on the other side was untouched. When the nutcrackers returned to search for their caches, they probed the ground at the "correct" places *with respect to the moved objects*, missing the caches by 20 cm on the manipulated side of the arena and retrieving them accurately on the undisturbed side. In the middle of the arena, the birds probed about 10 cm away from the caches, indicating that they were using information from both displaced and undisplaced landmarks.

Piloting is the navigational strategy employed in many instances of localized homing behavior and probably depends on a variety of familiar sensory cues, such as visual landmarks or odor profiles. Bees and other insects use landmarks to compose visual “snapshots” that are stored in memory in learning familiar paths. Like the digger wasps described previously, animals are most likely to pilot by the use of landmarks near home. For example, homing pigeons fitted with translucent contact lenses that obscure visual landmarks can still return to their home *area* (because they are using a different navigational strategy), but once in the area, they have difficulty finding their pigeon loft.

Path integration is a form of dead reckoning

As with piloting, animals that exhibit **path integration** behavior use this navigational strategy to accomplish homing, but unlike animals engaged in piloting, they do *not* refer to landmarks. In path integration, the navigating animal somehow keeps a running tally of its past directions and distances traveled, and it integrates this information in a manner that allows it to set a direct route back to its starting point at any time. Desert ants (*Cataglyphis fortis*) provide an excellent example of path integration behavior: They forage along tortuous, novel paths but can return from any point directly back to their hidden nesting site once they have located food (Figure 18.3).

Path integration in desert ants is equivalent to the method of dead reckoning often used by early mariners. *Dead reckoning* was a way of determining a ship’s position at sea without using landmarks or star positions. The sailors kept a record (the “logbook”) of the ship’s direction and speed, and accumulated this information into an aggregate direction and distance. Mariners used the position of the sun to ascertain their direction, and they assessed speed by throwing overboard a piece of wood (the “log”) attached to a long, knotted line that was cast off or played out as the ship sailed. The number of knots of line that were cast off over a period of time gave the speed and was entered in the logbook.

Ants navigate in a featureless desert rather than a featureless ocean, but their strategy is similar to sailors’ technique of dead reckoning. Ants gather directional information by using the sun’s position (or polarized light) as a compass. The ants measure distance by integrating proprioceptive information while walking, rather like counting steps for humans. Experimenters captured ants that had just found food and were ready to return home. They altered the length of the ant’s legs, cutting them short in some ants and gluing longer “stilts” on others, and displaced them as in Figure 18.3b. The ants made systematic errors in their attempt to return home: The ants with stilts walked too far before beginning their random search of the expected home area, whereas the ants with stumps underestimated the distance and shifted to random search too early.

Other animals use different methods to estimate distance traveled. A honeybee, for example, estimates the distance between its hive and a food source on the basis of **optic flow**, an impression of the speed at which objects sweep through the bee’s visual field as it flies. An object’s apparent distance determines its contribution

FIGURE 18.3 Path integration in desert ants (a) After finding food via a circuitous path, an ant takes a direct path back to its nest that does not depend on landmarks, but rather on path integration—adding all the direction and distance vectors in the tortuous outward path—and using a sun compass or polarized-sky-light compass to determine the direction back. (b) If an ant is artificially displaced when it has found food, it returns to where home would have been without the displacement, using external compass cues and ignoring local landmarks (except at the presumed nest location). Points mark positions at 1-min intervals. (After Collett and Zeil 1998.)

to optic flow. Nearby objects sweep by more quickly than distant ones, so they increase optic flow and heighten the sense of distance traveled.

To confirm that honeybees use optic flow, researchers manipulated the apparent distance of objects along their flight path. When bees were made to fly through a narrow tunnel with finely patterned walls (Figure 18.4), their optic flow increased and they overestimated their travel distances. Moreover, they communicated their overestimate to other bees in their waggle dance (see Figure 18.2), so that other bees (not flying through the tunnel) searched for the food source at too great a distance from the hive.

Animals can derive compass information from environmental cues

A **compass** is a mechanism that indicates geographical direction. Animals use compass information to *orient*—that is, to choose a direction in which to head. Orientation is a necessary component of compass navigation and map-and-compass navigation; no matter how you determine that you are north of your goal and need to go south, you need a mechanism to tell you which way is south. Ani-

FIGURE 18.4 Distance estimation by optic flow Bees assess the distance they travel by the flow of visual images past them as they move. The closer they are to objects they pass, the greater the objects' apparent motion is, and the greater the bees' estimation of distance. Bees that must fly through a narrow tunnel with densely patterned walls (shown in this composite photograph) consistently overestimate the distance they have traveled, because of the greater optic flow. Moreover, using a waggle dance, they signal their overestimate to other bees in the hive, so that the other bees (not flying in tunnels) fly in the correct direction but go too far in search of a food source. (From Srinivasan et al. 2000.)

mals derive compass information for navigation from a variety of environmental cues, such as the position of the sun and stars, the quality of polarized light, or the lines of force in Earth's magnetic field. It is useful to remember that we are using *compass* here as a metaphorical designation: Investigators can only infer the presence of a compass on the basis of an animal's behavior.

To study compass-based navigational strategies, researchers usually manipulate the sensory basis of a suspected animal compass while they measure the animal's *initial orientation*, the direction in which the animal orients its body and movements at the start of an actual or intended journey. In some cases this measurement might consist of observing the flight of a bird to vanishing point—the point at which it moves beyond the observer's viewing horizon. In the case of migratory birds, measuring initial orientation may entail quantifying the direction of *migratory restlessness*.¹ Birds in migratory phase will orient in a cage, facing and hopping in the direction of intended migration. Researchers can alter the suspected compass cues and then observe whether the orientation direction of migratory restlessness changes.

THE SUN COMPASS Many animals use the position of the sun as a source of compass information. In an early example demonstrating the presence of a sun compass, Gustav Kramer (1910–1959) showed that caged songbirds in migratory phase changed the orientation of their migratory restlessness when he altered the apparent position of the sun by using mirrors. The other original demonstration of sun-compass navigation was for foraging bees. The bee's waggle dance (see Figure 18.2) conveys information about the direction of a nectar source as an angle relative to the sun's position. Other worker bees in the hive use this sun-compass information to fly directly to the nectar source.

The sun moves across the sky from east to west at about 15° per hour, so animals must know the time of day to determine a compass heading from the sun's position. (Details of the sun's path also depend on latitude and season.) An animal that navigates using a sun compass must integrate solar position and circadian time information in order to orient its path of travel. The caged birds and the bees described earlier could maintain their sense of direction at different times of the day using their circadian clocks to account for the sun's movement.

Researchers can disrupt a suspected sun compass by resetting the animal's circadian clock, usually by imposing an artificial light–dark cycle that is different from natural sunrise and sunset (see Chapter 15, pages 411–412). If an animal experiences a shifted light–dark cycle, one in which the lights come on at noon and go

off at midnight (rather than at 6:00 AM and 6:00 PM, respectively), the new light–dark cycle will entrain the animal's circadian clock, causing the animal to misinterpret the sun's position.

Consider the following example: Guided by its normal circadian clock, a pigeon flying south at 9:00 AM will orient 45° to the right of the sun, which will be in the southeast (Figure 18.5a). If the pigeon flies south at 3:00 PM, it will orient 45° to the left of the sun, which will be in the southwest. A pigeon whose circadian clock is set ahead 6 h, however, will make predictable errors in sun-compass navigation (Figure 18.5b). If the pigeon thinks it is 3:00 PM when it is really 9:00 AM, the bird will fly due east, 90° from its intended southerly route, because it will fly 45° to the left of the sun. Experiments such as this one show that homing pigeons and most diurnal migrating birds use a sun compass as their primary mechanism of navigation.

THE POLARIZED-LIGHT COMPASS In addition to using a sun compass to navigate, many insects and birds appear to use polarized light as a source of compass information. This means of navigating is helpful on partly cloudy days, after sunset, or whenever the position of the sun is obscured from view.

Atmospheric particles polarize sky light. Recall from physics that white light from the sun is unpolarized; that is, it is a bundle of electromagnetic waves, each with an electrical vector (e-vector) that vibrates at right angles to the line of propagation of the light ray. In unpolarized light the e-vectors of different waves are at an infinite number of planes (Figure 18.6a). **Polarized light**, however, vibrates in only one plane with respect to its line of propagation. A fraction of the energy in a ray of sunlight will become polarized if it is reflected from a particle. Light reflecting from a surface at 90° from the incoming light ray is fully polarized; light reflecting at other angles is incompletely polarized.

Earth's atmosphere contains an abundance of suitably reflective particles—dust, water droplets, and ice crystals—that can polarize sunlight and provide the photic information that is the basis of an animal's polarized-light compass. Sky light in the vicinity of the sun reaches an observer's eye in a direct path, so it is unpolarized (see Figure 18.6a). Light reaching the eye from other parts of the sky, however, is reflected from atmospheric particles. As the reflec-

¹Migratory restlessness is sometimes known by the German term *Zugunruhe*.

FIGURE 18.5 Homing pigeons use a sun compass on sunny days The direction in which individual pigeons vanished over the horizon from a release point north of home. (a) Control pigeons oriented in the homeward direction (south) when released at any time of day. They used the sun's position and their internal circadian clocks to determine which direction was south. (b) Pigeons whose circadian clocks had been shifted 6 h ahead misinterpreted the sun's position and departed approximately 90° to the left of the homeward direction. If released at 9:00 AM, they thought it was 3:00 PM and departed 45° to the left of the sun's position (appropriate for 3:00 PM).

tion angle (from the sun, to the particles, to the eye) increases up to 90° , the proportion of light reaching the eye becomes increasingly polarized. Sky light, then, is maximally polarized in a band that is 90° away from the sun's position (Figure 18.6b).

Human eyes cannot detect useful differences in the polarization of sky light, but the eyes of many navigating insects (and birds) can. A bee, for example, has eyes that are sensitive to polarized ultraviolet light. As long as a patch of blue sky remains in view, a bee can detect the plane of light polarization and use this information to infer the position of the sun. Researchers cannot say with certainty *how* an animal experiences polarized light, but to extract compass information, it must be able to detect the angle of polarization, as well as gradients in the degree of light polarization (see Figure 18.6b).

The effect of light polarization detected by the bee may not be altogether different from what people experience when they wear polarized sunglasses. The polarizing filter in the lenses absorbs the horizontally polarized components of sunlight and passes the vertically polarized components. By tilting the head, a wearer of polarized glasses will observe that the sky appears to be noticeably darker in a band that is at right angles to the sun. Light reaching the eye from this part of the sky is maximally polarized, and the polarizing filter passes only the fraction of the light that is vertically polarized. The degree of darkness and the tilt angle of the wearer's head provide sensory cues from which the sun's position can be inferred.

How do the photoreceptor cells of insects respond to polarized light? First, an individual rhodopsin molecule must be differentially sensitive to the plane of light polarization. A rhodopsin

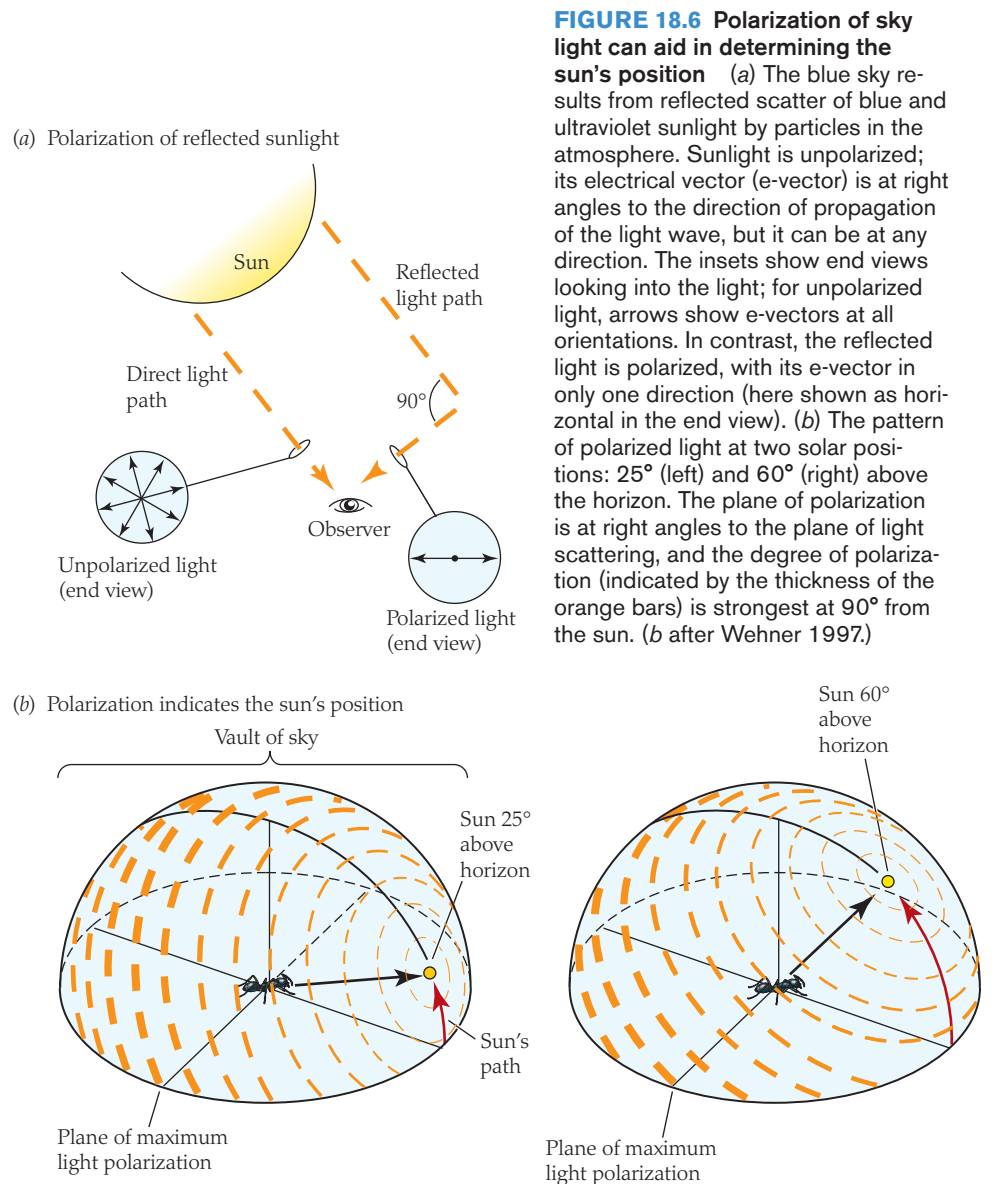

FIGURE 18.6 Polarization of sky light can aid in determining the sun's position (a) The blue sky results from reflected scatter of blue and ultraviolet sunlight by particles in the atmosphere. Sunlight is unpolarized; its electrical vector (e-vector) is at right angles to the direction of propagation of the light wave, but it can be at any direction. The insets show end views looking into the light; for unpolarized light, arrows show e-vectors at all orientations. In contrast, the reflected light is polarized, with its e-vector in only one direction (here shown as horizontal in the end view). (b) The pattern of polarized light at two solar positions: 25° (left) and 60° (right) above the horizon. The plane of polarization is at right angles to the plane of light scattering, and the degree of polarization (indicated by the thickness of the orange bars) is strongest at 90° from the sun. (b after Wehner 1997.)

molecule maximally absorbs light when the e-vector of the light is parallel to the long axis of the retinal chromophore (see Figure 14.23). Second, the many rhodopsin molecules in a photoreceptor must be aligned similarly, so that they all absorb light at the same plane of polarization.

In arthropod eyes, rhodopsin is localized in rhabdomeres, collections of microvilli arrayed at right angles to the long axis of the photoreceptor (retinular) cell (see Figure 14.24). The rhodopsin molecules are preferentially oriented so that the 11-*cis* retinal chromophore of each is parallel to the long axis of the microvillus. Therefore, light with its e-vector parallel to the long axis of the microvilli is preferentially absorbed. Different photoreceptor cells have their microvillar arrays aligned at right angles to each other and thus are differentially responsive to light at different planes of polarization.

THE STAR COMPASS Many species of birds that are normally diurnal migrate at night, perhaps to escape predation. They cannot effectively use the sun as a compass (although some nocturnally migrating birds do use the direction of the setting sun and sky-light polarization for initial nighttime orientation). The moon is an unreliable source of nocturnal directional information; it is visible at night only half the time, and its phases (resulting from a different periodicity than that of the sun) make lunar navigation a complex problem. The stars of the night sky provide more reliable information and are used by nocturnal migrants as a **star compass**. Earth's rotation makes the stars appear to sweep across the sky like the sun, but the region around Polaris (the North Star) provides a stable reference point for north (in the Northern Hemisphere).

Experiments by the behaviorist Stephen Emlen convincingly demonstrated that some nocturnal migrants use star patterns in the night sky as a compass to determine their heading. Emlen raised indigo buntings (*Passerina cyanea*) so that they could see the night sky but not local landmarks. When the birds reached spring migratory phase, he measured their pattern of migratory restlessness. Caged buntings that could see the night sky exhibited the expected north-oriented pattern of restlessness, as did buntings that could see the identical Northern Hemispheric constellations projected in a planetarium (Figure 18.7a). When Emlen projected the same constellations so that they faced south in the planetarium, the buntings reversed their pattern of migratory restlessness by 180° to the south (Figure 18.7b).

To orient successfully, young birds must learn the elements of the night sky during a critical period prior to their first migration. Birds in the Northern Hemisphere learn that the northern sky rotates around Polaris (the North Star), and they learn star patterns within 35° of Polaris. Emlen raised indigo buntings so that they never saw the real night sky, but only artificial night skies in a planetarium. One group saw the normal pattern of stellar rotation around Polaris. The other group saw the normal star pattern, but instead of rotating around Polaris, the constellations rotated around Betelgeuse, a bright star in the constellation Orion. When the birds came into fall migratory condition, Emlen tested their orientation in a planetarium, under a stationary sky. The control birds oriented away from Polaris, that is, away from their stellar north. The experimental birds oriented away from Betelgeuse, indicating that they had learned a star map in which the stationary star (Betelgeuse) was considered north! Apparently rotation of the

star pattern is necessary for learning the location of stellar north, but it is not necessary for using the pattern once that pattern has been learned.

MAGNETIC COMPASSES Earth acts like a gigantic bar magnet; it has north and south poles that are connected by magnetic lines of force (Figure 18.8a). Earth's magnetic field, in principle, provides a reliable source of directional information: The magnetic poles are close to the geographical poles, and they never change during an animal's lifetime. Because humans are quite unaware of magnetic fields, it is surprising to find that many species of animals can detect Earth's magnetic field and can use it to navigate.

Animals can sense the polarity and dip angle of Earth's magnetic field—two qualities that provide the navigational cues that animals use as a **magnetic compass**. Magnetic lines of force have a *polar component*: their north and south polarity. They also have an *inclination component*: the “dip angle” of the lines of force relative to Earth's surface (Figure 18.8b). Magnetic lines of force exit Earth nearly vertically at the south magnetic pole, and their angle of inclination steadily decreases at lower latitudes until they are parallel to Earth's surface at the magnetic equator. From there, their angle of inclination steadily increases until the lines of force are again nearly vertical at the north magnetic pole.

Accordingly, animals may use either a *magnetic polarity compass* (one sensing directional polarity) or an *inclination compass* (one sensing the magnetic inclination angle) to navigate. Experimental

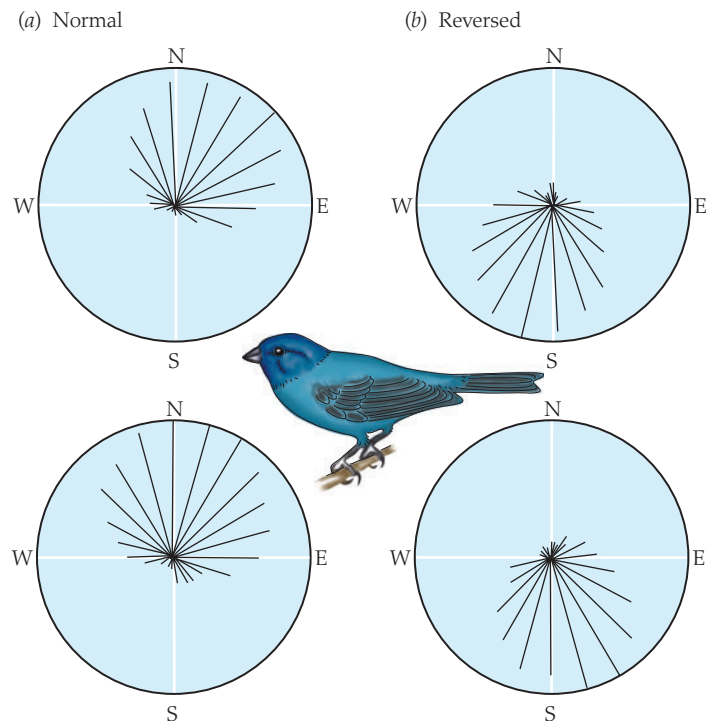

FIGURE 18.7 Planetarium experiments demonstrate that nocturnally migrating birds use star patterns for orientation. Indigo buntings were raised so that they could see the night sky but not local landmarks. The orientation preferences of their migratory restlessness (indicated by the radiating black lines) were then tested in a planetarium with either normal star patterns (a) or star patterns reversed in direction (b). The results for two buntings shown here reveal that the star pattern is the dominant determinant of orientation direction.

FIGURE 18.8 Earth's magnetic field can provide compass information (a) Lines of magnetic force leave the south magnetic pole vertically, curve around Earth's surface, and reenter vertically over the north magnetic pole. (b) Vectors of magnetic lines of force at different points on Earth's surface. Arthropods and some vertebrates use a directional compass (arrowheads point toward magnetic north), and many vertebrates use an inclination compass (into the ground = toward the nearer pole). (a after Goodenough et al. 2001; b after Wiltschko and Wiltschko 1996.)

evidence shows that arthropods such as bees sense magnetic polarity, whereas birds and other reptiles sense the inclination angle. Using an inclination compass, the direction “downward into Earth” is always poleward, as close inspection of Figure 18.8*b* reveals. Thus the downward inclination is toward magnetic north in the Northern Hemisphere but toward magnetic south in the Southern Hemisphere. At the magnetic equator the lines of force are parallel to Earth's surface, and an animal's inclination compass cannot discriminate between north and south. For this reason, birds that obtain navigational cues from an inclination compass may become disoriented as they migrate past the magnetic equator if they don't have a backup source of navigational information.

Researchers infer the presence of a magnetic compass from animal behavior. To detect an animal's use of a magnetic compass, a researcher may experimentally alter the magnetic sensory cues that the animal receives. One way to do this is to place the test animal in a box made of a type of metal (mu metal) that shields it from Earth's magnetic field. Alternatively, researchers may alter the magnetic field in the animal's vicinity by using permanent magnets or by placing tiny Helmholtz coils around the suspected locations of the animal's magnetic sensory apparatus (Figure 18.9*a*). A Helmholtz coil consists of a pair of ring-shaped electromagnets. When an electrical current is passed through the coils, a magnetic field is established in the space between the coils that can be used to nullify or reverse the effect of Earth's magnetic field. By placing a Helmholtz coil to either side of a homing pigeon's head, for example, researchers can control the bird's perception of magnetic fields.

The ability of animals to sense magnetic fields may be a primitive, relatively widespread mechanism, since it is found in some bacteria as well as many animals. Magnetic orientation is often used as a backup for other forms of compass navigation, as exemplified in homing pigeons. Recall from our discussion earlier that pigeons whose circadian clocks had been shifted forward 6 h flew in the wrong direction when they attempted to navigate south by following their sun compass (see Figure 18.5). However, the clock-shifted

birds had no trouble navigating in the desired direction on *cloudy* days, which suggests they have another navigational mechanism that is not based on solar position.

Evidence demonstrates that this second navigational system in homing pigeons is a magnetic compass. Pigeons with magnets attached to their backs or heads home normally on sunny days but are disoriented on overcast days; control pigeons with brass bars attached to their backs instead of magnets home normally on both sunny and overcast days. What's more, homing pigeons wearing Helmholtz coils (see Figure 18.9*a*) experience similar disruptions of their homing abilities when released on cloudy days. When the inclination angle of the induced field between the coils matches that of Earth's magnetic field, the pigeons orient normally (Figure 18.9*b*). But when the inclination angle of the induced field is reversed, the pigeons fly in the opposite direction from their intended course home (Figure 18.9*c*).

Another line of evidence for animals' use of a magnetic compass comes from studying the effects produced by natural magnetic anomalies (distortions of Earth's magnetic field by geological peculiarities) on a navigating animal's path of travel. On overcast days, pigeons homing in a northeasterly direction toward Boston sometimes become disoriented at a major magnetic anomaly called Iron Mountain, in Rhode Island. The mountain's metallic composition bends the magnetic-field lines in its vicinity, sending the hapless birds off course. In the ocean, magnetic-field lines cluster together to form high-intensity ridges or spread apart to form low-intensity troughs that can be mapped by satellite. Whales and dolphins are more likely to swim ashore and become stranded at locations where troughs in magnetic-field intensity meet the shore. This correlation suggests that whales migrate using a magnetic compass and perhaps follow the path of magnetic troughs.

Other organisms, including salamanders, turtles, salmon, and bacteria, have been shown to orient to magnetic fields. Such orientation is commonly weaker than that to solar or other celestial cues, supporting the idea that magnetic orientation is a primitive,

(a) The experimental setup

(b) Magnet in normal orientation

(c) Magnet in reversed orientation

FIGURE 18.9 Changing the magnetic field changes the orientation of released pigeons (a) A small Helmholtz coil is shown attached to a pigeon's head, with a power pack on the pigeon's back. Reversing the direction of electrical current flow through the coil reverses the direction of the magnetic field. (b,c) Pigeons with Helmholtz coils were released south of home on overcast days. They interpreted the direction in which magnetic lines dip into Earth as north. Each dot outside the circle represents the direction in which a released pigeon vanished over the horizon. The arrow at the center of each circle is the mean vanishing bearing for the group. (After Walcott and Green 1974.)

widespread mechanism, often used when other cues are unavailable. Monarch butterflies (*Danaus plexippus*), for example, use a sun compass when the sun is available, but in the absence of celestial cues, they may use magnetic-compass information to orient and navigate. Detection of magnetic fields in monarch butterflies and in *Drosophila* may depend on cryptochrome-based light reception (see **Box 18.1**). Bees are also able to detect magnetic fields, and the orientation of their dances at the hive can be influenced by magnetic fields. However, magnetic information plays little role in ordinary bee navigation.

For any animal that navigates using magnetic-compass cues, the magnetic response is innate and presumably genetically determined. But unlike the star compass—which appears to be fixed

once it has been learned during a critical period in the animal's life—an animal's magnetic compass seems to be subject to at least some degree of recalibration. The ability to recalibrate is important because migrants to Arctic latitudes must resolve conflicts between magnetic and celestial navigational cues. The north magnetic pole and the geographical North Pole are not identical (see Figure 18.8). Magnetic-field information points to a different location than celestial-compass information does, and the disparity between the two increases at higher and higher latitudes. For this reason, migrating Arctic birds must pause in their journey at intervals in order to allow their magnetic compasses to realign with celestial-compass cues such as polarized sky light. If prevented from pausing long enough to recalibrate, the birds may become disoriented.

The physiological mechanisms by which animals detect magnetic fields are discussed in **Box 18.1**.

Some animals appear to possess a map sense

Most animals probably do not use simple compass navigation in migration or homing without also using landmark or map information. In cases of **map-and-compass navigation**, the animal possesses in its brain some sort of representation of its position, and the position of its goal. This is the *map*, and the animal's *compass* provides bearings relative to the map.

For most animals that appear to have a map sense, we do not know the map's basis, although it might be based on various sensory cues. A map could be based on geomagnetic information, since both the vertical angle and the strength of magnetic fields increase near the magnetic poles. The disorientation of homing pigeons and migrating whales in the vicinity of magnetic anomalies suggests that magnetic information is an important basis of their maps. Solar cues could also provide map information; the height of the sun above the horizon varies with the latitude, and the times of sunrise and sunset vary with longitude. For some migrating creatures, infrasounds (very low-frequency sound waves—for example, from waves crashing on a distant shore) may serve as the basis of the map. Even olfactory cues are suspected of forming the basis of the map sense, as appears to be the case with pigeons. Whatever its basis, map construction and use represent a sophisticated instance of animal learning.

DISPLACEMENT EXPERIMENTS TEST FOR A MAP SENSE Displacement experiments show the difference between path integration and compass navigation on the one hand, and complex map-and-compass navigation on the other. If a desert ant is experimentally moved while it is feeding, its return path makes no correction for this passive displacement (see Figure 18.3). Therefore, the ant has no map sense that allows it to detect its displacement relative to its goal.

Birds, in contrast, are more likely to correct for a passive displacement, whether experimental or by natural means such as a storm. If a bird migrating southwest purely by compass navigation became displaced, say, 100 km to the southeast, it would continue to go southwest. If the bird were using map-and-compass navigation, it would realize it had been displaced (apparently without using local, familiar landmarks) and would correct its path to the west or northwest.

Figure 18.10 illustrates the distinction between path integration and compass navigation. European starlings (*Sturnus vulgaris*)

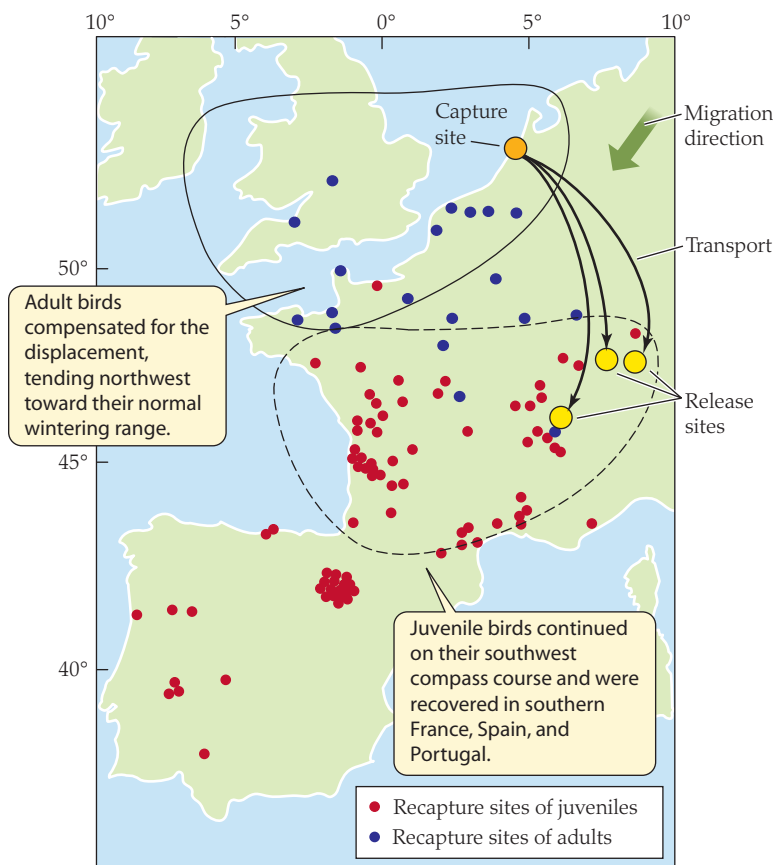

FIGURE 18.10 Migrating adult and juvenile starlings respond differently to displacement European starlings were captured in the Netherlands while in their autumn migration southwest from north-eastern Europe and were transported to release sites in Switzerland. The normal wintering range is bounded by the solid line; a dashed line shows a similar area displaced to the same extent as the displacement of the released birds. The adults' compensation for displacement suggests the use of map-and-compass navigation. (After Perdeck 1958.)

migrate from Baltic breeding grounds to wintering grounds in France and England. Migrants were captured in the Netherlands, transported to Switzerland, and released. The juvenile starlings continued southwest (by compass navigation) and ended up in Spain, but the older, experienced birds that had developed a map sense could detect the displacement and reorient to a new northwestern path. Map-and-compass navigation is sometimes called *true navigation*, an unfortunate term because it (wrongly) suggests that other methods of an animal's finding its way are not really navigation. Because we find that compass orientation is relatively complex, we may expect the basis of the less-understood map sense to be complex as well.

PIGEONS MAY HAVE AN OLFACTORY MAP Some of the clearest studies of map sense have focused on pigeons, and the dominant hypothesis of map sense in pigeons is the *olfactory-map hypothesis*. Displaced pigeons can determine their position relative to home without using visual or proprioceptive information from the outward journey to the release site. Therefore, investigators conclude that the pigeons must have some sort of map sense that, with the compass information previously discussed, allows them to return from more than 700 km away. According to the olfactory-map hypothesis, the pigeon's map sense is based on an odor profile somewhat analogous to the one used by homing salmon. The odor profile could consist of a mosaic of discrete odor sources or a few odor gradients.

Several lines of experimental evidence support the olfactory-map hypothesis. Pigeons are usually housed in somewhat open structures (lofts), often on the roofs of buildings. A pigeon that has its olfactory sense disrupted has difficulty homing to its loft. Manipulations of odors around the home loft can also affect homing performance, perhaps by affecting the learning of an olfactory map. In one example, pigeons were raised in a loft that was exposed to normal odors but also had an odor of benzaldehyde blown in by a fan from the north-northwest. Thus they presumably learned to associate north-northwest wind with benzaldehyde. At the end of the summer they were transported to various distant, unfamiliar release sites, exposed to benzaldehyde, and released. They flew primarily south, regardless of the release site. Control birds raised without benzaldehyde, but exposed to it just prior to release, oriented toward home normally from the release sites. The simplest interpretation of these findings is that the pigeons learned to associate benzaldehyde odor with north-northwest wind, so the experimental pigeons thought they had been released at a benzaldehyde source north-northwest of home, and flew south-southeast.

BOX 18.1 MAGNETORECEPTORS AND MAGNETORECEPTION

Kenneth J. Lohmann

The idea that animals perceive Earth's magnetic field was once dismissed as impossible by physicists and biologists alike. Earth's field is much too weak for an organism to detect, the argument went, and there are no possible biological mechanisms capable of converting magnetic-field information into electrical signals used by the nervous system.

Over time, however, evidence accumulated that animals do indeed perceive magnetic fields, until even the most hardened skeptics came to accept the idea. Today it now seems clear that diverse animals, ranging from invertebrates such as molluscs and insects to vertebrates such as sea turtles and birds, exploit information in Earth's field to guide their movements over distances both large and small. What has remained mysterious is exactly how they do this.

Determining how the magnetic sense functions is an exciting frontier of sensory physiology. For sensory systems such as vision, hearing, and smell, the cells and structures involved in perceiving relevant sensory stimuli have been largely identified, and the basic way in which the sense operates is understood. In contrast, the cells that function as receptors for the magnetic sense have not been identified with certainty in any animal. Even the basic principles around which magnetic sensitivity is organized remain a matter of debate. This box continues on the web in **Box Extension 18.1**. There you will find more information on magnetoreception in animals and on mechanisms that may underlie it.

Other investigators have criticized the olfactory-map hypothesis on several grounds. Olfactory anesthesia or nerve cuts to make pigeons unable to smell may have indirect effects on homing performance that have been mistakenly interpreted as affecting an olfactory map. Some indirect effects can be ruled out; for example, the olfactory manipulations do not simply make the animal sick. Other effects, such as a possible indirect disruption of the pigeons' use of magnetic signals, are harder to rule out. In addition, some experiments have been hard to replicate, perhaps because investigators in different countries raise their birds in different styles of lofts that may affect olfactory-map learning. Overall, however, there is substantial evidence to infer roles of olfactory cues in pigeon homing, and so we can consider the olfactory-map hypothesis to be supported by evidence but not proven.

Sea turtles exemplify the degree of our understanding of navigation

Sea turtles illustrate what we know and don't know about the behavioral mechanisms of navigational control. Turtles use different cues in navigation at different stages in their life cycle, and some of these cues are much easier to analyze than others. New hatchlings starting off the beach appear to engage in a sequence of orienting mechanisms. Loggerhead sea turtles hatching on Florida beaches initially orient toward a lighter sky, which will be toward

water (because the water reflects more sunlight or moonlight and makes the sky lighter). This light orientation and a tendency to move down a slope take the hatchlings to the water, where they swim out continuously for 24 h. The primary orientation cue for this frenzied outward swim is the waves; the turtles head into the waves, which come (with rare exceptions) from the open ocean. (During the exceptions, young turtles swim into the waves even if that orientation takes them back to shore.)

The young turtles can also detect Earth's magnetic field, and magnetic-compass orientation may replace wave orientation after their initial outward swim. This navigational sequence is thought to take the turtles out to the Gulf Stream, one of the currents flowing around the North Atlantic Subtropical Gyre (Figure 18.11). Adult turtles must use map-and-compass navigation to return to their natal beach to nest (in contrast to juveniles, which only have to reach the gyre). Tracking studies indicate that the adults navigate by direct, straight-line routes. Recent evidence indicates that even the younger turtles can use magnetic information as a map component that helps keep them in the gyre as they mature.

Experimental replication of the parameters of the magnetic field at different points in their migration route leads to different swimming orientations that match the turtles' swimming direction at that location (see Figure 18.11). For example, caged turtles in an artificial magnetic field that replicates the natural

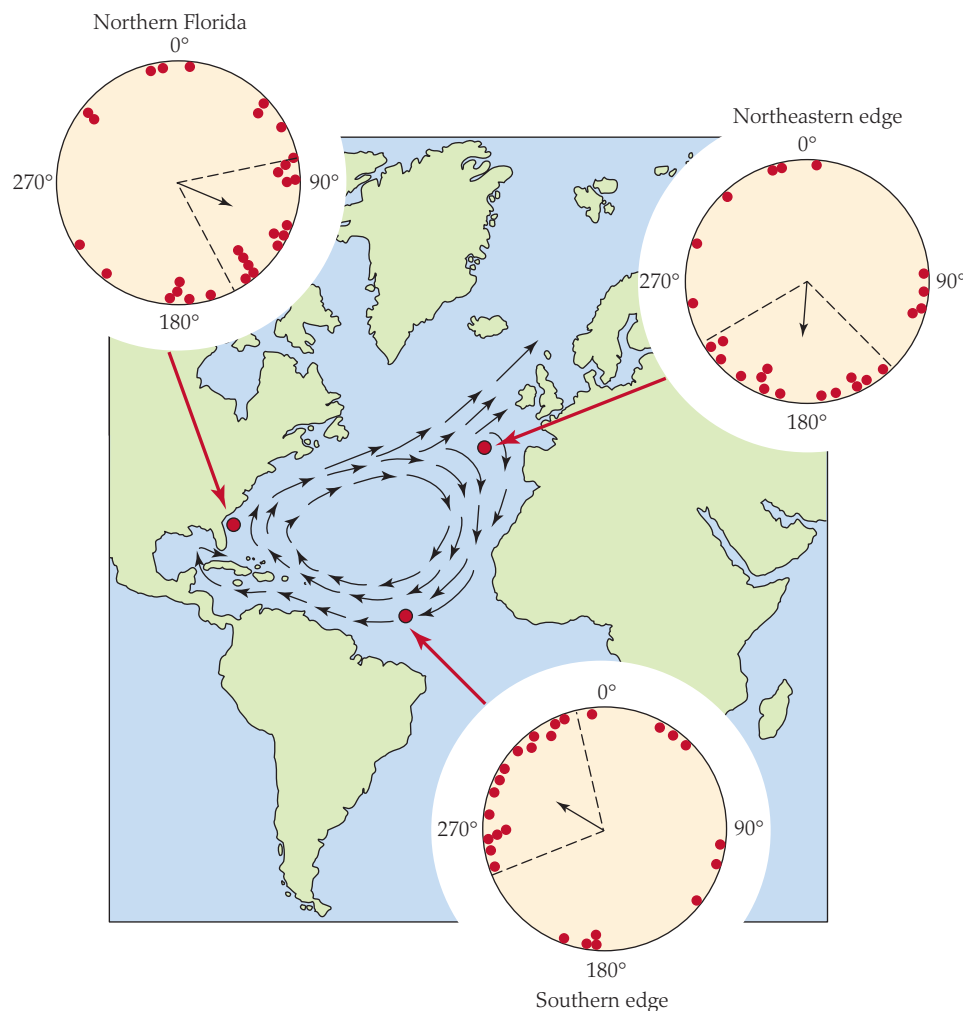

FIGURE 18.11 Hatchling turtles orient to artificial magnetic fields in ways that suggest a magnetic map Newly hatched loggerhead turtles were placed in artificial magnetic fields characteristic of three locations (red dots on map) along their prospective migratory route. Arrows on the map show major currents of the North Atlantic Subtropical Gyre, around which the turtles swim as they mature. Each dot in the orientation diagrams represents the mean angle of oriented swimming of one hatchling. The arrow in the center of an orientation diagram indicates the mean angle of orientation of each group; arrow length shows the statistical degree of orientation of the group. All three groups showed statistically significant orientation to the artificial magnetic fields. The angle of orientation differed greatly for the three groups tested with artificial magnetic fields corresponding to different locations. Moreover, the orientation at each simulated location was appropriate to keep turtles within the gyre, rather than (for example) straying into the fatally cold water of the North Atlantic and North Sea. Dashed lines represent the 95% confidence interval for the mean angle; data are plotted relative to magnetic north. (From Lohmann et al. 2001.)

magnetic field off the coast of Spain swim southward, a direction that keeps them in the North Atlantic Subtropical Gyre rather than washing into northern waters off Scandinavia. Similar experiments with turtles as well as with salamanders, spiny lobsters, and birds all show that experimental replication of the magnetic-field vectors and strengths of a particular location can alter orientation behavior in predictable ways. These studies suggest that animals can use magnetic information as a map (as well as a compass), a finding that may begin to clear up the murkiest area in complex navigation.

Innate and Learned Components of Navigation

We have indicated that many elements of navigation, such as using landmarks, imprinting to a home stream, and constructing a map, are largely learned behaviors. Here we discuss the roles of innate (“hardwired”) behavior and of learning in navigation, and we consider how vertebrates learn their spatial surroundings.

Some forms of navigation have strong innate aspects

Two examples demonstrate innate components of navigation that do not depend on prior learning. Monarch butterflies summer throughout the United States north of the Gulf states. Those east of the Rocky Mountains migrate south every fall to overwintering sites in forested mountains of central Mexico. In the spring the same individuals migrate north to the U.S. Gulf Coast states, where females lay eggs on milkweed and die. A new generation continues the migration to summering grounds in the northern states and produces two or more short-lived generations in a summer. The autumn migrants that return to the same restricted overwintering sites in the following year are thus descendants, three to five generations removed, of ancestors that occupied the sites the previous winter! The navigational performance of the monarch butterfly therefore must have a strong innate, genetic component; the butterflies cannot have learned the overwintering location from previous experience.

Some birds also have innate, apparently genetic components of their migratory navigation. European blackcaps (*Sylvia atricapilla*), for example, migrate from Europe to Africa around the Mediterranean Sea—those in western Europe going southwest via Gibraltar, and those in eastern Europe going southeast via Syria. When birds from the two sides of the divide are raised in isolation, they orient in cages in the correct direction for their area of origin, despite the lack of opportunity to learn their way. Cross-breeding experiments further demonstrate that the difference in orientation between eastern and western strains is genetic.

The hippocampus is a critical brain area for vertebrate spatial learning and memory

As we have discussed, an animal’s ability to navigate often involves learning, such as the recognition of landmarks by some homing animals, or the imprinting of home stream odors by salmon. Spatial learning is crucial for many sorts of navigation, and for vertebrates a major locus of spatial learning is the *hippocampus* of the brain.

By surgically creating hippocampal lesions in test animals and monitoring their performance in mazes, researchers have shown the importance of the hippocampus in spatial learning.

One standard test of spatial learning in laboratory rodents is the *Morris water maze*, which consists of a hidden, submerged escape platform in a pool of turbid water. The test animal must learn the location of the platform from local cues (landmarks) that are situated outside the pool. Mice or rats with hippocampal lesions do not remember the location of the platform, and they continue to swim about randomly, trial after trial. Another means of testing spatial learning is the *radial-arm maze*, which consists of several blind corridors that extend symmetrically from a central chamber. The researcher repeatedly baits the end of one arm (or shifts the bait from arm to arm in a recurring pattern); the test animal must remember which arm is baited to earn the reward. Normal mice and rats remember the arms they have visited and do not reenter them during a test session, but mice and rats with hippocampal lesions repeatedly enter the same arm and often bypass the arms they have not yet visited.

Does spatial learning in the hippocampus explain how food-caching birds such as Clark’s nutcrackers store information about the locations of thousands of cache sites? In fact, birds with bilateral hippocampal lesions continue to hide food normally, but they cannot recover their caches. They can, however, remember simple, nonspatial associative tasks (such as pairing a sound with a reward). Thus the deficit appears to be specific for spatial learning and memory. Also suggesting the importance of this brain region in spatial learning is that researchers have noticed that the hippocampus is significantly larger in food-caching birds than in size-matched species that do not cache. Moreover, for species that cache, preventing caching behavior in immature birds appears to diminish hippocampal growth.

The hippocampus also appears to be involved in homing in pigeons. It is critical for learning two aspects of pigeon navigation: piloting and navigational maps. Inexperienced pigeons with hippocampal lesions are impaired in learning local landmarks for piloting, as might be expected from the studies with seed-caching birds and rodents. They also fail to orient correctly from distant, unfamiliar release sites, indicating that they have failed to learn a navigational map. Experienced pigeons that receive hippocampal lesions *after* learning a navigational map orient correctly from distant release sites, but they still have difficulty with local, landmark-based navigation. Therefore, the hippocampus appears necessary throughout life for landmark-based navigation but not for using a navigational map once that map has been learned. Interestingly, the left hippocampus appears necessary for map learning in pigeons, but not the right.

The two hippocampi may also be used differently in humans. There are two aspects or strategies of spatial learning and memory, called *allocentric* (world-centered) and *egocentric* (body-centered) representations. These are comparable to two kinds of video games: the maplike bird’s-eye-view strategy games and the “first-person shooter” games in which the screen shows the view ahead of the character. Either allocentric or egocentric representations can be used to orient in an environment. A recent human study using fMRI and a virtual radial-arm maze concluded that activation of the right hippocampus predicted the use of an allocentric spatial representation, and activation of the left hippocampus predicted use of a sequential egocentric representation. Thus the right human hippocampus may code places and the left may code temporal sequences of movement.

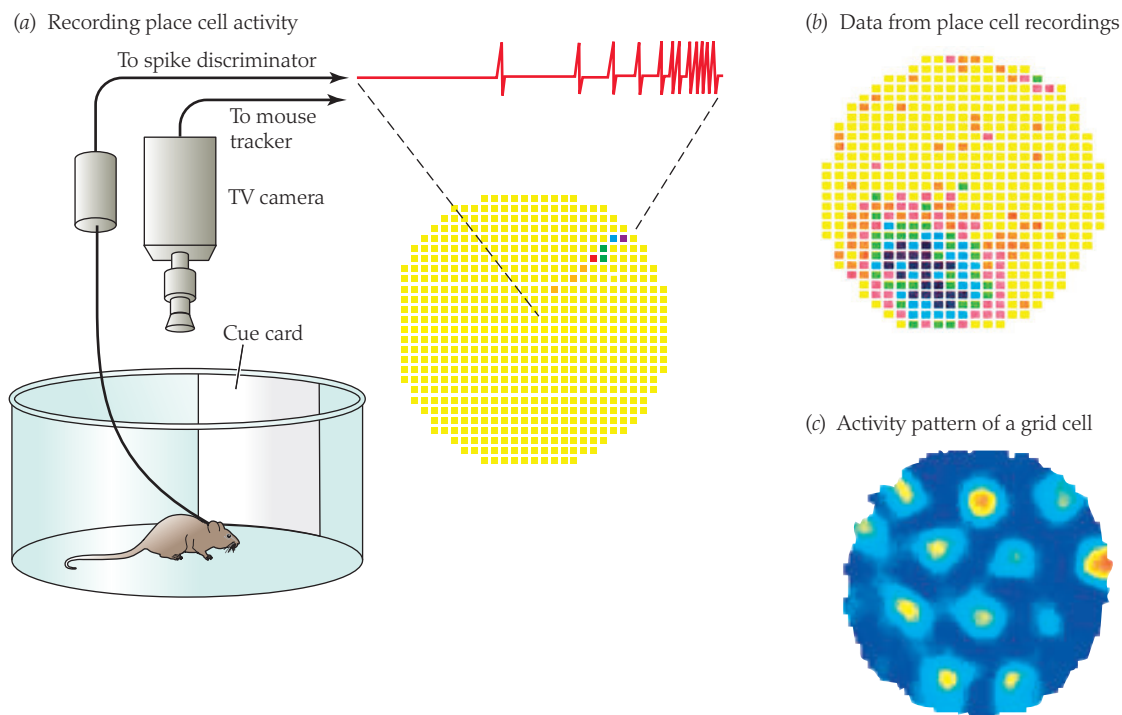

FIGURE 18.12 Place cells suggest how the hippocampus of the brain plays a role in spatial learning (a) A chronically implanted electrode records activity of an individual hippocampal pyramidal neuron while a mouse is moving around an arena. A TV camera records the mouse's position and correlates it with the neuronal activity. The cue card is a landmark to aid the animal in orientation. (b) An individual hippocampal neuron is active (cool colors) when the mouse is in a particu-

lar part of the arena. Such correlations are rather stable from day to day and are learned during exploration of initially unfamiliar environments. The diameter of the circle is 0.76 m. (c) A grid cell in the entorhinal cortex is active (warm colors) when the animal is at any apex of an invisible triangular grid within the environment. The circle's diameter is about 2 m. (b from Muller et al. 1987; c from Hafting et al. 2005.)

Exactly *how* the hippocampus stores and retrieves spatial memory has not been determined, but two interesting findings are relevant. First, the hippocampus is a principal site of long-term potentiation (LTP) (see Chapter 13, page 353). Gene knockouts that disrupt LTP in mice disrupt spatial learning in tests such as the Morris water maze. Overexpressions of genes that enhance LTP improve learning and memory of familiar objects, spatial tasks such as the Morris water maze, and other memory tasks.

Second, chronic electrical recordings from single neurons in the hippocampus of rats or mice show that some neurons generate action potentials only when an animal is in a particular part of a familiar area (Figure 18.12a,b). These hippocampal neurons are termed **place cells** because their activity encodes the spatial position of the animal. The existence of place cells in the hippocampus suggests that this brain area creates some sort of a spatial map of the environment in the brain. The spatial representations of place cell activity are dynamic; as an animal is exposed to new environments, some place cells may change their specification to incorporate new areas.

The hippocampus is not the only brain area that is involved in processing spatial information used in navigation. Investigators have recorded from neurons—termed **head direction cells**—that encode the direction the animal's head is pointing. These neurons occur in a circuit in the rodent forebrain that extends from the dorsal tegmental nucleus to the entorhinal cortex, and are activated by vestibular and other sensory information. Head direction cells are direction-specific but not location-specific, unlike place

cells, which are location-specific but not direction-specific. Other neurons appear to provide distance calibration for a mental map. Neurons in one part of the entorhinal cortex are called **grid cells**, because they are active when the animal is in any of several grid-like locations in its environment (Figure 18.12c). Grid cells do not provide locale information like place cells do; instead, they increase their activity when a rat walks through the vertices of an invisible grid of equilateral triangles that measure off distances within the environment. Different grid cells have somewhat different scales, representing 30-cm grids in the dorsalmost part of the area and 70-cm grids ventrally. The finding of grid neurons is certainly consistent with the idea that animals form a kind of maplike representation of their environment in their brains.

Such studies of the hippocampus and other brain areas are starting to build a physiological basis of navigation. It is not clear just how animals use the neural information these studies describe, but the findings are consistent with what animals would need for complex spatial representation. One can imagine how animals might use place cells that encode landmark-based learning of familiar areas, head direction cells that encode compass-heading information (and receive input from various directional sensors), and grid cells that provide a distance scale. Our increasing ability to relate sensory and brain mechanisms to map functions should provide an important link between brain processes and the complex spatial behaviors of navigation, and ultimately to the navigational basis of migration, homing, and other spatial behaviors.

Study Questions

1. Explain the effect on sun-compass orientation of a circadian-clock shift to a light schedule that is 4 h later (e.g., from lights-on at 6:00 AM to lights-on at 10:00 AM).
2. List the advantages and disadvantages to an animal of using information from magnetic, sun, star, and polarized-light compasses.
3. Experienced homing pigeons were thought not to need any information about the outward journey to a release site in order to home successfully. Much evidence for this conclusion came from depriving the birds of visual, magnetic, and vestibular information that could be used for path integration. What other sorts of studies would you want performed before accepting this conclusion?
4. Outline how a vertebrate might use place cells, head direction cells, and grid cells in different forms of navigation.

Movement and Muscle

CHAPTER 19 ■ Control of Movement: The Motor Bases of Animal Behavior

CHAPTER 20 ■ Muscle

CHAPTER 21 ■ Movement and Muscle *at Work*: Plasticity in Response to Use and Disuse

Previous page: This European tree frog *Hyla arborea* was photographed at three stages of a single jump. *H. arborea* feeds mainly on insects, and its jumping ability allows it to catch flying insects which make up more than half of its diet. *H. arborea* uses jumping not only to catch prey but also to avoid predators. Adults are usually less than 50 mm (2 inches) in length. Their prodigious jumping capability is believed to arise from a combination of hindlimb muscle contractions and elastic energy that gets stored in the tendons by muscle work performed early in the jump. The ability to move—one of the defining properties of animals—underlies the ability to obtain nourishment, escape predators, and reproduce. Many movements are achieved by muscle contractions, and these are finely controlled by neural input.

Control of Movement: The Motor Bases of Animal Behavior

When a salamander moves around, eats, or mates, its nervous system sends output to effectors that produce its behavior. All externally observable behavior is a direct result of the activation of effectors. That is, all behavior that can be observed consists of movements (usually resulting from muscle contractions), sounds (also from muscle contractions), gland secretions, color changes, and other outputs of effectors. Therefore, the mechanisms by which animals generate patterns of behavior involve the coordinated control of muscles and other effectors.

In this chapter we consider the neural control and coordination of movement, particularly the generation of motor behaviors such as walking, swimming, and flying. The salamander shown at the right resembles the first land-based tetrapod vertebrates: It can swim by undulating its body from side to side, and can walk by stepping its legs in a coordinated sequence. The robot shown below can do the same, since the investigators who built it modeled its locomotor control after that of the salamander. In doing so they have shown that the neural circuitry that controls and coordinates swimming behavior and walking behavior in salamanders may also provide a straightforward explanation for the transition from swimming to walking—a transition likely to have been important in vertebrate evolution.

Neural Control of Skeletal Muscle Is the Basis of Animal Behavior

A major function of an animal's nervous system is to generate its behavior. The ways in which the coordinated motor output of a nervous system produces behavior may be as simple as the withdrawal of a limb in response to a painful stimulus, or the tail-flip escape of a crayfish, or as complex as the mating behavior of a stickleback fish or of a songbird. In this chapter we concentrate on the neural circuits that produce relatively simple patterns of motor output to generate behavioral elements such as locomotion. (More elaborate behavioral performances are less readily understood in terms of the patterns of motor output of nervous systems to produce them, but physiologists consider them to represent elaborations of the simpler patterns discussed here.)

In Chapters 20 and 21 we will examine muscle physiology itself. It may seem odd to consider the physiology of neural control of muscle before examining the muscle itself, but because we have already discussed other functions of the nervous system, this sequence is appropriate. At this point, if you keep in mind that muscle contracts when it is excited by motor neurons, the actual contractile physiology can wait.

A major question in the analysis of the neural basis of behavior is, what are the neural circuits—the assemblies of neurons and the patterns of synaptic interconnections between them—that produce

A robot salamander shows how features of the neural control of locomotion may have eased the transition from swimming to walking in vertebrate evolution (Photograph of robot salamander from Ijspeert et al. 2007.)

particular patterns of behavioral movements? In this chapter we will examine several neural circuits and relate their actions to the behaviors they mediate. We will compare neural circuitry of invertebrates and vertebrates, illustrate models of circuits that are thought to underlie rhythmic patterns of behavior such as walking or flying, and look closely at the control of movements of vertebrate animals.

Invertebrate neural circuits involve fewer neurons than vertebrate circuits

Investigators have elucidated the neural circuits underlying several behaviors in invertebrates (mostly arthropods and molluscs) and in vertebrates. The circuits in these two groups of animals are qualitatively similar, but vertebrate circuits always include many more neurons than do those in invertebrates. As we will see in Chapter 20, an arthropod muscle receives innervation from only a few motor neurons, whereas a vertebrate muscle receives innervation from hundreds of motor neurons.¹ Similar disparities in neuron number occur in the central nervous system (CNS), with vertebrates having 10^4 to 10^5 times as many neurons as arthropods or molluscs.

This contrast leads to two generalizations about invertebrate and vertebrate neural circuits. First, in many cases an invertebrate neuron may be a uniquely *identified neuron*—that is, a neuron whose structure, location, electrical activity, or other properties are sufficiently distinctive that the neuron can be recognized and studied in every individual of a species. In contrast, nearly all vertebrate neurons cannot be uniquely identified, but can be recognized

¹Note that a whole muscle of a vertebrate is composed of thousands of muscle fibers, and each muscle fiber receives a synapse from only one motor neuron (see Chapter 13).

only as members of a population. The second generalization is that single individual neurons play functional roles in invertebrate circuits, whereas many neurons participate in a particular function in vertebrate neural circuits. For example, a single arthropod neuron may act as a *command neuron*, a neuron whose activity is sufficient to command a particular element of behavior. For vertebrates, a larger number of neurons nearly always act together to provide such a command function.

We have already described two simple invertebrate neural circuits, each mediating a **reflex**, which we can define as a simple, graded response to a specific stimulus. One of these circuits mediates the startle escape response of cockroaches, discussed in Chapter 12 (see Figure 12.3); the other controls the gill withdrawal reflex in the marine mollusc *Aplysia*, discussed in Chapter 13 (see Figure 13.23). Each of these circuits depends on only tens of neurons in the circuit. In both of these examples, a modest number of mechanosensory neurons excite central interneurons to excite some motor neurons (while inhibiting others), leading to selective activation of muscles to produce a reflexive response. Several neural circuits of invertebrates, whether reflexive as in these examples or centrally programmed, are well understood because of the relatively small number of neurons they contain. The vertebrate circuits we examine next, in contrast, contain thousands of individual neurons, although the neurons are the same few types as for invertebrates.

Vertebrate spinal reflexes compensate for circumstances, as well as initiate movements

Spinal reflexes are mediated by the neural circuits of the vertebrate spinal cord. As a result of pioneering studies by Charles Sherrington (1857–1952) and Ivan Pavlov (1849–1936) on spinal reflexes at the beginning of the twentieth century, analysis of behavior in terms of spinal reflexes dominated studies of neural circuits through most of the twentieth century. These spinal reflexes are therefore perhaps the best-known vertebrate neural circuits.

In spinal reflexes, sensory input (from receptors of the skin, muscles, tendons, and joints) enters the spinal cord through the dorsal roots (Figure 19.1). This sensory input, via intervening

FIGURE 19.1 The stretch reflex A tap on the patellar tendon at the knee joint is used to test the knee-jerk reflex. This reflex involves relatively simple neuronal circuits made up of sensory (afferent) neurons, motor (efferent) neurons, and interneurons. Open circles indicate excitatory synapses; closed circles are inhibitory synapses.

synapses in the spinal cord, excites some motor neurons and inhibits others (see Figure 13.7), leading to movements by selectively activating muscular contraction. The sensory inputs from different populations of receptors have different connections in the spinal cord and thereby initiate different reflexes. We will examine two of the many reflexes of the mammalian hindlimb that have been studied extensively: the stretch reflex and the flexion reflex.

THE STRETCH REFLEX The first spinal reflex we will consider is the **stretch reflex** (or *myotatic reflex*). A familiar example of the stretch reflex is the knee-jerk response to a tap on the patellar tendon at the knee joint, a test that is a staple of routine medical examinations (see Figure 19.1). The stretch reflex is essential for the maintenance of posture and the coordination of movements. As we discuss the familiar patellar reflex example, it is important to remember that all skeletal muscles are continuously involved in generating stretch reflexes. As we will see, the importance of this reflex is reflected by both the large diameters of the axons involved and the minimal number of synapses in the circuit. When the doctor taps you on the patellar tendon, the hit of the hammer stretches the knee extensor muscles in your thigh. This stretch stimulates *muscle spindles* (Box 19.1) located in the muscle, which contain stretch-sensitive endings of sensory receptors wrapped spirally around the noncontractile portions of specialized *intrafusal* muscle fibers.

The sensory axons associated with muscle spindles are known as **1a afferent** fibers—*afferent* meaning “conducting toward the central nervous system,” and *1a* because they are the largest and most rapidly conducting sensory fibers in the body. (Not all muscle-spindle sensory neurons are of the 1a class, but we will simplify the discussion by considering only the 1a sensory neurons here.)

The 1a axons from muscle spindles enter the spinal cord and make direct, excitatory synaptic contact with motor neurons to the same muscle (see Figure 19.1). This direct synaptic excitation is unusual; most vertebrate sensory neurons directly synapse only onto interneurons (intrinsic neurons that do not leave the CNS). The simplest manifestation of a stretch reflex, then, involves only two kinds of neurons: 1a sensory neurons and motor neurons.

When a muscle spindle is stretched, its 1a afferent neuron generates a train of nerve impulses. These impulses elicit excitatory postsynaptic potentials (EPSPs) in motor neurons, which—if their depolarizations exceed threshold—lead to motor neuron impulses and ultimately to contraction of the stretched muscle, and the leg kicks upward. Muscle spindles are said to be *in parallel* to the extrafusal fibers that generate the substantive contractile forces of a muscle because they act *beside* the extrafusal fibers (see Box Extension 19.1). Because muscle spindles are in parallel to the force-producing extrafusal muscle fibers, they are sensitive to muscle *length*. They respond to increasing muscle length by increasing their activity.

Other aspects of the neural circuit of the stretch reflex, however, complicate the picture. The 1a afferent axons also synapse on other neurons in addition to motor neurons. Some of these connections stimulate excitatory interneurons that excite the motor neurons to the same or to other muscles that work in parallel with the first muscle. Other synapses excite inhibitory interneurons that inhibit the motor neurons to the antagonist (opposing) muscle. Thus a tap on the patellar tendon not only excites motor neurons to the

BOX 19.1 MUSCLE SPINDLES

A muscle spindle is an example of a *proprioceptor*—a mechanosensory receptor (see Chapter 14) that is associated with the musculo-skeletal system. Proprioceptors are important for the control of movement because they provide an animal with information about where the parts of its body are positioned in space—information that is necessary both to program a movement and to monitor how the movement is progressing.

The *muscle spindle organ* monitors the *length* of a skeletal muscle. **Box Extension 19.1** describes a muscle spindle organ and shows how it monitors length and thereby acts as the sensor in compensating for changes in load in posture and movement.

extensor muscle to produce the familiar knee jerk, but also inhibits motor neurons to the antagonist flexor muscle (see Figure 19.1).

These synaptic connections illustrate one of the most basic features of reflexes and of the organization of motor systems: the principle of **reciprocity**. Muscles (or groups of muscles) tend to be arranged in antagonist pairs that oppose each other, such as the flexor muscles that bend the knee and the extensor muscles that straighten it. The principle of reciprocity states that any signal that activates movements, whether it is the sensory input to a reflex or a command of the CNS, is coordinated to contract a set of muscles that work together (the *agonists*) while relaxing the opposite (*antagonist*) set. This reciprocal control of muscles ensures that two mutually antagonistic muscles do not usually counteract each other and suppress the movement. Thus in the stretch reflex, stretch of the extensor muscle activates extensor motor neurons to contract the extensor and relieve the stretch, while inhibiting flexor motor neurons to prevent co-contraction of the antagonist flexor muscle.

Another added complexity in the stretch reflex (and in motor circuits in general) is the number of neurons involved in even the simplest behavioral act. Figure 19.1 shows one 1a sensory neuron and one extensor motor neuron, but these only represent larger populations of these neuron types. A large leg muscle contains many muscle spindles, so its stretch activates many sensory neurons. Moreover, the muscle is supplied by at least 300 motor neurons. Unlike the situations in crayfish and *Aplysia*, none of these neurons are identified; you cannot find the same extensor motor neuron from animal to animal. Each 1a sensory neuron synapses with most, and probably all, of the motor neurons to the same muscle, as well as with many interneurons of different types. For example, in addition to the neurons that are part of the stretch reflex circuit, many interneurons convey 1a sensory information to higher brain centers.

The stretch reflex circuit illustrates the principle of **divergence** of central neural connections: Each presynaptic neuron usually contacts many postsynaptic neurons. The converse principle, **convergence**,

FIGURE 19.2 The neural circuit of the flexion reflex and the crossed extension reflex The flexion reflex mediates protective withdrawal of a limb (a), whereas the crossed extension reflex extends the opposite limb for compensatory support (b). Smaller arrows indicate direction of nerve impulse propagation; plus signs (+) indicate increases in activity, and minus signs (–) indicate decreases. Open circles indicate excitatory synapses; closed circles are inhibitory synapses.

also occurs, because each postsynaptic neuron is contacted by many presynaptic neurons. For example, each of the motor neurons receives input from about 10,000 synapses, representing many 1a sensory neurons and many more excitatory and inhibitory interneurons. Thus the cartoon view of the circuit for a stretch reflex in Figure 19.1 is a great oversimplification.

THE FLEXION REFLEX When you step on a tack, you reflexively withdraw your foot from the offending stimulus. Your foot is drawn upward by contraction of the flexor muscles of the thigh. The neural

circuit mediating this flexion reflex is shown at the left in **Figure 19.2**. A diverse array of sensory neurons known as *flexion-reflex afferents* have endings in the skin, muscles, and joints; some of these are sensitive to painful and noxious stimuli. The flexion-reflex afferents make excitatory synaptic contacts on interneurons in the CNS that in turn excite motor neurons to the flexor muscles, as well as inhibitory interneurons that inhibit motor neurons to the extensor muscles. Thus, as in the stretch reflex (and in other spinal reflexes), synaptic interactions in the spinal cord maintain the reciprocity of action between antagonist pools of flexor and extensor motor neurons. Unlike the sensory neurons of the stretch reflex, however, flexion-reflex afferents make only indirect connections to motor neurons, via at least one layer of intervening interneurons.

The obvious function of the flexion reflex is protective; the offended limb is flexed, lifted, and withdrawn from a painful and potentially damaging stimulus. The reflex circuit is relatively short, local, and rapid. Of course, flexion-reflex afferents also connect to other interneurons that ascend the spinal column to the brain, so you become aware of the painful stimulus. This slower process occurs while the reflex flexion is taking place, so in most cases the foot is lifted (or the hand is withdrawn from the hot stove) before you are aware of the stimulus triggering the withdrawal. Note that many receptors other than pain receptors can trigger flexion reflexes, and that the main function of the flexion-reflex afferents is to provide proprioceptive and cutaneous information to the brain and spinal cord, not just to elicit flexion reflexes.

If you stepped on a tack with your left foot while your right foot was lifted off the ground, it would be a good idea to extend your right foot while flexing your left foot. In fact, one component of the flexion reflex ensures this. As Figure 19.2 shows, flexion-reflex afferents synapse onto interneurons that cross the midline of the spinal cord and indirectly excite extensor motor neurons of the contralateral (“opposite side”) leg. Thus the right leg is extended (by exciting extensor motor neurons and inhibiting flexor motor neurons) while the stimulated left leg is flexed (by exciting flexor motor neurons and inhibiting extensor motor neurons). The reflex extension of the contralateral leg has been given a separate name—the *crossed extension reflex*—but functionally it is an integral part of the flexion reflex, a product of the synaptic connections “wired in” to the spinal cord.

This example illustrates that reflexes do not operate in a vacuum, influencing only a single antagonist pair of muscles. Instead, reflexes may have diverse and widespread effects, and they must interact with all other synaptic influences on motor neurons.

FUNCTIONAL ROLES OF REFLEXES We noted previously that flexion reflexes have a clear protective role, but the functions of the stretch reflex are more complicated. We can illustrate one aspect of the function of stretch reflexes with the following example: Suppose that while you are standing, a large monkey or a small person jumps on your back. The added weight will cause your knees to start to buckle, stretching the extensor muscles and activating the sensory neurons of muscle spindles. This sensory activity will reflexively excite motor neurons to the extensor muscles, generating more muscle force to counteract the increased load and maintain upright posture. This scenario illustrates a functional role of the stretch reflex in maintaining posture, by counteracting changes in load, muscle fatigue, or other factors.

To understand other functions of the stretch reflex, we need to consider another complexity in its organization. The stretch receptor organ receives motor innervation by **gamma (γ) motor neurons** (see Figure 19.3). Recall that in muscle spindles, the stretch-sensitive 1a sensory neurons are associated with intrafusal muscle fibers. The intrafusal muscle fibers are innervated by a population of small motor neurons, the γ motor neurons. The extrafusal muscle fibers (i.e., all the fibers that are not part of muscle spindles) are innervated by alpha (α) motor neurons. (When the term *motor neuron* is used without the Greek-letter prefix, it denotes an α motor neuron. Hence, the previous discussions of vertebrate motor neurons in Chapter 13 and in this chapter refer to α motor neurons.)

Activation of γ motor neurons excites the 1a afferent neuron by contracting the contractile ends of intrafusal fibers, thereby stretching the noncontractile central sensory portion of the spindle, and consequently distorting the distal end of the 1a afferent neuron. Therefore, there are two ways to increase muscle-spindle receptor activity: by stretching the muscle and by γ -motor-neuron activity. Note also that activity of γ motor neurons to intrafusal fibers and activity of α motor neurons to the surrounding extrafusal fibers have opposite effects on muscle-spindle sensory activity. Action potentials of the γ motor neurons that cause contraction of the intrafusal muscle fibers stimulate the 1a sensory neuron, whereas action potentials of the α motor neurons that cause contraction of the extrafusal muscle fibers relieve the stretch stimulus on the muscle spindle.

Motor neurons are activated primarily by central input rather than by spinal reflexes

Although reflexes play important roles in controlling the activity of motor neurons and coordinating motor behaviors, it is more accurate to consider the *primary* input to the motor circuitry of the spinal cord to be the descending input from the brain and spinal central circuits; the sensory fibers mediating spinal reflexes are a *secondary* input. This viewpoint is shown in Figure 19.3, in which the primary descending inputs enter from the top of the diagram and sensory inputs enter from the bottom. Such a view implies that a major role of the sensory input to the spinal cord is to supply *sensory feedback* that can modulate or correct the responses of motor neurons to central signals.

To illustrate how spinal reflex circuits provide sensory feedback, let's consider how the stretch reflex compensates for a resistance or load during the execution of a centrally generated, voluntary movement. To emphasize that similar neural circuits control arms and legs, we will use arm movements for this illustration. Suppose you decide to pick up a pamphlet from a table (Figure 19.4). Because this is a voluntary movement, the CNS must program the activation of motor neurons, rather than sensory input initiating the movement. Essentially the CNS estimates the amount of force necessary to pick up the pamphlet and sends a command to the motor neurons to generate that force. At the same time, the stretch reflex mediates **load compensation**, augmenting the contraction if there is extra weight or resistance added to the intended movement.

The central command for a voluntary movement excites both α and γ motor neurons, a process termed **α - γ coactivation**. This coactivation has two functions. First, it ensures that the ongoing sensitivity of the muscle spindle is maintained during muscle

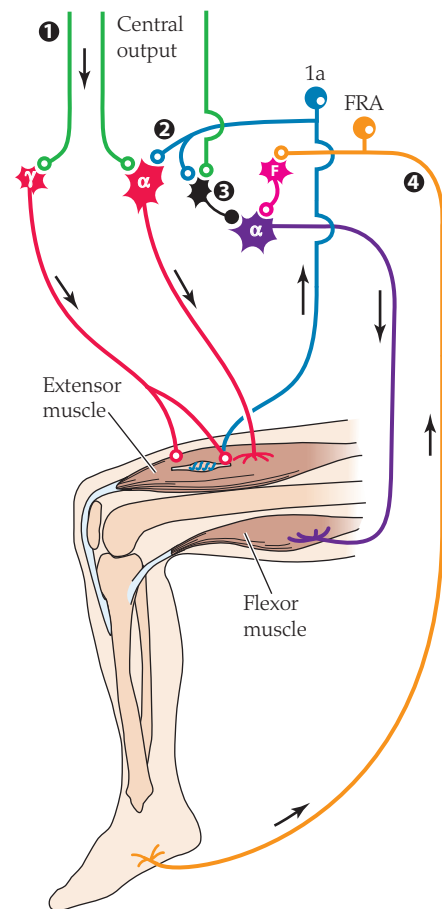

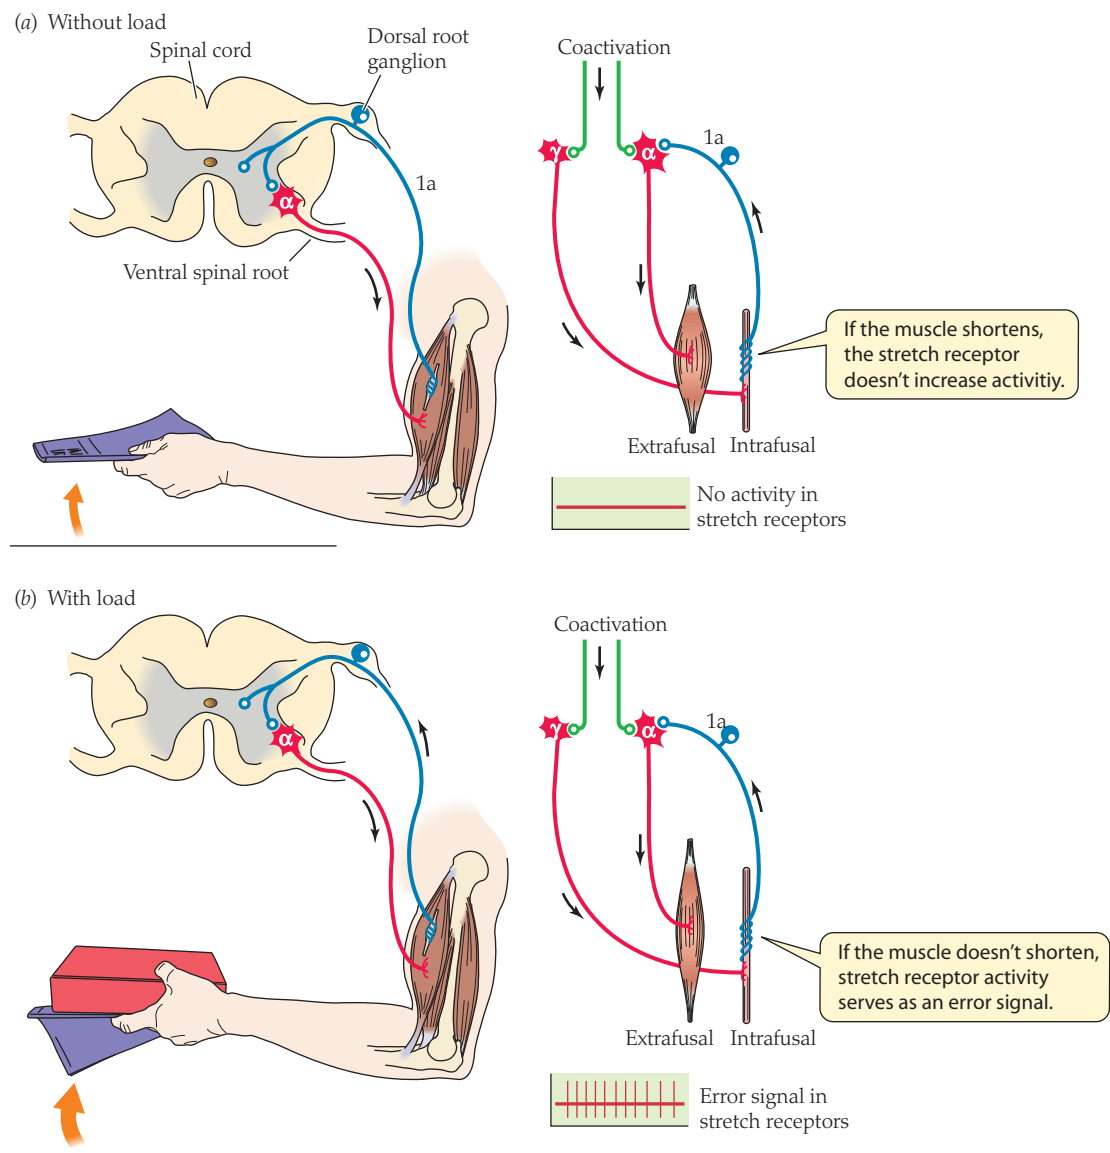

FIGURE 19.3 The basic circuit diagram of the ventral horn of the mammalian spinal cord. The motor output neurons of the spinal cord are the alpha (α) motor neurons to flexor and extensor muscles, and gamma (γ) motor neurons to intrafusal fibers of muscle spindles. Input pathways to the motor neurons and interneurons of the ventral horn include central descending pathways from the brain (1) shown in green; the 1a afferent (shown in blue) excitatory (2) and inhibitory (3) pathways from muscle spindles; and the flexion-reflex afferent (FRA) pathway (4, shown in orange). Local interneurons shown are a 1a inhibitory interneuron (black) and an interneuron (F; magenta) in the flexion-reflex pathway. Arrows indicate direction of impulse propagation.

shortening. In the absence of coactivation, a contraction that shortens the muscle would slacken the intrafusal muscle fiber and unload the muscle spindle, decreasing its sensitivity. Coactivation prevents this decrease. Second, coactivation allows the spindle to determine whether the muscle shortens during the intended movement. Suppose that the pamphlet is not very heavy, and the CNS has correctly estimated its weight. (We will call this the *no-load* condition, although it is more accurately described as light-load.) As shown in Figure 19.4a, the coactivation of α and γ motor neurons activates contraction of both the intrafusal fibers and the extrafusal fibers of the working muscle. In the absence of a substantial load, the extrafusal muscle fibers shorten to flex the arm, allowing the intrafusal fiber associated with a muscle spindle to shorten as it contracts. The shortening of the intrafusal fiber as the γ motor neurons activate it decreases its tension and lessens its activation of the stretch receptor. Because shortening unloads the muscle spindle, the 1a afferent neuron of the stretch receptor generates

FIGURE 19.4 The stretch reflex mediates load compensation in a voluntary movement A descending command coactivates both α and γ motor neurons, maintaining muscle spindle sensitivity during muscle shortening and allowing for load compensation. The γ motor neurons innervate intrafusal muscle fibers in parallel to the extrafusal muscle fibers that will lift the load. (a) If there is no load, the extrafusal fibers shorten the whole muscle, preventing intrafusal fiber shortening from activating the muscle-spindle stretch receptor. (b) If there is a load that prevents the muscle from shortening, intrafusal fiber contraction activates the muscle spindle 1a afferent neuron. This load-dependent excitation of the muscle spindle is an error signal that activates the α motor neuron and adds proportional excitation to the muscle to achieve the desired shortening.

few if any action potentials. That is, if the muscle shortens when it is signaled to shorten, no follow-up is needed.

Now suppose that the pamphlet is very heavy and the force estimate of the CNS is insufficient (see Figure 19.4b). (We will call this the *loaded* condition.) Coactivation excites the α and γ motor neurons as before, but now the extrafusal muscle fibers do not shorten, because of the unanticipated load. In the absence of shortening of the whole muscle, excitation of an intrafusal fiber by γ motor neurons will activate the stretch receptor, producing a train of action potentials. This stretch receptor activity constitutes an *error signal*, a measure of how much the muscle failed to shorten as commanded.

As Figure 19.4 shows, the stretch receptor's 1a axon makes excitatory synaptic contact with an α motor neuron that innervates the working extrafusal muscle fibers. Activity in the stretch receptor neuron (the error signal) excites proportional activity in the α motor neuron, generating additional tension in the working muscle to overcome the load. The neuron pair of the stretch receptor and α motor neuron is a reflex circuit that functions as a *load-compensating servo loop*, detecting an error (failure to shorten) and counteracting it ("more force, please") within a centrally commanded movement.

SUMMARY Neural Control of Skeletal Muscle Is the Basis of Animal Behavior

- The pattern of motor output of a nervous system produces behavioral actions. The nervous system can generate motor patterns centrally or in response to discrete stimuli. Simple, stimulus-evoked responses are often reflexive: Stronger stimulation evokes stronger responses.
- Neural circuits that generate simple patterns of behavior in invertebrates typically involve relatively small numbers of identifiable neurons. The circuits for similar acts of vertebrates involve many more individual neurons, which are not uniquely identifiable.
- Vertebrate spinal reflexes (such as the stretch reflex and the flexion reflex) have the simplest and best-understood neural circuits for a vertebrate behavior. Even the simplest vertebrate reflexes, however, have large numbers of neurons in a circuit.
- The primary synaptic input of spinal motor neurons is from the central nervous system (CNS); sensory (reflex) input is secondary. Many reflexes mediate adjustments of centrally programmed movements, such as load compensation.

Neural Generation of Rhythmic Behavior

Most animal behavior consists not just of isolated single acts of the sorts that we have been discussing, but rather of action patterns: *sequences* of effector actions that result from sequences of motor output of the nervous system. These sequences of motor activity are patterned in space and time. For example, consider the activity of your nervous system that is required to pick up a pencil. First you extend your arm by contracting muscles at the shoulder and upper arm, then you flex your fingers to oppose your thumb, and then you elevate and flex the arm to lift the pencil. You may alter the activity of postural muscles in your trunk or legs to compensate for the arm movements. This motor performance may involve varying amounts of visual, tactile, and proprioceptive sensory input; moreover, the temporal and spatial pattern of the sequence of contractions may differ considerably from one time to the next. Variability of this sort heightens the difficulty of investigating action patterns.

As a way to approach the study of sequences of behavioral action patterns, neurophysiologists have concentrated on **rhythmic behavior**: stereotyped, repetitive sequences of movement such as walking, swimming, and flying in which the motor output is stable,

repeatable, and predictable from cycle to cycle of the activity. We now examine several examples of neurophysiological analysis of rhythmic behavior, attempting to extract principles that may be of general importance in motor control systems.

Locust flight results from an interplay of central and peripheral control

Let's begin our exploration of the control of rhythmic behavior by asking: How does a locust fly? As **Figure 19.5a** shows, the movement of a single wing of a flying locust can be viewed as a simple up-and-down oscillation, generated by a set of elevator (or levator) and depressor muscles. The electrical activity of these muscles can be recorded from a tethered locust flying in a wind stream. This activity consists of alternating bursts of muscle potentials—the depressors being activated when the wings are up, and the levators being activated when the wings are down. Because each muscle depolarization results from an action potential in a motor neuron to that muscle, it is clear that flight results from the generation in the CNS of alternating bursts of action potentials in levator and depressor motor neurons. This kind of pattern—alternating bursts

(a) The motor pattern of locust wing muscle excitation

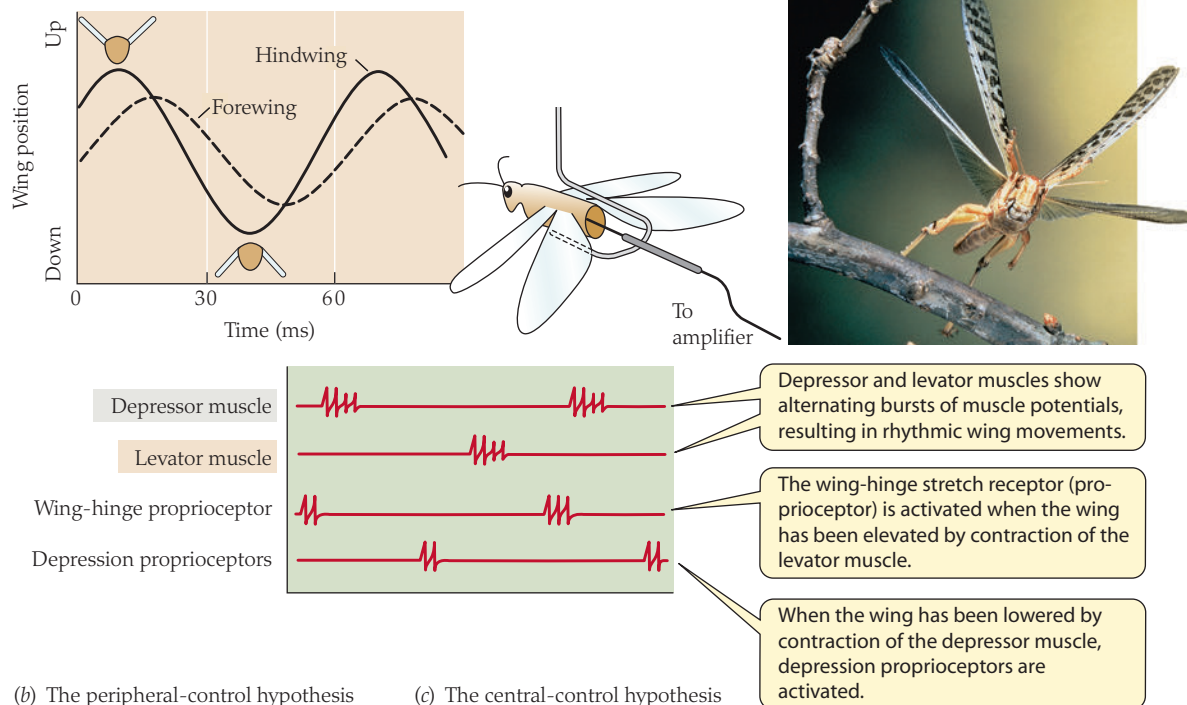

FIGURE 19.5 Control of flight in the locust (a) Cyclic wing movements and the associated temporal pattern of motor and sensory activity, recorded from a tethered locust. Two hypotheses could explain the generation of the motor pattern of wing muscle excitation: a peripheral-control hypothesis (b), in which sensory feedback resulting from a movement triggers the next movement; and a central-control hypothesis (c), in which a central pattern generator (CPG) produces the motor pattern without requiring moment-to-moment sensory timing. (The CPG is gated by tonic sensory input: wind on the head and the absence of leg contact with the ground.)

of activity in motor neurons to antagonist muscles—underlies most forms of rhythmic behavior.

How are the motor neurons to antagonist muscles activated in alternation to produce a rhythmic movement such as that of a locust wing? Historically, two kinds of hypotheses have been advanced to explain the neural basis of rhythmic movements: peripheral control and central control. According to the hypothesis of **peripheral control**, each movement activates receptors that trigger the next movement in the sequence. The position of a locust wing is monitored by several proprioceptors (see Figure 19.5a): a single wing-hinge stretch receptor that generates a train of impulses when the wing is elevated, and several other receptors that are activated when the wing is depressed.

Locust flight could (in principle) operate by peripheral control, by having sensory feedback from wing sensory receptors activate the motor neurons for the next movement (Figure 19.5b). Thus elevation of the wings would excite the wing-hinge stretch receptor, which would synaptically excite depressor motor neurons, thereby lowering the wing. The lowered wing would terminate excitation of the wing-hinge stretch receptor and would excite the depression-sensitive receptors, which would synaptically excite levator motor neurons, elevating the wing and completing the cycle. The peripheral-control hypothesis is also called the *chained-reflex* hypothesis because each movement is a reflex response to sensory feedback resulting from the last movement.

According to the hypothesis of **central control**, locust flight is sustained by a **central pattern generator (CPG)**—a neural circuit in the CNS that can generate the sequential, patterned activation of motor neurons to antagonistic muscles that underlies a behavior pattern, without requiring sensory feedback to trigger the next movement. Thus, in central control of locust flight, the basic pattern of alternation of activation of levator and depressor motor neurons would result from an intrinsic CPG rather than from a chained reflex (Figure 19.5c).

How would one determine whether peripheral control or central control is responsible for the patterned motor activity underlying locust flight? The obvious answer is to remove the relevant sensory input, a process termed *deafferentation*. In the locust, most if not all wing sensory input can be removed by cutting the nerves to the wing-hinge area. Donald Wilson, who pioneered analysis of locust flight control, found that tethered locusts could maintain flight in the absence of wing sensory feedback. This result indicates that central control (not peripheral control) is responsible for locust flight. However, he observed that the flight frequency of the test animals was slower than normal. When he stimulated the cut sensory nerve stumps or the ventral nerve cord with temporally unpatterned stimulation, normal flight frequency was restored. This restoration suggested that the sensory stimulation provided general excitation to the CNS but was not necessary to supply *timing* information for pattern generation. These experiments demonstrated the existence of a CPG for locust flight.

Subsequent experiments in other animals have shown that many patterns of rhythmic behavior are under central control. These rhythmic activities include walking, swimming, feeding, and breathing or ventilation (see Chapter 23) in a variety of invertebrates and vertebrates. Thus the concept of central pattern generation is a generally important aspect of the control of coordinated behavior.

The hypotheses of central control and peripheral control may appear to be logical alternatives, but they are not mutually exclusive.

Therefore, the demonstration of a CPG for a behavior pattern such as locust flight does not mean that sensory input is unimportant. Sensory feedback can play significant roles in a centrally controlled behavior. This statement may seem paradoxical, but consider the fact that if you were walking down the sidewalk and suddenly lost all sensation to your legs, you would probably still be able to generate the motor output sequence of walking. Evidence from cats (see page 515) suggests that most mammals have a CPG for walking. Does that mean that sensory input is irrelevant? Of course not.

For example, sensory input may affect the quality of performance of walking and is essential for correcting the basic pattern, such as when one is walking over uneven terrain. In the locust, several functions of sensory feedback have been found. First, as already noted, sensory input has a generally stimulatory effect, speeding up the flight rhythm. Moreover, sensory feedback can provide specific timing information, adding an element of peripheral control to the system. Electrophysiological studies have shown that wing proprioceptors *do* have the synaptic effects diagrammed in Figure 19.5b: The stretch receptor monitoring wing elevation excites depressor motor neurons, and depression-sensitive receptors excite levator motor neurons. Thus the synaptic connections necessary for a chained reflex are present, and these reflexes operate with latencies appropriate to reinforce the flight rhythm—although they are *not necessary* for it.

Sensory feedback can *entrain* a CPG. In another experiment, one wing of a tethered, flying locust was moved up and down at a set frequency by a motor, the forced cyclic movement overriding normal flight-generated sensory feedback. When the forced movement of the one wing was at a rate close to the normal flight frequency, the flight frequency (recorded from muscles to all four wings) changed to match the driving frequency of the motor! Therefore, sensory information from the driven wing can entrain the CPG to the driven frequency.

Our conclusions at this point are these: (1) There is a central pattern generator for flight that can maintain the flight pattern in the absence of sensory timing information, and (2) sensory timing information (when present) can reset the CPG, entraining it to a slightly different driven frequency.² Thus the original hypotheses of central and peripheral (reflex) control are not mutually exclusive. The CPG is *sufficient* to maintain flight, but this sufficiency does not rule out contributions of peripheral control. Similar interactions of CPGs with sensory entrainment have been demonstrated in other activities and animals, such as swimming in dogfish sharks. The relative contributions of central control and peripheral control can be expected to differ in different cases. It is likely, however, that the two kinds of control interact in most cases.

There are different mechanisms of central pattern generation

How do neurons and networks of neurons in the CNS act as a CPG that determines the spatiotemporal patterns of motor output

² The roles of the CPG and the sensory timing information in this case are analogous to those in a circadian (about 24-h) endogenous activity rhythm of an animal. As discussed in Chapter 15, many animals kept in constant light conditions will exhibit an activity rhythm with a period near (but not exactly) 24 h. If a light-dark cycle (such as 12 h light, 12 h dark) is added, it provides timing information (the *zeitgeber*) that will entrain the endogenous circadian rhythm to an exactly 24-h period (see Figure 15.14). In the same manner, sensory timing information in locust flight can entrain the CPG.

to generate a rhythmic behavioral pattern? Because many of the rhythmic behavior patterns studied are oscillatory, cycling in a roughly sine-wave fashion, the CPGs underlying them have been termed **oscillators**. Studies have clarified the neural basis of some of these oscillators.

OSCILLATOR THEORY In theory, there are two logical categories of oscillators: cellular oscillators and network oscillators. The CPGs that have been studied appear to employ a mix of these two kinds of oscillatory mechanisms in differing degree—some with cellular oscillators playing a dominant role, and others dominated by network properties. We will introduce the theoretical types first and then describe their roles in a real example of a central-pattern-generating neural circuit.

A **cellular oscillator** is a neuron that generates temporally patterned activity by itself, without depending on synaptic interaction with other cells. Such cells may generate endogenous bursts of action potentials (Figure 19.6a), or they may show oscillations of membrane potential without generating any action potentials (Figure 19.6b). The underlying mechanisms of oscillation may be similar for both types because some cells that generate impulse bursts will continue to oscillate after impulse generation is blocked with tetrodotoxin (TTX) (see Chapter 12, page 314).

Cellular oscillators are thought to play a role in central pattern generation in several cases studied, including those controlling molluscan feeding, crustacean heartbeat, and crustacean scaphognathites (gill bailers) (see Figure 23.27).

A **network oscillator** is a network of neurons that interact in such a way that the output of the network is temporally patterned, although no neuron in the network functions as a cellular oscillator. Thus the oscillatory or pattern-generating property is said to be an *emergent property* of the network, resulting from cellular interactions in the network rather than from intrinsic cellular properties. The simplest model of an oscillatory network, termed a *half-center model*, is shown in Figure 19.6c. Two neurons (or pools of neurons) receive a common tonic excitatory (“command”) input but synaptically inhibit each other. With command excitation, one neuron will have a lower threshold and fire first, inhibiting the other. When the first neuron stops generating impulses, the other is released from inhibition and generates a train of impulses, inhibiting the first.

The half-center model appears straightforward but is actually rather unstable in its simplest form. Unless an additional time-dependent property is added to allow the first half-cycle to run down, the first neuron to reach threshold will tend to remain active and perpetually inhibit the other. There are several possible mechanisms to “fatigue” a half-center, such as postinhibitory rebound, slow inactivation of the impulse-generating capability of the cells, or antifacilitation of the inhibitory synapses (see Figure 13.22).

Another model network oscillator, which is more stable, contains three or more neurons that inhibit each other in a cyclic inhibitory loop. Figure 19.6d shows a *closed-loop model* that would produce a stable pattern of bursts in the sequence 1–2–3–1–2–3... without any cell possessing endogenous oscillator properties. Because there are three neurons inhibiting each other rather than two, one neuron is always being released from inhibition and is thus able to fire and inhibit its follower.

Neural circuits acting as network oscillators are reported to underlie several sorts of rhythmic behaviors, including the neuro-

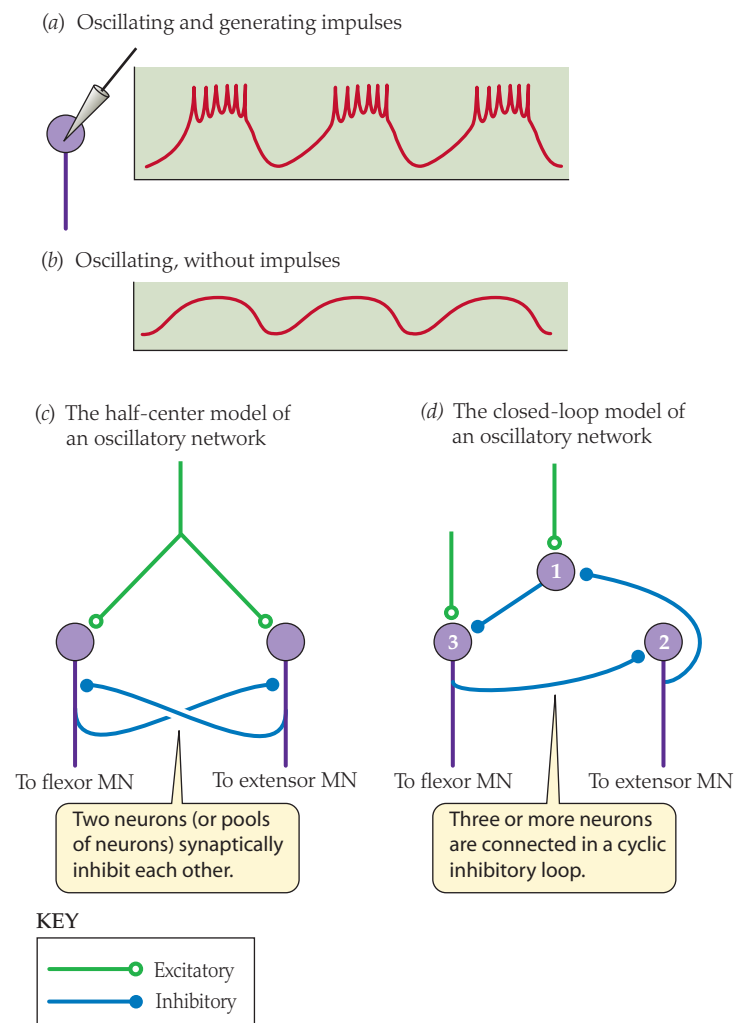

FIGURE 19.6 Models of oscillators underlying central pattern generators (a) An oscillator neuron generating bursts of impulses (e.g., in *Aplysia*). (b) A neuron with membrane-potential oscillation but without impulses (e.g., a neuron controlling pumping of the crustacean scaphognathite, or gill bailer). (c) A network oscillator composed of reciprocal inhibitory half-centers; interneurons of one half-center inhibit those of the other, while exciting a set of motor neurons (MN). (d) A network oscillator composed of closed-loop cyclic inhibition. All three inhibitory neurons may be spontaneously active or may receive unpatterned excitatory input (green lines). If cell 1 is active first, its activity inhibits cell 3, but this inhibition prevents cell 3 from inhibiting cell 2. Cell 2 can now be active, inhibiting cell 1 and thus releasing cell 3 from inhibition. Cell 3 can then be active, inhibiting cell 2 and releasing cell 1 from inhibition, and so forth.

genic leech heartbeat, as well as swimming in leeches, molluscs (*Tritonia* and *Clione*), lampreys, and clawed toad (*Xenopus*) tadpoles. Each described circuit is different, but each displays some of the mutual inhibition that is characteristic of half-center models, as well as closed-loop inhibitory and excitatory elements.

CIRCUITS FOR CENTRAL PATTERN GENERATION: THE STOMATO-GASTRIC GANGLION A central pattern generator (CPG) can combine the properties of both cellular oscillators and network oscillators. Such a **hybrid oscillator** might have one or more oscillatory cells acting within a network that stabilizes and reinforces the oscillation. Most examples of CPGs will probably turn out to

be hybrid oscillators with a mixture of cellular and network oscillatory properties. Here we describe one of the most completely studied CPG networks, in the crustacean stomatogastric ganglion, which is a hybrid oscillatory network. We will use this example to introduce principles of general importance about oscillatory circuits and their control.

The **stomatogastric ganglion** sits on the external surface of the stomach of a lobster, crayfish, crab, or other decapod crustacean. It contains about 30 neurons, most of which are motor neurons controlling stomach muscles. Why is studying the stomatogastric ganglion important? The main reason is that the stomatogastric ganglion generates two robust rhythms (and participates in two others) with a network of only 30 neurons! In addition, crustacean stomachs are ectodermal, chitin-lined, and controlled by striated muscle; thus their control is more like that of an appendage than what we would expect of a stomach. Crabs and lobsters swallow large pieces of food and chew the pieces with chitinous teeth in their stomachs, so the behavior mediated by the stomatogastric ganglion is more analogous to the control of vertebrate jaws than that of vertebrate stomachs.

As we discussed in Chapter 6 (see Figure 6.19b), the crustacean stomach consists of two chambers: an anterior cardiac chamber containing teeth that function as a *gastric mill* to grind and chew food, and a posterior pyloric chamber containing a sieve that serves to keep food particles from passing to the rest of the gut until the particles are small enough. **Figure 19.7** shows a simplified neural circuit and rhythmic output of one rhythm of the stomatogastric ganglion: the *pyloric rhythm* that controls the straining of food particles by the pyloric filter.

The pyloric circuit (see Figure 19.7b) acts as a hybrid oscillator, containing an oscillator neuron (AB) that serves as the pacemaker for the rhythm. The oscillator cell is tightly electrically coupled to two pyloric dilator (PD) neurons so that these three burst together, inhibiting the other neurons in the network (see Figure 19.7c). The oscillatory AB neuron and the coupled PD neurons burst first, inhibiting follower cells (LP, PY, and two others not shown). At the end of the AB/PD burst, the LP cell recovers from inhibition faster than the PY cells; therefore, the LP cell bursts next and prolongs PY inhibition. PY neurons then burst and inhibit LP, until the next AB burst starts a new cycle.

The pyloric circuit thus has both cellular oscillator and network oscillator properties. The generation of the pyloric rhythm depends primarily on the AB cellular oscillatory neuron, but its triphasic cycle (AB/PD → LP → PY → ...) and timing depend on the strength and time course of inhibitory synapses and on intrinsic currents of the follower cells.

The rhythms and circuits of the stomatogastric ganglion exemplify another feature that may be of general importance: They are profoundly subject to *modulation*. The stomatogastric ganglion receives about 100 axons of neurons from other parts of the nervous system, many of which can secrete neuromodulators that act diffusely in the small ganglion to alter its motor output. At least 15 modulators are present, including the amines serotonin, dopamine, octopamine, and histamine; the classical transmitters acetylcholine and GABA; and several peptides, including proctolin, FMRFamide-like, and cholecystikinin (CCK)-like peptides.

The most common effect of a neuromodulator is to initiate and maintain rhythmic activity in a network. For example, adding sero-

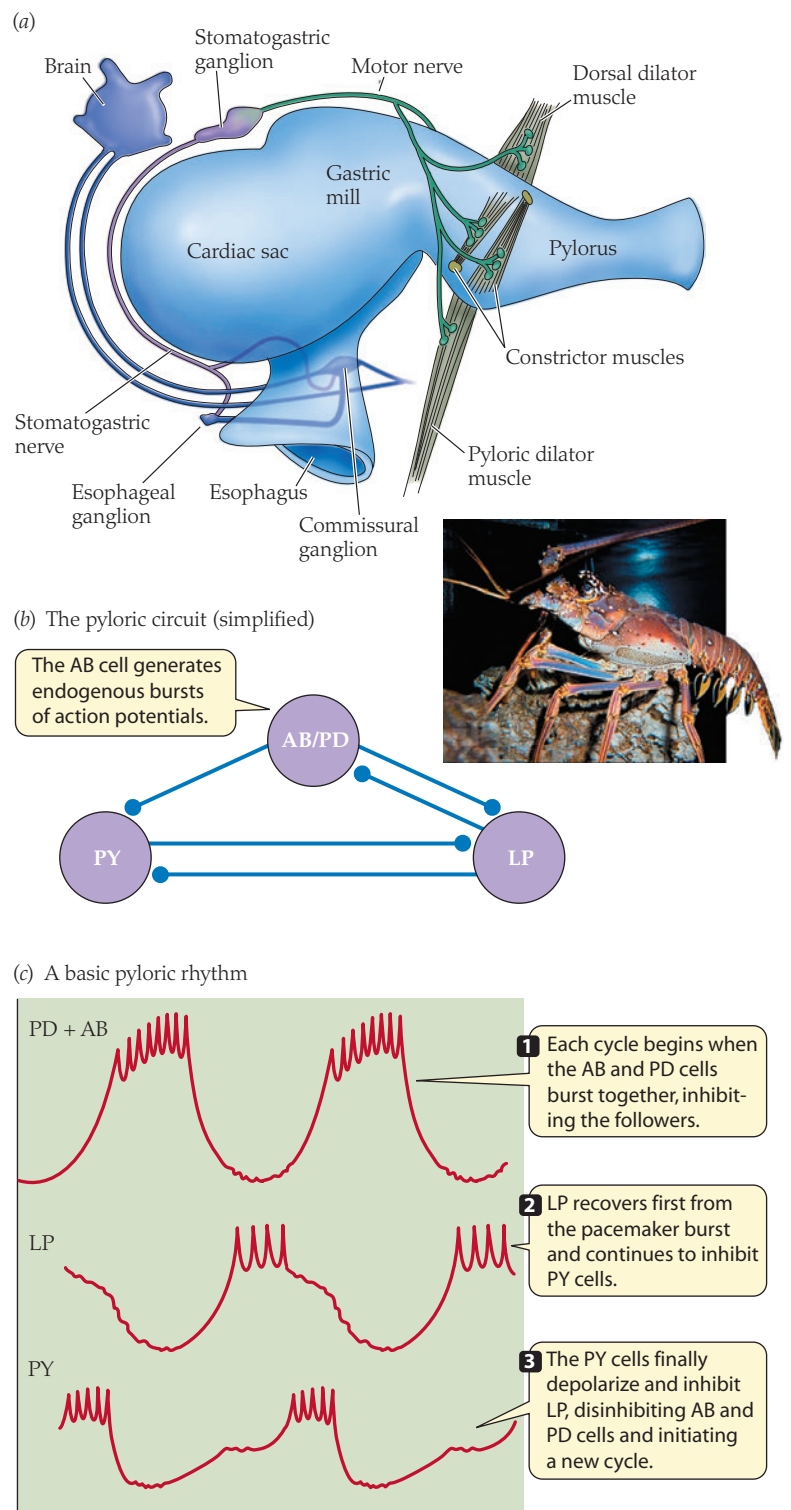

FIGURE 19.7 The network of neurons producing the pyloric rhythm of the crustacean stomatogastric ganglion (a) The stomatogastric ganglion lies on the dorsal surface of the heart; the stomatogastric nerve connects it to the esophageal ganglion and the rest of the CNS. The 30 or so neurons of the stomatogastric ganglion receive modulatory input from extrinsic neurons. (b) The pyloric circuit of stomatogastric ganglion neurons (simplified). AB is a strong cellular oscillator that serves as the pacemaker for the rhythm. The AB and PD cells are strongly electrically coupled and represented by a single symbol. They are interconnected with other (follower) cells by inhibitory chemical synapses. (c) A basic pyloric rhythm.

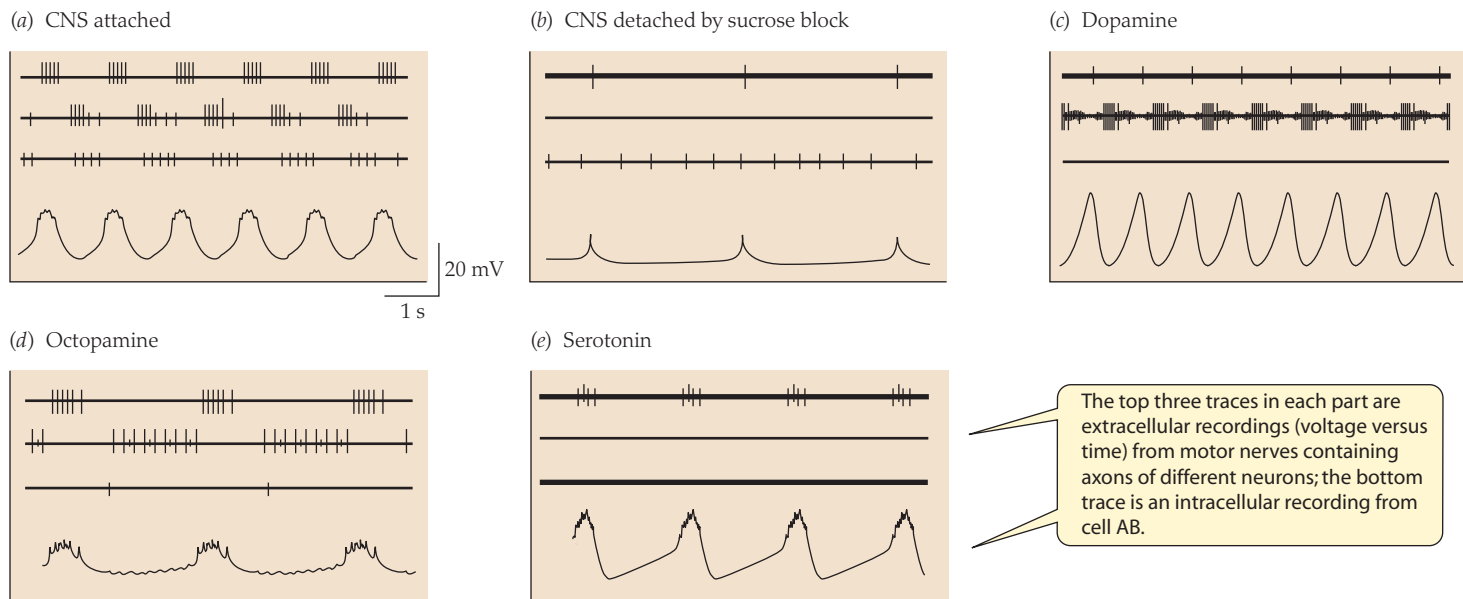

FIGURE 19.8 Neurotransmitters modulate the pyloric rhythm of the stomatogastric ganglion (a) When the stomatogastric ganglion is attached to the rest of the central nervous system (CNS), endogenous neuromodulators maintain a normal pyloric rhythm. (b) Separating the ganglion from the rest of the CNS (by sucrose block or by cutting the stomatogastric nerve) often leads to cessation of bursts of rhythmic activity, as shown. (c–e) Addition of any of the indicated neuromodulators to the bathing solution reestablishes the rhythm in the isolated ganglion. Note that the pattern of the rhythm differs somewhat with different modulators. These effects result from specific, individualized actions of the modulators on both cellular ionic currents and synaptic strengths. (From Harris-Warrick and Flamm 1986.)

tonin, octopamine, or dopamine to a previously quiescent isolated stomatogastric ganglion induces a pyloric rhythm (Figure 19.8), although the rhythms induced by the three modulators differ in detail. In general, the stomatogastric ganglion requires permissive modulatory input from extrinsic neurons for the expression of its rhythms. Many of the central and sensory neurons that provide this modulatory input are well characterized.

The neuromodulators of the stomatogastric ganglion act in two ways: They alter the intrinsic membrane properties of individual stomatogastric neurons, and they alter the strengths and dynamics of synaptic connections of the neurons. Modulatory effects on intrinsic neuronal currents can induce cellular oscillation (many stomatogastric neurons are conditional oscillators), excite or inhibit particular neurons, or alter other excitable properties. Moreover, modulators can make individual synapses more or less potent, changing the functional circuit connections, as well as cellular activities.

It is at once exhilarating and sobering to realize that neuronal circuits such as those of the stomatogastric ganglion are not rigidly “hard-wired,” but rather are plastic and malleable—exhilarating because the ability of neuromodulation to free a circuit from the “tyranny of the wiring” may underlie adaptive plasticity of neural control of behavior, but sobering because of the realization that a circuit diagram such as that in Figure 19.7b is descriptive of only one state of a dynamically shifting circuit. Neurons can even shift from one functional circuit to another, firing in “gastric time” or

“pyloric time” under modulatory influence, and circuit elements can combine to form new patterns of output. Growing evidence suggests that these roles of neuromodulators are of widespread importance among CPGs.

Central pattern generators can underlie relatively complex behavior

How elaborate a behavioral performance can we expect to depend on mechanisms of central pattern generation? It is, after all, a long way from a short-term rhythmic activity such as locust flight to complex behavior patterns such as the ritualized mating behavior of many animals. Are complex patterns such as courtship rituals simply elaborations and chains of centrally programmed acts? For technical reasons, it has been difficult for scientists to explore the neurophysiological bases of increasingly complex behaviors, but some progress has been made.

Central-pattern-generating mechanisms have been shown to be sufficient for some behavior patterns that are significantly more complex and longer lasting than the simple cyclic patterns already described. One such long-term sequence involves gill movements of the horseshoe crab *Limulus*. Figure 23.25 shows the unusual *book gills* of these animals. These gills consist of many thin sheets of tissue termed *lamellae* (singular *lamella*) (the “pages” of the book) positioned under segmental flaps termed *gill plates*, shown in Figure 19.9. Rhythmic beating of the gill plates ventilates the gill lamellae. This gill ventilation, however, is often intermittent: Periods of rhythmic ventilation a few minutes long may alternate with shorter periods of quiescence (apnea) or of gill cleaning. Gill cleaning is an intricate behavioral pattern in which the paired gill plates are brought across the midline and a part of one plate rhythmically cleans the lamellae of the opposite book gill. Horseshoe crabs roughly alternate between two mirror-image patterns of gill cleaning, termed *left-leading* and *right-leading*.

When the abdominal ventral nerve cord is dissected out of a *Limulus* and its unstimulated motor activity is recorded in isolation, the motor output pattern underlying all of the behavior just described persists (see Figure 19.9): Periods of a ventilatory motor

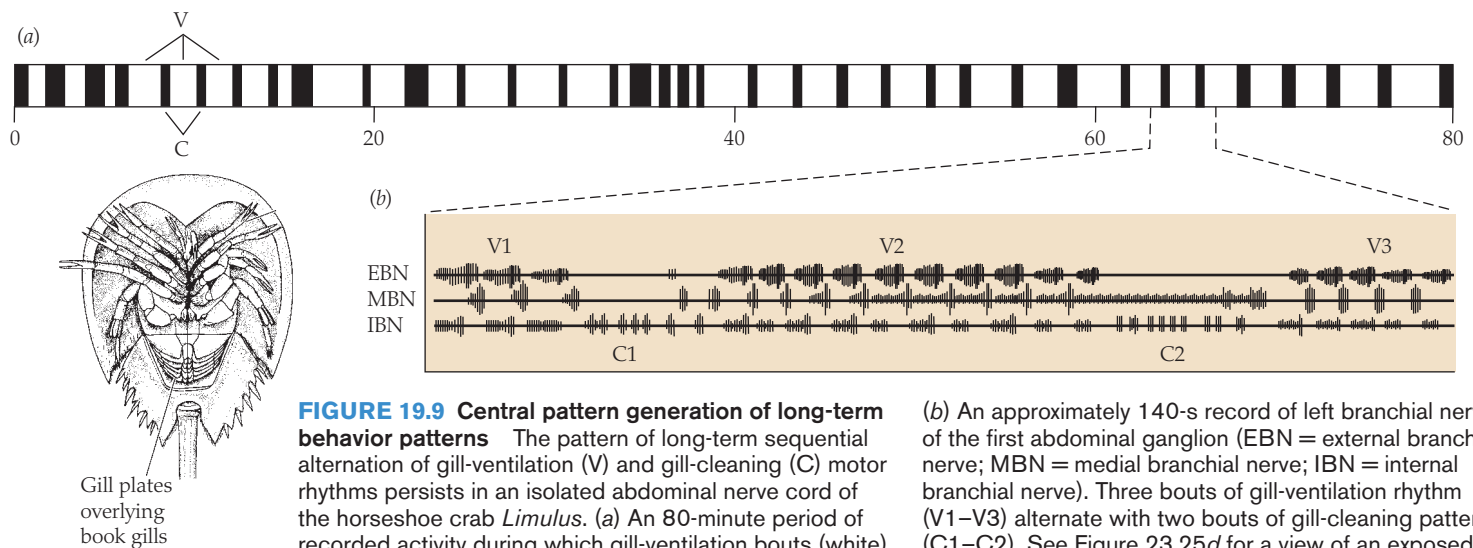

FIGURE 19.9 Central pattern generation of long-term behavior patterns The pattern of long-term sequential alternation of gill-ventilation (V) and gill-cleaning (C) motor rhythms persists in an isolated abdominal nerve cord of the horseshoe crab *Limulus*. (a) An 80-minute period of recorded activity during which gill-ventilation bouts (white) and gill-cleaning bouts (black) alternate fairly regularly. Such stable alternation is common in intact animals.

(b) An approximately 140-s record of left branchial nerves of the first abdominal ganglion (EBN = external branchial nerve; MBN = medial branchial nerve; IBN = internal branchial nerve). Three bouts of gill-ventilation rhythm (V1–V3) alternate with two bouts of gill-cleaning pattern (C1–C2). See Figure 23.25d for a view of an exposed book gill. (After Wyse et al. 1980.)

output rhythm alternate with periods of a gill-cleaning motor pattern. Moreover, the rough alternation between left-leading and right-leading gill cleaning can also be expressed in isolation. Thus long and relatively elaborate sequences of behaviorally significant motor patterns can be expressed in isolated CNS tissue, without muscles, movement, or sensory feedback.

Behavioral patterns that are still more complex have been analyzed in insects, including molting activity (see Figure 16.20) of crickets and moths and reproductive behavior in several insects. These stereotyped behaviors appear to have centrally patterned components but also to have stages at which appropriate sensory feedback is necessary to proceed to the next stage. The central motor programs could function as modules, like stored subroutines in a computer program; when “called” by the CNS, a module would generate a particular motor pattern, after which sensory input would determine how to proceed next. It is likely that increasingly complex behavior patterns will have increasingly elaborate interactions between sensory components and central motor programs.

SUMMARY Neural Generation of Rhythmic Behavior

- Most rhythmic patterns of animal behavior (walking, swimming, flying, and so on) involve a central pattern generator (CPG), which can produce the basic motor pattern without requiring sensory input at particular times in the cycle. The CPG interacts with sensory feedback from the cyclic movements, which can entrain the CPG.
- CPG circuits may depend on cellular oscillators, network oscillators, or a combination of both, as in the crustacean stomatogastric ganglion.
- CPG circuits are subject to neuromodulation, in which a neurotransmitter/neuromodulator can alter circuit function to generate or alter rhythmic output.

Control and Coordination of Vertebrate Movement

The principles of central pattern generation and the interaction of central and peripheral control of movement were first developed from invertebrate studies, principally with arthropods and molluscs. In this section we consider the degree to which these principles also apply to vertebrates. We can start with the question: How does a cat walk? For the moment, let’s consider the cat nervous system as composed simply of three compartments that can influence movement: brain, spinal cord, and sensory input (Figure 19.10).

The immediate generators of walking movements in a cat are the spinal motor neurons that control the limb muscles. The spinal circuitry associated with these motor neurons was introduced earlier (see Figure 19.3). The motor neurons receive direct or indirect synaptic input from three sources: (1) descending input from the brain, (2) sensory input from proprioceptors and other receptors in the periphery, and (3) local input from intrinsic spinal circuits. If

FIGURE 19.10 The major components of the control of movement in a vertebrate Motor neurons in the spinal cord activate muscles as a result of receiving three sorts of input: input from local spinal circuits, descending input from the brain, and sensory input. The movement produced by muscle contractions leads to further sensory input, termed sensory feedback.

the spinal motor neurons are to be activated in the correct spatio-temporal pattern to produce walking, what are the roles of these three compartments in generating this pattern?

Locomotion in cats involves a spinal central pattern generator

In the arthropod systems already discussed, the compartments of neural control could be experimentally isolated with relative ease. For example, it is technically easy to isolate the abdominal ganglia of a horseshoe crab, and to ask the question: What do abdominal ganglia do by themselves, without the brain and without sensory feedback? Such questions are harder to investigate experimentally in vertebrates, in which an isolated spinal cord usually dies quickly. With refinements of technique in the last 30 years, however, it has become possible to perform experiments analogous to those in invertebrates.

To determine their roles in walking, it is possible to separate the functions of the brain, spinal cord, and sensory feedback experimentally in a vertebrate such as a cat, by lesions in the CNS or peripheral nerves. A cat is able to make fairly normal stepping movements on a treadmill after transection of the spinal cord to remove brain influence. First, in chronic (long-term) experiments, cats with the spinal cord transected 1 to 2 weeks after birth recover the ability to walk on a treadmill at a speed dependent on the treadmill speed. Second, in acute (short-term) experiments, spinally transected cats can walk on a treadmill if given the norepinephrine precursor L-dopa or the norepinephrine receptor stimulator clonidine.

These experiments show that the brain does not need to provide timing information for walking. Noradrenergic fibers descending from the brain in intact cats presumably command or enable the expression of the walking pattern by spinal circuits, but they are not necessary for timing the stepping cycle of a limb; certainly injected L-dopa does not provide timing information. In other experiments, cats with brain sections (at level 1 in [Figure 19.11](#)) can walk on a treadmill when given unpatterned electrical stimulation to a mesencephalic locomotor command region. With increasing strength of stimulation, the rate of locomotion increases and the gait changes to a trot and finally to a gallop. Thus the brain may initiate locomotion and modulate it subject to conditions, but the brain is not necessary for generating the locomotor pattern.

Sensory feedback from the hindlimbs is also unnecessary for hindlimb stepping movements, as can be shown by experiments similar to those just described. Cats with or without spinal transection (at level 2 in [Figure 19.11](#)) can make normally alternating stepping sequences following hindlimb deafferentation by cuts of the dorsal roots that contain the sensory afferent axons. (For the spinally transected cats, walking is initiated with L-dopa or clonidine.) These experiments indicate that the cat spinal cord contains a CPG for walking movements. Similar experiments indicate that fish, salamanders, toads, and turtles also have spinal locomotor CPGs.

Sensory feedback can still play important functional roles in locomotion of intact vertebrates. Spinal reflexes stabilize and modulate the effects of centrally patterned locomotor output, but spinal reflexes themselves may also be modulated by the CPG. For example, the effect of mechanical stimulation of the top of the foot of a walking cat depends on the position of the foot in the stepping cycle. If the foot is off the ground and swinging forward, it is lifted higher when stimulated (“exaggerated flexion”). If the foot is on the ground and bearing the cat’s weight, the same stimulation produces a more forceful extension. This reversal of a spinal reflex (which is clearly adaptive for stable walking) shows that the central events of the stepping cycle can strongly modulate reflex function.

The experiments described in this section demonstrate that the mechanisms of control of rhythmic locomotor movements are fundamentally similar in many invertebrates and vertebrates. Although the cellular aspects may vary (e.g., different network mechanisms of central pattern generation), the functional roles of central and reflex aspects of control appear to be similar in many cases.

Central pattern generators are distributed and interacting

So far we have considered a single CPG controlling a single limb. What about coordination of multiple limbs in walking? In fact, there are multiple CPGs to control different segments of the animal, and these CPGs must all interact to control the entire patterned movement. Let’s return to the salamander with which we started the chapter. Salamanders swim by bending their bodies laterally in S curves, which progress posteriorly to propel the animal forward. This swimming pattern is similar to that of some fish and may be a primitive pattern for vertebrates. The traveling wave of contrac-

FIGURE 19.11 Spinal and brain control of mammalian locomotion (a) The spinal cord and lower brainstem of a cat isolated from cerebral hemispheres by transection at level 1. Electrical stimulation of the mesencephalic locomotor command region can produce locomotion in this preparation. Transection of the spinal cord at level 2 isolates the hindlimb segments of the cord. The hindlimbs are still able to walk on a treadmill after recovery from surgery. (b) Locomotion on a treadmill of a cat with a spinal transection at level 2. Reciprocal bursts of electrical activity are recorded from flexors during the swing phase of walking and from extensors during the stance phase. (After Kandel et al. 1995.)

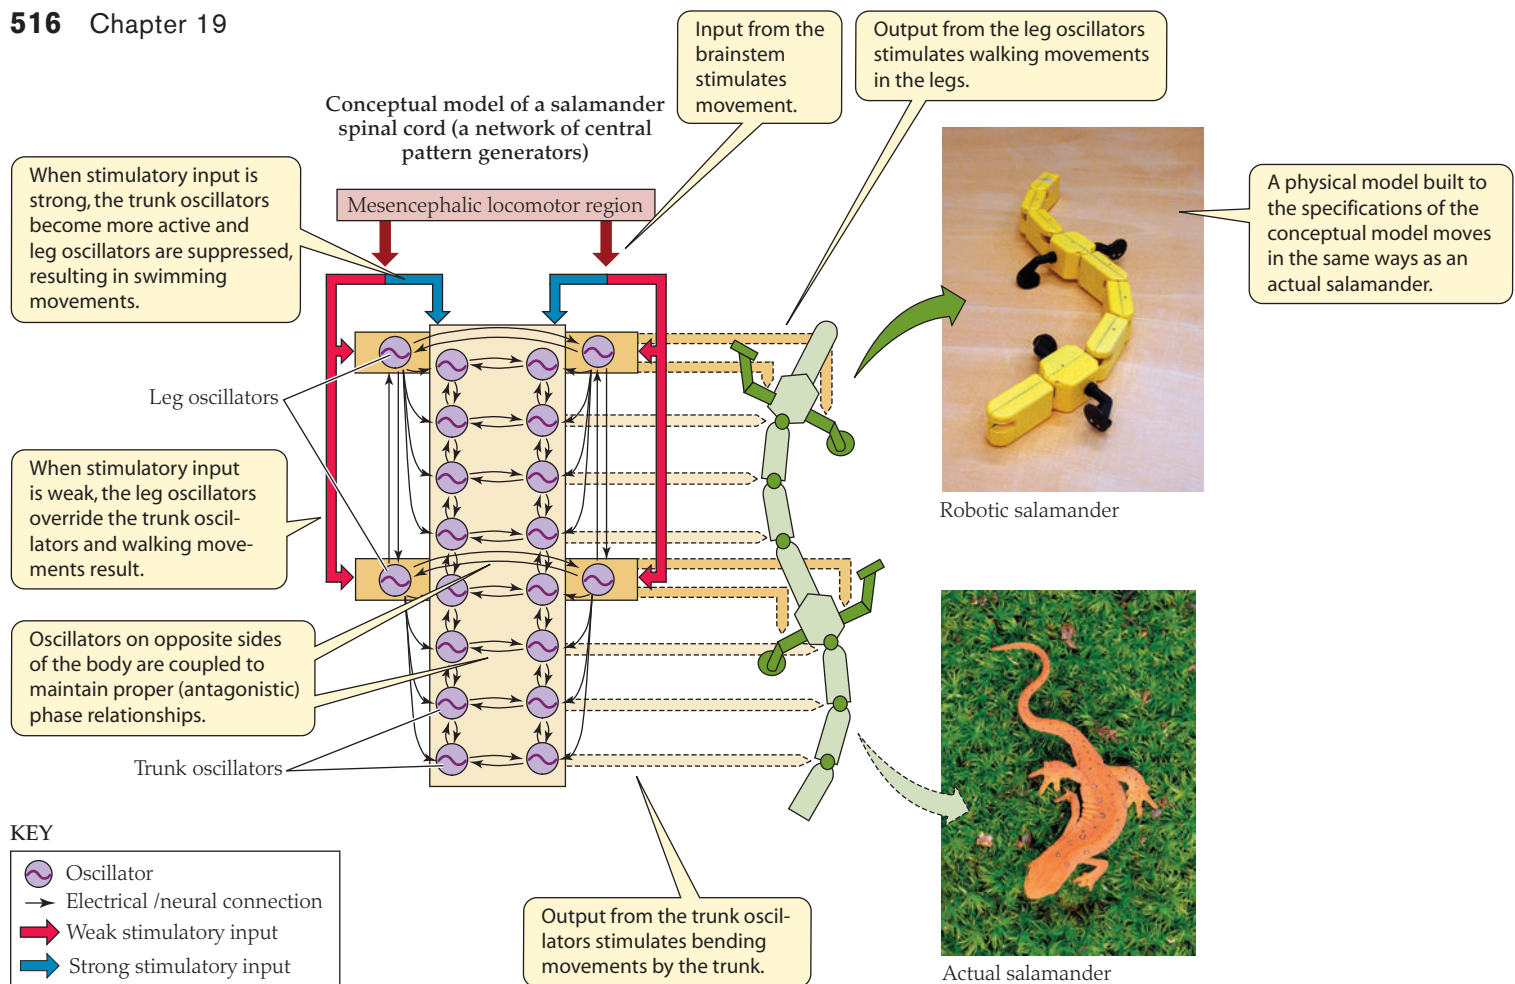

FIGURE 19.12 Design of a robot salamander that walks and swims The robot has segmental oscillators controlling body bending, and leg oscillators controlling leg stepping. The oscillators are stimulated by brainstem commands, diagrammed by blue and red arrows, and are coupled to maintain correct phase relationships (black arrows). During walking, the leg oscillators override the trunk oscillators. With stronger stimulatory input, leg oscillators saturate and stop oscillating, allowing trunk oscillators to generate the traveling waves of swimming. (After Ijspeert et al. 2007.)

tions results from the activities of many segmental trunk CPGs that interact to coordinate the swimming movement. Salamanders also have leg-controlling CPGs for walking, and these coordinate with each other (so that opposite legs alternate, for example) and also interact with the segmental body CPGs (Figure 19.12). As in the cat, stimulation of a mesencephalic locomotor command center can elicit walking; stronger stimulation elicits faster walking, and ultimately, swimming movements. Figure 19.12 shows how the network of interacting CPGs is modeled in the robotic salamander to produce this transition from walking to swimming with increasingly stronger command input. The investigators arranged the coupling between oscillators in the robot so that the leg oscillators overrode trunk oscillators, but the leg oscillators saturated (stopped oscillating) at high frequencies. With these interactions, investigators found that the robot could simulate effectively both salamander walking and swimming, with reasonably “natural” transitions between the two! This modeling study suggests that the known interactions of CPGs are sufficient to coordinate different gaits as well as their transitions.

The generation of movement involves several areas in the vertebrate brain

The vertebrate brain is profoundly important in the control of movement. We have discussed experiments showing that patterned locomotor movements can persist in spinally transected vertebrates and hence do not require the brain. This finding, however, does not contradict the importance of the brain in initiation, coordination, and regulation of normal movements. Let’s now consider the ways in which brain areas interact with sensory input and spinal centers in movement control. These have been studied most extensively in mammals.

Until recently, the production and control of complex motor functions have been substantially attributed to brain structures such as the cerebral cortex, basal ganglia, and cerebellum. In such views, the spinal cord was assigned a subservient function in the production of movement, playing a largely passive role of relaying the commands dictated to it by the brain. Many recent studies (including the locomotion studies described previously) provide evidence that the spinal motor circuits are active participants in several aspects of the production of movement, contributing to functions that had been ascribed to “higher” brain regions. Moreover, the roles of various brain areas in motor control can be difficult to separate from sensory, motivational, and other aspects of brain function. Views on motor control are changing as a result of new data and interpretations.

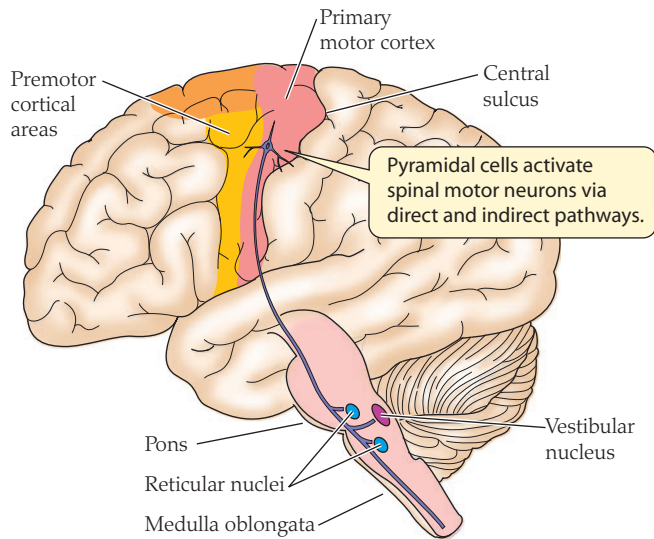

FIGURE 19.13 The location of major motor areas of the human cerebral cortex and brainstem The primary motor cortex is just anterior to the central sulcus (which separates it from the somatosensory cortex). Anterior to the primary motor cortex is a mosaic of areas collectively termed the premotor region. Neurons from the primary motor cortex descend to activate motor nuclei of the brainstem and circuits of the spinal cord.

CEREBRAL CORTEX We begin our examination of the execution of a voluntary movement with the motor areas of the cerebral cortex (Figure 19.13). The **primary motor cortex** (or simply *motor cortex*) lies just anterior to the central sulcus, a prominent valley in the convoluted cortical surface of most mammals.

Early studies demonstrated that electrical stimulation of areas of the primary motor cortex elicited movements of particular parts of the body, with a point-to-point correspondence between the area stimulated and the movements produced. Thus the body regions are represented on the surface of the primary motor cortex by a somatotopic map (Figure 19.14; see also Figure 15.8). The motor cortical somatotopic map was long viewed as a detailed representation of individual body parts (such as digits of the hand) or even

of individual muscles, but recent studies support a rougher, more complex map of movement patterns, organized to promote coordination among muscles and joints rather than to control single muscles.

The neurons of the primary motor cortex that mediate motor responses to stimulation are pyramidal cells (neurons with pyramid-shaped cell bodies), the axons of which synapse on brainstem motor nuclei and also continue down the spinal cord as major components of the corticospinal tract. (This tract is known as the *pyramidal tract* because the axons funnel through a pyramid-shaped structure on the ventral surface of the brainstem—not because the cells are pyramidal neurons.) The corticospinal axons end primarily on interneurons in the spinal cord, although in primates some axons also end directly on spinal motor neurons. The neurons of the primary motor cortex therefore activate spinal motor circuits directly via the corticospinal tract, and indirectly via brainstem motor nuclei (see Figure 19.13): the pontine and medullary reticular nuclei, the vestibular nucleus, and (in some species) the red nucleus. The brainstem motor nuclei are generally more important in involuntary postural control than in voluntary movements.

The activation of pyramidal cells in the primary motor cortex governs the expression of voluntary movements. The corticospinal tract appears essential for voluntary movement, but subcortical areas are also important. Activity of neurons in the primary motor cortex precedes and correlates well with voluntary movements, a finding that suggests a control function. Individual neuron activities in the primary motor cortex encode the force and direction of movements. For some neurons the amount of activity predicts the *amount* of force of a movement, for others it predicts the *change* of force, and for still others it predicts the *direction* of the movement independent of the muscles and forces used to achieve it. This last type of cellular activity suggests that neurons in the primary motor cortex can code a parameter of the movement that is more abstract than the forces and muscles that generate it.

How does the initiation of a voluntary movement trigger the neural events that lead to the activation of motor-cortex pyramidal cells? How does the motor cortex interact with other brain areas, such as the cerebellum and basal ganglia, to produce smoothly

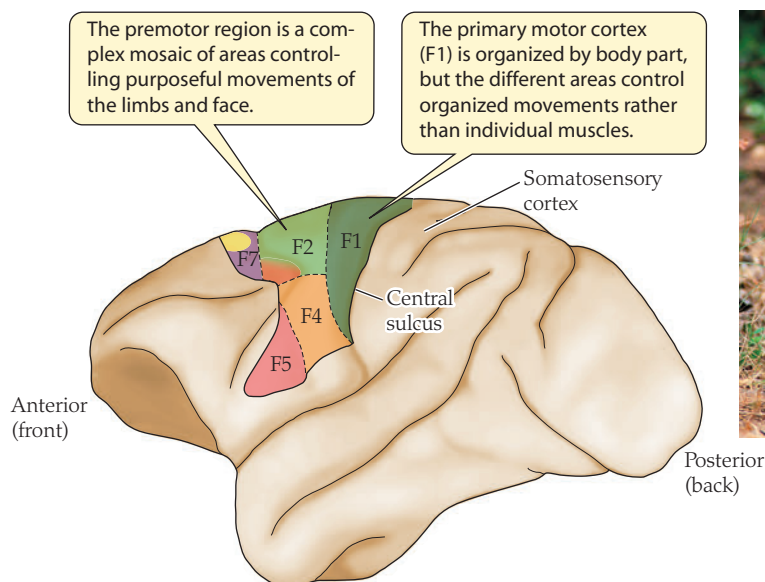

FIGURE 19.14 The primary motor cortex and premotor region of a rhesus monkey The primary motor cortex (F1) is just anterior to the central sulcus and is somatotopically organized: Neurons in different areas control movements of different parts of the body. A mosaic of premotor cortical areas (F2–F7) receives inputs from different regions of the cortex and is active in organizing and executing different kinds of movements. For example, F5 organizes grasping movements and has spatially overlapping projections to the hand and mouth. (F3 and F6 are on the medial surface and not visible in this view.) (After Rizzolatti and Lupino 2001.)

coordinated, skilled movements without our having to expend continuous conscious effort?

For the first question, we know from recordings and from imaging studies that extensive areas of the brain are active before a decision to move. For example, if we place surface electroencephalogram (EEG) electrodes on the skull of a subject and ask her to move one finger whenever she wishes, we record a consistent pattern of activity from much of the entire cortical surface: a small, widespread rising wave of electrical activity that precedes the movement by about 800 milliseconds (ms). This electrical activity, termed a *readiness potential*, becomes localized to the relevant portion of the primary motor cortex only in the last 50 to 80 ms preceding the movement. The decision to initiate a voluntary movement appears to involve many areas of the cortex, including so-called association areas, and to be passed to a specific motor cortical site for initiation of the movement.

In addition to the primary motor cortex, other regions of the cerebral cortex participate in organizing movements. The frontal cortex anterior to the primary motor cortex (see Figure 19.14) consists of a mosaic of areas that participate in the planning, organization, and execution of purposeful movement. These areas had been thought to activate motor cortical regions in a hierarchical arrangement, but more recent primate studies show that some areas of the anterior mosaic connect directly to the spinal cord. Moreover, electrical stimulation of both motor and premotor cortices with stimulus trains longer than 100 ms leads to coordinated movements of different types. These results suggest that regions of both primary motor cortex and the mosaic of premotor areas control different categories of complex movement, rather than being hierarchically arranged.

One complication of the function of premotor areas is that the properties of neurons in these areas are not simply motor. An interesting example is that of **mirror neurons**, found in area F5 in monkeys (see Figure 19.14). Individual mirror neurons are activated when a monkey generates a particular movement such as reach-and-grasp. But they are also activated when the monkey sees another individual (another monkey or the experimenter) make the corresponding movement. Mirror neurons, then, appear to code for the abstract concept of the movement rather than its execution. Mirror neurons may function in the understanding of actions, as well as in imitative learning.

The premotor areas may project directly to the primary motor cortex, but they (and other cerebral areas) also have important projections to subcortical areas. Many studies suggest that both the initial preprogramming of a movement and its modification once initiated involve interaction of the cerebral cortex with two subcortical areas that are important in voluntary movement. Next we will consider these subcortical areas: the cerebellum and the basal ganglia.

CEREBELLUM The **cerebellum** is a large, highly convoluted structure at the dorsal side of the hindbrain. It is present in all vertebrates. The cerebellum regulates movement indirectly, adjusting the descending motor output of other brain areas. The cerebellum is clearly involved in the coordination of movement, as demonstrated by the effects of cerebellar lesions in various animals, including humans. Voluntary movements are still possible following cerebellar lesions, but they are clumsy and disordered, lacking the smooth and effortless precision of normal movements. Movements

are accompanied by tremor, and patients with cerebellar injuries report that they have to concentrate on each part of a movement, joint by joint. The cerebellum supports the smooth and coordinated execution of complex movements, by evaluating motor commands and sensory feedback to provide error correction signals for motor control during a movement.

The cerebellum contains two major parts: an outer **cerebellar cortex** and underlying **deep cerebellar nuclei**. The sole output of the cerebellar cortex is to the deep cerebellar nuclei. Three functional divisions of the cerebellar cortex receive inputs from and project (send outputs) to different parts of the brain via different deep cerebellar nuclei: the *vestibulocerebellum* (posterior, interacting with the vestibular system), the medial *spinocerebellum* (coordinating ongoing movement via its output directed toward the motor cortex and brainstem motor nuclei), and the lateral *cerebrocerebellum* (concerned with motor planning as well as with planning and sequencing of non-motor cognitive behavior).

The cellular architecture and synaptic interactions of the cerebellar cortex are elegantly precise and are as well known as those of any other area of the brain. As **Figure 19.15a** shows, the cerebellar cortex contains five types of neurons and two principal types of input fibers. The axons of Purkinje cells constitute the only output of the cerebellar cortex; these end in the deep cerebellar nuclei below the cortical surface. The major synaptic interactions of the cerebellar cortex are shown in Figure 19.15a. Climbing fibers make powerful excitatory 1:1 synaptic contacts with Purkinje cells. Mossy fibers, in contrast, provide divergent excitatory input to many granule cells. Axons of granule cells ascend to the surface layer of the cortex and branch in opposite directions to become the parallel fibers, which make excitatory synaptic contacts with the other types of cerebellar cortical cells. The roles of climbing-fiber and mossy-fiber input are not completely clear. Climbing fibers are thought to convey error signals (sensory feedback from errors in movements), whereas mossy fibers may convey broader information about the sensory context of a movement.

The synaptic interaction of parallel fibers and Purkinje cells is especially prominent. The parallel fibers pass through the flattened, planar dendrites of Purkinje cells at right angles (**Figure 19.15b**). Each Purkinje cell receives excitatory synapses from about 100,000 parallel fibers (in addition to 1 climbing fiber). Thus the climbing-fiber and mossy-fiber inputs differ greatly in the degree of divergence and convergence of their synaptic effects.

With the exception of the granule cells, which exert excitatory synaptic effects, all of the other cell types of the cerebellar cortex are *inhibitory* in their effects. Basket cells, stellate cells, and Golgi cells mediate different sorts of inhibition within the cerebellar cortex. Moreover, the Purkinje axons that are the sole output of the cerebellar cortex are inhibitory in their effects on the deep cerebellar nuclei. The inhibitory output of the cerebellar cortex is balanced at the level of the deep cerebellar nuclei, because the climbing fibers and mossy fibers make excitatory synapses on the neurons of the deep nuclei. The inhibitory output of the Purkinje cells of the cerebellar cortex may then refine and sculpt movements by selectively opposing the excitatory effects of climbing- and mossy-fiber input at the deep cerebellar level.

Despite extensive studies of the circuitry of the cerebellum (only superficially described here), we still do not have a clear understanding of how it modulates or coordinates movements. There are several

(a) The cellular structure of the cerebellar cortex

(b) Synaptic interactions of the cerebellar cortex

FIGURE 19.15 The neuronal organization of the mammalian cerebellar cortex (a) Cerebellar inputs are mossy fibers and climbing fibers. The output neuron is the Purkinje cell. Local interneurons are the granule cell, stellate cell, basket cell, and Golgi cell. Parallel fibers are granule cell axons that run along a folium (fold), at right angles to the planar dendritic trees of Purkinje cells. (b) Motor learning model of the cerebellar cortex. The two inputs to the cerebellum (mossy fibers and climbing fibers) converge on Purkinje cells. The learning of a motor task involves heterosynaptic interaction in which a climbing fiber depresses the synaptic actions of the parallel fibers on a Purkinje cell. Excitatory synapses are indicated with a plus sign (+) and inhibitory synapses with a minus sign (-).

models of cerebellar action—some stressing millisecond timing of motor discharges, others stressing corrective feedback or coordination of disparate body regions and muscle groups. One popular model is that the cerebellum learns motor tasks so that they can be performed unconsciously and automatically in the appropriate sensory context. This motor learning is thought to involve changes in synaptic strength, specifically long-term depression at synapses of parallel fibers onto Purkinje cells (see Figure 19.15b). This long-term synaptic depression and the related long-term potentiation are discussed in Chapter 13 (see pages 353–354).

BASAL GANGLIA The **basal ganglia** are a set of nuclei (clusters of brain neurons) located in the forebrain and midbrain, under the cerebral hemispheres. The most important areas (in terms of motor control) are the *caudate nucleus*, the *putamen*, and the *globus pallidus*. The caudate nucleus and putamen are similar in origin and function, and together they are termed the *neostriatum* (or simply *striatum*). The caudate nucleus and putamen receive excitatory input from many parts of the cerebral cortex, both motor and association areas. The caudate nucleus and putamen send inhibitory neurons to the globus pallidus. The major output of the basal ganglia is inhibitory; neurons from the internal segment of

the globus pallidus inhibit neurons in the thalamus that excite the cerebral motor cortex.

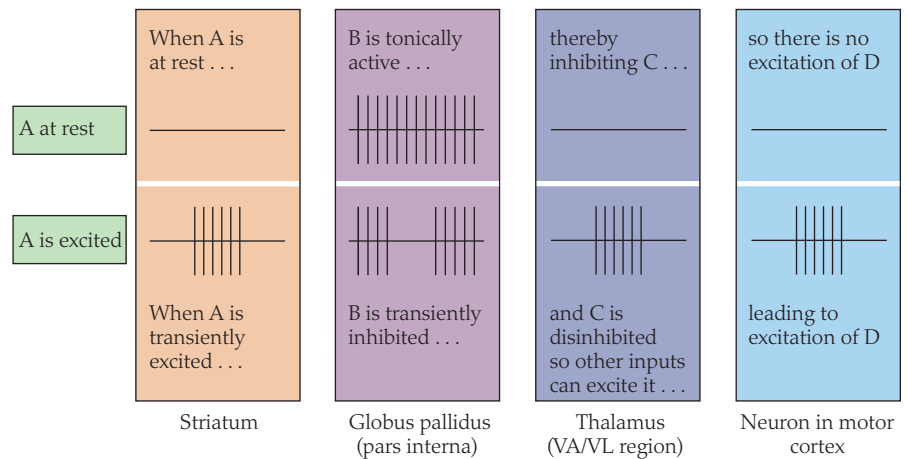

The basic circuit of the basal ganglia is considered an example of a **loop** circuit—one in which the output of the circuit loops back to the site of the circuit's input. (This designation is not strictly accurate, however, because the motor cortex affected by basal ganglia output is much more restricted than the broad areas of cerebral input to the basal ganglia.) Loop circuits are common in the vertebrate brain, and they appear to be important for many aspects of motor control, emotions, and other brain activities. The basal ganglia also form a second loop circuit, between the striatum and the substantia nigra. Dopaminergic neurons from the substantia nigra project to the striatum and receive inhibitory feedback from it.

The basal ganglia are important in selecting movements, suppressing competing or unwanted movements, and initiating the selected movement. Most of the neurons in the circuits of the basal ganglia are inhibitory, so these functions involve considerable inhibitory interaction. Figure 19.16 shows how the basic synaptic connections of the basal ganglia function to disinhibit movement. The output of the globus pallidus pars interna (GP_i) inhibits movements. For the initiation of a movement, this tonic inhibition is lifted, by *disinhibition*. The striatum (caudate nucleus and putamen)

FIGURE 19.16 Basal ganglia aid the initiation of movement by disinhibition In the direct pathway through the basal ganglia, neurons from the cerebral cortex excite striatal neurons, which inhibit neurons in the globus pallidus pars interna. These globus pallidus neurons inhibit neurons in the thalamus that promote movement. Cerebral cortical activation of striatal neurons transiently inhibits the tonic inhibitory output of the globus pallidus, disinhibiting the thalamus and activating a movement. Excitatory synapses are indicated with a plus sign (+) and inhibitory synapses with a minus sign (-).

receives excitatory input from the cerebral cortex, and striatal neurons inhibit neurons in the globus pallidus via two pathways. In the *direct* pathway there are two inhibitory synapses: Striatal neurons inhibit GP_i, and GP_i neurons inhibit neurons of the thalamus. Thus activation of striatal neurons inhibits GP_i neurons and disinhibits the thalamus, thereby allowing a movement (see Figure 19.16). The *indirect* pathway, in contrast, involves a chain of three inhibitory neurons: Striatal neurons inhibit neurons of the globus pallidus pars externa (GP_e), GP_e neurons inhibit GP_i neurons, and GP_i neurons inhibit the thalamus. This triple inhibition means that striatal activity via the indirect path will suppress other activity in the thalamus, strengthening the tonic suppression of other unwanted movements and preventing them from competing with the movement selected.

The balanced roles of the direct and indirect pathways in the basal ganglia serve in the selection, suppression, and initiation of movements. These roles contrast with the cerebellum, which appears to “fine-tune” movement, coordinating and smoothly modifying the execution of a movement to match a command. Degenerative changes in neurons of the basal ganglia underlie human movement disorders such as Parkinson’s disease and Huntington’s disease (Box 19.2).

THE INTERACTION OF BRAIN AREAS IN MOVEMENT CONTROL We will now attempt to integrate the hypothesized roles of the cerebral cortex, cerebellum, and basal ganglia in the control of voluntary movement. As Figure 19.17 shows, the planning and programming of a movement can be viewed as separate from the execution of the movement. We can suppose that the decision to move starts in the

association cortex (cortex that is not linked to any particular sensory or motor system), because the readiness potentials recorded prior to a movement are not localized to a specific cerebral area. Two loop circuits from the association cortex are thought to be involved in preprogramming a movement: one loop goes through the basal ganglia (selection and initiation) and another through the lateral cerebrotocerebellum (initial programming). Both loops feed back to the motor cortex via the ventrolateral nucleus of the thalamus. The motor cortex then generates the appropriate pattern of activity to initiate the movement.

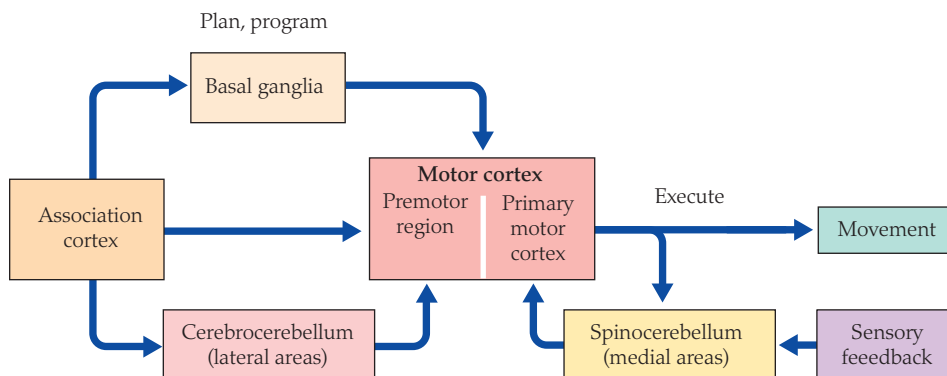

FIGURE 19.17 The interaction of brain areas in the planning, execution, and control of voluntary movement The sensory association cortex (as well as other cortical areas) funnels activity to premotor cortical areas, including loops through the basal ganglia and the cerebrotocerebellum, in the planning and programming of the movement. Activity passes to the primary motor cortex for executing the movement, with correction from a cerebellar loop through the spinocerebellum. Inputs to the cerebral cortex pass through the thalamus (not shown).

Information about the command is sent to the spinocerebellum, via several subcortical nuclei. This process, termed *command monitoring*, “informs” the cerebellum of the intended movement. The spinocerebellum also receives ascending information—both sensory information about joint position and muscle tension, and central information from spinal and brainstem motor centers. The spinocerebellum may integrate this feedback information about the state of lower motor centers (internal feedback) and about the periphery (external feedback) with the monitored cerebral command. The cerebellar output can then modify and correct the command on a continuous basis as the movement evolves, using an integral of all relevant information (command, motor state, and sensory feedback). This continuous correction is presumably faster and smoother than, say, a correction system based on sensory feedback alone.

There remains considerable controversy over the roles of all these brain areas in the control of movement, and the areas are also implicated in other functions in addition to motor control. Even if the preceding description of brain area interaction in the execution of a voluntary movement is correct, it begs other questions (such as, how is a decision to move actually made?). Nevertheless, the relations shown in Figure 19.17 illustrate how brain areas may interact in planning, coordinating, and commanding movements in mammals.

BOX 19.2 BASAL GANGLIA AND NEURODEGENERATIVE DISEASES

In humans, two movement disorders result from neurodegenerative changes in basal ganglia function: Parkinson's disease and Huntington's disease (Huntington's chorea). Parkinson's disease is characterized by difficulty in initiating movements (*akinesia*), so a simple task such as climbing stairs or getting up from a chair becomes almost impossible to carry out. Akinesia is often accompanied by postural rigidity and by tremors in limbs at rest. Huntington's chorea represents the converse of parkinsonism: Movements occur uncontrolledly and are difficult to stop. Both *chorea* (uncontrolled but coordinated jerky movements) and *athetosis* (slow writhing movements) are associated with damage to the striatum. **Box Extension 19.2** discusses these neurodegenerative disorders and suggests how they shed light on the normal generation of voluntary movements in humans and other mammals.

SUMMARY Control and Coordination of Vertebrate Movement

- The vertebrate brain and spinal cord interact in the generation of behavior patterns such as locomotion and voluntary movements.
- Tetrapod vertebrates have a spinal CPG for stepping during walking. Descending commands from the brain can activate the CPG, and sensory feedback can modulate it.
- Several brain areas are important in generating and coordinating movements in mammals. In the cerebral cortex, the primary motor cortex directly activates spinal motor centers to generate movements; premotor cortical areas are involved in planning and organizing movements.
- The cerebellum and the basal ganglia are connected to the cerebral cortex in looping circuits. The cerebellum is active in coordinating movements and in motor learning. The basal ganglia are involved in the initiation of movements by disinhibition. Parkinson's and Huntington's diseases stem from abnormalities in function of the basal ganglia.

Study Questions

1. Suppose that an arthropod such as a locust or crayfish has about 10^5 neurons, a fish 10^8 , and a rat 10^{10} . Is the behavior of the fish 1000 times more complicated than that of the arthropod? Why or why not? What does the difference in number of neurons suggest about how these different animals generate patterns of behavior?
2. How do we find out whether a vertebrate such as a cat or a salamander has a central pattern generator (CPG) for walking?
3. A neural circuit for a CPG (see Figure 19.6) may include motor neurons or may consist entirely of interneurons. How do you think the inclusion of motor neurons might restrict the flexibility of a CPG circuit? For what sorts of behavior patterns do you think a CPG circuit might include motor neurons?
4. Why would an oscillator of the closed-loop model be expected to provide a more stable rhythmic output than one employing the half-center model?
5. Some movements (such as picking up a cup) are visually guided, or *steered*. Others (such as throwing a football) cannot be corrected once launched and are termed *ballistic*. How, and to what extent, might you expect the neural control of these movements to differ?

Muscle

This scanning electron micrograph of glycerinated rabbit psoas muscle shows muscle fibers containing bundles of myofibrils, the intracellular structures that execute muscle contraction. Muscles are specialized for movement, and all animals use muscles to generate movements that accomplish physiological activities or behaviors. Hearts beat, gastrointestinal tracts mix and move food, insects follow pheromone trails in pursuit of mates, clams snap shut, and elephants use their trunks to touch and maneuver the bones of their deceased relatives. In this chapter we explore the physiology of muscles that underlie such activities.

Not all movements are generated by muscles, however. Chromosomes move during cell division, flagella and cilia make whiplike or wavelike motions, single cells such as amoebae or white blood cells travel from one place to another, and plants slowly bend toward sources of light. Organized motion is essential for survival, and natural selection continuously hones and improves mechanisms of movement. All organized movements, whether produced by muscles or not, depend on the generation of forces that require the conversion of chemical energy to mechanical energy. Muscle cells use the *molecular motor* **myosin** to capture and convert the chemical energy of ATP into the mechanical energy of movement. Myosin is a large protein that interacts with another protein, **actin**, to generate force. Myosin and actin are referred to as *contractile proteins*.

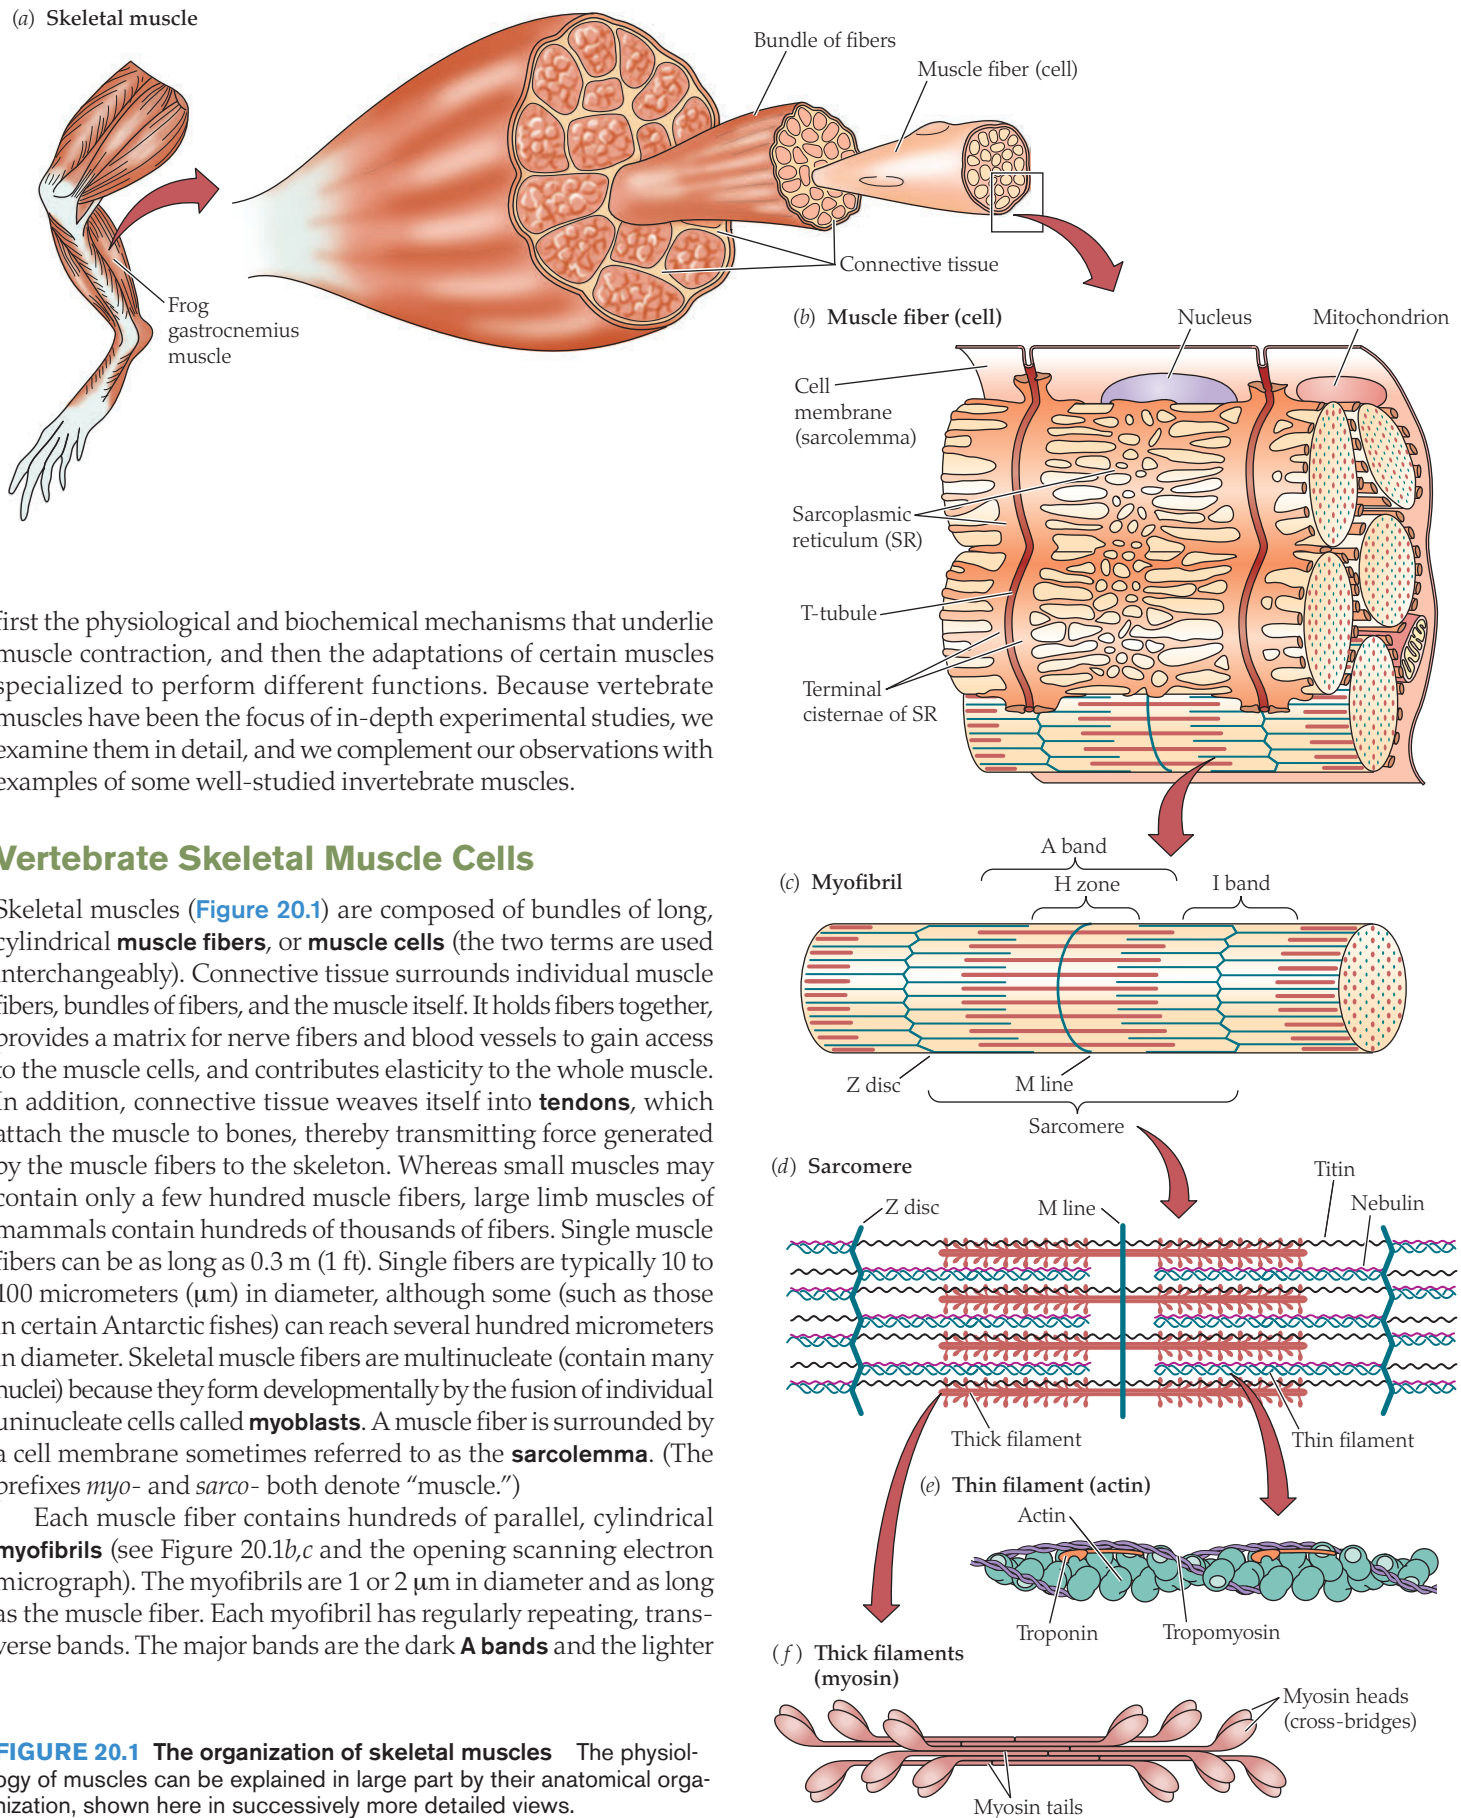

Muscle is a tissue that consists of specialized contractile cells. All animal phyla have two categories of muscle cells: **striated** and **smooth** (or unstriated). Striated muscle cells have alternating transverse light and dark bands, giving them a striped appearance. The pattern of bands reflects the organization of the contractile proteins myosin and actin into regularly repeating units called *sarcomeres*. Smooth (unstriated) muscle cells also possess actin and myosin, but these proteins are not organized into sarcomeres.

In vertebrates, striated muscles make up **skeletal** (attached to bones) and **cardiac** (heart) muscles. Smooth muscles of vertebrates are found primarily in hollow or tubular organs such as the intestine, uterus, and blood vessels. Invertebrates also have striated and smooth muscles, but they are not always found in the same distribution as in vertebrates. In arthropods, for example, the skeletal (attached to the exoskeleton) and cardiac muscles are both striated, but so are muscles of the alimentary (digestive) tract.

In this chapter we consider muscles in light of the major themes of this book: mechanism and adaptation. We examine

The rabbit's psoas muscle is a favorite for both structural and physiological studies The psoas muscle attaches to the skeleton between the lower vertebrae and the top of the femur. Its action is to rotate and flex the thigh. Treating muscle cells with glycerin makes their cell membranes so leaky that they no longer separate the intracellular and extracellular fluids. Glycerinated muscle fibers are sometimes described as "skinned." All soluble contents of the cytoplasm diffuse out of the cell, but nonsoluble molecules such as contractile proteins and enzymes remain intact and, amazingly, retain their functional capabilities. Because soluble substances pass freely through the glycerinated cell membrane, experimenters can add key ingredients (such as calcium and magnesium ions and ATP) to the bathing medium and thereby generate contractile activity. (Scanning electron micrograph courtesy of Richard Briggs, Smith College.)

first the physiological and biochemical mechanisms that underlie muscle contraction, and then the adaptations of certain muscles specialized to perform different functions. Because vertebrate muscles have been the focus of in-depth experimental studies, we examine them in detail, and we complement our observations with examples of some well-studied invertebrate muscles.

Vertebrate Skeletal Muscle Cells

Skeletal muscles (**Figure 20.1**) are composed of bundles of long, cylindrical **muscle fibers**, or **muscle cells** (the two terms are used interchangeably). Connective tissue surrounds individual muscle fibers, bundles of fibers, and the muscle itself. It holds fibers together, provides a matrix for nerve fibers and blood vessels to gain access to the muscle cells, and contributes elasticity to the whole muscle. In addition, connective tissue weaves itself into **tendons**, which attach the muscle to bones, thereby transmitting force generated by the muscle fibers to the skeleton. Whereas small muscles may contain only a few hundred muscle fibers, large limb muscles of mammals contain hundreds of thousands of fibers. Single muscle fibers can be as long as 0.3 m (1 ft). Single fibers are typically 10 to 100 micrometers (μm) in diameter, although some (such as those in certain Antarctic fishes) can reach several hundred micrometers in diameter. Skeletal muscle fibers are multinucleate (contain many nuclei) because they form developmentally by the fusion of individual uninucleate cells called **myoblasts**. A muscle fiber is surrounded by a cell membrane sometimes referred to as the **sarcolemma**. (The prefixes *myo-* and *sarco-* both denote “muscle.”)

Each muscle fiber contains hundreds of parallel, cylindrical **myofibrils** (see **Figure 20.1b,c** and the opening scanning electron micrograph). The myofibrils are 1 or 2 μm in diameter and as long as the muscle fiber. Each myofibril has regularly repeating, transverse bands. The major bands are the dark **A bands** and the lighter

FIGURE 20.1 The organization of skeletal muscles The physiology of muscles can be explained in large part by their anatomical organization, shown here in successively more detailed views.

I bands.¹ In the middle of each I band is a narrow, dense **Z disc**, or **Z line**. The portion of a myofibril between one Z disc and the next Z disc is called a **sarcomere** (see Figure 20.1d). Thus one myofibril consists of a longitudinal series of repeating sarcomeres. The Z discs of adjacent myofibrils are lined up in register with each other, so the pattern of alternating A bands and I bands appears continuous for all the myofibrils of a muscle fiber. This alignment of banding within a muscle fiber gives the fiber its striated appearance. The striations are visible by light microscopy.

Higher-magnification electron micrographs show that the myofibrils contain two kinds of **myofilaments**. The **thick filaments** (see Figure 20.1f) are composed primarily of the protein *myosin* and are confined to the A band of each sarcomere. A single thick filament consists of 200 to 400 myosin molecules. The **thin filaments** (see Figure 20.1e) are composed primarily of *actin*. A single thin filament consists of two chains of globular actin molecules wrapped around each other in a helix. Thin filaments are anchored to proteins in the Z discs. They extend from the Z discs partway into the A bands of each flanking sarcomere, where they interdigitate with thick filaments. The central region of the A band, which contains only thick filaments and appears lighter than the rest of the A band, is called the **H zone**. A narrow dense region called the **M line** bisects the H zone.

In the M line, the thick filaments of the myofibril are webbed together with accessory proteins to maintain their regular spacing. The Z disc and M line ensure that neither the thin filaments nor the thick filaments float free. In vertebrates, the thick filaments are about 1.6 μm long and 12 to 15 nanometers (nm) across. The thin filaments are about 1.0 μm long and 7 to 8 nm across. Muscle fibers also contain *intermediate filaments*, so named because their diameters are about 10 nm, intermediate between those of thick and thin filaments. Intermediate filaments contribute to the architectural integrity of the muscle fiber. The protein *desmin*, for example, forms a scaffold around Z discs of adjacent myofibrils to hold them together. This scaffold extends to the cytoskeleton that lies beneath the cell membrane as well as to the nucleus and mitochondria. These connections help maintain the structural organization of the cell during contractile activity.

Cross sections of a myofibril show the relationship of thick and thin filaments in a sarcomere (Figure 20.2). A cross section through the I band shows only thin filaments. A section through the part of the A band in which the thick and thin filaments overlap shows each thick filament surrounded by six thin filaments. A section through the H zone shows only thick filaments.

The myosin molecules have radial projections on them called heads or **cross-bridges** (see Figure 20.1f). When the muscle cell is stimulated to contract, the myosin cross-bridges interact transiently with the overlapping actin thin filaments. The interactions of the myosin cross-bridges with actin molecules generate the force for muscle contraction. The sarcomeres contain specialized proteins in addition to actin and myosin. **Titin** and **nebulin** (see Figure 20.1d)

¹Microscopists gave the A band its name because they observed that it is *anisotropic* (strongly polarizes visible light). They named the I band *isotropic* because it does not polarize visible light. The names of other components of the sarcomere come from the German language. The Z disc that separates sarcomeres comes from *Zwischenscheibe* ("between line"); the bright H zone at the center of the A band from *hell* ("clear or bright"); and the M line down the middle of the H zone from *Mittelscheibe* ("middle line").

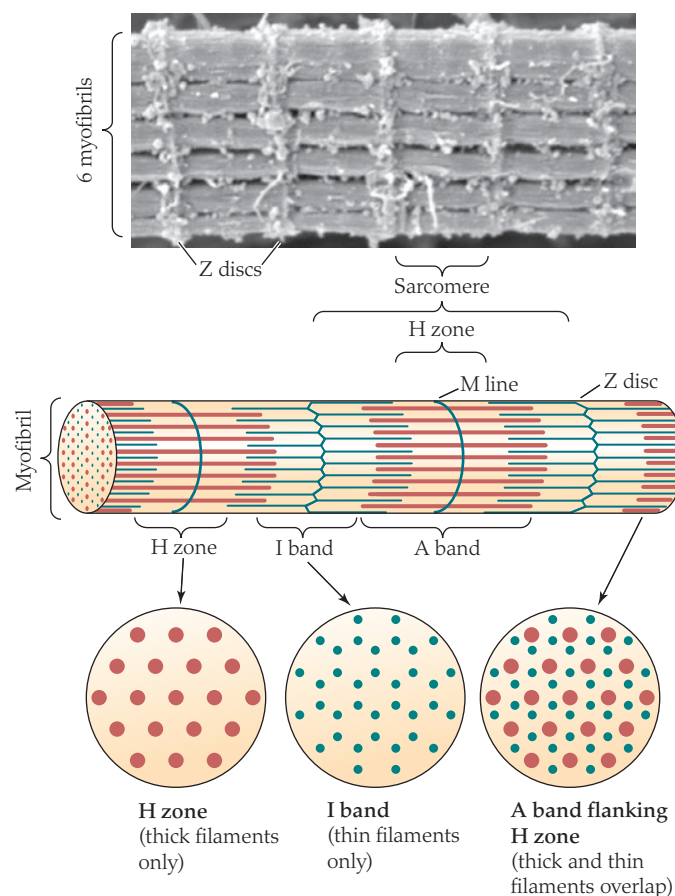

FIGURE 20.2 Thick (myosin) and thin (actin) myofilaments are arranged in parallel in a sarcomere. A longitudinal view of a cylindrical myofibril shows that it consists of a series of sarcomeres. Cross sections illustrate the regions of overlap of the thick and thin myofilaments. Both the M line and the Z disc contain accessory proteins that anchor the thick and thin filaments. Top: This enlarged segment of the scanning electron micrograph in the chapter opener illustrates series of sarcomeres in six myofibrils.

are structural proteins that help align the contractile proteins actin and myosin. A single molecule of titin spans the distance between the Z disc and the M line.² Its properties vary along its length: The amino-terminal end is embedded in the Z disc; the region along the I band is highly folded and elastic; the region along the A band is integrated into the lattice of the thick filaments and inelastic; and the carboxy-terminal end anchors in the M line. This big titin molecule maintains the thick filament at the center of the sarcomere, and its elasticity over the I band region confers the ability of the sarcomere to spring back after the muscle fiber is stretched. *Nebulin* is inelastic; it runs the length of a thin filament and stabilizes it. The nebulin molecule also specifies the length of the thin filament to optimize the overlap between thick and thin filaments. *Troponin* and *tropomyosin* are protein molecules associated with the actin chains of the thin filaments (see Figure 20.1e). They regulate the

²Titin (also known as connectin) is the largest known protein. Composed of nearly 27,000 amino acids, it has a molecular weight of 3 million Daltons (Da). Whereas the thick and thin myofilaments of similar length are polymers made up of hundreds of myosin or actin molecules, a single molecule of titin extends from the Z disc to the center of the sarcomere!

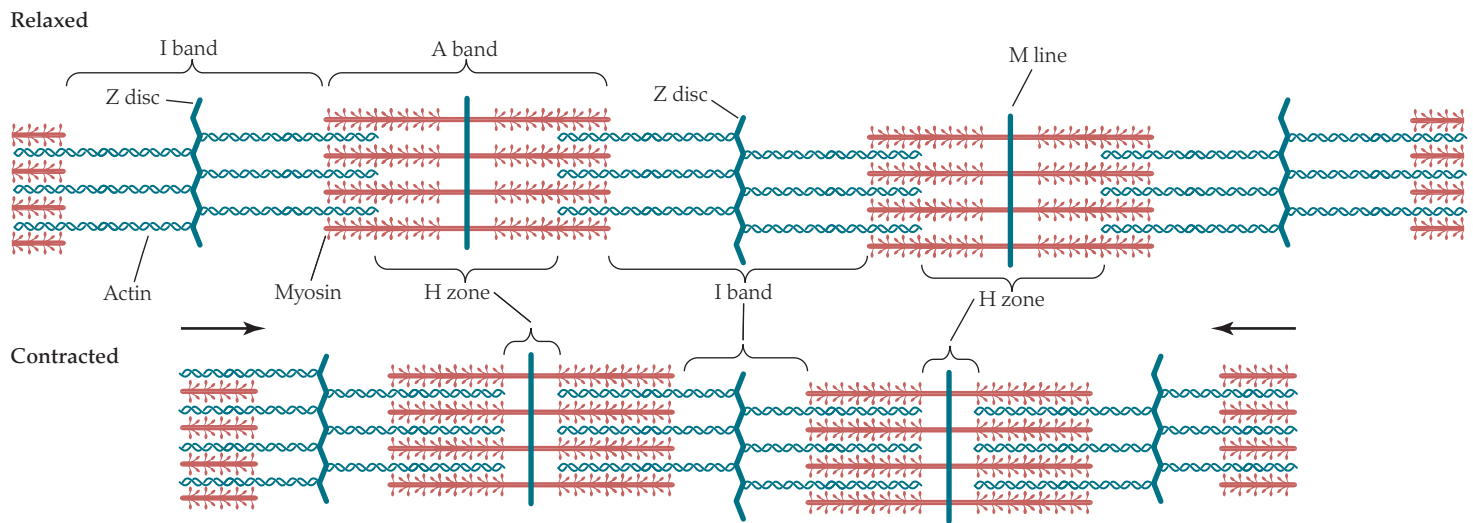

FIGURE 20.3 Muscle contraction is produced by thick and thin myofilaments sliding by one another. The polarized organization of the molecules in both types of myofilaments ensures that the thin filaments are drawn toward the center of each sarcomere. The myofila-

ments do not shorten, but the I band and H band of each sarcomere do. Because the sarcomeres are arranged in series in a myofibril, the entire myofibril shortens. Arrows indicate shortening of two adjacent sarcomeres during contraction.

process of contraction by controlling whether or not the myosin cross-bridges can interact with the thin filaments.³

When a muscle fiber contracts, the thick and thin filaments do not shorten but instead slide by one another. Investigators in the 1950s noted that the A band, which is the length of the thick filaments, does not shorten during contraction. Furthermore, the distance between the margins of the two H zones on either side of a Z disc (the length of the thin filaments) stays the same, no matter what the length of the adjacent sarcomeres. When a sarcomere changes length, the regions that also change length are the H zone and the I band. Two independent teams—A. F. Huxley and R. Niedergerke,

and H. E. Huxley and J. Hanson—made these observations in 1954 and formulated the *sliding-filament theory* of muscle contraction, which has since been amply confirmed. It states that the force of contraction is generated by the cross-bridges of the thick filaments attaching to the thin filaments and actively pulling them toward the center of the sarcomere (Figure 20.3).

Thick and thin filaments are polarized polymers of individual protein molecules

Individual myosin molecules are large proteins of about 500 kilodaltons (kDa), each consisting of two globular heads joined to a long rod, or tail. The heads are the cross-bridges, and the tail contributes to the backbone of the thick filament (Figure 20.4). During polymerization the myosin molecules orient themselves with their tails pointing toward the center of the thick filament and their heads

³The presence of all of these proteins in striated muscle fibers is now well established. Currently, investigators are using proteomics to characterize the profiles of many proteins in different muscles and to follow changes that occur within muscles over time, such as those in holometabolous insects that undergo complete metamorphosis (see Chapter 16) or those in disease states.

FIGURE 20.4 Myosin molecules form the thick filament. (a) About 200 to 400 myosin molecules polymerize to form a polarized thick filament. (b) Each myosin molecule contains two heavy chains of amino acids. The tail of the molecule consists of the two chains coiled around each other. The amino-terminal end of each heavy chain forms one of the heads. The head region has a surface for binding actin and a different site for binding and hydrolyzing ATP (ATPase activity). A link (or hinge) region of the heavy chain connects the head to the tail. In addition, the myosin molecule includes two smaller light chains associated with each head. Thus, each complete myosin molecule contains six polypeptide chains: two heavy and four light. The molecular composition of the heavy and light chains varies in different types of muscles. The different myosin isoforms of heavy chains and light chains confer variations of functional properties, such as the rate at which the myosin ATPase hydrolyzes ATP. The myosin molecules that produce contractile force in smooth and striated muscles are classified as myosin II. They are part of the myosin superfamily that consists of at least 18 different classes of myosins found in protozoans, fungi, plants, and animals.

toward the ends. As a result, the two halves of the thick filament become mirror images of each other with a short bare zone of only tails in the middle of the filament. The cross-bridges on either side of the bare zone point in opposite directions.

Each actin molecule is a globular protein (42 kDa) called *G-actin*. *G-actin* monomers form chains of *F-actin* (filamentous actin). The two chains of *F-actin* wind around each other in a helix (see Figure 20.1e). Like the myosin molecules in thick filaments, *G-actin* molecules in thin filaments are arranged so that those on one side of the Z disc have one orientation, and those on the other side have the opposite orientation. The consequence of the polarized organization of the thick and thin filaments is that the cross-bridges

in contact with the thin filament can act like oars to pull the thin filaments toward the center of the sarcomere.

Muscles require ATP to contract

Myosin heads cyclically attach to actin molecules and then swivel to pull on the actin filament. Each myosin head has two binding sites: one for actin and the other for ATP. The binding site for ATP is an ATPase with enzymatic activity that splits inorganic phosphate from the ATP molecule and captures the released energy. The energy is used to power cross-bridge action.

The cycle of molecular interactions underlying contraction is shown in Figure 20.5. In step 1 the myosin head is bound to actin

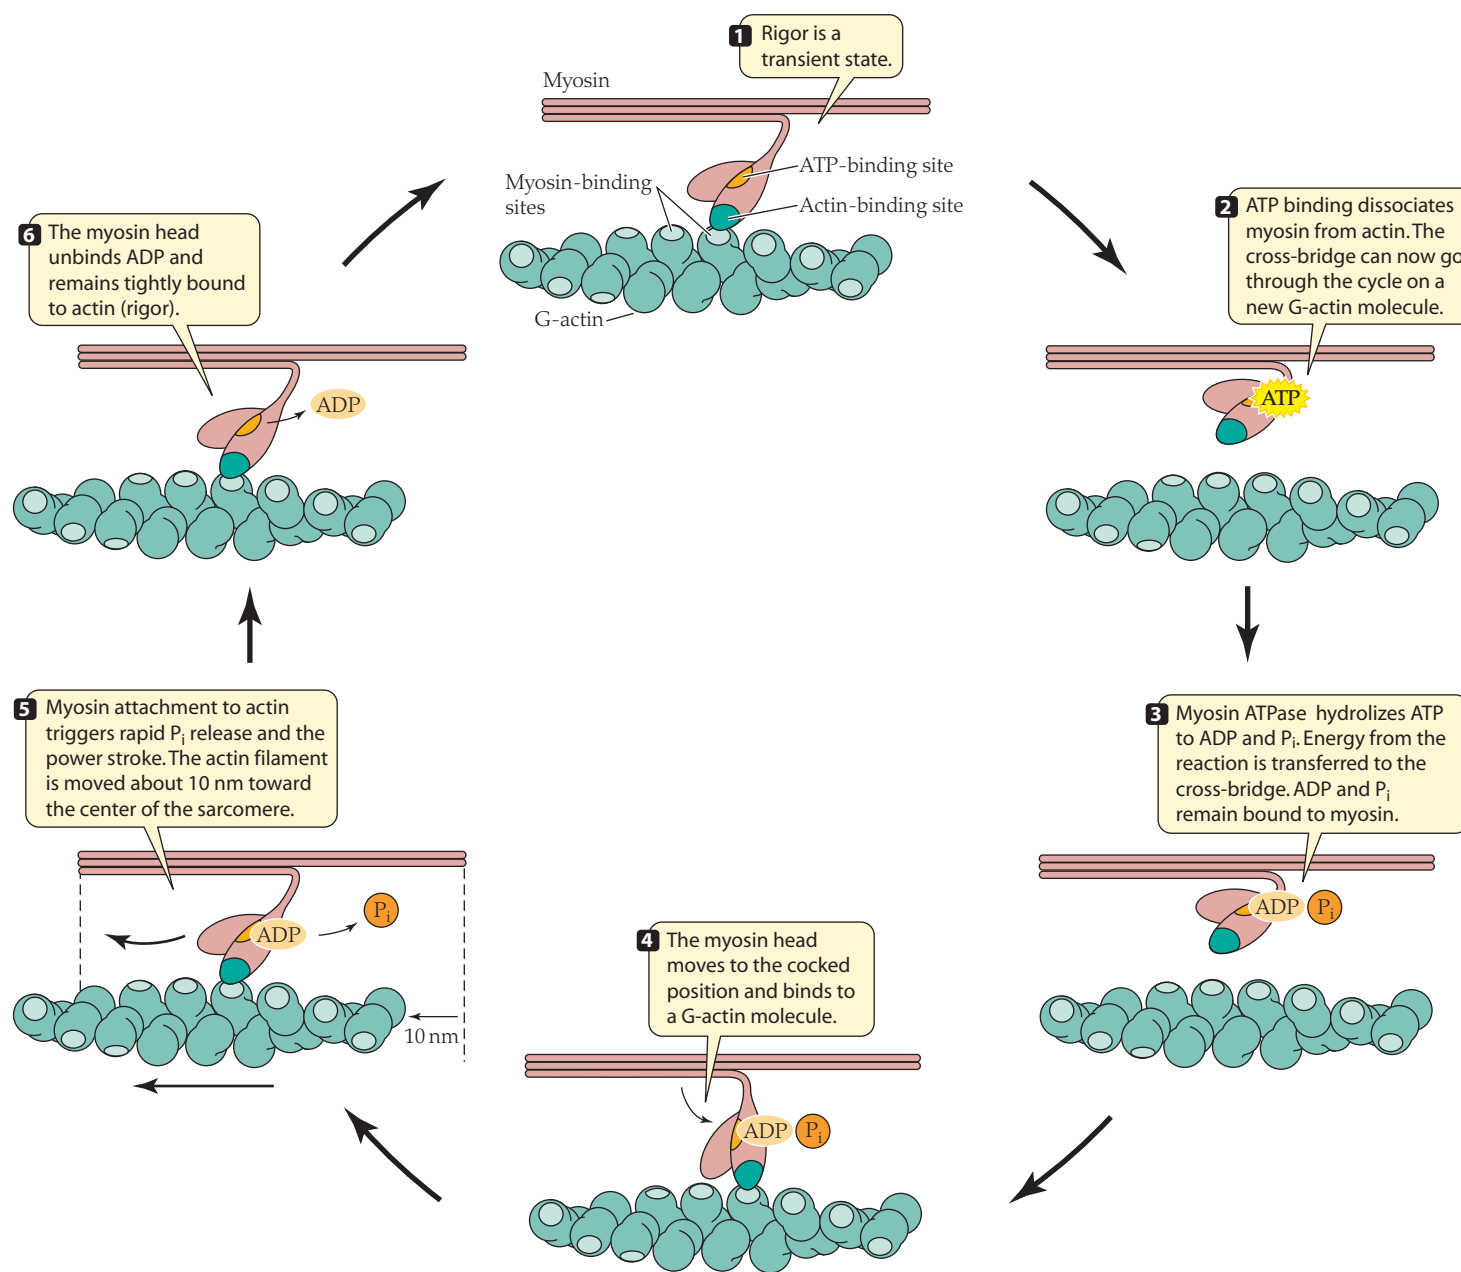

FIGURE 20.5 Molecular interactions that underlie muscle contraction Each cross-bridge goes through several cycles during a single contraction. The two myosin heads function independently. During contraction, only one head of each pair binds to actin at a time. Structural studies

suggest that no more than four myosin heads can attach over a span of seven *G-actin* monomers. Single-molecule studies suggest that each myosin head moves the actin filament by about 10–12 nm.

but is not binding ATP. This is the *rigor* conformation, as in *rigor mortis*, in which muscles of a dead person (or other animal) are rigidly fixed in place because of the absence of ATP in death. ATP is required for myosin to *unbind* from actin (step 2). In life, the rigor stage of each cross-bridge cycle is brief because the globular myosin head readily binds ATP, which causes the myosin head to detach from actin. It is important to understand that the detachment of myosin from actin requires the *binding* of ATP to change the conformation of myosin's actin-binding site, but it does not require the energy derived from the ATP.

Once released from actin, the myosin head hydrolyzes the ATP to ADP and inorganic phosphate (P_i) (step 3). A change in angle of the myosin head (termed *cocking*) accompanies hydrolysis, but the ADP and P_i remain attached to the head. The energy released by hydrolysis of ATP is stored in the myosin-ADP- P_i complex. The complex then binds actin (step 4), forming an actin-myosin-ADP- P_i complex. Initially actin binding is weak, but it triggers P_i release, tighter binding, and the power stroke (step 5). The myosin head swivels, pulling the attached actin toward the middle of the myosin filament. At the end of the power stroke, the ADP is released and the myosin remains tightly bound to the actin (step 6). A new molecule of ATP then binds to the myosin head, triggering its release from actin.

With each cycle, one ATP is consumed, and the myosin molecule moves the actin filament a short distance. During a single contractile event (stimulated by a muscle fiber action potential), each cross-bridge repeats several binding/unbinding cycles. The cross-bridges work independently and asynchronously, so that at any instant during a contraction some of the cross-bridges are bound to actin while the rest are in other phases of the cycle. At no time during contraction do all cross-bridges simultaneously detach from actin. The summed effect of all the repeated cross-bridge cycles is to pull the thin filaments toward the middle of the sarcomere. In living, relaxed muscle, all cross-bridges have stored energy and bound ADP and P_i , but most are temporarily unable to bind actin. As we will see next, cross-bridge cycling requires the presence of calcium.

Calcium and the regulatory proteins tropomyosin and troponin control contractions

In a resting muscle, each myosin head has detached from actin, hydrolyzed the ATP, and stored the energy obtained from hydrolysis. It is "primed" for another cycle. However, the regulatory proteins **tropomyosin (TM)** and **troponin (TN)** prevent contraction by inhibiting most of the myosin heads from binding to actin. TM is a protein dimer of two polypeptides that form an α -helical coiled-coil, which lies along the groove between the two actin chains of the thin filament (Figure 20.6). A single TM molecule extends the length of seven globular actin molecules. Each TM molecule is associated with one TN molecule.

TN is a golf club-shaped complex of three subunits. The "handle" is troponin T (TN-T), which binds to tropomyosin. The "club" includes troponin I (TN-I), which binds to actin, and troponin C (TN-C), which binds Ca^{2+} ions. In the resting state (see Figure 20.6a), the TM molecule lies over the myosin-binding sites of the adjacent actin molecules and prevents myosin cross-bridges from binding to actin. For contraction to occur, TM's inhibition of cross-bridge binding is counteracted by the binding of Ca^{2+} to TN.

(a) No Ca^{2+} ions present in cytoplasm (relaxed)

(b) Ca^{2+} ions released from the sarcoplasmic reticulum

FIGURE 20.6 Ca^{2+} ions, troponin (TN), and tropomyosin (TM) regulate contraction (a) When Ca^{2+} ions are scarce in the cytoplasm, the TN-I subunit binds to two adjacent actin monomers, and the TN-T subunit binds to the tropomyosin molecule. These connections hold TM in a position that covers the myosin-binding sites on actin and inhibits cross-bridge action. (b) The TN-C subunit binds to Ca^{2+} ions when they are released from the sarcoplasmic reticulum. This binding causes conformational changes that detach TN-I from actin and allow TM to roll over the actin surface. The changed position of TM, as well as allosteric changes, permits cross-bridge action.

The key physiological regulator of muscle contraction is calcium. When Ca^{2+} ions bind to TN-C, they trigger conformational changes in TN, TM, and probably actin, which permit myosin cross-bridges to interact with actin (see Figure 20.6b). The changes that occur when Ca^{2+} binds to TN appear to involve both removal of TM's steric blocking of the myosin-binding sites on actin and also more subtle allosteric interactions among the proteins. Once interaction between actin and myosin is possible, the primed myosin cross-bridges are permitted to go through cross-bridge cycles until the Ca^{2+} is removed. The muscle will therefore contract only when Ca^{2+} ions are available to bind TN. In relaxed skeletal muscle fibers, the intracellular concentration of calcium is extremely low: less than $1 \times 10^{-7} M$, which is below the concentration that will induce (by mass action) calcium association with troponin.

SUMMARY Vertebrate Skeletal Muscle Cells

- Each whole muscle consists of a bundle of longitudinally arrayed muscle fibers, which in turn consist of myofibrils made up of thick (myosin) and thin (actin) myofilaments organized into sarcomeres.
- A single myofibril consists of a series of sarcomeres aligned such that the muscle fiber, when viewed longitudinally, appears striped (striated). Titin and nebulin help align and stabilize the thick and thin filaments in the sarcomeres.
- The contractile proteins actin and myosin polymerize in a polarized fashion to form the thin and thick filaments. When the filaments slide by each other during contraction, the heads of individual myosin molecules bind to sites on individual actin molecules and draw the thin filaments toward the center of each sarcomere.
- Each myosin head also functions as an ATPase to provide the energy required to power cross-bridge motion. In relaxed muscle, each “primed” cross-bridge is detached from actin and contains ADP, P_i, and stored energy obtained from the hydrolysis of ATP.
- The regulatory proteins troponin (TN) and tropomyosin (TM), located on the thin filament, inhibit myosin cross-bridges from interacting with actin, except when cytoplasmic Ca²⁺ is elevated. When Ca²⁺ binds to TN-C, it triggers dynamic conformational changes that allow myosin cross-bridges to interact with myosin-binding sites on actin molecules.

Excitation–Contraction Coupling

Neural excitation triggers skeletal muscle contraction. Each skeletal muscle fiber is innervated by a motor neuron at the motor end-plate (Figure 20.7; see also Figure 13.9). An action potential conducted to the axon terminal of the motor neuron releases acetylcholine, which binds to postsynaptic acetylcholine (ACh) receptors in the end-plate and causes permeability changes that result in depolarization of the muscle fiber membrane (sarcolemma) and generation of an action potential. Depolarization of the muscle fiber is referred to as *excitation*. This excitation leads to rapid activation of the contractile machinery of the muscle fiber. The relationship between depolarization and contraction is called **excitation–contraction coupling**.

Excitation and contraction are coupled by two separate but intimately associated membrane systems. The first of these is a system of tubules that is continuous with the sarcolemma: the **transverse tubules**, or **t-tubules** (see Figure 20.7). Each t-tubule dips into the muscle fiber at an angle perpendicular to the sarcolemma, transverse to the long axis of the muscle fiber. The t-tubule invaginations occur at regular intervals along the length of the sarcolemma. The position of invagination varies between phyletic groups, usually at the level of the Z discs (e.g., amphibian muscle) or at the junction of the A and I bands (e.g., mammalian and reptilian muscles). Because the t-tubule membrane is a continuation of the outer sarcolemma, the tubule lumen is continuous with extracellular space. When the sarcolemma is depolarized, the t-tubules conduct this excitation deep into the interior of the muscle fiber. The t-tubules come into close association with the second membrane system required for excitation–contraction coupling, the **sarcoplasmic reticulum (SR)**.

The SR is a branching lacework of tubules contained entirely within the muscle fiber. Each myofibril is enveloped in SR. The SR membrane has Ca²⁺-ATPase active-transport pumps (see Chap-

ter 5) that maintain a low concentration of Ca²⁺ ions in the cytoplasm and a high concentration (~1 × 10⁻³ M) of Ca²⁺ ions within the SR.⁴

The SR between two t-tubules is called an *SR compartment*. Each compartment of the SR forms a sleeve of branching tubules around each myofibril (see Figure 20.1b). Enlarged sacs called *terminal cisternae* (singular *cisterna*) lie next to the t-tubules. In resting muscle, Ca²⁺ is largely confined to the terminal cisternae of the SR. Once an action potential conducted along the sarcolemma depolarizes the t-tubule, Ca²⁺ ions are released from the SR into the cytoplasm. How does depolarization of the t-tubule membrane produce Ca²⁺ release from the separate membrane system of the sarcoplasmic reticulum? In skeletal muscle, the two membrane systems are linked by two kinds of membrane proteins (see Figure 20.7): the *dihydropyridine receptors* (DHPRs) of the t-tubules and the *ryanodine receptors* (RyRs) of the SR. Both of these proteins are actually calcium channels, but they were both named for the drugs that bind to them specifically. The t-tubular DHPR and the SR RyR Ca²⁺ channel of skeletal muscle interact directly with each other in a one-on-one fashion.

The DHPRs are voltage-sensitive calcium channels. In skeletal muscle, the DHPRs do not appear to permit calcium flux from the extracellular fluid into the cytoplasm. Still, their sensitivity to voltage changes plays an important role in excitation–contraction coupling. The RyRs in the SR membrane face the t-tubule DHPRs. When the RyRs open, they let Ca²⁺ diffuse out of the SR into the cytoplasm. Thus, to answer the question above, depolarization of the t-tubule changes the conformation of the DHPR, which alters conformation of the associated RyR in the SR, opening it to release Ca²⁺ into the cytoplasm.⁵

Figure 20.7 illustrates a motor neuron action potential triggering excitation (top panel) and contraction (middle panel) of a muscle fiber. When the RyR channels of the SR open, Ca²⁺ ions rapidly diffuse the short distance to the adjacent myofilaments, bind to troponin, and initiate processes that allow cross-bridge action. In vertebrate skeletal muscle, sufficient Ca²⁺ diffuses to the myofibrils so that every TN–TM complex moves to allow all cross-bridges to function. Indeed, the cytoplasmic concentration of Ca²⁺ increases from <10⁻⁷ M to >10⁻⁶ M. When the muscle fiber action potential ends (bottom panel), the t-tubules repolarize and the RyRs close. Ca²⁺ ions no longer leave the SR, and those that left when the channels were open are returned by the action of Ca²⁺-ATPase pumps. As the cytoplasmic Ca²⁺ concentration decreases, Ca²⁺ ions unbind from TN, TM again blocks the myosin-binding sites on actin to prevent cross-bridge action, and relaxation occurs. In some fast-contracting muscles, *parvalbumin* (a low-molecular-weight protein in the cytoplasm) binds Ca²⁺. The action of parvalbumin in concert with the SR Ca²⁺-ATPase pumps enhances the rate of removal of Ca²⁺ from TN and hastens relaxation. Quicker relaxation ensures sooner readiness for the next contraction. The Ca²⁺ ions bound to parvalbumin later unbind and are transported back into the SR.

⁴The sarcoplasmic reticulum is homologous to the smooth endoplasmic reticulum of other cells. Its Ca²⁺-ATPase pumps are often referred to as SERCA (SarcoEndoplasmic Reticulum Calcium transport ATPase). Ca²⁺ is stored in the SR both free and bound to the protein calsequestrin.

⁵Cardiac muscle also has both DHPR and RyR proteins (in different isoforms), but their interaction is entirely indirect. The DHPR in cardiac muscle functions as a Ca²⁺ channel. It opens in response to depolarization and lets in extracellular Ca²⁺ from the t-tubular lumen. This Ca²⁺ from outside the cell opens the RyR calcium channel of the SR by a process called Ca²⁺-induced Ca²⁺ release. The indirect coupling seen in cardiac muscle is probably more primitive and was replaced in skeletal muscle by evolution of the faster direct coupling of the two proteins.

FIGURE 20.7 Excitation–contraction coupling is accomplished by the interactions of the transverse tubules (t-tubules) and the sarcoplasmic reticulum (SR). ACh, acetylcholine; AChE, acetylcholinesterase; DHPR, dihydropyridine receptor; RyR, ryanodine receptor.

SUMMARY Excitation–Contraction Coupling

- The sarcoplasmic reticulum (SR) sequesters Ca^{2+} ions to keep the cytoplasmic concentration of Ca^{2+} low. The terminal cisternae of the SR possess RyR calcium channels. Transverse tubules include voltage-sensitive DHPRs that come into intimate contact with the RyRs of the SR.
- Each skeletal muscle contraction is initiated by an action potential in a motor neuron that releases acetylcholine, which in turn gives rise to a muscle fiber action potential.
- The action potential propagates over the cell membrane of the muscle fiber and depolarizes the DHPRs in the t-tubules. The DHPRs cause the RyR calcium channels to open and allow Ca^{2+} ions to diffuse out of the terminal cisternae of the SR into the cytoplasm.
- Ca^{2+} ions bind to TN and cause conformational changes of TN and TM that expose the myosin-binding sites of adjacent actin molecules. Previously primed myosin heads bind to the actin sites. Repeated cross-bridge cycles continue as long as sufficient Ca^{2+} is present. The cross-bridges move the thick and thin filaments relative to each other, pulling the thin filaments toward the center of the sarcomere.
- Once the muscle fiber action potential is over, the RyR channels close. The Ca^{2+} -ATPase pumps of the SR sequester Ca^{2+} back into the SR. As the Ca^{2+} concentration in the cytoplasm decreases, Ca^{2+} dissociates from TN, and the TN–TM complex again prevents actin–myosin interactions. The muscle relaxes. Parvalbumin (prevalent in fast muscles) also binds cytoplasmic Ca^{2+} and thereby enhances the rate of relaxation.

Whole Skeletal Muscles

Many skeletal muscles in vertebrates work in **antagonistic pairs** arranged around joints. When one muscle shortens, its antagonist lengthens; and vice versa. Muscles generate force only by contraction; they lengthen passively. The antagonistic arrangement ensures relengthening of the member of a pair that shortened during contraction. For example, the quadriceps muscles on the front of the thigh and the hamstring muscles on the back of the thigh work together as an antagonistic pair of muscles. The hamstring muscles shorten to bend the knee joint. The quadriceps muscles shorten to straighten the knee joint. Often muscles work in combination with connective tissues that store elastic energy. For example, grazing animals such as camels and cows use muscles to pull their heads down to feed. Lowering the head stretches a ligament that attaches to the back of the head at one end and to the vertebral column at the other end. The stretched ligament stores energy like that in a stretched spring. This energy is expended as the ligament springs back to its original length, helping the muscles that lift the animal's head.

Muscle contraction is the force generated by a muscle during cross-bridge activity

Although the term *contraction* suggests that the muscle shortens during cross-bridge activity, this is not always the case. For example, you can “tighten up” your biceps without allowing your elbow joint to flex. Even though cross-bridge cycling occurs, the

bones do not move, and the whole muscle stays the same length. This type of contraction is called **isometric** (“same length”) **contraction**. The sarcomeres in the muscles shorten slightly during isometric contraction (the biceps “bulges”) because they pull on elastic elements within the muscle. Elastic structures include not only the connective tissue surrounding the muscle fibers, which continue into tendons, but also components of the myofibrils such as titin and the cross-bridge links themselves. **Figure 20.8** illustrates the relationship of contractile and elastic components in a muscle.

Whole muscles can indeed shorten. For example, when your hand brings a heavy book toward your face, the biceps muscle shortens to decrease the angle at your elbow. This type of contraction, in which the whole muscle shortens, is called **concentric contraction** because the muscular action brings the hand closer to the center of the body. Cross-bridges can also be active when the muscle is lengthening. For example, if you hold a 10-pound weight in your hand with your elbow bent, and slowly extend your arm, the sarcomeres of your biceps are lengthening at the same time that the cross-bridges are generating force. Similarly, when you go through the motion of sitting down, or hike down an incline, the quadriceps muscles on the top of your thighs are actively contracting, but the muscles are actually longer than they are when the knee is not bent. The contractile activity in these cases is resisting stretch imposed by an external force. These contractions are called **lengthening**, or **eccentric, contractions**. Lengthening contractions are thought to produce minor damage to muscle fibers that lead to delayed soreness following exercise.

Concentric and eccentric contractions are both examples of **isotonic** (“same tension”) **contractions** (see Figure 20.8b), which we explain below. Muscles hardly ever produce pure isotonic contractions. Most muscle activity involves dynamic combinations of both isometric and isotonic contractions. Physiologists separate these types of contractions experimentally in order to study particular properties of muscles.

A muscle exerts its force on a **load**. For example, when you lift an object with your hand, the load on which the biceps muscle exerts force includes the mass of the lower arm plus the mass of the object. The force of the muscle is opposed by the force of the load. If the force developed by a muscle is greater than the force exerted on it by a load, the muscle will change length.

Once the muscle begins to change length, the force it produces is constant and equal to the force of the load. Experimenters recording *isotonic* contractions measure changes in *length* of the muscle. If the force exerted by the load is greater than the muscle force (e.g., an extremely heavy weight), the muscle will produce an isometric contraction. Experimenters recording *isometric* contractions measure the *tension* developed by the muscle. **Tension** is the force exerted on a load by a unit of cross-sectional area of muscle.⁶ To record isometric contractions, experimenters usually attach the muscle to a very stiff force transducer that measures tension (force/cross-sectional area) while permitting only minuscule changes in length.

⁶Physiologists often use the terms *muscle tension* and *muscle force* interchangeably. Tension has the units of force/cross-sectional area. We know that cross-bridge action at the level of the sarcomere underlies the action produced by a whole muscle. The tension generated by a muscle fiber is directly proportional to the number of attached cross-bridges between the thick and thin filaments.

A twitch is the mechanical response of a muscle to a single action potential

Figure 20.9 shows the twitch response of the same mammalian muscle recorded under isometric and isotonic conditions. Both twitches have three phases: a latent period, a contraction phase, and a relaxation phase. The isometric twitch has a brief latent period before any contractile tension is recorded (see Figure 20.9a); this latent period largely reflects the time required for excitation–contraction coupling to occur. The isotonic twitch has a longer latent period (see Figure 20.9b). Before the muscle can lift the load and shorten, excitation–contraction coupling must occur, and the cross-bridges must develop enough tension isometrically to overcome the force exerted by the load. If the load were greater, the latency would be longer because additional time would be required to develop tension to equal the heavier load.

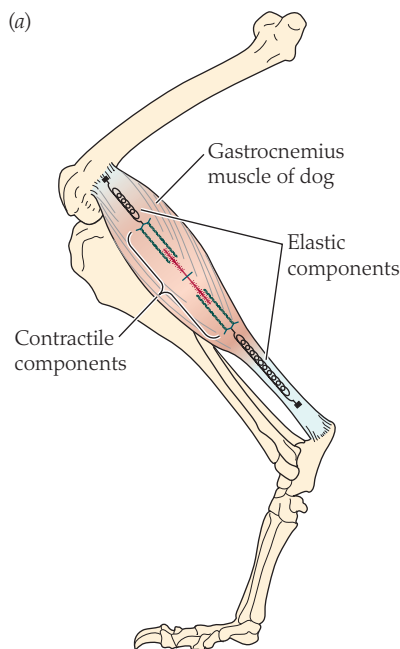

FIGURE 20.8 Contractile and elastic components interact during contraction The cross-bridge action within sarcomeres pulls on immediately adjacent sarcomeres and also on elastic elements within the muscle. (a) A single schematic sarcomere in a dog gastrocnemius muscle represents contractile components that are associated with intracellular and extracellular elastic elements. (b) Schematic representations of contractile and elastic elements at rest (when cross-bridges are not active) and during contractions (when cross-bridges cycle).

The velocity of shortening decreases as the load increases

Isotonic recordings are ideal for revealing that the load directly influences the velocity (speed) at which a muscle shortens. You know from experience that you can lift a pencil faster than an unabridged dictionary, and you cannot lift your car at all. The fact that velocity of shortening decreases progressively with increasing loads is referred to as the **load–velocity relationship**. Current models suggest that greater loads somehow decrease the rate at which the myosin heads detach from actin, and therefore slow the speed of shortening. This relationship is also referred to as the **force–velocity relationship**. The words *load* and *force* can be used interchangeably because—in isotonic contractions—the force produced by the muscle equals the force of the load. Indeed, the force generated by the muscle decreases with velocity of shortening because there is decreased probability of cross-bridge action as a sarcomere’s speed starts from zero to reach a finite value. The load–velocity (force–velocity) relationship is illustrated in Figure 21.1, which also shows muscle *power* (power = force × velocity).

The frequency of action potentials determines the tension developed by a muscle

Depending on the muscle, twitches can vary from tens to hundreds of milliseconds in duration—much longer than the duration of the skeletal muscle action potential, which is about 2 ms. When a muscle is stimulated more than once within a brief period, the successive twitches produced add to each other, so the overall response is greater than the twitch response to a single stimulus. Such addition is called **summation**. Summation can be recorded either iso-

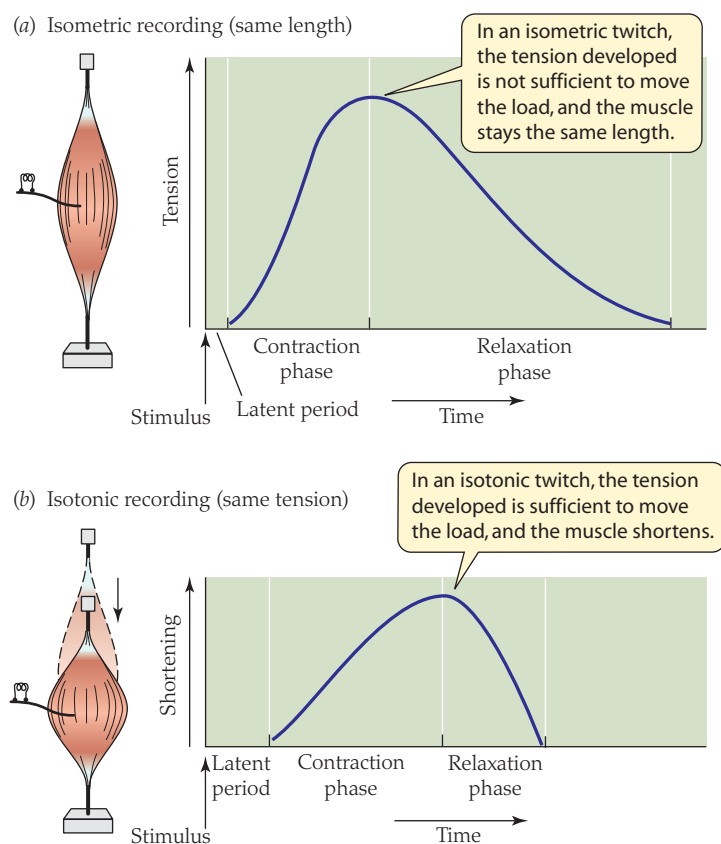

FIGURE 20.9 Recordings reveal differences between isometric and isotonic contractions. Isometric contractions (twitches) are measured as changes in tension produced by the muscle; isotonic contractions are measured as changes in length of the muscle. (a) In the isometric experimental arrangement, the muscle contracts but is not allowed to move a load. (b) In the isotonic experimental arrangement, the muscle shortens and moves the load, once its contractile activity generates tension (force) that equals the force of the load.

metrically or isotonicly. **Figure 20.10** shows isometric records of summation. The electrical events triggering the contractions (the action potentials of the motor neurons and muscle fibers) are all-or-none and do not sum. However, because the action potentials last only 1 to 2 ms, and a muscle twitch lasts many milliseconds, the muscle can generate a second (or even multiple) action potential(s) before the end of the twitch produced by the first action potential.

The amplitude of the summed contractions depends on the interval of time between stimuli. Low frequencies of stimulation with relatively long intervals between stimuli produce contractions that sum but are not fused. Higher-frequency stimulation produces a fused contraction called a **tetanus**. In mammalian muscle, the amplitude of the tetanus is usually three or four times the amplitude of a single twitch. In amphibian muscle, the tetanic response can exceed ten times the amplitude of a single twitch.

A sustained high calcium concentration in the cytoplasm permits summation and tetanus

As we noted earlier, each action potential triggers the release of a sufficient number of Ca^{2+} ions from the SR to allow every TN-TM complex to move away from the myosin-binding sites on the actin thin filaments. Thus every cross-bridge in every stimulated skeletal muscle fiber is capable of interacting with actin and pulling the thin filaments toward the center of the sarcomere. If all cross-bridges are fully engaged, how is it possible to produce a tetanic force several times greater than the response to a single stimulus?

The answer is that the contractile apparatus requires *time* to pull on the various elastic components of the muscle. The elastic components include the connective tissue associated with the muscle fibers and the elastic components of the myofibrillar apparatus. These all lie in series with each other. Thus the elastic structures are referred to as *series elastic elements*. For maximal tension to be recorded at the ends of the muscle fiber, the elastic elements must be stretched taut.

During a single twitch produced by a single action potential, the Ca^{2+} released into the cytoplasm is pumped back into the SR before the cross-bridges can fully stretch out the elastic elements.⁷

⁷The condition of the muscle fiber during the time Ca^{2+} ions are available to permit cross-bridge action is often referred to as the *active state*.

FIGURE 20.10 Summation and tetanus. Increasing the frequency of stimulation produces summation of twitches up to a maximum contractile response called fused tetanus. In this example, short trains of stimuli were applied to the sciatic nerve that innervates the gastrocnemius muscle of a frog. The muscle was allowed to rest briefly between trains of applied stimuli. No summation occurred when stimuli were applied at rates of 1/s and 2/s. Incomplete, or unfused, tetanus occurred at a rate of 10/s, with some relaxation between individual contractions. Fused

tetanus occurred at a rate of 20/s. Experimenters use known weights to calibrate the recording apparatus. Because weight is the magnitude of the force of gravity on an object, it is expressed as the product of the mass of the object (in kilograms, kg) times the strength of the gravitational field (9.8 N/kg). Therefore, tension produced by the muscle is accurately expressed in units of newtons (N). (Published values of muscle tension are often expressed in units of grams instead of newtons.)

Successive action potentials, however, open the RyR channels with sufficient frequency to keep the cytoplasmic concentration of Ca^{2+} high enough so that the actin-binding sites for myosin remain exposed over time. Thus cross-bridges can cycle repeatedly until the elastic elements are stretched taut and the full contractile potential of the muscle fiber is realized.

The amount of tension developed by a muscle depends on the length of the muscle at the time it is stimulated

Whole skeletal muscles, because of their attachments to bones (or to exoskeleton in invertebrates), do not change greatly in length. Nevertheless, muscles develop the most tension if they start contracting at an ideal initial length. Isometric recordings

from isolated whole muscles illustrate this idea. **Figure 20.11a** shows the tension produced by a muscle when it was set at several different lengths prior to stimulation. Maximal tension was achieved when the muscle was set at lengths near its normal relaxed length in the animal. When the muscle was set at shorter lengths or stretched to longer lengths, the development of tension dropped off.

This **length–tension relationship** is entirely explained by the sliding-filament model of muscle contraction. Elegant isometric recordings of tension developed by *single* frog skeletal muscle fibers unambiguously demonstrated the length–tension relationship at the level of the sarcomeres. **Figure 20.11b** shows the tension developed by single muscle fibers set at different lengths prior to stimulation. The set length of the muscle fiber affected the

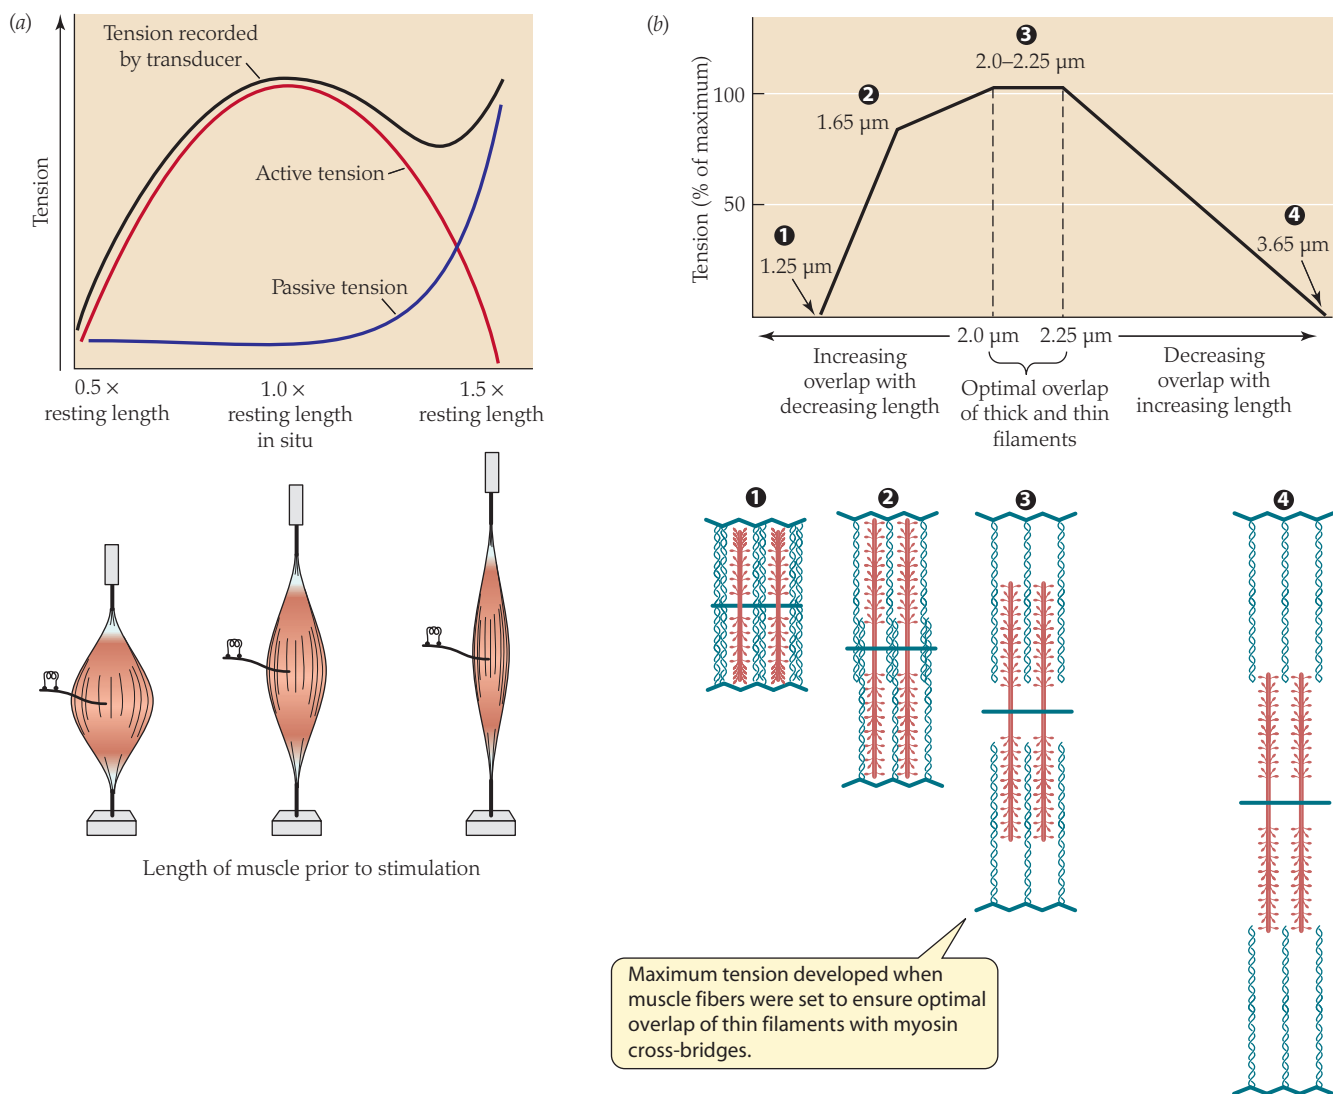

FIGURE 20.11 The length–tension relationship in whole muscles is explained by the sliding-filament theory (a) Maximal active isometric tension developed in a whole muscle when it was set near its normal resting length prior to stimulation. Active tension decreased when the muscle was shortened or stretched. The transducer records total tension developed by the muscle. Active tension (developed by the sarcomeres) is determined by subtracting the passive tension (produced by the experimenter’s pulling on the muscle to stretch it) from the total tension recorded during contraction. (b) Isometric tension recorded from single fibers is related to the sarcomere length set prior to stimulation. It is maximal when the actin filaments overlap the greatest number of myosin cross-bridges. (b from Gordon et al. 1966.)

length of the sarcomeres within it and therefore the degree of overlap of the thick and thin filaments within each sarcomere. The experimenters plotted the amount of tension developed upon stimulation as a function of sarcomere length. Maximum tensions were recorded when the sarcomere lengths were set near those found in the intact animal.

The diagrams in Figure 20.11*b* illustrate that, at the lengths that yielded maximum tension, the overlap of thick and thin filaments permits optimal cross-bridge binding with actin (③). Stretching or compressing the sarcomeres leads to less tension developed in response to stimulation. Sarcomeres set at longer-than-ideal lengths have less overlap of thick and thin filaments and therefore fewer available sites for myosin cross-bridges to bind (④). At sarcomere lengths that are shorter than ideal, the thin filaments overlap each other, probably interfering with myosin cross-bridge action (②) and finally push up against the Z disc (①).

The striking agreement of the length–tension curve of single muscle fibers with the observed regions of filament overlap strongly implies that each cross-bridge contributes an independent and equal increment of tension, and provides strong support for the sliding-filament theory of muscle contraction. Below we will see the powerful effects of sarcomeres arranged in series within myofibrils, and of myofibrils arranged in parallel.

In general, the amount of work a muscle can do depends on its volume

Work performed by a muscle can best be understood by the use of isotonic recording. **Work** is the product of force produced by the muscle and the distance that the muscle shortens. **Figure 20.12** shows the distance a muscle shortened when it was given

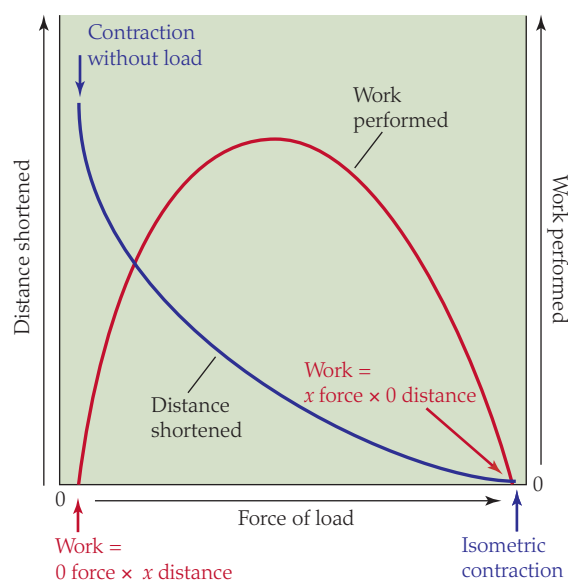

FIGURE 20.12 Work of contraction Isotonic recordings show that the muscle shortens the greatest distance when it lifts no load, and shortens progressively shorter distances with increasing loads. Multiplying the force developed (equal to the force of the load, in newtons, N) by the distance shortened for each load (in meters, m) gives a curve that represents work performed by the muscle (in joules, J). (After Schmidt-Nielsen 1997.)

increasingly greater loads to lift. The muscle shortened the greatest distance when it lifted no load. It did not shorten at all when the force of the load exceeded the maximum force it could develop. When the muscle lifted no load, although it shortened, it performed little work because it exerted negligible force. When the muscle attempted to lift a very heavy load, it exerted isometric force but performed no work because it did not move the load. At intermediate loads, the muscle did increasing amounts of work, up to about 40% of the maximum load, and then it did progressively decreasing amounts of work while lifting loads of increasing mass.

The *force* exerted by a muscle is proportional to the cross-sectional area (CSA) of its contractile elements. In all muscles examined that use actin and myosin as contractile proteins, the diameters of the thick and thin filaments are essentially the same. This means that a cross section through the contractile components of any muscle would reveal the same number of cross-bridges per unit of area. Because of this constant number of cross-bridges, most vertebrate skeletal muscle fibers (and many invertebrate muscle fibers) exert about the same amount of force per unit of area. A muscle that has a greater total CSA would therefore be able to produce a greater total force than a thinner muscle, because of the additive effect of myofibrils in parallel. Investigators refine this concept by taking into account the orientation of the muscle fibers within a given muscle. In some muscles, the individual muscle fibers are arranged in parallel and extend the full length of the muscle. However, other muscles may include shorter muscle fibers arranged at an angle to the long axis of the muscle. This arrangement adds complexity to understanding the amount of force generated by a particular type of muscle.

The *length* of a muscle fiber does not contribute to the force it generates. However, the length is important in determining how much work the muscle can do. The sarcomeres in most vertebrates are about 2.5 μm long. Thus, if each sarcomere contracts, for example, 10% of its length during a twitch, a muscle that has myofibrils consisting of 100 sarcomeres in series will shorten 25 μm . A muscle that has myofibrils consisting of 300 sarcomeres in series would shorten three times that distance. Assuming that both muscles had the same CSA, they would both exert the same force. However, the longer muscle would perform more work because work is the product of force times the distance shortened. A muscle that was both greater in CSA and longer would produce even more work because it would both exert greater force and shorten a greater distance. Thus muscles that have a greater volume of contractile machinery are generally capable of doing greater work.

The length of a muscle fiber also affects the velocity of shortening. Because the sarcomeres are arranged in series, velocities—like length changes—are also additive. For example, if each sarcomere shortened at a speed of 20 $\mu\text{m}/\text{s}$, then a 100-sarcomere myofibril would shorten at $(20 \mu\text{m}/\text{s}) \times 100 = 2 \text{ mm}/\text{s}$. A 300-sarcomere myofibril would shorten at a speed of 6 mm/s . Therefore, assuming sarcomeres of equivalent lengths, the longer a muscle fiber, the greater its velocity of shortening.

Interestingly, the muscles of some animals have been so drastically modified that they possess hardly any contractile machinery at all. For example, the electric organs of some fish do not do contractile work but instead produce electric shocks (**Box 20.1**).

BOX 20.1 ELECTRIC FISH EXPLOIT MODIFIED SKELETAL MUSCLES TO GENERATE ELECTRIC SHOCKS

In addition to using skeletal muscles for locomotion, electric fish have incorporated highly modified skeletal muscle cells into **electric organs** which they use for stunning prey, exploring the environment, and even communicating. The voltage changes generated by electric organs can be very large: The electric eel *Electrophorus electricus* (see figure) from freshwater rivers of South America can produce electrical potentials of up to 600 V! **Box Extension**

20.1 describes the structure of the electric organ of this strongly electric fish and how it generates electric shocks. Some electric fish produce weak electric shocks that are not strong enough to stun prey. We will see that both strongly and weakly electric fish use their electric organs in combination with sensory electroreceptors to accomplish behaviors such as electrolocation and communication.

SUMMARY Whole Skeletal Muscles

- Cross-bridge activity within individual muscle fibers accounts for the force generated by a muscle. Force exerted by a muscle is proportional to the cross-sectional area of its contractile elements.
- The tension (force per cross-sectional area) generated by a whole muscle is directly related to the number of actively contracting muscle fibers.
- The amount of tension developed by each contracting fiber in a muscle is determined by the frequency of action potentials from its motor neuron (to produce summation of twitches and tetanus) and the length of the muscle fiber at the time it is stimulated (the length–tension relationship).
- The speed with which a muscle shortens decreases as the load it lifts increases (the load–velocity relationship).
- Work performed by a muscle is the product of force produced by the muscle and the distance it shortens.

Muscle Energetics

The muscle that does the work described in the previous section consumes energy to do so. In this section we examine the sources of energy available to muscle fibers and the ways in which energy is used by different types of muscle fibers.

ATP is the immediate source of energy for powering muscle contraction

ATP performs at least three functions in the contraction–relaxation cycle:

1. ATP binding to the cross-bridge (but not hydrolysis) is necessary for detachment of myosin from actin.
2. Hydrolysis of ATP activates (cocks) the myosin cross-bridge in preparation for binding to actin and undergoing a power stroke.
3. Energy from the hydrolysis of ATP drives the calcium pump that transports Ca^{2+} ions into the sarcoplasmic reticulum.

However, muscle contains only enough ATP (2–4 mM) to sustain contraction for a few seconds. Thus, nearly all forms of muscular

work depend on regeneration of ATP while the muscle is working. The rate of muscular work strictly depends on the rate at which ATP is provided to the contractile apparatus.

In broad outline, vertebrate muscle fibers possess three biochemical mechanisms that produce ATP (see Chapter 7 for a detailed discussion of ATP resupply):

- ① *Use of the phosphagen creatine phosphate.* Phosphagens temporarily store high-energy phosphate bonds. The high-energy phosphate of creatine phosphate can be donated to ADP to produce ATP, as shown in Figure 8.7. Creatine phosphate is produced in resting muscle from creatine and ATP. The formation of ATP from creatine phosphate is driven by simple mass action. Whereas creatine phosphate is the phosphagen found in muscles of vertebrates, it and other phosphagens, such as arginine phosphate, are found in invertebrates (see Chapter 8, page 192).
- ② *Anaerobic glycolysis.* This form of catabolism requires no oxygen (see Figure 8.5). It must have glucose or glycogen as fuel. In addition to ATP, it produces *lactic acid*, which in vertebrates is always retained in the body and disposed of metabolically.
- ③ *Aerobic catabolism.* This form of catabolism requires oxygen and can use all three major classes of foodstuff as fuel (see Figures 8.1–8.3). It produces ATP principally by *oxidative phosphorylation*. Its other major products are CO_2 and H_2O .

Figure 20.13 summarizes major elements in the production and use of ATP in a vertebrate muscle fiber. As emphasized in Chapter 8, the three mechanisms of ATP production differ greatly in how fast they can make ATP when operating at peak output, how much ATP they can make, and how quickly they can accelerate their rate of ATP production. **Table 20.1** summarizes attributes that are presented in greater detail in Table 8.1.

If a resting muscle is called upon suddenly to engage in all-out effort, creatine phosphate supplies much of the ATP in the first seconds because phosphagen-based ATP synthesis can be accelerated very rapidly. During this time, the rate of ATP supply to the contractile apparatus is exceedingly high because of the intrinsic properties of the phosphagen mechanism. But because the avail-

FIGURE 20.13 The production and use of ATP
Three metabolic pathways supply the ATP for muscle contractile activity: ① transfer of high-energy phosphate from creatine phosphate to ADP; ② anaerobic glycolysis; and ③ aerobic catabolism involving oxidative phosphorylation.

able phosphagen can yield only a small total quantity of ATP, this exceedingly high rate of ATP supply is short-lived.

As a muscle runs out of creatine phosphate, anaerobic glycolysis takes over as the principal mechanism of ATP synthesis. With this transition, the rate of ATP supply to the contractile apparatus decreases (although it is still very high) because the peak rate of ATP synthesis by anaerobic glycolysis is lower than that using creatine phosphate. Anaerobic glycolysis can make somewhat more total ATP than phosphagen, but it, too, exhausts its ability to make ATP if a muscle stays in a state of all-out exertion.

At that point, aerobic catabolism becomes the sole source of ATP. The rate of ATP supply falls still further because aerobic catabolism exhibits the lowest rate of ATP synthesis. But the aerobic mechanism can make ATP on a sustained basis. These transitions in the biochemistry of ATP synthesis are the reason that the rate of work by a muscle declines with time during all-out exercise. Figure 8.12 illustrates this concept.

Vertebrate muscle fibers are classified into different types

As discussed in Chapter 8, muscles of an animal are typically made up of a heterogeneous population of muscle fibers. By far the most common types of muscle fibers are **twitch fibers**. These fibers generate action potentials, and each action potential gives rise to a muscle twitch. Twitch fibers vary in their biochemical and metabolic features, which gives them different contractile abilities, as we

discuss shortly. **Tonic muscle fibers** are relatively rare. They are found mainly in postural muscles of lower vertebrates.⁸ Tonic muscle fibers do not generate action potentials, but they do undergo changes in membrane potential. They contract more slowly than the slowest twitch fibers. Their slow cross-bridge cycling permits the maintenance of long-lasting contractions with low energetic costs.

Twitch fibers are generally classified into three main categories: *slow oxidative (SO)*, *fast oxidative glycolytic (FOG)*, and *fast glycolytic (FG) fibers*. Twitch fibers are classified on the basis of differences in isoforms of the myosin ATPase and metabolic features of the cells. In mammals, the myosin heads in FG and FOG fibers split about 600 ATP molecules per second, whereas those in SO fibers split ATP about half as rapidly. Because the rate of ATP hydrolysis governs the rate of cross-bridge cycling, higher ATPase activity allows faster contraction.

It is important to remember that the amount of tension developed *per cross-bridge cycle* is the same in both fast and slow types of muscle, but the number of cycles accomplished per unit of time differs. Earlier we saw that the velocity of contraction of a muscle fiber depends on the load being moved (the *load–velocity*, or *force–velocity, relationship*). This relationship applies to all muscle fibers but varies depending on the type. Therefore, the velocity of contraction depends on *both* the type of muscle fiber and the load against which it exerts force.

Recall from Chapter 8 (see page 195) that the SO fibers are mitochondria-rich and poised to make ATP principally by aerobic catabolism; they have small diameters and are rich in myoglobin (an intracellular hemoglobin-like molecule that facilitates O₂ transport), red (because of the myoglobin), well supplied with blood capillaries, and slow to fatigue. The FG fibers have large diameters, are invested with fewer capillaries, have little myoglobin, and are *white*. They have few mitochondria and make ATP mainly by anaerobic glycolysis; they are rich in glycogen (the principal fuel of anaerobic glycolysis), quickly accumulate lactic acid, and fatigue rapidly. The FOG fibers are intermediate. Although their isoform of myosin is different from that of FG fibers, the activity of their myosin ATPase is high, and they are therefore capable of rapid tension development. Unlike FG fibers, however, FOG fibers are relatively rich in mitochondria, and because they make ATP aerobically, they are relatively resistant to fatigue.

TABLE 20.1 Characteristics of the three principal mechanisms of ATP regeneration in vertebrate muscle

	Use of phosphagen	Anaerobic glycolysis	Aerobic catabolism
Peak rate of ATP synthesis	Very high	High	Moderate
Total possible yield of ATP in one episode of use	Small	Moderate	High (maintained indefinitely)
Rate of acceleration of ATP production	Fast	Fast	Slow

Note: See Table 8.1 for more detail.

⁸In mammals, tonic fibers occur only as intrafusal fibers of muscle spindles and in extraocular muscles. In many mammals, the extraocular muscles, which control complex motions of the eyes, also contain extremely fast-contracting muscle fibers.

FIGURE 20.14 Whole muscles typically consist of mixtures of different types of fibers. In this transverse section, small-diameter slow oxidative fibers (red) stain dark because of their abundant mitochondria, and they are surrounded by many capillaries (black). Large-diameter fast glycolytic fibers (yellow) have fewer mitochondria and few immediately adjacent capillaries. Fast oxidative glycolytic fibers (orange) are intermediate in diameter and in abundance of capillaries.

Figure 20.14 shows that different types of fibers are usually intermingled within a muscle. Table 20.2 provides a rough comparative guide to the three fiber types. The distinctions, although useful, should not be viewed too rigidly, however, because the fiber types vary considerably in other characteristics. For example, fibers of a given type may differ from each other because they have different isoforms of troponin, tropomyosin, or other proteins. Furthermore, varying conditions of use can cause one type of fiber to be converted into another (see Chapter 21).

Different fiber types are specifically adapted to subserve different functions, which gives muscles a broad repertoire of contractile abilities. SO fibers (and tonic fibers when present) do not generate much tension, but they operate efficiently and without fatigue. They are adapted for isometric postural functions and for small, slow movements. The myosin isoform in SO fibers has low ATPase activity and therefore can produce tension economically.

FOG fibers generate more tension and faster contractions, yet they are fatigue-resistant. They are adapted for repeated movements such as locomotion. FG fibers generate rapid contractions and large increments of tension, but they lack endurance. They are used for occasional, forceful, fast movements such as leaps or bursts of speed in escape or prey capture.

The ankle extensors in the cat hindlimb illustrate the functional roles of different fiber types. Three muscles—the *soleus*, *medial gastrocnemius*, and *lateral gastrocnemius*—comprise the ankle extensors. They all insert on the Achilles tendon at the heel. The soleus contracts slowly and consists entirely of SO fibers. It is most active in postural standing. The medial and lateral gastrocnemii are faster muscles of mixed fiber composition. For example, the medial gastrocnemius contains approximately 45% FG, 25% FOG, and 25% SO fibers. (The remaining 5% of fibers are intermediate in their properties between those of FG and FOG fibers.)

Because the FG fibers have relatively greater diameters (see Table 20.2), the 45% that they contribute to the muscle fibers contributes 75% of the maximal total tension of the medial gastrocnemius. However, walking and most running use only about 25% of the maximal tension of the medial gastrocnemius. This is the amount of tension produced by the FOG and SO fibers without any contribution from the FG fibers. Thus these fatigue-resistant

TABLE 20.2 Characteristics of mammalian skeletal twitch muscle fibers

	Slow oxidative (SO)	Fast oxidative glycolytic (FOG)	Fast glycolytic (FG)
Myosin ATPase activity	Slow	Fast	Fast
Speed to reach peak tension	Slow	Intermediate to fast	Fast
Duration of twitches	Long	Short	Short
Rate of Ca ²⁺ uptake by sarcoplasmic reticulum	Slow to intermediate	High	High
Resistance to fatigue	High	Intermediate	Low
Number of mitochondria	Many	Many	Few
Myoglobin content	High	High	Low
Color	Red	Red	White
Diameter of fiber	Small	Intermediate	Large
Number of surrounding capillaries	Many	Many	Few
Levels of glycolytic enzymes	Low	Intermediate	High
Ability to produce ATP using oxidative phosphorylation	High	High	Low
Force developed per cross-sectional area of entire fiber	Low	Intermediate	High
Function in animal	Posture	Standing, walking, rapid repetitive movements	Jumping, bursts of high-speed locomotion
Frequency of use by animal	High	Intermediate to high	Low

Sources: After Randall et al. 2002 and Sherwood 2004.

Note: The names of different types of skeletal muscle fibers vary in the literature. Slow oxidative fibers are also called Type I; and fast oxidative fibers, Type IIa. Different types of fast glycolytic fibers are found in mammals, IIb in small mammals and IIx in large mammals.

fibers are sufficient for most locomotion. The large force contributed by FG fibers is believed to be reserved for short bursts of contraction required in motions such as jumping.

In fish, the trunk muscles of the body are divided into separate regions of red slow muscle and white fast muscle. The muscle fibers in the two regions bear many histological, biochemical, and physiological similarities to mammalian fiber types. SO-like fibers are found in the red muscle and FG-like fibers in the white muscle. The slow red muscle makes up less than 10% of the total trunk muscle in most fish species, and it never exceeds 25%. Yet only the slow red muscle is used at all speeds of steady cruising. The white fast muscle that constitutes the great bulk of the muscle mass is used only for bursts of high-speed swimming, and it fatigues rapidly. The sheer size of the white muscle is a testimony to the extreme importance to the fish of being able to accelerate rapidly through its dense water environment when necessary to capture food or escape a predator.

Several animals possess exceptional muscles that are adapted for very rapid contractions. Certain vertebrates possess rapidly contracting muscles that consist of fibers that are oxidative and fatigue-resistant. Hummingbird flight muscle, for example, can contract and relax at frequencies approaching 80 times/s (hertz, Hz), so the contraction–relaxation cycle is completed in less than 15 ms. Sound-producing muscles of insects, fish, birds, and bats can be even faster.⁹ In all of these cases there are extreme adaptations for rapid generation of tension, and also rapid relaxation.

Experimenters have shown that three main factors contribute to increased speeds of contraction: (1) myosin isoforms capable of rapid cross-bridge cycling, (2) troponin isoforms that have a low affinity for Ca^{2+} so that Ca^{2+} unbinds rapidly, and (3) increased density of Ca^{2+} -ATPase pumps in the SR and parvalbumin in the cytoplasm for rapid relaxation. Large amounts of ATP are required to support rapid cross-bridge cycling and pump functions, and not surprisingly, these muscles require a well-developed SR, many mitochondria, and a rich supply of capillaries to deliver O_2 and nutrients.

The benefit of rapid contraction brings with it a cost of limited ability to generate tension, because space in cells is limited. In most muscles used for locomotion, about 90% of the space is filled by myofibrils; mitochondria, glycogen, and SR fill the remaining 10% of the space. Consider the tail-shaker muscle of the rattlesnake, which can produce contractions at a frequency of up to 90 Hz (at optimum temperatures). Rattlesnakes make themselves conspicuous by rattling their tails continuously, sometimes for hours. The tail-shaker muscle fibers have high metabolic demands and require reserves of fuel, abundant mitochondria, and also extensive SR.

The space required for these “supporting” components necessarily limits the space available for contractile proteins (the tension-generating components). Indeed, in rattlesnake shaker muscle fibers, only about 30% of the space is occupied by myofibrils. The remaining space is filled by SR (26%), glycogen (17%), and mitochondria

(26%). The diminished contractile machinery results in less ability to generate tension. These muscle fibers illustrate a general point: that space in cells can be at a premium, and thus trade-offs may be required among various cell components. In contrast, the asynchronous flight muscles of some insects produce extremely high frequencies of robust contractions, and their fibers contain a large volume of contractile elements with relatively few mitochondria and little SR. In a dramatic departure from all other known skeletal muscles, the asynchronous flight muscles of insects have evolved an excitation–contraction mechanism in which one action potential triggers several contraction–relaxation cycles. In *Drosophila melanogaster*, for example, the motor neurons to the asynchronous flight muscles generate action potentials at a rate of about 5 Hz, but the muscles’ contraction frequency is approximately 200 Hz. The wing beats of these insects result from changes in the shape of the thorax produced by opposing sets of muscles that are alternately activated by stretch. The action potentials ensure that sufficient Ca^{2+} is present in the cytoplasm to permit actin–myosin cross-bridge action. In **Box 20.2** we compare asynchronous and synchronous flight muscles of insects.

SUMMARY Muscle Energetics

- Contractile activity requires the hydrolysis of ATP to provide energy for cross-bridge power strokes and to support the Ca^{2+} -ATPase pumps of the sarcoplasmic reticulum.
- ATP is produced by three principal means: (1) transfer of the high-energy phosphate from creatine phosphate to ADP, (2) glycolysis, and (3) oxidative phosphorylation.
- Vertebrate muscle fibers are classified into different types on the basis of their biochemical and metabolic features, and each type is adapted to subserve different functions. Muscles usually contain a mixture of different fiber types.
- Muscles adapted for extremely rapid contractions typically produce less tension than muscles that contract at slower rates. The presence of large numbers of mitochondria and abundant SR reduces the cross-sectional area of contractile machinery, and therefore the ability to generate tension.

BOX 20.2 INSECT FLIGHT

Humans have long admired and envied the ability of other animals to fly. Insects—from lazily looping butterflies to dive-bombing mosquitoes—have captivated our attention. Insect flight muscles possess the familiar features of striated skeletal muscle fibers found in other animals. The myofibrils are organized into sarcomeres; t-tubules and sarcoplasmic reticulum are present; and Ca^{2+} ions bind to the TN–TM complex to permit cross-bridge cycling that produces tension. **Box Extension 20.2** describes the special features of insect flight muscles that underlie their aerial feats.

Honeybee (*Apis mellifera*)

⁹The sound-producing muscles of the male toadfish swim bladder are the fastest known vertebrate muscles, contracting at frequencies of up to 200 Hz. In insects, the sound-producing muscle of the shrill-chirping male cicada can contract and relax at a frequency of 550 Hz!

Neural Control of Skeletal Muscle

Whole skeletal muscles in both vertebrates and invertebrates produce smooth, fluid movements that are physiologically and behaviorally useful. These movements are generated by continuous and finely controlled neural input. Unlike smooth and cardiac muscles (which may generate contractions endogenously and may respond to hormonal as well as neural control), skeletal muscles contract only when stimulated by motor neurons. Two contrasting evolutionary approaches are known to provide gradation of tension in a muscle, one exemplified by vertebrates (the *vertebrate plan*) and the other by arthropods (the *arthropod plan*). In most of the well-studied invertebrate groups other than arthropods, muscle tension is controlled by variations on the arthropod plan.

The vertebrate plan is based on muscles organized into motor units

A vertebrate skeletal muscle is innervated typically by about 100 to 1000 motor neurons. The axon of each motor neuron typically branches to innervate multiple muscle fibers, and each muscle fiber receives synaptic input from only one motor neuron. A motor neuron and all the muscle fibers it innervates are collectively termed a **motor unit** (Figure 20.15). When the motor neuron generates an action potential, all of the muscle fibers in the motor unit generate action potentials and contract to produce a twitch. Trains of action potentials of increasing frequencies can produce summation of twitches up to fused tetanic contraction.¹⁰ Thus, as in whole muscles, the amount of tension produced by a single motor

FIGURE 20.15 Vertebrate skeletal muscles consist of many different, independent motor units. An action potential in the motor neuron of one motor unit stimulates an action potential and contraction in all of the muscle fibers it innervates. Varying the number of active motor units varies the amount of tension produced by the whole muscle.

unit can be varied by varying the frequency of action potentials generated by the motor neuron. Although the amount of tetanic tension varies in different animals, in many vertebrate muscles it is only two to five times the twitch tension.

A more dramatic effect on the amount of tension developed by a whole muscle can be accomplished by varying the number of active motor units. Increasing the number of active motor units is called **recruitment of motor units**. Recruitment requires stimulating increasing numbers of motor neurons that innervate the muscle. For example, the tension in a muscle innervated by 100 motor neurons could be graded in 100 steps by recruitment. The amount of tension developed by the whole muscle increases as more motor units are activated (recruited). Recruitment is the dominant means used to control the amount of tension produced in vertebrate twitch muscles. Varying the number of active motor units, as well as the timing of their activation, ensures precise and smooth movements. The elastic properties of the muscle also contribute to the smoothness of movement.

The innervation of vertebrate tonic muscle is intermediate between the general vertebrate and arthropod plans

Whereas each fiber of a twitch muscle has a single synaptic contact near the middle of the fiber, each muscle fiber of a tonic muscle receives many branches of a motor neuron, so it has many synaptic contacts distributed over its length. This pattern, shown in Figure 20.16a, is termed **multiterminal innervation**. An action potential generated by a motor neuron produces an excitatory postsynaptic potential (EPSP) at each of the distributed junctions. The muscle fiber has little or no ability to generate action potentials. Each depolarizing EPSP spreads passively over a region of membrane and down the t-tubules in that area. Contraction occurs by excitation–contraction coupling. Because an EPSP is produced at each of the many terminals along the entire length of the fiber, the contractile elements along the entire fiber are activated. The amount of tension generated depends directly on the amount of depolarization produced by the EPSPs.

The arthropod plan is based on multiterminal innervation of each muscle fiber by more than one neuron

Although the fibers of arthropod skeletal muscles share many features of vertebrate skeletal muscle, including the organization of thick and thin filaments into sarcomeres and excitation–contraction coupling by way of t-tubules and SR, they show interesting differences in their patterns of innervation. A typical arthropod whole muscle is innervated by one to ten motor neurons, in contrast to the hundreds or thousands of motor neurons that innervate a whole vertebrate muscle. Most individual arthropod muscle fibers are innervated by more than one motor neuron, a pattern termed **polyneuronal innervation** (Figure 20.16b).

As in tonic muscle, each neuron in arthropod skeletal muscle branches to provide multiterminal innervation. Arthropod muscle fibers typically do not generate all-or-none action potentials. (Insect flight muscles, which do generate action potentials, are an exception.) Because arthropod muscle fibers are innervated

¹⁰In mammals, fused tetanus occurs at about 300 action potentials/s in slow-twitch, oxidative muscle fibers, and at about 100 action potentials/s in fast-twitch, glycolytic fibers.

FIGURE 20.16 Innervation patterns of vertebrate tonic muscle fibers and arthropod muscle fibers (a) Each vertebrate tonic muscle fiber is innervated by a single axon that branches to make many synaptic contacts along the length of the fiber. Tonic fibers do not produce action potentials. (b) Each arthropod muscle fiber receives multiple synaptic contacts from several different neurons, some of which may be inhibitory. These muscle fibers often do not produce action potentials. Muscles innervated according to the arthropod plan have overlapping motor units.

polyneuronally, the motor units of arthropods overlap; each muscle fiber is part of several motor units. Thus arthropods have only a few overlapping motor units per muscle, whereas vertebrates have many, nonoverlapping motor units per muscle.

Some arthropod muscles are innervated by both excitatory and inhibitory motor neurons. This feature—distinctly different from vertebrate muscles, which are innervated solely by excitatory neurons—allows *peripheral inhibition*. In arthropods, the excitatory transmitter is typically glutamate (not acetylcholine) and the inhibitory transmitter is gamma-aminobutyric acid (GABA). The algebraic summation of graded inhibitory postsynaptic potentials (IPSPs) and EPSPs *in the muscle fiber* determines the amount of tension developed. The greater the depolarization, the greater the amount of Ca^{2+} released from the SR, and the greater the tension developed. Thus the dominant mechanism for controlling tension in arthropod muscles is *controlling the degree of depolarization of muscle fibers*, which in turn depends on the frequency of action potentials in the excitatory and inhibitory motor neurons.

Arthropod muscle fibers have a range of speeds of contraction, but unlike in vertebrate fibers, the velocity of contraction of arthropod muscle fibers is associated with different sarcomere lengths: Short-sarcomere fibers contract quickly, and long-sarcomere fibers contract slowly. Most arthropod muscles contain a variety of fibers with different sarcomere lengths and contraction speeds. Some muscles, however, are composed of all long-sarcomere slow fibers or all short-sarcomere fast fibers. For example, the muscles of crayfish and lobsters that control flexion and extension of the abdomen are made up of either all fast or all slow fibers. Thus there are fast and slow flexor muscles and fast and slow extensor muscles. The slow flexor and extensor muscles each receive up to five excitatory motor neurons and one inhibitory neuron. Many of the fast muscles receive three excitatory axons and one inhibitory axon.

An additional pattern of innervation is found only in insects. The skeletal muscles in insects receive synaptic input not only from excitatory and inhibitory neurons but also from a third type of neuron that releases octopamine or tyramine. The octopamine/tyramine transmitters do not directly trigger or inhibit muscle contraction, but instead perform two different functions that affect muscle activity. First, they *modulate* neuromuscular activity elicited by input from glutamatergic excitatory motor neurons and GABA-ergic inhibitory neurons. For example, octopamine accelerates the relaxation rate of muscles by influencing the functions of chloride and potassium channels in the muscle membrane. Second, the octopamine/tyramine neurons to skeletal muscle fibers also promote glycolysis, and therefore ATP production from carbohydrates, during contractions. This direct neural control of metabolism plays an adaptive role in adjusting muscle ATP production to the energy demands of motor behaviors. Sometimes, however, it is not adaptive to use carbohydrates as metabolic fuel. Indeed, the flight muscles of certain insects that possess synchronous flight muscles (see Box Extension 20.2) switch from carbohydrate to lipid metabolism during long flights. For example, locusts have synchronous flight muscles and are well known for their ability to fly across oceans. In these animals, the octopamine neurons to the flight muscles stimulate glycolysis of carbohydrate stores during rest, but the neurons are inhibited during flight. In the absence of octopamine input, the flight muscles metabolize lipids instead of carbohydrates.

SUMMARY Neural Control of Skeletal Muscle

- The neuromuscular organization of vertebrates is characterized by many nonoverlapping motor units, each controlled by a single motor neuron. Each muscle fiber within a motor unit generates an action potential that spreads rapidly over the entire cell membrane and triggers the contractile response.
- Vertebrate tonic fibers usually do not generate action potentials. Each fiber is typically innervated by a single motor neuron that makes multiple synaptic contacts along its length.
- The neuromuscular organization of arthropods is characterized by few motor neurons, overlapping motor units, and in some cases, by peripheral inhibition. Each muscle fiber is typically innervated by more than one motor neuron, and each neuron makes multiple synaptic contacts on the fiber. Arthropod muscle fibers typically do not generate action potentials. Instead, the postsynaptic potentials produced at several points along the length of the fiber provide graded electric signals that each trigger the contractile machinery in a small section of the fiber and control the degree of tension developed. Insect muscles are innervated not only by excitatory and inhibitory neurons but also by neurons that release octopamine or tyramine at synaptic contacts. These transmitters modulate neuromuscular activity and regulate energy metabolism.

Vertebrate Smooth (Unstriated) Muscle

Whereas the main function of skeletal muscle in vertebrates is to accomplish locomotion, and that of cardiac muscle is to pump blood through the heart, smooth muscles are important in the homeostatic functions of many different systems within vertebrate animals. Smooth muscles are found in the gastrointestinal, respiratory, reproductive, and urinary tracts and in the blood vessels. In addition, smooth muscles are in the eye (they control the size of the pupil and shape of the lens) and at the base of hairs or feathers (see Chapter 10, page 256). In hollow and tubular organs, smooth muscles permit a variety of functions, including changing size and volume (such as the bladder or stomach), propelling materials along a tube (such as chyme through the intestine or urine through the ureter), and maintaining tension for long periods of time (as in the walls of arterioles or sphincter muscles).

Because of their wide distribution throughout the body, smooth muscles have numerous effects on homeostatic coordination of cardiovascular and respiratory functions, vision, gastrointestinal peristalsis, urinary excretion, and male and female fertility. Compared with vertebrate skeletal muscles, which are relatively uniform in their structure and function, smooth muscles are richly varied in their architectural arrangement within organs, the types of stimuli that trigger their contraction, and the types of electrical activity they generate. Like skeletal and cardiac muscles, smooth muscles use the contractile proteins actin and myosin. Because these proteins are not organized into sarcomeres, smooth muscle cells do not appear striated. However, interdigitating myosin and actin filaments are organized into bundles around the periphery of the cell, and cross-bridge action causes them to slide by one another to accomplish contraction. Smooth muscle cells have a greater proportion of actin relative to myosin than do striated muscles—a difference that is reflected in the larger ratio of thin to thick filaments in smooth muscles (about 12–15 thin filaments per thick filament) relative to striated muscles (about 2–4 thin filaments per thick filament). The actin filaments attach to **dense bodies** in the cytoplasm and to **attachment plaques** on the inner surface of the cell membrane. Intermediate filaments (e.g., desmin) also attach to the dense bodies and plaques to help form a stable cytoskeleton. The thick myosin filaments have cross-bridges along their entire length (unlike skeletal and cardiac thick filaments, which are “bald” in the middle). The myosin structure increases the probability that actin-binding sites will overlap cross-bridges even when the muscle is stretched.

Smooth muscle cells range from 40 to 600 μm in length (shorter than most skeletal muscle fibers). They are widest in diameter around the single nucleus (2–10 μm , only somewhat wider than the 1–2 μm diameter of a single myofibril of a skeletal muscle fiber) and taper toward the ends. This cell shape is referred to as *spindle-shaped*. When stimulated to contract, the cross-bridge action of the peripherally arranged myofilaments causes the cell to shorten and plump up in the center. Smooth muscle cells are linked by mechanical connections to each other and to surrounding connective tissue to ensure transmission of contractile force throughout a tissue or organ.

In addition to their small dimensions and single nucleus, smooth muscle cells are characterized by the absence of transverse tubules, troponin, and nebulin. They have a reduced sarcoplasmic reticulum (SR) but typically have *caveolae*, invaginations of the cell membrane that are thought to contribute to the rise of Ca^{2+} in the

cytoplasm when the cell is activated. As in cardiac and skeletal muscles, the myosin ATPase of smooth muscle hydrolyzes ATP to power cross-bridge motions. However, the smooth muscle myosin ATPase hydrolyzes ATP much more slowly than do the ATPases of different types of skeletal and cardiac myosins. Because of the slow rate of ATP hydrolysis, myosin cross-bridges cycle at a slower rate in smooth muscle, resulting in slower speed of contraction and longer contraction time. Many smooth muscles can maintain contractions for long periods using only a small portion of available cross-bridges and small expenditures of energy. The smooth muscle of the esophageal sphincter that guards the opening of the stomach is a good example. Except when food is swallowed, this muscle stays contracted continuously and prevents stomach acid and enzymes from entering the esophagus.

Smooth muscle cells are broadly classified

One useful classification scheme differentiates vertebrate smooth muscle into two main types: *single-unit* and *multiunit* smooth muscles (Figure 20.17). In **single-unit smooth muscle**, the muscle cells are tightly electrically coupled by numerous gap junctions (see Figure

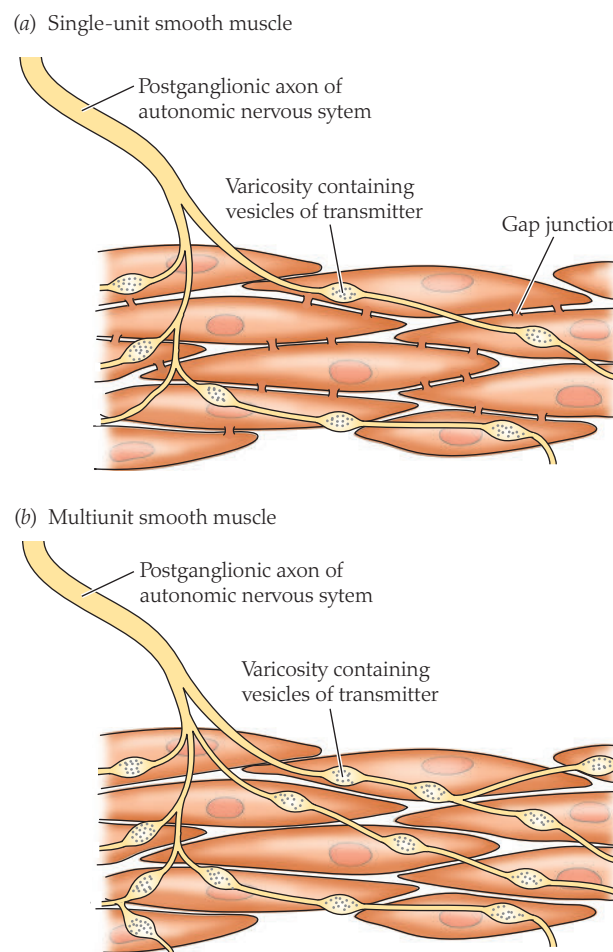

FIGURE 20.17 Both multiunit and single-unit smooth muscle fibers receive innervation from the autonomic nervous system (a) Single-unit smooth muscle cells are connected by gap junctions, so electrical signals can pass directly from cell to cell. (b) The individual muscle cells of multiunit smooth muscles are excited and contract independently.

20.17a). Because of this coupling, groups of muscle cells are depolarized and contract together, functioning as a single unit. The smooth muscles of the gastrointestinal tract and small-diameter blood vessels are examples of the single-unit type. Single-unit smooth muscle is often spontaneously active, with electrical activity propagating from cell to cell via the gap junctions. This type of muscle can also be activated by stretch. Neural and hormonal controls may modulate the endogenous activity to varying degrees.

Multiunit smooth muscles have few if any gap junctions, so the muscle cells function as independent units (see Figure 20.17b). They are innervated by autonomic nerves, and individual cells are under more direct neural control than are cells of single-unit smooth muscles. Multiunit smooth muscles may or may not generate action potentials, and they may be activated hormonally or by local chemical stimuli as well as neurally. They are not stretch-sensitive. Smooth muscles of the hair and feather erectors, eye, large arteries, and respiratory airways are examples of multiunit smooth muscles.

The smooth muscle of the mammalian uterus changes between multiunit and single-unit depending on circulating levels of reproductive steroid hormones. For example, during late pregnancy the uterine smooth muscle cells form many gap junctions that electrically couple adjacent cells. Thus the uterus is able to function as a single-unit smooth muscle to produce coordinated contractions during the birthing process.

A second classification used to distinguish different types of smooth muscle is based on contractile and electrophysiological properties. **Tonic smooth muscles**, such as those in the airways and certain sphincter muscles, maintain contractile force (“tone”) for long periods and do not generate spontaneous contractions or action potentials (although they do undergo changes in membrane potential). **Phasic smooth muscles**, such as those in the stomach and small intestine, produce rhythmic or intermittent activity. They contract rapidly, produce spontaneous contractions, and generate action potentials that propagate through gap junctions from cell to cell. These gastrointestinal muscles can also be classified as single-unit smooth muscles. It is important to keep in mind that although classification schemes are useful when considering smooth muscles broadly, smooth muscles are hugely diverse, so not all of them fit neatly into specific categories.

Some smooth muscle cells undergo slow-wave changes in membrane potential in the absence of external stimulation. Slow waves recorded in these muscle cells may trigger action potentials if they exceed the voltage threshold of the fiber. In smooth muscle, the inward current of the action potential is a Ca^{2+} influx, so action potentials lead to a direct increase in intracellular Ca^{2+} concentration. However, because action potentials are not required to open voltage-gated Ca^{2+} channels, even subthreshold depolarizations will allow an influx of Ca^{2+} ions that may produce measurable tension in the muscle.

Ca^{2+} availability controls smooth muscle contraction by myosin-linked regulation

Like skeletal and cardiac muscles, smooth muscles maintain a low resting internal Ca^{2+} concentration (using pumps in both the SR and the cell membrane), and a rise in cytoplasmic Ca^{2+} initiates contraction. As we have seen, different smooth muscle cells respond to different types of stimuli, some respond to more than one type of stimulus, and some undergo spontaneous changes in membrane potential. The sum of inputs and membrane functions determines

the moment-to-moment level of Ca^{2+} in the cytoplasm. Because the amount of available cytoplasmic Ca^{2+} determines the degree of force generated by the contractile proteins, smooth muscle cells produce *graded contractions*.

When a smooth muscle cell is stimulated to contract, Ca^{2+} enters the cytoplasm down its concentration gradient from both the SR and the extracellular space. The cells are small, so diffusion distance for Ca^{2+} is short, whether it enters from the SR or across the cell membrane. Unlike skeletal and cardiac muscles, smooth muscles do not use the thin filament regulatory proteins troponin (TN) and tropomyosin (TM) to regulate contraction. Instead, the proteins that regulate smooth muscle contraction are on the thick filament. **Figure 20.18** shows that Ca^{2+} activates smooth muscle predominantly by regulating the phosphorylation of myosin light chains (MLCs) (see Figure 20.4). In this *myosin-linked regulation*,¹¹ entering Ca^{2+} ions combine with the Ca^{2+} -binding protein *calmodulin*, which is present in the cytoplasm. The Ca^{2+} -calmodulin complex activates the enzyme *myosin light-chain kinase (MLCK)*, which phosphorylates one of each pair of MLCs of individual myosin molecules. Phosphorylation of the MLCs enhances the ATPase activity of the myosin heads and triggers them to bind to actin filaments and generate cross-bridge motions. As in skeletal muscle, hydrolysis of one ATP molecule powers one cross-bridge cycle. As long as Ca^{2+} is present and the MLC remains phosphorylated, repeated cross-bridge cycles occur. The degree of force generated by the contractile proteins reflects the number of active cross-bridges. The number of active cross-bridges increases with increasing Ca^{2+} in the cytoplasm. This property of smooth muscle, in which the number of active cross-bridges is variable, is similar to cardiac muscle. However it is distinctly different from skeletal muscle, in which a muscle action potential triggers the release of sufficient Ca^{2+} from the SR to allow every cross-bridge to be active.

Relaxation is accomplished by the pumping of Ca^{2+} from the cytoplasm into the SR or out of the cell. As free Ca^{2+} decreases, Ca^{2+} unbinds from calmodulin, and the MLCK becomes inactive. Another enzyme, *myosin light-chain phosphatase (MLCP)*, dephosphorylates the light chains.

The processes shown in Figure 20.18 are often modulated by additional signaling molecules that influence the functions of MLCK and MLCP. For example, a smooth muscle cell activated by one type of signal may also receive an additional signal to turn on the G protein RhoA and its effector Rho kinase (ROK). The RhoA/ROK system inhibits MLCP. By preventing the dephosphorylation of MLCs, more myosin heads retain ATPase activity, so that—at any level of Ca^{2+} in the cytoplasm—more cross-bridges are active and generating force. This effect is referred to as *Ca^{2+} sensitization*. Interestingly, in tonic smooth muscles that produce especially prolonged contractions, such as the lower esophageal sphincter, the cross-bridges remain attached to actin in a **latch state** long after cytoplasmic Ca^{2+} is reduced. In this condition, ATP replaces the bound ADP of the myosin head ATPase extremely slowly, so the majority of cross-bridges “latched” to actin maintain tension without using ATP. The mechanisms responsible for maintaining the energy-saving latch state, and terminating it, are not fully clarified. It is possible, for example, that the relative activities of MLCK

¹¹Additional mechanisms, including those that involve proteins on the thin filament, also play a role in regulating contraction in smooth muscle. Caldesmon, calponin, and tropomyosin are three such proteins thought to influence cross-bridge action.

FIGURE 20.18 Myosin-linked regulation of smooth muscle contraction requires Ca^{2+} ions, calmodulin, and myosin light-chain kinase. MLC, myosin light chain; MLCK, myosin light chain kinase.

and MLCP are involved, or that proteins of the thin filament play a role, or that second messengers, such as those influenced by the paracrine nitric oxide (NO), have an effect.

Myosin-linked regulation of contraction (instead of troponin-tropomyosin-actin-linked regulation) also occurs in the muscles of molluscs and several other invertebrate groups. The muscles that hold shut the shells of bivalve molluscs (such as scallops) are known to remain contracted for hours or even days with very little O_2 consumption. These muscles actively contract, but relax

extremely slowly, a condition termed the *catch state*. In this state, the muscles are stiff and resistant to stretch. Some investigators have suggested that an intermediate state of actin-myosin-ADP similar to the latch state of vertebrate smooth muscle could account for the economical maintenance of tension in molluscan muscle. An alternative idea is that the catch state is produced by the formation of a rigid network of connections between the myofilaments, a condition not dependent on myosin cross-bridges. These ideas are currently under investigation.

Most smooth muscles are innervated by the autonomic nervous system

Postganglionic sympathetic and parasympathetic axons branch and ramify among the muscle cells (see Figure 20.17). The autonomic axons have repeated swellings, or varicosities, near their terminations, giving them a beaded appearance. The varicosities of the postganglionic axons function in a similar way to the presynaptic axon terminals of the somatic nervous system. Neurotransmitters are synthesized in the varicosities, stored in vesicles, and released by exocytosis. Neural activity triggers transmitter release, and the transmitter molecules diffuse over the surface of the muscle cells until they encounter receptor molecules. Unlike skeletal muscle fibers, smooth muscle cells lack distinct postsynaptic regions such as endplates. Two examples illustrate both the power and the versatility of the autonomic nervous system and smooth muscles working in concert. In the first case, the smooth muscle of the urinary bladder is innervated by both divisions of the autonomic nervous system. The parasympathetic transmitter acetylcholine (ACh) stimulates the smooth muscle cells to contract in the process of voiding urine, and the sympathetic transmitter norepinephrine inhibits the smooth muscle cells from contracting so that urine is retained.

In contrast, the smooth muscles in most blood vessels are innervated only by sympathetic postganglionic axons, and norepinephrine stimulates these cells to contract. Norepinephrine produces opposite responses—relaxation of bladder smooth muscle cells and contraction of blood vessel smooth muscle cells—because the two types of smooth muscle cells express different postsynaptic receptors that initiate different cellular responses. Chapter 15 provides a detailed description of the autonomic nervous system.

SUMMARY Vertebrate Smooth (Unstriated) Muscle

- Smooth muscles make up the walls of tubular and hollow organs, and are found in the eye and at the base of hairs and feathers. Smooth muscles contract slowly because their myosin ATPase isomers hydrolyze ATP very slowly. Some types of smooth muscle maintain contractions for protracted lengths of time using very little energy.
- Smooth muscle cells are small, spindle-shaped and uninucleate. They contain thin actin filaments and thick myosin filaments arranged around the periphery of the cell. Although the thick and thin filaments overlap with each other, they do not form sarcomeres, which accounts for the muscles' "smooth" appearance.
- Smooth muscles receive innervation from the autonomic nervous system, and may be influenced by hormones, paracrines, and even stretch. Smooth muscles vary in the number of gap junctions present and in their contractile and electrophysiological properties. Cells in *single-unit* smooth muscles are connected by numerous gap junctions so that excitation spreads from cell to cell. Cells in *multiunit* smooth muscles have few gap junctions and function independently of each other. *Tonic* smooth muscles contract for long periods of time and typically generate only graded membrane depolarizations. *Phasic* smooth muscles produce rhythmic or intermittent contractions and generate action potentials.

- Smooth muscle contraction is controlled by Ca^{2+} , which enters the cytoplasm from the extracellular space or SR and binds to calmodulin. The Ca^{2+} -calmodulin complex activates MLCK, which phosphorylates myosin light chains and thereby increases the ATPase activity of the myosin head. Because the number of active cross-bridges in a smooth muscle varies depending on the amount of Ca^{2+} present at any given time, smooth muscle cells are capable of producing graded contractions. Relaxation occurs when cytoplasmic Ca^{2+} decreases, Ca^{2+} unbinds from calmodulin, and MLCK is no longer activated. MLCP dephosphorylates the light chains. Other signaling pathways can influence MLCK and MLCP activity and thus modulate the Ca^{2+} sensitivity of smooth muscle cells.

Vertebrate Cardiac Muscle

Vertebrate cardiac muscle, the muscle that forms the walls of the heart and functions to propel blood through the vascular system, is discussed in Chapters 12 and 25. We note its main features here to provide a comparison with smooth and skeletal muscle. Cardiac muscle is classified as striated because its myofibrils are organized into sarcomeres, which possess the same structural and regulatory proteins that skeletal muscle sarcomeres have (see pages 524–525) (Figure 20.19). The cells are typically branched instead of straight like skeletal muscle fibers or spindle-shaped like smooth muscle cells. They are usually uninucleate. In mammals, the SR and t-tubules are well developed, but they are variable in other vertebrate animals.

Cardiac muscle fibers have functional properties that contribute to their effectiveness in pumping blood. First, they are characterized by the presence of **intercalated discs** between adjacent cells. Intercalated discs include gap junctions and localized mechanical adhesions called *desmosomes* and *fasciae adherentes* (singular *fascia adherens*). The adhesions provide mechanical strength so that the force of contraction generated by one cell can be transmitted to the next to ensure coordinated pumping. The electrical coupling at gap

FIGURE 20.19 Cardiac muscle Striated cardiac muscle fibers are connected by intercalated discs (arrows) that contain electrical gap junctions and two types of mechanical connections called desmosomes and fasciae adherentes.

TABLE 20.3 Characteristics of the three major types of muscles in vertebrates

	Skeletal	Multiunit smooth	Single-unit smooth	Cardiac
Structure	Large, cylindrical, multinucleate fibers	Small, spindle-shaped, uninucleate cells	Small, spindle-shaped, uninucleate cells	Branched uninucleate fibers, shorter than skeletal muscle fibers
Visible striations	Yes	No	No	Yes
Mechanism of contraction	Thick myosin and thin actin filaments slide by each other	Thick myosin and thin actin filaments slide by each other	Thick myosin and thin actin filaments slide by each other	Thick myosin and thin actin filaments slide by each other
Cross-bridge action regulated by Ca^{2+} ions	Yes	Yes	Yes	Yes
Innervation	Somatic nervous system initiates contractions	Autonomic nervous system initiates contractions	Autonomic nervous system modulates contractions	Autonomic nervous system modulates contractions
Spontaneous production of action potentials by pacemakers	No	No	Yes	Yes
Hormones influence function	No	Yes	Yes	Yes
Gap junctions present	No	No (few)	Yes	Yes
Transverse tubules	Yes	No	No	Yes
Sarcoplasmic reticulum	Abundant	Sparse	Sparse	Moderate
Source of Ca^{2+} ions for regulation	Sarcoplasmic reticulum	Extracellular fluid and sarcoplasmic reticulum	Extracellular fluid and sarcoplasmic reticulum	Extracellular fluid and sarcoplasmic reticulum
Troponin and tropomyosin	Both present	Tropomyosin only	Tropomyosin only	Both present
Ca^{2+} regulation	Ca^{2+} and troponin; tropomyosin–troponin complex moves to expose myosin-binding sites on actin	Ca^{2+} and calmodulin; phosphorylation of myosin light chains	Ca^{2+} and calmodulin; phosphorylation of myosin light chains	Ca^{2+} and troponin; tropomyosin–troponin complex moves to expose myosin-binding sites on actin
Speed of contraction (reflecting myosin ATPase activity)	Varies from fast to slow depending on fiber type	Very slow	Very slow	Slow

Sources: After Randall et al. 2002 and Sherwood 2004.

junctions ensures that all cells connected by gap junctions contract (beat) nearly synchronously. Gap junctions and desmosomes are illustrated in Figure 2.7.

A second property of cardiac muscle cells is that they are capable of generating endogenous action potentials at periodic intervals. Typically, specialized pacemaker cells with the fastest endogenous rate impose their rhythm on the contractile activity of the rest of the heart. Finally, the action potentials of vertebrate cardiac fibers have very long durations, typically 100 to 500 ms (see Figure 12.23). Their long durations ensure a prolonged contraction rather than a brief twitch. Indeed, the action potentials last as long as the contractions. Because the cardiac cells are refractory during the prolonged action potentials, contractions cannot sum; thus the coordinated pumping of blood is ensured.

Table 20.3 summarizes the properties of vertebrate skeletal, smooth, and cardiac muscles.

Study Questions

1. Knowing the dimensions of a vertebrate skeletal muscle and the relationship between the SR and the myofilaments, estimate the approximate distance that a single Ca^{2+} ion would travel from a terminal cisterna of the SR to a TN-binding site.
2. Experimenters can separate F-actin thin myofilaments from myosin thick myofilaments. First they homogenize muscle cells in a blender (to break cell membranes); then they place the homogenate in a Ca^{2+} -free “relaxing solution” that contains ATP. Explain why ATP must be present and Ca^{2+} ions must not be present in order to isolate thick and thin myofilaments from each other.
3. List and describe the events that take place (and the structures involved) between excitation of the skeletal muscle cell membrane by an action potential and the initiation of cross-bridge action.
4. Combining your knowledge of rates of diffusion with your knowledge of muscle physiology, explain why it is advantageous for oxidative muscle fibers (which depend on aerobic metabolism

to generate ATP) to have smaller diameters than glycolytic muscle fibers have.

5. What is the difference between a single cross-bridge power stroke and a single twitch of a skeletal muscle fiber?
6. In skeletal muscle, if all cross-bridges are activated when a single action potential triggers Ca^{2+} release from the SR, why is the amount of tension produced by a train of action potentials greater than the amount of tension of a single twitch?
7. Arthropod muscle fibers typically do not generate action potentials. Using your knowledge of their innervation, explain how their contractile elements are activated in a rapid and coordinated fashion.
8. Describe the organization of a motor unit in vertebrate skeletal muscle, and explain how recruitment of motor units influences the amount of tension produced by a whole muscle.
9. Two muscles have the same diameter, but one is twice as long as the other. Which muscle produces more work? Explain your answer.
10. Contraction in both skeletal and smooth muscles requires the influx of Ca^{2+} into the cytoplasm. Compare and contrast the locations and functions of the molecules to which Ca^{2+} binds in skeletal and smooth muscles, and explain the steps that lead to cross-bridge cycling in each type of muscle.

Movement and Muscle *at Work*: Plasticity in Response to Use and Disuse

The success of any living species is achieved by the ability of its individuals to pass their genes on to their offspring, and to ensure survival of sufficient numbers of the offspring so that they in turn reach reproductive maturity. To achieve success, animals need to obtain nourishment, grow, and reproduce—and also escape predators. Muscle tissues support all of these abilities. Indeed, in vertebrates, striated muscles constitute nearly half of the tissues of an animal. Muscle tissue continually synthesizes and degrades proteins, assembles and disassembles contractile elements, and maintains itself through repair. Imagine these processes occurring not only in actively contracting skeletal muscles but also in cardiac muscle, which (in mammals) contracts 30 to 700 times per minute! The dynamic nature of muscle tissue underlies its *phenotypic plasticity* (see Chapter 4, page 90).

Governed by a myriad of controls, muscle is capable of changing in both mass and cellular characteristics. The remarkable ability of muscle to change with use is especially interesting because muscle cells (muscle fibers) in adults are postmitotic; that is, once a muscle forms, the cells do not divide by mitosis, and their number cannot increase. For example, we know from Chapters 8 and 20 that muscles typically consist of mixtures of different types of muscle fibers that are characterized by different speeds of contraction and different metabolic properties.¹ Researchers have found that a muscle's activity causes interconversion between certain of these types of fibers, but not a change in the number of fibers. Furthermore, it is widely agreed that when a muscle increases in bulk, it does so by **hypertrophy**—that is, by adding structural proteins to individual cells—not by adding new cells by mitosis. When a muscle is not used, it becomes smaller because the individual muscle fibers lose actin and myosin components of myofibrils. This reduction of muscle mass is called **atrophy**. Atrophy of a muscle can also result from loss of cells, a phenomenon seen in some disease states and also in aging.

Other changes also occur in response to different types of activity. For example, a weight lifter does resistance exercises (such as lifting free weights or working against an external resistance such as a strength-training machine) that lead to hypertrophy of the exercised muscle fibers. These exercises stimulate the individual fibers to increase their synthesis of actin and myosin, which form more myofibrils. The exercised muscle fibers also add nuclei by fusing with satellite cells (mononuclear precursors of muscle cells) that lie close to a muscle fiber's cell membrane. The added nuclei support the overall functions of a larger-volume cell. Recent experiments in rodents showed that added nuclei persist even when a once-hypertrophied cell undergoes atrophy. This result led researchers to suggest that the nuclei of hypertrophied muscles may play a role in “muscle memory,” the ability of previously trained muscles to regain their former strength with less retraining than was required to gain strength initially.

¹ The three main types of fibers are slow-twitch fibers (*slow oxidative* [SO]) and two types of fast-twitch fibers (*fast oxidative glycolytic* [FOG] and *fast glycolytic* [FG] see Chapter 20, Table 20.2).

Different activities produce changes in skeletal muscles

Different changes take place in the individual fibers in the leg muscles of a person training for long-distance running. These muscle fibers form more and larger mitochondria so that more ATP is produced by oxidative phosphorylation. Unlike the fibers in resistance-trained muscles, the fibers in the endurance-trained muscles of runners show relatively little hypertrophy. This morphology is in keeping with maintaining short diffusion distances between the blood in capillaries and the interior of the muscle fibers. As we will see, endurance exercise also stimulates more capillaries to form around the muscle fibers. Although the muscles of athletes provide extreme examples, similar but more subtle changes occur in any person's muscles over the course of day-to-day activities.

There is no shortage of examples demonstrating that muscles can—and do—change in response to functional demands. Researchers are actively studying the signals that trigger these changes. How does the nature of a muscle's mechanical activity cause individual muscle fibers to convert from one type to another? What conditions lead to atrophy? Indeed, the aim of many ongoing studies is to find ways to inhibit the muscle atrophy that occurs under conditions such as microgravity during space travel, in diseases such as muscular dystrophy, and in aging. What conditions lead to hypertrophy? Answers to questions such as these have potential use not only in health care but also in economic contexts. For example, research in the meat and livestock industries is aimed at defining conditions that maximize growth rates and also provide optimum quality of meats. Studies of humans and laboratory mammals have contributed a great deal to our current understanding of use-related changes in muscle. Studies of other animals provide complementary perspectives of muscle function. In this chapter we explore several studies on vertebrate striated muscles that highlight their remarkable phenotypic plasticity.

Muscle Phenotypes

The phenotype of muscle tissue depends on the type of actions it performs. In the following sections, we will use endurance exercise and resistance exercise to illustrate the ways in which muscle tissue changes to respond optimally to different actions. **Endurance exercise**, such as long-distance running, cycling, or swimming, is exercise that involves repetitive actions that generate relatively low forces. Slow-twitch fibers that have narrow diameters and depend on aerobic metabolism play a dominant role in endurance exercise. They are well designed for maintaining isometric force economically and for carrying out repetitive isotonic contractions. As we saw in Chapter 20, most movements involve both isometric and isotonic contractions. Isometric contractions do not shorten the whole muscle or move the limb; they typically occur at the beginning and at the end of an action. Isotonic contractions move the limb. **Resistance**, or strength, **exercise**, such as stair running or weight lifting, is exercise that involves fewer repetitions of movements that generate large forces. Fast-twitch fibers that depend more on anaerobic metabolism are important in resistance exercises, which are often referred to as “power pursuits.”

The different types of muscle fibers contain different *isoforms* (that is, different molecular forms) of two important molecules, the myosin heavy chain of the thick filament and the Ca^{2+} -ATPase pump of the sarcoplasmic reticulum (SR). The different isoforms of these two molecules strongly influence a muscle fiber's functional properties. The rate of ATP hydrolysis by the ATPase of the myosin head is directly related to the rate at which cross-bridges cycle, and therefore to the speed of contraction. The rate at which Ca^{2+} ions are taken back into the SR from the cytoplasm also affects the twitch. Different isoforms of the Ca^{2+} -ATPase pump have different kinetics and are expressed at different levels in muscle fibers. The faster the cytoplasm is cleared of Ca^{2+} ions by the pump, the faster a single twitch is completed. The different isoforms of myosin and the SR Ca^{2+} -ATPase explain several of the properties of the three main types of muscle fibers described in Chapter 20, Table 20.2—slow oxidative (SO), fast oxidative glycolytic (FOG), and fast glycolytic (FG).

Table 21.1 shows that SO (also called Type I) twitch fibers have the slowest myosin isoform and thus the slowest rates of cross-bridge cycling. SO fibers also have a slow Ca^{2+} -ATPase isoform in the SR. They contain abundant mitochondria and tend to be fatigue-resistant. FOG (also called Type IIa) twitch fibers have a myosin isoform that hydrolyzes ATP faster than does the myosin isoform of SO muscle fibers, and a fast Ca^{2+} -ATPase isoform in the SR; they are relatively resistant to fatigue. FG (in humans, also called Type IIx) twitch fibers have the fastest myosin isoform and a fast SR Ca^{2+} -ATPase isoform. FG fibers have the fastest speed of contraction. Indeed, in humans the FG (Type IIx) muscle fibers can contract up to ten times faster than SO (Type I) fibers. FG (Type IIx) fibers typically have the largest diameters of the three main fiber types (see Figures 8.13 and 20.13), contain relatively few mitochondria, and fatigue easily.

Motor units composed of different fiber types have different physiological characteristics. The muscle fibers of any single *motor unit* (a motor neuron and all of the muscle fibers it innervates; see Figure 20.15) are all of the same fiber type. The muscle fiber type is strongly influenced by the motor neuron. We know from early experiments that some motor units could be converted from one type to another by cross-innervation (cutting the original nerve fibers and allowing different ones to innervate the muscle fibers). Typically, motor units are recruited in a fixed order: first SO, then FOG, and finally FG. The two fast fiber types are recruited to pro-

TABLE 21.1 Muscle fiber types and molecular isoforms

General terms	Slow oxidative (SO)	Fast oxidative glycolytic (FOG)	Fast glycolytic (FG)
Human terms	Type I	Type IIa	Type IIx ^a
Myosin heavy-chain isoform	Slow cross-bridge cycling	Rapid cross-bridge cycling	Rapid cross-bridge cycling
Sarcoplasmic reticulum Ca^{2+} -ATPase	Slow Ca^{2+} uptake by SR	Fast Ca^{2+} uptake by SR	Fast Ca^{2+} uptake by SR
Speed of contraction	Slow	Fast	Fast

^aEarly studies on humans referred to what are now known as IIx fibers as IIb fibers. In current nomenclature, IIb fibers are a type of fast muscle fiber found in small mammals. An additional type of fast fiber found in small mammals is IIId/x.

duce more powerful isotonic movements than slow fibers produce, or to supplement isometric contractions produced by slow fibers. The pattern of recruitment and the diversity of fibers with different velocities of contraction and fatigability allow a muscle to shorten at varied, appropriate speeds as it generates the forces required for different types of movement.

Power output determines a muscle's contractile performance, and changes in response to use and disuse

We know from Chapter 20 (see page 535) that the greater the cross-sectional area devoted to the contractile elements in a muscle fiber, the greater the force it can generate. We also know that the speed of contraction is determined by the rate at which a given myosin isoform hydrolyzes ATP and produces cross-bridge actions. These qualities—*force* generated and *velocity* (speed) of shortening—determine the contractile performance of a muscle. Indeed, the force generated by a muscle multiplied by the velocity of shortening determines the mechanical power produced:

$$\text{Power} = \text{force} \times \text{shortening velocity} \quad (21.1)$$

Figure 21.1 shows a *power curve* superimposed on the force–velocity relationship described in Chapter 20 (see page 532). The force–velocity (load–velocity) relationship reflects the interaction between the force a muscle generates against a load and the speed at which it shortens: The velocity of shortening decreases as the load increases.

Points on the power curve are determined from the instantaneous product of force and velocity. Power is zero (P_0) when the muscle shortens against no load (at maximum velocity, V_{\max}) and

FIGURE 21.1 The power a muscle is capable of generating determines its functional capabilities. The blue line represents the force–velocity relationship; the red line represents the power curve. Power is zero (P_0) when shortening velocity is at its maximum (no load; V_{\max}) or at zero (isometric contraction).

also when the muscle contracts isometrically but does not shorten. Power output of most muscles is maximal when the muscle shortens at 20% to 40% of V_{\max} and at about 30% to 40% of the load that prevents it from shortening. Power is measured in watts: 1 watt = 1 newton (N) \times 1 m/s, or 1 watt = 1 joule (J)/s.

We know that in isotonic contractions the force generated by a muscle equals the force of the load it moves. Thus, the x axis of the graph indicates the force exerted by the load, and it also reflects the force produced by the muscle. For a particular muscle, the cross-sectional area of the myofibrils in its muscle fibers determines the maximum force it can produce. The y axis of the graph, which indicates velocity of shortening, is related to the myosin isoforms expressed by the motor units of a particular muscle. Therefore, the force–velocity relationship—and thus the power output—of a whole muscle will be determined by the cross-sectional area of individual muscle fibers (how many myofibrils they contain) and the different fiber types that make up the muscle. Because the myofibrils are structured similarly in all skeletal muscle fiber types, a unit of cross-sectional area will generate the same force in both slow and fast types of fibers. However, the *power* is much greater for fast-twitch fibers than for slow-twitch fibers because of their greater speed of contraction. When the individual fibers of muscles change in response to different kinds of use or to disuse, their cross-sectional area (determined by hypertrophy or atrophy) and speed of contraction (determined by fiber type) also change. The changes directly affect power output and therefore contractile performance.

Endurance training elicits changes in fiber type, increased capillary density, and increased mitochondrial density

In an average active person, the muscles used in locomotion typically have a mix of about half slow Type I fibers and half fast fibers; the majority of fast fibers are Type IIa.² Elite athletes show distinct differences from the average person and also from one another. For example, the leg muscles of marathon runners tend to have a preponderance of Type I fibers and relatively few fast fibers, which are mainly Type IIa. By contrast, the leg muscles of sprinters tend to have a preponderance of fast fibers (a mix of Types IIa and IIx) and relatively few Type I fibers. Between these extremes, humans and other animals show considerable variation in the distributions of fiber types within their muscles. It appears likely that individuals vary genetically, with some programmed to have muscles more like those of a marathoner and others to have muscles more like those of a sprinter. Still, studies of humans and experimental animals have shown that exercise training can cause some degree of interconversion between these fiber types, in particular between Type IIa and Type IIx fibers.

Table 21.2 presents the results of two studies of endurance training in humans. These “classic” histological studies in both men and women illustrate in single experiments the now well-known association between endurance training and changes in muscle fiber-type composition and also sprouting of new capillaries to improve circulatory supply to the muscle. Subsequent and ongoing studies have shed light on the mechanisms underlying these changes by applying biochemical, molecular biological, genomic, proteomic, and

²Different muscles in the body of a human or other animal differ in their composition of fast and slow fiber types depending on the muscle's function (see Chapter 20, pages 538–539).

TABLE 21.2 Fiber type distribution and capillaries around each fiber before and after endurance training in two studies

Fiber type	Before Training		After Training	
	Distribution (%) (mean \pm S.E.M.)	Capillaries around each fiber (mean \pm S.E.M.)	Distribution (%) (mean \pm S.E.M.)	Capillaries around each fiber (mean \pm S.E.M.)
7 women				
Type I	58.2 \pm 2.8	4.11 \pm 0.15	57.5 \pm 2.9	5.04 \pm 0.21**
Type IIa	24.9 \pm 2.6	3.4 \pm 0.16	31.6 \pm 2.7*	4.15 \pm 0.21**
Type IIx	11.8 \pm 2.7	2.33 \pm 0.19	2.7 \pm 2.5*	2.68 \pm 0.14**
Intermediate	5.2	6.9	7.9*	8.0**
5 men				
Type I	39 \pm 2.1	3.9 \pm 0.18	42 \pm 2.2	5.4 \pm 0.32*
Type IIa	36 \pm 2.9	4.2 \pm 0.2	42 \pm 2.4*	5.5 \pm 0.45*
Type IIx	20 \pm 1.6	3.0 \pm 0.22	13 \pm 1.5*	4.2 \pm 0.5*

Sources: After Ingjer 1979 (women) and Andersen and Henriksson 1977 (men).

Note: The data shown from the study on women were based on 168 to 265 muscle fibers analyzed per subject prior to training, and 137 to 197 per subject after training. Asterisks indicate significant differences from pre-training values: *, $P < 0.005$; **, $P < 0.01$. The intermediate category of fibers had histological properties intermediate between those of Type IIa and Type IIx fibers, suggesting that different myosin isoforms were coexpressed at the same time. In the study on men, 1035 \pm 126 fibers were analyzed per subject prior to training, and 937 \pm 270 fibers per subject after training. Asterisks indicate significant differences from pre-training values ($P < 0.05$).

imaging techniques. In one of these early studies, seven previously untrained women, 21 to 24 years old, did supervised cross-country running for 24 weeks, running 45 minutes (min) a day, 3 days a week. In the other study, five previously untrained men, 20 to 23 years old, trained for a period of 8 weeks by pedaling a bicycle ergometer (a bicycle equipped to measure the work done by muscles) 40 min a day, 4 days a week. In both studies, samples of muscle tissue were taken before and after training from the *vastus lateralis* muscle of the quadriceps group (Figure 21.2). Figure 21.3 illustrates the instruments used in a needle biopsy, the procedure used to obtain the samples. The *vastus lateralis* is a mixed muscle, with representation of all three fiber types. In an average active person, the myosin isoform profile is about 50% Type I, 40% Type IIa, and 10% Type IIx.

In both studies, the proportion of Type I fibers remained unchanged as a result of training. However, endurance training caused a significant change in the proportions of the two types of fast fibers in the *vastus lateralis* muscle. The proportion of Type IIa fibers increased and was accompanied by a decrease in the proportion of Type IIx fibers. The authors of the study on the women noted that the proportion of Type I fibers in the tested muscles of these subjects (~58%) was greater than usually found in untrained female subjects. Indeed, the proportion of Type I fibers in the *vastus lateralis* muscles of eight subjects who dropped out of this study after only a few weeks was approximately 47%. This observation raised the question of whether the anatomy or physiology of volunteers in long-term studies influence their interest in participating. The authors suggested that the seven women who completed the nearly half-year study may have chosen to participate in (and stick with) it because the fiber-type composition of their muscles (determined by their genetic makeup) contributed to their inherent ability to respond to endurance training.

Because the tissue samples showed no evidence of cells dying or new cells being formed, the results are interpreted to mean

that Type IIx fibers changed into Type IIa fibers. Changes in gene expression must have occurred to accomplish the shift in propor-

FIGURE 21.2 Quadriceps muscles of the anterior thigh The four muscles of the quadriceps group lie on the top of the thigh and insert on the quadriceps tendon. The *vastus lateralis*, frequently biopsied for studies on human muscle, is the most lateral of the four muscles.

FIGURE 21.3 A needle biopsy is used to obtain samples of muscle tissue (a) The biopsy sample is a small plug of tissue removed from the muscle. (b) The biopsy apparatus consists of a pointed outer needle and an inner slider with a razor-sharp cutting edge. After application of local anesthetic, the apparatus is inserted into the muscle through an incision. A small amount of surrounding muscle tissue bulges into the opening on the side of the pointed needle. The inner slider is pressed forward to sever the protruding bit of muscle tissue. The slider is withdrawn and the tissue sample removed from the pointed needle using forceps. (a courtesy of S. P. Scordilis, Smith College.)

tions of the fast fiber types observed in both studies. Some of the original Type IIx muscle fibers must have repressed their genes for the faster IIx myosin isoform and switched on their genes for the IIa myosin isoform. The signals that trigger this change in gene expression—and subsequent changes in muscle structure—are topics of active inquiry. For example, changes in cytoplasmic Ca^{2+} concentrations or in rates of ATP use during increased contractile activity are thought to trigger intracellular signaling pathways that lead to changes in gene expression.³ The two studies also showed that training led to an increase in the number of capillaries in contact with each muscle fiber. These data indicate that endurance training caused new capillaries to grow by sprouting branches from existing vessels, a process called **angiogenesis**. Subsequent studies using a variety of tissues have demonstrated that exercised muscles produce and release the cytokine **vascular endothelial growth factor (VEGF)**, which stimulates angiogenesis.

Studies using laboratory mice allow finer resolution over time of the effects of endurance training on fiber-type composition and angiogenesis in muscle. In one study, male mice (8 weeks old) were housed individually in cages with running wheels. The wheels of control (sedentary) mice were locked so they would not rotate. The wheels of endurance-trained mice were connected to a data-acquisition system that measured the distance run by each mouse. The mice ran voluntarily and clocked an average of 10 km per day. Mice ran for 1, 3, 7, 14, or 28 days. Five or six mice were included in test and control groups. At the end of each test period, the *plantaris* muscle (Figure 21.4) was removed and used to analyze muscle fiber types, capillary density, and concentration of VEGF. Figure 21.5 shows the expected increase in capillary density and conversion from the fastest fiber types (Type IIb and also a mouse fiber type called IId/x) to the fast oxidative Type IIa. Whereas the sedentary animals' *plantaris* muscles had about 83% of the fastest fiber types, the *plantaris* muscles of animals trained for 28 days showed a reduction of the fastest fiber types to about 67%. The reduction of the fastest fibers was accompanied by an increase

in the fast oxidative Type IIa from about 15% to about 32%. The *plantaris* muscle includes only about 2% of the slow Type I fibers, which did not change during training. No cell death occurred (as in other studies), and the researchers concluded that the fastest fibers

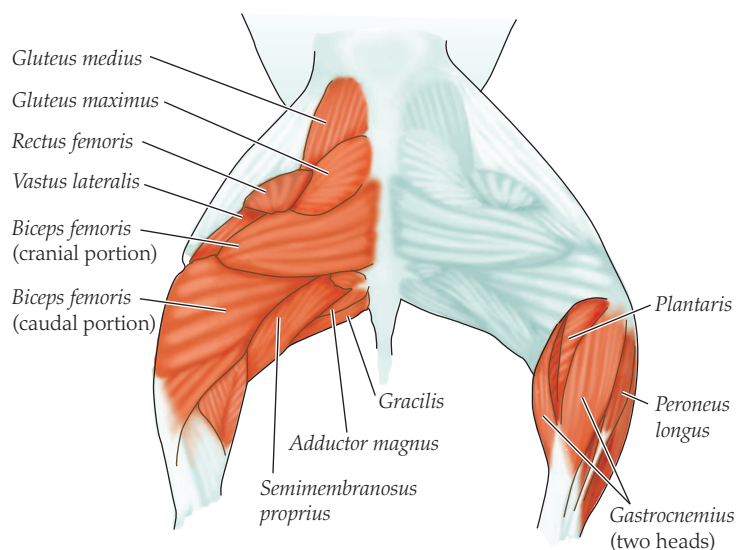

FIGURE 21.4 Experiments using laboratory mice test the effects of endurance training on skeletal muscle fibers Top: Experimental arrangement. Bottom: Muscles of the rodent hindlimb (dorsal view). The *plantaris* muscle can be seen by spreading apart the heads of the *gastrocnemius* muscle.

³Stimuli such as changes in cytoplasmic Ca^{2+} concentrations or in rates of ATP use activate enzymes that regulate transcriptional factors, coactivators, and repressors. These factors in turn control the transcription of contractile protein genes involved in the transformation of fibers from one type to another. Examples of enzymes that initiate intracellular signaling networks are calcineurin, which responds to increased cytoplasmic Ca^{2+} , and AMP-activated protein kinase (AMPK), which is sensitive to increased metabolic demands.

transformed into Type IIa fibers. Figure 21.5 also gives an intriguing record of the time course of changes that occurred over a month of endurance training. The sequence of changes was first a rise in VEGF (day 3), then a significant rise in capillary density (day 7), and finally an increase in Type IIa fibers (day 14). These data correlate the presence of VEGF and the occurrence of angiogenesis, and they

FIGURE 21.5 Angiogenesis precedes change of fiber type in the plantaris muscle of endurance-trained mice. Data are means \pm S.E.M., and * indicates a significant difference from the control (0 days of training): $P < 0.05$ (VEGF), $P < 0.01$ (capillaries), $P < 0.001$ (fiber abundance). (After Waters et al. 2004.)

suggest that angiogenesis precedes the conversion of fiber types. The researchers raise the interesting question of whether or not increased density of capillaries around a particular muscle fiber may permit or promote its switch to a slower type.

Studies on human subjects showed that the *acute* VEGF response to exercise is very rapid. Muscle cells of biopsied tissue samples had increased amounts of messenger RNA (mRNA) for VEGF within 1 hour after an exercise bout. Figure 21.6 shows changes in VEGF mRNA in response to exercise in six untrained human subjects. At the beginning of the study, each subject exercised only the left leg for 30 min on an ergometer. In this pre-training *knee-extensor exercise* bout, the subjects repeatedly contracted the quadriceps muscle group against a load to extend the leg from a "sitting angle" to a straightened position. About 1 h after the exercise bout, biopsies were taken from the *vastus lateralis* muscle of the exercised leg (Untrained, Exercise sample) and from the same muscle of the rested right leg (Untrained, Rest sample). The subjects then trained the left quadriceps muscle (with varying exercises and loads to optimize training) for a period of 8 weeks. At the end of the training period, they performed the same exercise as in the pre-training bout (but at a higher load), and biopsies of the exercised *vastus lateralis* were taken about 1 h afterward (Trained, Exercise sample). Two days later, biopsies were taken from the same, now rested, muscle (Trained, Rest sample).

The biopsies showed low levels of VEGF mRNA at rest in both untrained and trained muscles. A single exercise bout initiated upregulation of VEGF mRNA within 1 h in both untrained and trained muscles. Interestingly, the response in the trained muscles was less than that in the untrained muscles. Morphological studies of the same biopsied tissues showed that the training program induced significant angiogenesis, with an 18% increase in the number of capillaries around each muscle fiber. When chronic exercise training upregulates VEGF repeatedly, capillaries are stimulated to proliferate. Once angiogenesis has taken place in the exercise-adapted muscle, a single bout of exercise appears to stimulate less upregulation of VEGF. Thus it is clear from both human and experimental animal studies that exercise causes mechanical and/or metabolic perturbations in muscle cells that trigger increased expression of VEGF, and that VEGF acts as a paracrine to induce angiogenesis. Researchers are currently focusing

FIGURE 21.6 VEGF responses to a single bout of endurance exercise. Vascular endothelial growth factor (VEGF) mRNA increased in the *vastus lateralis* muscle after a single bout of knee-extensor exercise in both untrained and trained muscles, but the increase was attenuated in the trained muscles. Morphological studies of the muscle tissues showed a significant increase in the number of capillaries around each fiber after training, from about 3.6 capillaries per fiber in the untrained muscle to about 4.3 capillaries per fiber in the trained muscle. Bars are means ± 1 S.E.M., and * indicates a significant difference from untrained values ($P < 0.05$). Tissue samples were taken from six subjects. (After Richardson et al. 2000.)

FIGURE 21.7 Endurance training increases the proportion of cell volume occupied by both mitochondria and lipid droplets Tissue samples of *vastus lateralis* muscle were taken from five women and five men who trained on a bicycle ergometer 30 min a day, 5 times each week for a period of 6 weeks. Bars represent means \pm 1 S.D., and * indicates a significant difference ($2P < 0.05$ in a paired *t* test). (After Hoppeler et al. 1985.)

their studies on identifying intracellular signaling molecules that link the contractile activity with increased VEGF expression and subsequent angiogenesis.

Endurance exercise increases not only the density of capillaries in muscles, but also the number and size of mitochondria. **Figure 21.7** shows data obtained in an experiment in which five women and five men (29 ± 5.1 years old)—all previously untrained—participated in a 6-week endurance regimen using bicycle ergometers. Tissue samples were taken by biopsy from the *vastus lateralis* muscle before and after the training period. Measurements of structures in electron micrographs of the tissue samples showed that the total volume of mitochondria per volume of muscle fiber increased by 40% and that the volume occupied by lipid droplets within the muscle fibers nearly doubled, increasing by 97%. In addition, the number of capillaries per muscle fiber increased by 26%.

Recent and ongoing studies of *mitochondrial biogenesis* have shown that exercise also stimulates changes in the structural and enzymatic proteins of the mitochondria themselves. These phenotypic changes contribute to greater resistance to fatigue. More mitochondria permit the cells to use more oxygen (supplied by capillaries). Further, the newly generated mitochondria tend to make more use of fatty acids as their primary substrate instead of glucose. Using fatty acids decreases lactic acid production, saves glycogen, and spares creatine phosphate (see **Figure 20.13**). The increase in lipids within the cells parallels this shift. The signals that transduce the effects of exercise into mitochondrial biogenesis

appear to include changes in intracellular Ca^{2+} , a reduction in intracellular ATP with a concomitant increase in ADP, and activation of specific kinases (enzymes that catalyze phosphorylation of substrate molecules). These kinases activate transcription factors that stimulate transcription of nuclear genes encoding products that, in turn, trigger transcription of mitochondrial genes and the production of appropriate proteins. The transcription factors are expressed in exercised muscles within a few hours of an exercise bout. These concepts are also discussed in Chapter 3 (see page 77, **Figure 3.9**, and **Table 3.1**).

In sum, endurance exercise triggers multifaceted responses in skeletal muscles. Three main sets of genes exert specific and independent effects that coincide to enhance the muscles' functions during endurance exercise. Signaling mechanisms control the expression of contractile protein genes (for specific myosin isoforms), angiogenesis genes (for growth factors such as VEGF that support angiogenesis), and mitochondrial genes (for mitochondrial biogenesis). Future studies will no doubt reveal additional and more detailed information about the signals that influence gene expression in muscles responding to endurance demands.

It is interesting that interconversions between the two types of fast fibers appear to occur readily, whereas transformations from Type II fibers to Type I fibers, and vice versa, do not. Researchers have observed conversions of fast fibers into slow fibers in rodent muscles treated with more aggressive techniques than possible in exercise training programs. Whether such changes could be achieved under physiological conditions over longer periods than those so far tested in humans is still an open question. It is possible that remodeling of entire motor units, including the motor neurons, is necessary to achieve more extensive interconversions between slow- and fast-twitch muscle fibers.

Resistance training causes hypertrophy and changes in fiber type

Resistance training aims at increasing muscle strength. Resistance-exercise programs use repetitions of short, intensive bouts of shortening and/or lengthening contractions as well as isometric contractions. Key to resistance training is keeping exercise bouts as short bursts so that they stimulate hypertrophy of the muscle fibers but not the angiogenesis and mitochondrial biogenesis that are produced by longer-duration endurance exercise. Resistance training usually does not increase the aerobic capacity of the muscle or produce an increase in capillary density. In addition to stimulating hypertrophy, resistance training produces changes in the muscle's fiber type composition similar to those seen in endurance training. Biopsies of muscle tissue taken from previously untrained human subjects who participate in resistance-training programs over several weeks typically show no change in the proportion of Type I fibers in the trained muscle. Instead, resistance training causes the transformation of Type IIx fibers into Type IIa fibers. Investigators have proposed that mechanical deformations of the muscle fiber membrane and cytoskeleton could stimulate a stretch-activated signal that influences gene expression. Such a signal could promote expression of the Type IIa genes and repress expression of the Type IIx genes.

Figure 21.8 and **Table 21.3** show the results of a resistance-training experiment for which nine untrained men, 27 ± 3 years old, volunteered. Each subject underwent supervised resistance

FIGURE 21.8 Fast myosin heavy-chain isoforms change during training and detraining Biopsied tissue samples were taken from the *vastus lateralis* of nine subjects immediately before training, immediately after training, and after the 90-day period of detraining. Tissue samples were analyzed to determine the composition of myosin heavy-chain (Mhc) isoforms, which correlated with fiber type. The bars represent means \pm S.E.M., and * indicates a significant difference: *, $P < 0.05$, **, $P < 0.01$. (After Andersen and Aagaard 2000.)

training of the legs three times a week for a period of 90 days. The training consisted of the following exercises: hack squat, incline leg press, knee extension, hamstring curl, and calf raise. As training proceeded, the loads against which the leg muscles worked were progressively increased. After 90 days of training, the subjects were directed to return to their previous (nontraining) level of activity for the next 90 days (a period of detraining). Needle biopsies were taken from the *vastus lateralis* muscle immediately before training, at the end of the training period, and after 90 days of detraining. The tissue samples were analyzed to determine the relative amounts of different myosin heavy-chain (Mhc) isoforms, which distinguish different fiber types (see Table 21.1).

Neither training nor detraining had an effect on the amount of Mhc I isoform present in the *vastus lateralis* muscle (see Figure 21.8). As expected, after 3 months of training, the amount of Mhc IIa isoform increased in all nine subjects, from about 42% to about 50%, and the amount of Mhc IIx isoform decreased, from about 9% to about 2%. However, surprising changes occurred during the 90 days of detraining after resistance exercises were stopped. The Mhc IIx and IIa isoforms did *not* return to their pre-training proportions. Instead, the Mhc IIx isoform actually increased to about 17%—twice

its proportion in untrained muscles—during the detraining period. This increase was accompanied by a corresponding decrease in the Mhc IIa isoform, which declined to an average of 37%. The signals responsible for this “overshoot” of Mhc IIx isoform are not known, but many sprint athletes have based their training programs on it. Because large-diameter, glycolytic Type IIx fibers produce the fastest and most powerful contractions, they offer sprinters a strong competitive advantage. Thus, to increase the Type IIx fibers in their muscles, sprinters often follow a heavy regimen of resistance exercise by tapered training in advance of a major competition. This training plan is useful for specialized competitions that require the exertion of high power over a very limited period of time, such as a 100- or 200-m sprint. However, because the Type IIx fibers are prone to fatigue, training programs that aim toward more hypertrophied Type IIa fibers in exercised muscles will benefit performance in a broader range of competitions.

In this study, the fast Type II fibers in the nine subjects increased an average of 16% in diameter following training (see Table 21.3). Slow Type I fibers appeared to increase slightly in diameter, but this result was not statistically significant because there was large variation in the cross-sectional area of individual fibers. Other resistance-training experiments have elicited significant hypertrophy of Type I fibers. It will be interesting to follow further studies on human subjects designed to determine whether Type I or Type II fibers preferentially undergo hypertrophy.

In exploring the effects of endurance and resistance training, we have seen that both produce similar changes in fiber type composition. However, endurance training triggers increased capillary and mitochondrial density, but not hypertrophy, and resistance training produces hypertrophy without increased capillaries and mitochondria. Most studies on human subjects have considered the effects of endurance and resistance training separately. What would be the effects if athletes undertook both types of training together?

Recently, researchers found that combined resistance and endurance training improved the performance of elite male cyclists, who are recognized as endurance athletes. Fourteen men, 19.5 ± 0.8 years old, participated in 16 weeks of either endurance training alone or a combination of resistance and endurance training (seven assigned to each training group). Both groups performed 10 to 18 h of endurance (cycling) training each week. In addition, the combined strength and endurance training group followed a regimen of resistance exercises (knee extension, incline leg press, hamstring curls, and calf raises) with carefully timed rest periods. Before and after the training period, biopsies were taken from the *vastus lateralis* muscle, maximal force exerted by the quadriceps muscle was measured as an indicator of muscle strength, and endurance was assessed by all-out cycling trials on an ergometer. Compared with cyclists in the endurance training group, those who underwent combined endurance and resistance training showed greater endurance capacity, increased muscle strength, an increase in Type IIa fibers, and a reduction in Type IIx fibers. Significantly, the endurance phenotype of the muscle fibers was retained: They did not show hypertrophy, and there was no change in the number of capillaries around individual muscle fibers. The results of this study suggest that combined resistance and endurance training can improve the performance of endurance athletes—as long as careful attention is paid to the type and timing of resistance-training exercises.

TABLE 21.3 Average cross-sectional areas of individual *vastus lateralis* muscle fibers in nine men

	Type I (μm^2)	Type II (μm^2)
Pre-resistance training	3660 ± 349	4104 ± 369
Post-resistance training	4114 ± 315	$4881 \pm 244^{a,b}$
Post-detraining	3993 ± 403	4512 ± 255

Hypertrophy also occurs in cardiac muscles

Like skeletal muscle, mammalian cardiac muscle increases in size by hypertrophy (adding proteins to individual cells), not by hyperplasia (adding new cells). Normal physiological hypertrophy of the heart occurs during growth from birth to adulthood as well as in response to changing physiological conditions such as exercise training and pregnancy. Increased pressure or volume of blood in the heart chambers stimulates the heart cells (uninucleate *myocytes*) to add proteins to myofibrils, which increases cross-sectional area, and to add sarcomeres to the ends of myofibrils, which lengthens the cells. The increased cross-sectional area of the myocytes produces thicker heart walls, and the increased cell length increases the internal diameter of the heart chambers. Both of these changes occur mainly in the left ventricle. New capillaries are also added during hypertrophy (correlated with increased levels of VEGF). These morphological changes enhance cardiac function by allowing increased oxygen consumption by the myocytes, increasing the force and speed of contraction and increasing the volume of blood pumped out of the heart with each heartbeat.

Different types of exercise have different effects on the heart muscle. Endurance training stimulates increased wall thickness and increased internal diameter of the left ventricle. By contrast, resistance training such as weight lifting stimulates increased wall thickness but produces little change in the internal diameter of the left ventricle. Sports such as cycling that involve both endurance and resistance training stimulate intermediate changes.

Hypertrophy in response to imposed physiological demands on the heart is reversible when those demands diminish. For example, during pregnancy a woman's blood volume increases by up to 50% and her circulatory system grows an entire new circuit of vessels through the placenta. Both of these changes profoundly affect the heart's function. Physiologists have equated a pregnant woman's cardiovascular demands to those of an endurance-trained runner. After birth, these demands are reduced, and the heart muscle atrophies to its pre-pregnancy state.

Similarly, the hearts of grizzly bears (*Ursus arctos horribilis*) undergo reversible changes in size. During summer months, the animals are active and their hearts beat at an average rate of 84 beats per min. During the 4 to 6 months of winter, when the animals hibernate, the heart rate slows to an average of 19 beats per min. Along with this reduced function, the mass of the ventricular tissue atrophies by about 26%. When a bear arouses from hibernation and resumes its summer activities, its heart regains its summer size through hypertrophy.

In humans, heart tissue also becomes hypertrophic under pathological conditions such as chronic high blood pressure or following heart attacks. Researchers have shown that cardiac myocytes undergo different cellular changes during pathological hypertrophy than they do during normal, physiological hypertrophy. For example, pathological hypertrophy is associated with cell death, and the remaining cells switch from using mainly lipids as an energy source to using glucose. Because pathologi-

cal hypertrophy is associated with increased mortality, researchers are interested in detailing the distinction between physiological and pathological hypertrophy and designing therapies to prevent pathological hypertrophy or ameliorate its effects. Recently, they have turned to an unusual model, the Burmese python (*Python molurus*), to better understand normal hypertrophy.

The cardiac myocytes of the Burmese python show an extraordinary capacity to grow in response to stimuli. Metabolically speaking, a python leads a quiet life punctuated by occasional large meals that may be up to 50% of its body mass. With eating, rapid and dramatic changes occur. The alimentary tract elaborates structurally to support digestive processes (see Box 6.2), and other organs also increase in mass, including the liver, pancreas, kidneys, lungs, and heart. Indeed, within 48 h of feeding, the mass of the ventricle of the heart (pythons have just one ventricle; see Chapter 25) increases by 40% (Figure 21.9)!

The python's enlarged heart allows for increased arterial blood flow to support the increased metabolic demands of digesting and assimilating the meal. For example, the digestive tissues consume

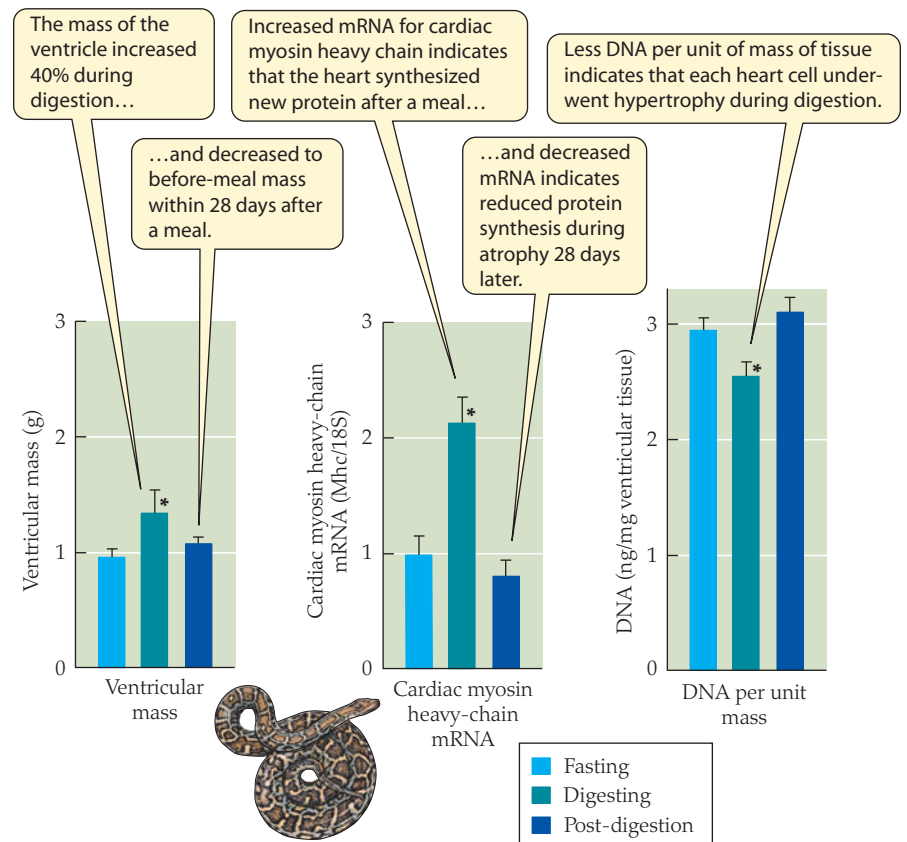

FIGURE 21.9 The heart of the Burmese python (*Python molurus*) undergoes hypertrophy within 48 h of a meal. Like other carnivorous reptiles, *P. molurus* experiences periods of metabolic quiescence between bouts of feeding, and a rapid increase in metabolism shortly after a meal. Several tissues increase in mass, including the heart. The mass of the ventricle, cardiac myosin heavy-chain (Mhc) mRNA, and DNA per unit of mass of ventricular tissue all show significant changes within 2 days of consuming a meal. The changes are reversible. The Mhc mRNA is shown relative to the 18S ribosomal subunit mRNA expression, which is constant. Six animals were included in each experimental group. The bars represent mean values ± 1 S.E.M., and * indicates a significant difference ($P < 0.05$) from the fasting value, determined by a one-tail *t* test. (After Andersen et al. 2005.)

more oxygen as they produce enzymes and transport nutrient molecules. Other tissues increase metabolic activity to store assimilated nutrients or build structural and functional molecules. During digestion, the pythons in the study shown in Figure 21.9 increased their oxygen consumption per unit of mass of body tissue nearly sevenfold. Thus cardiac hypertrophy following a meal provides an exquisite adaptation to meet transiently increased metabolic demands. And the change is reversible. When digestion ceases, the python's heart diminishes in size until the next meal is consumed.

The study illustrated in Figure 21.9 also showed that the huge growth of the python's heart was accomplished by the synthesis of new contractile proteins in the cardiac muscle cells. The researchers studied several different parameters in pythons under three different conditions: after fasting for 28 days, 2 days after consuming a meal of rats equal to 25% of their body weight, and 28 days after the meal. First the researchers determined that fluid accumulation did not account for the increase in the mass of the python's ventricle. They measured both the wet mass of the ventricle and its dry mass (after removal of water). They found that the dry mass constituted the same proportion of the wet mass in all three conditions. Had added fluid contributed to the increase in size of the ventricle, the dry mass sampled 48 h after feeding would have constituted a *smaller* proportion of the wet mass. Thus fluid accumulation did not appear to contribute to the increased mass.

To determine if increased protein synthesis accounted for the increase in wet mass of the ventricle during digestion, the research-

ers measured the amount of mRNA for the cardiac myosin heavy chain, a major protein constituent of cardiac myocytes. They found that the amount of this mRNA more than doubled, indicating that myosin was being synthesized at a greater rate during digestion than before and after digestion (see Figure 21.9). The researchers also found that the mass of DNA per unit of mass of the ventricle decreased during digestion. This result means that the mass of the tissue increased without an accompanying increase in DNA, and it indicates that the uninucleate myocytes did not divide. Thus hyperplasia did not account for the increase in mass of the ventricle. Instead hypertrophy, the same process that accounts for increase of heart size in mammals, produced the increase in ventricular mass of the python heart.

Another research group examined the molecular and cellular mechanisms that underlie cardiac hypertrophy in pythons and in mice (Figure 21.10). The researchers found that the heart of a fasted python grew in size when the animal was infused with blood plasma from a fed python for a period of 48 h (see Figure 21.10a). (They used a catheter inserted into the snake's hepatic vein to introduce the added plasma.) This result indicates that something in a fed python's plasma was able to induce hypertrophy in an unfed animal. The researchers used gas chromatography to analyze the constituents of python plasma, and they turned up three fatty acids that increased upon feeding: myristic acid, palmitic acid, and palmitoleic acid. When the researchers infused fasted pythons with a mixture of these fatty acids (in a molar ratio of 1 palmitoleic acid :

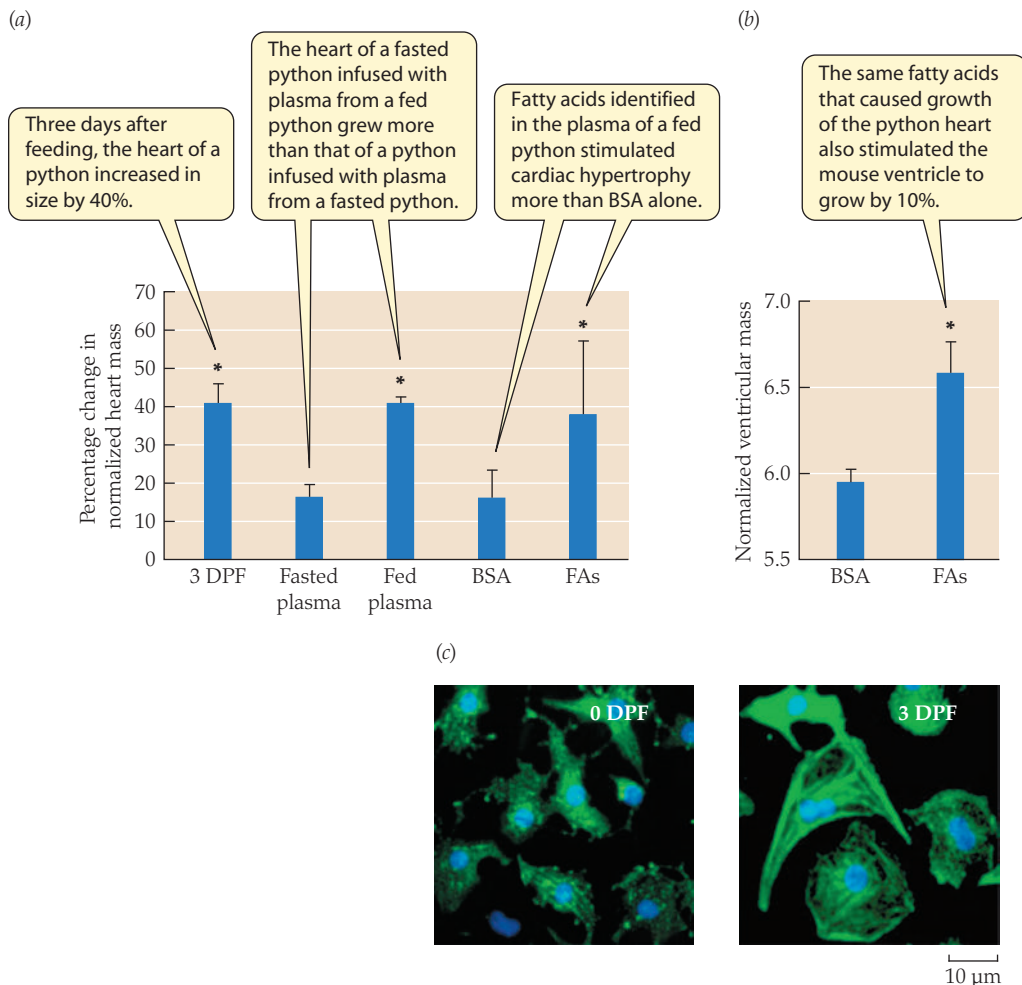

FIGURE 21.10 Fatty acids (FAs) in the plasma of fed Burmese pythons stimulate growth of the python heart, mouse heart, and rat cardiac cells. As described in the text, researchers identified three FAs that increased in the plasma of fed pythons. To determine whether these FAs were acting to induce cardiac hypertrophy, the researchers infused unfed pythons with an artificial mixture of the three FAs dissolved in a bovine serum albumin solution (BSA). (a) Three pythons were infused for 48 h with plasma from a fed or a fasted python, with BSA alone, or with the FAs in BSA and were then compared with pythons that had been fed 3 days earlier (3 days post-feeding [DPF]). The python heart mass was normalized by dividing heart weight by body weight. Error bars represent \pm SE; * indicates $P < 0.05$ for tested python heart versus a fasted heart. (b) Six mice were infused for 7 days with either BSA alone or the FAs in BSA. The mouse heart mass was normalized by dividing left ventricular mass by tibia length. The error bars represent \pm SE; * indicates $P < 0.05$ for the effect of FAs versus BSA on mouse ventricle. (c) Cultured rat cardiac myocytes were treated with plasma from fasted pythons (0 DPF) or from fed pythons (3 DPF). The fed plasma caused hypertrophy of the myocytes. Similar results were obtained by treating cultured cells with the FA mixture (not shown). In these fluorescence micrographs, the nuclei are blue and a cytoskeletal protein in the cytoplasm is green. (After Riquelme et al. 2011.)

6 myristic acid : 16 palmitic acid), they observed an increase in the size of the heart that was similar to that seen in a fed python 3 days after eating (days post-feeding [DPF]; see Figure 21.10a). Amazingly, when mouse pups were infused with the same fatty acid mixture for 7 days, their ventricles grew by about 10% (see Figure 21.10b).

In different experiments, the researchers found that culture medium containing either plasma from a fed python or the fatty acid mixture stimulated hypertrophy of cultured rat ventricular cells (see Figure 21.10c). The molecular characteristics of the hypertrophic rat cells were those of physiological, not pathological, hypertrophy. This study's findings are encouraging to cardiologists in their quest for interventions that would steer cardiac myocytes away from pathological hypertrophy in human disease states. The finding that the same combination of molecules stimulates physiological hypertrophy in widely divergent species is also intriguing from an evolutionary perspective.

Atrophy

Muscle that is not used will atrophy. When a person wears a cast on her leg, for example, that immobilizes the muscles of the leg, she can lose as much as 20% of the mass of the affected muscles in just a few weeks. The tissue wastes away, and for this reason atrophy is also referred to as *wasting*. Clinical forms of *disuse atrophy* arise not only from limb casting but also from bed rest, spinal cord injuries that cut off nerve input to skeletal muscles, and direct injuries to nerves that innervate muscles. Further, disuse atrophy in sedentary elderly persons adds to and compounds the inevitable atrophy that occurs with aging. Because skeletal muscles play important roles in maintaining posture and producing body movements, impairment of their functions has a strong impact both on the quality of life of individuals and on broader dimensions of public health. Prolonged disuse can lead to changes in muscle structure and function that require lengthy rehabilitation programs and major commitments of health care resources. Atrophy also occurs during starvation, in chronic diseases such as HIV/AIDS, and in genetic diseases such as muscular dystrophy.

Because muscle is the body's main protein store, all muscles continuously synthesize and degrade structural proteins. Normally these two processes are kept in balance. When muscles atrophy, the muscle fibers decrease their uptake of amino acids from the circulation and reduce protein synthesis. However, the most important cause of atrophy appears to be increased enzymatic breakdown of proteins. With the loss of actin and myosin, the myofibrils are reduced, and the diameter of the muscle fibers decreases. Additional structural changes include a reduction in numbers of both mitochondria and nuclei. Biochemical changes reflect these structural changes. For example, atrophic muscles have decreased amounts of actin mRNA, cytochrome *c* mRNA, and oxidative enzymes. As we will see, the molecular signals that trigger these catabolic actions (in which protein degradation exceeds protein synthesis) are not simply the opposite of those that trigger anabolic actions (net protein synthesis) in hypertrophy.

Humans experience atrophy in microgravity

One cause of disuse atrophy is weightlessness during space travel. For example, when researchers used imaging techniques to analyze the cross-sectional area of astronauts' leg muscles after space shuttle missions of 8 to 17 days, they found that the cross-sectional area had decreased 4% to 10% in *gastrocnemius* (calf) muscles and 5% to 15% in quadriceps muscles. In another study, researchers used electron microscopy to examine the fine structure of muscle tissue samples taken from four astronauts who spent 17 days on a space shuttle mission. Forty-five days before launch, tissue samples were taken from the *soleus* muscle by needle biopsy. Within 3 h after the shuttle had landed, postflight biopsies were taken. In humans, the *soleus* consists of about 70% slow Type I fibers. It is an important weight-bearing ("anti-gravity") muscle that lies just beneath the *gastrocnemius* muscle on the posterior of the lower leg (Figure 21.11). Electron micrographs of longitudinal sections of two Type I muscle fibers (Figure 21.12) provide evidence of atrophy that occurred in microgravity. Compared with the myofibrils in the preflight tissue, the diameters of the postflight myofibrils were drastically reduced, indicating loss of both thick and thin myofilaments. Indeed, within 17 days, the average diameter of the Type I fibers measured from all four astronauts on the mission decreased from $96 \pm 1 \mu\text{m}$ to $88 \pm 1 \mu\text{m}$.

Subsequently researchers analyzed the effects of longer periods of microgravity on the calf muscles of nine astronauts who spent 161 to 192 days on the International Space Station. While in space, the astronaut volunteers carried out prescribed resistance and endurance exercises. Despite the exercise regimens, the mass of the astronauts' calf muscles decreased, as did that of individual muscle

FIGURE 21.11 Major muscles of the human lower leg (a) The *tibialis anterior* muscle lies lateral to the tibia. (b) The *gastrocnemius* muscle, seen in profile, forms the calf. The *soleus* muscle is partially covered by the *gastrocnemius*.

FIGURE 21.12 Disuse atrophy occurs during space travel These electron micrographs show longitudinal sections of Type I fibers from the *soleus* muscle of an astronaut (a) 45 days before launch and (b) within 3 h of landing after a 17-day space shuttle mission. To minimize any effects of locomotion on the muscle fibers, the astronauts used wheelchairs after landing until the biopsies were taken. The dramatic reduction in myofibrillar diameter is indicated by the smaller Z discs

fibers. For example, the Type I fibers of the *soleus* diminished an average of 20% in diameter. In addition, the fiber-type composition of the *gastrocnemius* and *soleus* muscles shifted from slow to fast. The reductions in muscle size correlated with reductions in muscle strength tested before and after flight. The researchers who carried out this study noted that it is possible that even greater reductions could have occurred had the astronauts not exercised while on the Space Station.

Because the production of maximal force is proportional to the cross-sectional area of a muscle, atrophy reduces both maximal force production and power output. Decreased contractile performance caused by atrophy could contribute to a variety of risks during space flights, including inability to perform emergency escape procedures and to carry out tasks specific to a mission. The studies of astronaut muscles emphasize the importance of understanding the changes of muscle in microgravity and developing exercise plans that effectively stave off reduction of muscle mass. Until these gains are made, atrophy will remain a major obstacle to overcome before humans can achieve long-term interplanetary space travel.

Disuse influences the fiber-type composition of muscles

Studies on the *soleus* muscles of small mammals under conditions of disuse have shown increases in Type II fibers and decreases in Type I fibers.⁴ These results were observed using different experimental techniques, such as immobilizing the hindlimb with a cast to set the muscle in a shortened position (to eliminate the possibility of

⁴As in humans, the *soleus* is normally composed of predominantly slow muscle fibers. The *soleus* muscle of rats consists of 89% Type I fibers and 11% Type IIa fibers, whereas the *soleus* muscle of cats consists of 99% Type I fibers and only 1% Type IIa fibers. The fast Type IIb is entirely absent from the *soleus* in both rats and cats.

(brackets) in the postflight tissue. These slow Type I fibers have relatively little sarcoplasmic reticulum. The large lipid droplets indicate that these postflight muscles accumulated lipids. Interestingly, electron micrographs of muscle fibers of astronauts who spent 6 months on the International Space Station showed reduced lipid accumulation. (From Widrick et al. 1999.)

its exerting force on a load or receiving any mechanical stimulus) and denervation (to eliminate neural stimulation). Changes in fiber-type composition appear to occur very shortly after the onset of disuse. One study reported that rat *soleus* muscles immobilized in a shortened position for 5 days began to transcribe the fast Type IIb genes within 1 day of immobilization.

In humans, some short-term studies of disuse (such as imposed bed rest) have found changes in fiber-type composition, whereas others have found little evidence of change. Limitations on the length as well as the stringency of controls of such studies in humans probably contribute to variations in results. However, we know that long periods of no activity at all produce profound changes in the paralyzed muscles of persons with spinal cord injuries. Muscles paralyzed for several years are severely atrophied and have hardly any slow Type I fibers. Instead, they consist of fast oxidative Type IIa and fast glycolytic Type IIx fibers, with a preponderance of Type IIx fibers. These muscles also express a fast SR Ca^{2+} -ATPase.

Taking these observations into account, researchers have proposed that the fast Type IIx fiber is the “default” fiber type of muscles. If a muscle fiber does not produce contractions that generate force, or is not mechanically stretched, it expresses the Type IIx genes, produces the fastest myosin isoform, and attains a fast phenotype. Mechanical activity is thought to activate expression of the Type I and Type IIa genes, and probably to repress the Type IIx genes.

Muscles atrophy with age

Starting around age 40, humans lose as much as 1% to 2% of muscle mass each year, and this rate accelerates after age 65. The loss occurs in men and women and all ethnicities. It is reflected in declining contractile performance of even the most physically fit individuals.

Figure 21.13 shows the record speeds achieved by athletes in track

FIGURE 21.13 Record speeds achieved by athletes decrease with age (a) Record speeds for men and women running in the 400-m dash. (b) Record running speeds for men in events of three different lengths. The curves were fitted to data obtained from published records. (After Moore 1975.)

and field events. No matter the event, peak speed declines with age. Peak performance is reached at different ages for events of different distances. Thus, sprinters in the 200-m dash achieve their maximum performance at about 21 or 22 years of age, whereas record marathon runners peak in their late 20s. In addition, the slopes of decline in speed with age are steeper for the fast events, which depend more on power output, than for the marathon, which requires endurance. These observations suggest that power output (combined force and velocity of shortening) decreases more rapidly with age than does stamina.

What happens to muscles as they age that causes them to decrease in contractile performance? If disuse atrophy were the only change, then world-class athletes who maintain rigorous exercise programs would not show a decline. But they do. In fact, aging muscles show not only disuse atrophy of individual fibers, but also the loss of muscle fibers. Age-related loss of muscle mass, with its related loss of strength and function, is called **sarcopenia**. Initial studies on aging muscles suggested that the death of motor neurons in the spinal cord was the main cause of the loss of muscle fibers. All of the muscle fibers of a motor unit of a dead motor neuron would lose their innervation and also die (see Figure 20.15). However, only about 10% to 15% of motor neurons die during normal aging. Recently researchers have found evidence that suggests that structural abnormalities develop in some but not all of the distal branches of an aging motor neuron, and that these branches disconnect from the muscle fibers they innervate. The remaining branches retain functional contacts with the muscle fibers. If the denervated muscle fibers were reinnervated by new neural sprouts, they would survive. However, aging motor neurons are less capable of sprouting new distal branches, and some muscle fibers die because they lose neural contact permanently. The motor neuron survives, but the muscle has lost a portion of the muscle fibers of that motor unit.

Other studies have shown that aging muscle fibers retain the molecular machinery for regeneration. Through normal daily activities, muscles of all ages undergo minor injuries and continual processes of repair. Studies of aging animals show that their muscles actively express molecules that trigger repair and regeneration

(including proliferation of satellite cells; see page 564). This robust regenerative activity is very different from the proteolytic degradation that occurs in atrophy of disease and disuse. The presence of molecules required for repair and regeneration suggests that aging muscle fibers show normal responses to activity. But regenerative processes of many fibers in aging muscle ultimately fail before completion, and atrophy results. Numerous growth factors and hormones influence the maintenance and repair of motor neurons, nerve–muscle synapses, and muscle cells. Studies on the effects of these chemical signals and the roles they play in the interactions between muscle fibers and motor neurons may yield information on treatments that could prevent or delay the loss of muscle mass.

At present no treatments are known to stop the effects of aging on muscle. The loss of muscle mass contributes to an inability to adjust posture and maintain balance, which leads to the potential for falls or inappropriate movements that lead to injury. Encouraging studies on elderly populations strongly suggest, however, that resistance training maintained for prolonged periods is feasible and increases not only muscle strength but also coordination. Thus caregivers encourage elderly persons to remain active. Conditioning exercises to prevent injuries and reduce atrophy from disuse can forestall the effects of muscle fiber loss (which at present is inevitable) and contribute to ensuring mobility and independence well into old age. It is generally believed that younger persons can also forestall some of the effects of aging by exercising regularly to maintain endurance capacity, muscle strength, and coordination.

Some animals experience little or no disuse atrophy

As we saw in Chapter 20, the muscles of all vertebrate animals are structurally and functionally very similar. Yet, although humans and many experimental mammals experience notable losses of muscle after remarkably short periods of disuse, other animals can spend extended periods hibernating or estivating and have very little loss of muscle structure and function. **Box 21.1** describes the amazing resistance to atrophy shown by an estivating Australian frog. Black bears (**Figure 21.14**) also show little disuse atrophy. They

BOX 21.1 NO TIME TO LOSE

The Australian green-striped burrowing frog (*Cyclorana alboguttata*) can undergo months or even years of immobility and starvation with little muscle atrophy. *C. alboguttata* estivates underground within a cocoon of shed skin and mucus and emerges only during periods of heavy summer rains, which do not necessarily happen every year. During the few weeks when water is available, these frogs must breed and feed before again becoming dormant. To be successful in accomplishing these goals in a limited amount of time, they require muscles that are immediately functional. Interestingly, a study of frogs that estivated for 3 months found no atrophy in all muscles examined, and isolated muscles tested in vitro did not show a decrease in force production compared with those of control nonestivating frogs. Additional studies of frogs that estivated for 6 or 9 months showed evidence of atrophy based on decreased muscle fiber diameters. However, the large jumping muscles showed less atrophy than did smaller non-jumping muscles.

The contractile functions of muscles tested in vitro after 6 and 9 months' estivation showed greater fatigue and somewhat slower

rates of contraction. However, the power output of the muscles was still similar to that of controls. Thus, over long periods of disuse and anorexia, the muscles of *Cyclorana* show selective atrophy that allows them to retain contractile properties that ensure the frog's ability to emerge and breed.

The authors of these studies noted that frogs typically have low metabolic rates, which decrease to extremely low levels during estivation. Still, over several months of anorexia, lipid reserves would be depleted and proteins would be catabolized for fuel to maintain metabolism. In *Cyclorana*, the proteins of non-jumping muscles appear to be catabolized preferentially in order to conserve the myofibrils of the jumping muscles for actions required at emergence.

Reduced metabolism would result in frog muscle tissues producing only low levels of reactive oxygen species (ROS), such as hydrogen peroxide. ROS are released from mitochondria during aerobic metabolism, and they are known to cause cellular damage

Green-striped burrowing frog (*Cyclorana alboguttata*)

(see Box 8.1). To protect against ROS, cells produce antioxidants, such as superoxide dismutase, that scavenge and inactivate ROS. It is possible that the frog's low metabolic rate is one factor that slows disuse atrophy of its muscles. Low mitochondrial activity would yield very low levels of ROS and keep protein degradation and atrophy at a minimum. A possible additional protective measure in estivating *Cyclorana* is that the jumping muscles produce higher levels of antioxidants than do the non-jumping muscles.

FIGURE 21.14 The American black bear (*Ursus americanus*) spends several months each winter in its den without eating or drinking. Females give birth and suckle their cubs during this period. Hibernating bears were anesthetized in their dens during early and late winter and taken to the laboratory where they were fitted with an apparatus used to assess muscle strength. After testing, the bears were returned to their dens. (After Harlow et al. 2001.)

remain inactive in their winter dens for 5 to 7 months a year, but their muscles undergo little decline in contractile capability. Field biologists give heart-stopping accounts of accidentally disturbing overwintering bears and discovering that they show no loss of locomotor ability. Experiments performed to test the strength of the *tibialis anterior* (TA; see Figure 21.11) muscles of black bears in the fall, shortly after they entered their dens, and again in the spring, shortly before they emerged, revealed that the muscles lost only 25% to 30% of their strength (measured as production of force) after 110 to 130 days of inactivity. A subsequent study of the TA muscles of bears in their dens focused on measurements of contractile parameters (such as contraction and relaxation times) and fatigue. The results showed only marginal reductions in contractile capabilities, further supporting the idea that bears resist atrophy of locomotor muscles despite inactivity and not eating.

These and other studies have led researchers to propose that overwintering bears (which do not eat, drink, urinate, or defecate) may preserve skeletal muscle protein by recycling nitrogen from urea into amino acids that can be used in protein synthesis. Indeed, measurements of protein metabolism in biopsied samples of *vastus lateralis* muscles taken from bears suggest that maintained protein balance contributes to preserving the integrity of muscles. Researchers collected biopsies in summer and during early and late winter. Protein synthesis was greater than protein breakdown in the summer, but synthesis and breakdown occurred at equal rates throughout the winter; thus the muscles did not experience net protein loss. In dormancy, bears periodically increase the blood flow to their limbs and shiver (showing some similarity to the bouts of *arousal* seen in small mammalian hibernators; see Chapter 11, page 286). They may use shivering as a form of isometric exercise to maintain a low level of muscle use. Studying the functions of animals with muscles that resist atrophy may provide insights into how to preserve structure and function in animals (including humans) whose muscles are susceptible to wasting.

Regulating Muscle Mass

Skeletal muscles move all parts of the skeleton, generate heat, and are involved in regulating metabolism. Maintaining muscle mass, therefore, is essential to homeostasis. It is not surprising that multiple (and overlapping) controls influence the balance between anabolic and catabolic processes in this crucial tissue. As we know, net protein synthesis takes place in hypertrophy, and net protein degradation occurs in atrophy. Here we describe two mechanisms for controlling these processes: myostatin and the PI3-K–Akt1 pathway.

Myostatin

Currently researchers are avidly investigating the effects of **myostatin** on muscle mass. This growth factor (also called growth and differentiation factor-8, GDF-8) was discovered in 1997 and found to be expressed specifically in developing and adult skeletal muscles. Its function is to regulate muscle mass. Laboratory animals with mutations of the myostatin gene that make the myostatin protein inactive show remarkably increased skeletal muscle mass. Thus myostatin is referred to as a negative growth regulator.

Experiments using laboratory animals and animals with natural mutations indicate that without myostatin's regulatory effects,

hypertrophy (increase in fiber size) occurs as a result of increased protein synthesis and satellite cell activation. Myostatin binds to a receptor on the muscle cell membrane to induce intracellular signaling sequences that control growth of the cell. The growth factor negatively regulates additional features of the whole muscle, including the amount of fat deposited between muscle fibers. Studies have also shown that the myostatin gene is highly conserved in vertebrate evolution. The coding sequence of the biologically active region is identical in mouse, rat, human, pig, chicken, and turkey myostatins. Myostatin also regulates muscle growth in zebrafish, but its gene sequence is not identical to that found in mammals and birds.

Genetic studies of animals such as racing dogs and the Belgian Blue breed of cattle—and now one human child—have uncovered natural mutations in the myostatin gene that render the myostatin nonfunctional. Animal breeds with the mutation are often referred to as “double-muscled” because of the muscles' extreme bulk. For example, **Figure 21.15** compares two whippets (greyhound-like racing dogs). The whippet in Figure 21.15a is homozygous for a mutation of the myostatin gene that causes reduced production of myostatin and a striking double-muscled phenotype. Breeders describe these dogs as “bully” whippets. The whippet in Figure 21.15b is homozygous for the normal myostatin gene. Whippets that are heterozygous for the myostatin gene show some increased muscle bulk and are swifter in races than dogs that have two copies of the normal myostatin gene. Owners report that the homozygous double-muscled dogs experience cramping in the shoulder and thigh, and they are seldom used in racing.

Myostatin is of interest to researchers in human medicine, animal husbandry, and human performance. Medical therapies that reduced myostatin expression could be used to diminish muscle wasting in disease states and in aging. Ongoing efforts in animal breeding are aimed at selecting animals that produce high quantities of succulent meat but that are also cost-effective to breed (for example, the heavily muscled pelvis of a myostatin mutant

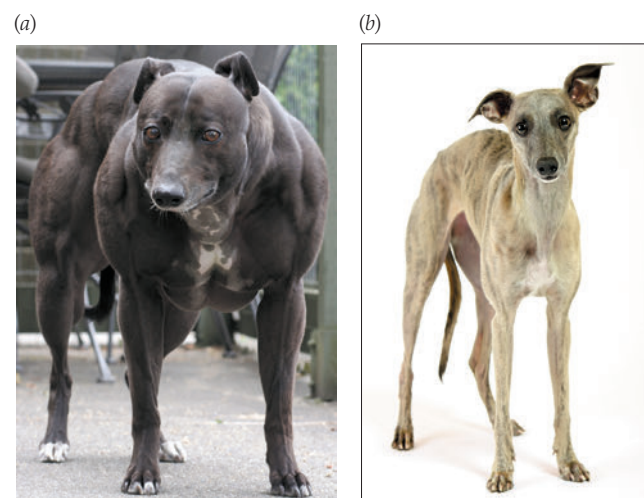

FIGURE 21.15 Whippets illustrate the role of myostatin as a negative growth regulator (a) This double-muscled dog is homozygous for a mutation of the myostatin gene that results in impaired production of myostatin. (b) This dog does not have the mutation; it expresses myostatin, which limits the growth of its skeletal muscles.

female can impede calving, making such an animal cost-ineffective to breed). Following the publication of a report in 2004 of a child possessing a myostatin mutation, coaches worldwide realized that reduced myostatin expression could have a positive effect on athletic ability. Indeed, the mother of the child was muscular, and other family members were known to be especially strong. Currently, there is lively interest in assessing the extent of polymorphisms of the myostatin gene in the human population, and the possibility of identifying “natural” athletes who could be trained to achieve peak performance.

The PI3-K–Akt1 pathway

Experiments using mouse models have revealed a pivotal protein—**Akt1**—in muscle cells that appears to regulate the balance between synthesis and degradation. Akt1 (also called protein kinase B [PKB]) is a signal-transduction molecule that regulates several molecules that promote both net protein synthesis and cell survival. Its function is strongly influenced by mechanical stimuli (that is, use and disuse) and endocrine signals. **Figure 21.16** shows that Akt1 simultaneously promotes protein synthesis and inhibits protein degradation. When a muscle exerts contractile force against a load, its cells secrete IGF-1 (insulin-like growth factor-1, also referred to as IGF-I). There are several different isoforms of IGF-1. Some circulate in the blood; for example, a major producer of IGF-1 is the liver in response to growth hormone. Other isoforms of IGF-1 act as paracrines or autocrines within the muscle. In the model shown in Figure 21.16, IGF-1 binds to its receptor on the muscle cell membrane and triggers signals that involve phosphoinositol

3-kinase (PI3-K) and Akt1 molecules. When Akt1 is activated by phosphorylation, it sets in motion molecular processes that result in increased protein synthesis. At the same time, some of the phosphorylated Akt1 molecules enter the nucleus and prevent the transcription of genes that turn on pathways leading to protein degradation. Thus in response to contractile activity, activated Akt1 ensures protein synthesis and limits protein degradation. The hormone insulin, binding to its receptor on the muscle cell membrane, also stimulates protein synthesis by the Akt1 pathway. The IGF-1–PI3-K–Akt1 pathway also balances protein synthesis and degradation in cardiac muscle cells.

When skeletal muscle fibers (which are multinuclear) become hypertrophic, they typically have the same DNA-to-protein ratio as do cells with smaller cross-sectional areas. To direct the protein synthesis necessary for repair and hypertrophy, a skeletal muscle cell incorporates satellite cells that lie just outside the muscle cell membrane, and these provide additional nuclei (and DNA) to support its increased functions. Experiments suggest that an important function of locally acting IGF-1 is to stimulate satellite cells to proliferate and fuse with the muscle fibers. Thus net protein synthesis in the muscle fiber occurs in coordination with the activation of satellite cells.

The basic Akt1 pattern is intertwined with additional processes. First, the molecules downstream from Akt1 that are involved in protein synthesis are influenced by additional factors, including available amino acids and ATP production within the cell. Second, several genes direct atrophy, and Akt1 may not inhibit all of them. Finally, there are three isoforms of Akt—Akt1, Akt2, and Akt3—each encoded by a separate gene. Whereas Akt1 regulates growth, Akt2

FIGURE 21.16 The PI3-K–Akt1 pathway provides molecular signals that govern the balance between protein synthesis and degradation. IGF-1 and insulin trigger the pathway that stimulates protein synthesis and inhibits protein degradation. When proteins are added to the cell, satellite cells contribute nuclei to support increased cellular functions. Hormones and growth factors modulate the mass of the muscle cell by mechanisms that are not yet fully elucidated. Growth hormone and androgens support protein synthesis. Glucocorticoids inhibit the PI3-K–Akt1 pathway to permit protein degradation. Myostatin limits protein production and satellite cell activation.

regulates metabolism of muscle cells in response to insulin binding to its receptor on the cell membrane (see Chapter 16, page 436. Akt3 is not expressed in muscle. Interestingly, in muscle tissue, IGF-1 and insulin overlap in function. Both stimulate protein synthesis via Akt1, and IGF-1 appears able to regulate glucose metabolism to some extent. In the overall life cycle, researchers have found that IGF-1 is essential to ensure that protein synthesis exceeds degradation during growth of young animals. In adult animals, protein synthesis is needed mainly for maintenance and repair and IGF-1 plays a lesser role—unless its secretion is stimulated by increased loading (such as resistance training), in which case its action is stepped up to produce hypertrophy. Insulin is essential for skeletal muscle metabolism in both young and adult animals, but it is not so important in hypertrophy. Growth hormone (GH) and androgens such as testosterone also promote protein synthesis. Studies are ongoing to clarify the molecular mechanisms by which these hormones work.

Atrophy occurs in an inactive muscle (such as one in a cast that does not exert force against a load) because the PI3-K–Akt1 pathway is not activated, or is activated to a lesser degree. Akt1 directs less protein synthesis, the atrophy genes it had kept in check are expressed, degradation of proteins exceeds synthesis, and there is a reduction in mass (see Figure 21.16). The Akt1 pathway is also inhibited by glucocorticoids. As we saw in Chapter 16 (see pages 433–434), glucocorticoids are secreted as part of the *stress response* to stimulate protein catabolism in muscles. The liver uses the released amino acids as a carbon source to produce glucose that is released into the blood as a fuel, especially for the brain. This response is very important to survival during starvation, for example. But corticosteroids such as prednisone, which are prescribed clinically to combat inflammation, produce muscle wasting as an unwanted side effect. Researchers are actively investigating possible interventions in the PI3-K–Akt1 pathway to prevent atrophy.

Summary

In this chapter we have considered the remarkable malleability of striated muscle. We have seen that muscles respond to use or disuse, and that they respond in particular ways to specific kinds of use. Muscle fibers decrease in mass by atrophy and increase by hypertrophy. Depending on conditions of use, they express different isoforms of functional molecules, such as the myosin heavy chain of the thick filament, the Ca^{2+} -ATPase pump of the sarcoplasmic reticulum (SR), or mitochondrial enzymes. The functions of muscle fibers are also influenced by their associations with capillaries (which proliferate around muscle fibers engaged in endurance exercise), motor neurons (which control the fiber type of an entire motor unit and also maintain a muscle fiber's viability), and hormones and growth factors (which affect the balance of protein synthesis and degradation in the muscle fiber). Although muscle fibers change in response to specific activities, an individual's genetic make-up also influences muscle function, for example by directing the proportions of different fiber types within a skeletal muscle or the degree of hypertrophy muscle fibers can achieve. Because research on muscle plasticity is motivated to a large extent by interest in human health and performance, humans and small mammals are often used as research subjects. However, other animal models (including amphibians, reptiles, and large mammals) provide useful perspectives for understanding the plastic potential of muscle.

Study Questions

1. List and describe three changes that occur during endurance training and explain how each improves endurance.
2. Define and describe hypertrophy of skeletal muscles. What conditions stimulate it?
3. Discuss the adaptive advantage of cardiac hypertrophy in a human and in a python.
4. Myostatin is termed a negative growth regulator. Explain the meaning of this term, and describe the consequences of gene mutations that cause myostatin to be nonfunctional.
5. Explain the reason sprinters benefit from tapered training before a competition. Include considerations of changes in fiber-type distribution during detraining and the factors that influence power output of muscles. Consider the fiber-type composition of muscles that would give a competitive edge to 800-m runners or to rowers who engage in rapid motions that require high power output over longer periods of time.
6. Speculate on the reasons dormant animals experience little disuse atrophy, despite inactivity and anorexia.
7. Why can't resistance exercises prevent decreased power output in aging muscles?

- Chapter 26 ■ Oxygen, Carbon Dioxide, and Internal Transport *at Work:* Diving by Marine Mammals

Previous page: By making a tube in which it lives, this marine annelid worm (*Spirographis spallanzani*)—a type of sabellid fan worm—is well poised to defend itself against predators by quickly withdrawing into the tube when danger approaches. However, supplies of oxygen (O_2) inside the tube are too meager to meet metabolic needs. Worms such as this get their O_2 from the open water. For O_2 uptake, the worms have evolved elaborate arrays of pinnately divided tentacles that they project into the open water, as seen here. The tentacles collectively present a large surface area to the water for gas exchange. Blood containing a hemoglobin-like O_2 -transport pigment circulates between the body of the worm in the tube and its tentacles. A worm quickly withdraws its exposed body parts into its tube when approached by a predator such as a carnivorous fish. Predators, however, are sometimes faster than the worms and nip off their tentacles. Worms such as these are among the most sophisticated of all animals in their ability to regenerate body parts lost in this way. They can regenerate the full array of tentacles and even their entire anterior end, including the brain.

Introduction to Oxygen and Carbon Dioxide Physiology

These aquatic animals are collecting oxygen (O_2) from the water in which they live. The O_2 is dissolved in the environmental water and must move to the cells of each animal for the cells to use it. As we discuss the movement of gases, we will follow the same convention we adopted in Chapter 5 and use the word **transport** as a general term to refer to all movements; thus when we speak of “gas transport,” we will refer in an entirely general way to any and all movements of gases from place to place, regardless of mechanism. An important characteristic of animals in their relations to O_2 is that, insofar as we now know, active transport mechanisms for O_2 do not exist, as stressed in Chapter 5 (page 109). Thus, for O_2 to move from the environmental water to the cells of an animal, conditions must be favorable for passive transport toward the cells during each and every step along the way.¹ The coral-reef worms have an elaborate circulatory system, filled with blood that is rich in a hemoglobin-like O_2 -transport pigment, and their spectacular arrays of tentacles act as gills. As their blood flows through their tentacles, O_2 enters the blood, provided conditions are favorable for passive transport from the environmental water into the blood; then the circulation of the blood delivers the O_2 to all cells. The bubble carried by the water beetle also acts as a gill. People often think that a water beetle gains O_2 solely by picking up a bubble of air from the atmosphere. In reality, a beetle gains far more O_2 by having the bubble serve as a gill while the beetle is under water. When a beetle is submerged, O_2 moves steadily into its bubble from the water, provided conditions are favorable for passive transport in that direction. The O_2 is then distributed to all the beetle’s cells by entering a system of gas-filled tubules (the tracheal system) that ramifies throughout the insect body.

How can we determine if conditions are favorable for O_2 to enter animals from their environments? Given that O_2 transport is strictly passive, why doesn’t O_2 move in the opposite direction: from the animals into their environments? These are some of the central questions we will address in this chapter. As we discuss O_2 transport, we will also discuss carbon dioxide (CO_2) transport, because O_2 and CO_2 are the principal gases that are consumed by and produced by cellular respiration (aerobic catabolism). Together, O_2 and CO_2 are called the **respiratory gases**.

Of all the exchanges of materials between an animal and its environment, the exchanges of the respiratory gases are usually the most urgent. A person, for example, dies within minutes if denied

¹See Chapter 5 for a rigorous discussion of the distinction between *active* and *passive* transport across cell membranes. A quick way to distinguish them here is to say that ATP is used in active transport but not passive transport. *Passive* transport is always in the direction of equilibrium (see page 108). *Active* transport can be opposite to that direction because during active transport, metabolic energy is employed to force materials to move in selected directions (much as a person can force a rock to roll uphill by the application of metabolic energy, even though the direction toward equilibrium is downhill). Because there are no active-transport mechanisms for O_2 , the direction of O_2 movement must always be toward equilibrium.

Both of these aquatic animals take up dissolved O_2 from the water by breathing with gills Coral-reef worms of the genus *Spirobranchus*—marine annelids (often called “Christmas tree worms”) that live in tubes embedded in corals—acquire O_2 with elaborate arrays of highly vascularized tentacles that serve as gills. The tentacles also collect food. Water beetles ostensibly breathe by acquiring bubbles of air from the atmosphere. In fact, a beetle’s bubble also serves as a gill to acquire O_2 from the water while the beetle is under water. This gill action often accounts for most of a beetle’s O_2 uptake.

O₂ but can live for days without exchanging nutrients, nitrogenous wastes, or water. The urgency of the need for O₂ arises from the role that O₂ plays as the final electron acceptor in cellular respiration. As discussed in Chapter 8 (see Figure 8.3), energy cannot be transferred from bonds of food molecules to bonds of ATP by the aerobic catabolic apparatus of a cell unless O₂ is available in the cell's mitochondria to combine with electrons exiting the electron-transport chain. The need to void CO₂ is ordinarily not as urgent as the need to acquire O₂. Nonetheless, export of CO₂ is often a pressing concern because accumulation of CO₂ in the body can rapidly acidify the body fluids and exert other harmful effects.

The respiratory gases move from place to place principally by two mechanisms: *simple diffusion* and *convection (bulk flow)*. These in fact are the only mechanisms of O₂ transport because, as already stressed, active transport of O₂ is unknown. Carbon dioxide, however, is sometimes actively transported across cell membranes in the form of bicarbonate ions (HCO₃⁻) formed by reaction with water.

An important first step in understanding respiratory gases and gas transport is to address the concept of *chemical potential* and how it is expressed in studies of gases. In Chapter 5, when we discussed the diffusion of glucose and other uncharged solutes in aqueous solutions, we concluded that (1) a solute such as glucose always diffuses from regions of a solution where it is relatively high in *concentration* to regions where it is relatively low in *concentration*, and that (2) the rate of diffusion of such a solute from region to region is directly proportional to its difference in concentration between regions (see Equation 5.1). Whereas these principles apply to the sorts of solutes and situations that have dominated our attention in earlier parts of this book, the principles are not in fact entirely general.

A truly general statement of the principles of diffusion is worded in terms of **chemical potential**. The abstract definition of chemical potential is a topic in physical chemistry; loosely, chemical potential is the strength of the tendency of a chemical substance to undergo a physical or chemical change. A practical definition of chemical potential for our purposes is to say that chemical potential provides the basis for a *truly general law of diffusion*: In all cases of diffusion, without exception, materials tend to move in net fashion from regions where their *chemical potential* is high to regions where their *chemical potential* is low, and at a rate proportional to the difference in chemical potential.

In the study of diffusion *within a single aqueous solution*, the *concentration* of a solute (the amount of solute per unit of volume) is a useful surrogate for *chemical potential* because, for most purposes, if one uses diffusion equations expressed in terms of the concentrations of solutes, one obtains correct answers. Concentration, however, is not a useful surrogate for chemical potential when analyzing the diffusion of materials *between gas mixtures and aqueous solutions*. Materials such as O₂ and CO₂ exist in both phases—both gas mixtures and aqueous solutions—and they diffuse between them. If one attempts to analyze their diffusion between phases on the basis of their concentrations, grossly erroneous conclusions are sometimes reached. To analyze such diffusion accurately, a measure of chemical potential other than concentration is needed. Physiologists use *partial pressure* to express chemical potential in the study of gases. Thus, as we proceed in our study of gases, we will often encounter the concept of partial pressure. We now turn to a discussion of partial pressure itself and of the relation of partial pressure to concentration.

FIGURE 22.1 The total pressure exerted by a mixture of gases is the sum of the partial pressures exerted by the individual constituents of the mixture. The diagram shows a container surrounding a body of dry atmospheric air at sea level. Data on the four most abundant constituents of dry air are shown. The air exerts a total pressure of 1 atmosphere (1 atm), which is the sum of the partial pressures. Each constituent would exert its same partial pressure even if the other constituents were absent.

The Properties of Gases in Gas Mixtures and Aqueous Solutions

In addition to existing in air and other types of gas mixtures, gases also *dissolve* in aqueous solutions, as already suggested. When a gas dissolves in an aqueous solution, molecules of the gas become distributed among the H₂O molecules in much the same way as glucose molecules or Na⁺ ions are incorporated among H₂O molecules when solids dissolve. The molecules of a gas *disappear* when they go into solution. They do not appear as tiny bubbles any more than glucose in solution appears as tiny sugar grains; when we see bubbles of gas, they represent gas that is *not* in solution. In this section, we first address gases in gas mixtures, then gases in aqueous solutions. We will sometimes refer to these two conditions as the *gas phase* and *liquid phase*, respectively.

Gases in the gas phase

The modern study of gases in the gas phase traces back to John Dalton (1766–1844), who articulated the *law of partial pressures*. According to this concept, the total pressure exerted by a mixture of gases (such as the atmosphere) is the sum of individual pressures exerted by each of the several component gases in the mixture (Figure 22.1). The individual pressure exerted by any particular gas in a gas mixture is termed the **partial pressure** of that gas. An important property of the partial pressure of each gas in a mixture is that it is independent of the other gases present. Moreover, in a volume of mixed gases, each component gas behaves in terms of its partial pressure as if it alone occupied the entire volume. Thus the partial pressure of each gas in a gas mixture can be calculated from the **universal gas law**,

$$PV = nRT \quad (22.1)$$

where P represents pressure, V is volume, n is the number of moles (the quantity) of gas, R is the universal gas constant, and T is the absolute temperature.² To use the universal gas law to calculate

²The partial pressure of a particular gas is symbolized by writing P with the molecular formula of the gas as a subscript. Thus, for example, the partial pressure of O₂ is symbolized P_{O_2} . In the SI, R is 8.314 J/mol·K (where K represents a Kelvin and is equivalent to one degree Celsius). Values for R in other systems of units are listed in standard reference books on chemistry and physics. When we say T is absolute temperature, we mean it is temperature on the Kelvin scale; in a room at 20°C, for example, T is 293 K.

the partial pressure of a particular gas in a gas mixture, one sets n equal to the molar quantity of the *particular gas* of interest and V equal to the volume occupied by the *gas mixture as a whole*.

A simple procedure exists to calculate the partial pressure of a gas in a mixture if one knows the proportions of the various gases in the mixture. The proportions of gases in a mixture are expressed as *fractional concentrations*. The **mole fractional concentration** of any particular gas in a mixture is the fraction of the total moles of gas present represented by the gas in question. To illustrate, in a volume of dry atmospheric air near sea level, the number of moles of O_2 is 20.95% of the total number of moles of all gases taken together; therefore, the mole fractional concentration of O_2 in dry air is 0.2095. The **volume fractional concentration** of a particular gas in a mixture is the fraction of the total volume represented by that particular gas. Equal molar quantities of different gases occupy essentially equal volumes. Thus the volume fractional concentration of a gas in a mixture is essentially the same as its mole fractional concentration. This means, for example, that if we remove the O_2 from a volume of dry atmospheric air at a given temperature and pressure and we then restore the remaining gas to the same temperature and pressure, the final volume will be 20.95% less than the original volume. It is easy to show, using the universal gas law (see Equation 22.1), that the partial pressure exerted by each gas in a mixture is “its fraction” of the total pressure, where “its fraction” means the mole fractional concentration or volume fractional concentration of the gas. Expressed algebraically, if P_{tot} is the total pressure of a gas mixture, P_x is the partial pressure of a particular gas (x) in the mixture, and F_x is the mole or volume fractional concentration of that gas, then

$$P_x = F_x P_{\text{tot}} \quad (22.2)$$

To illustrate the application of Equation 22.2, let's calculate the partial pressures of O_2 , nitrogen (N_2), and CO_2 in dry atmospheric air. Near sea level, dry air consists chemically of 20.95% O_2 , 78.08% N_2 , and 0.04% CO_2 .³ If the total pressure of the air is 1 atmosphere (atm), then the partial pressure of O_2 in the air is $(0.2095)(1 \text{ atm}) = 0.2095 \text{ atm}$, and the partial pressures of N_2 and CO_2 are 0.7808 atm and 0.0004 atm (see Figure 22.1). We discuss other units for pressure later in this chapter.

What is the relation between the *partial pressure* of a gas in a gas mixture and the *concentration* (amount per unit of volume) of the gas in the mixture? If one rearranges the universal gas law (Equation 22.1), one gets $P = (n/V)RT$. If n is the molar amount of a particular gas in a gas mixture that occupies a total volume V , then n/V is the concentration of the gas, and P is its partial pressure. Moreover, RT is a constant if the temperature T is constant. Thus, in a gas phase, the *partial pressure* and the *concentration* of any particular gas are simply proportional to each other at any given T . For example, if there are two gas mixtures that are identical in temperature and if the concentration of O_2 is 5 millimole per liter (mmol/L) in one and 10 mmol/L in the other, the partial pressure of O_2 will be exactly twice as high in the latter.

Gases in aqueous solution

The partial pressure of a gas dissolved in an aqueous solution (or any other sort of solution) is defined to be equal to the partial

pressure of the gas in a gas phase with which the solution is at equilibrium. To illustrate, consider what happens if O_2 -free water is brought into contact with air containing O_2 at a partial pressure of 0.21 atm. Let's assume, specifically, that the volume of air is so great that as O_2 dissolves in the water, there is essentially no change in the O_2 concentration of the air, and thus the partial pressure of O_2 in the air remains 0.21 atm. Oxygen will dissolve in the water until equilibrium is reached with the air. Then the partial pressure of O_2 in the aqueous solution will be 0.21 atm. If this solution is later exposed to air that contains O_2 at a partial pressure of 0.19 atm, the solution will lose O_2 to the air until a new equilibrium is established. The partial pressure of O_2 in the solution will then be 0.19 atm. The term **tension** is sometimes used as a synonym for partial pressure when speaking of gases in aqueous solutions, as when the O_2 partial pressure is called the “ O_2 tension.” We do not use the tension terminology in this book.

The *partial pressure* and the *concentration* of a gas in an aqueous solution are proportional to each other, but the nature of this proportionality is more complicated than that in gas phases. **Henry's law** is the fundamental law that relates partial pressure and concentration in aqueous solutions. There are several ways in which this law is expressed, and the various expressions employ several different, but related, coefficients.⁴ Our approach here is to use the **absorption coefficient**, defined to be the dissolved concentration of a gas when the partial pressure of the gas in solution is 1 atm. If P_x is the partial pressure of a particular gas (x) in solution, C_x is the dissolved concentration of the gas, and A is the absorption coefficient,

$$C_x = AP_x \quad (22.3)$$

In gas phases, where C_x is also proportional to P_x , the equation relating C_x and P_x is essentially identical for all gases (because all adhere to the universal gas law). In aqueous solutions, however, the proportionality constant A varies a great deal not only from one type of dissolved gas to another, but also from one solution of a particular gas to another, depending on the temperature and salinity of the water (values of A can be looked up in reference books on gas physical chemistry).

The coefficient A , the absorption coefficient, is a measure of gas *solubility*. A high absorption coefficient signifies high solubility, meaning that a lot of gas will dissolve at any particular partial pressure. With this in mind, three important characteristics of gases dissolved in aqueous solutions come to light when absorption coefficients are examined:

- The solubilities of different gases are different. Specifically, CO_2 has a far higher solubility than O_2 or N_2 . The absorption coefficients of CO_2 , O_2 , and N_2 in cold ($0^\circ C$) distilled water are 77, 2.2, and 1.1 mmol/L, respectively. These absorption coefficients tell you that if each of these gases is brought to a partial pressure of 1 atm in cold distilled water, the amount dissolved in each liter of water will be 77 mmol of CO_2 but only 2.2 mmol of O_2 and 1.1 mmol of N_2 .

³In the mid-twentieth century, the value for CO_2 was 0.03%. Burning of coal, petroleum, and forest wood has raised it to 0.04%.

⁴During the history of the study of gases in aqueous solution, an uncommonly large number of coefficients were defined by various scientists working on the subject. Many of these have survived into the present time and today are referred to by names such as *Henry's law coefficients*, the *Bunsen coefficient*, and the *Ostwald coefficient*. Although differing in detail, all describe the same principles and can be interconverted using standard equations.

FIGURE 22.2 Everyday illustrations of the effects of temperature and salinity on gas solubility

- The solubilities of gases in aqueous solutions decrease strongly with increasing water temperature. This is true of all gases. To illustrate, the absorption coefficients of O_2 in distilled water at 0°C , 20°C , and 40°C are 2.2, 1.4, and 1.0 mmol/L, respectively. Thus, if the partial pressure of O_2 is 1 atm, a liter of distilled water dissolves 2.2 mmol of O_2 when at 0°C but less than half as much, 1.0 mmol, when at 40°C . Gases tend to come out of solution and form bubbles as water warms (Figure 22.2a).
- The solubilities of gases in aqueous solutions decrease with increasing salinity. For instance, the absorption coefficients of O_2 at a fixed temperature (0°C) in distilled water, 80% seawater, and full-strength seawater are 2.2, 1.8, and 1.7 mmol/L, respectively. Increasing the salinity of an aqueous solution tends to drive gases out of solution by decreasing the solubilities of the gases, a phenomenon called the *salting-out effect* (Figure 22.2b).

SUMMARY The Properties of Gases in Gas Mixtures and Aqueous Solutions

- The total pressure of a gas mixture is the sum of the partial pressures exerted by the individual gases in the mixture. The partial pressure of each gas is independent of the other gases present.
- In gas mixtures, the concentration and the partial pressure of any given gas are simply proportional to each other. The proportionality coefficient is the same for all gases, at any given temperature, because it is a corollary of the universal gas law.
- When gases dissolve in aqueous solutions, they disappear into solution, just as sugars disappear when they dissolve. Bubbles of gas, no matter how tiny, are not in solution.

- The partial pressure of a gas dissolved in an aqueous solution is equal to the partial pressure of the same gas in a gas phase with which the solution is at equilibrium.
- In an aqueous solution, the concentration and the partial pressure of any given dissolved gas are proportional. However, the coefficient of proportionality, termed the absorption coefficient, varies greatly from gas to gas, and depends on temperature and salinity.
- Gas solubility decreases with increasing temperature and also with increasing salinity.

Diffusion of Gases

Simple diffusion, as earlier noted, is one of the two principal mechanisms of respiratory gas transport. When gases diffuse from place to place, they do so by the same fundamental mechanism by which solutes diffuse through solutions (see Chapter 5, page 101). Gas molecules move ceaselessly at random on an atomic-molecular scale. Merely by the operation of the laws of probability, when the chemical potential of a gas differs from place to place, these random movements carry more gas molecules away from regions of high chemical potential than into such regions. Macroscopically, therefore, net gas transport occurs.

The fundamental law of gas diffusion is that *gases diffuse in net fashion from areas of relatively high partial pressure to areas of relatively low partial pressure. This is true within gas mixtures, within aqueous solutions, and across gas–water interfaces.* In view of this law, the coral-reef worms we discussed at the start of this chapter can get O_2 from their environmental water only if the partial pressure of O_2 dissolved in the water is higher than the partial pressure of O_2 dissolved in their blood as the blood flows through their tentacles. Similarly, the water beetle can get O_2 from the water only if the partial pressure of O_2 dissolved in the water exceeds the partial pressure of O_2 in its bubble gas.

The diffusion of gases in the direction of the partial-pressure gradient does *not* necessarily mean that diffusion occurs in the direction of the concentration gradient. To see this enormously important point, let's first consider the most elementary cases. *Within* a gas mixture of *uniform temperature* or *within* an aqueous solution of *uniform temperature and salinity*, if the partial pressure of a particular gas is greater in one region than in another, the concentration is also greater. Thus, within such gas mixtures and aqueous solutions, when gases diffuse from high to low partial pressure, they also diffuse from high to low concentration. These elementary cases are merely simple and special cases, however. Under more complex circumstances, situations commonly exist in which gases—while obeying the fundamental law of gas diffusion—diffuse from low concentration to high concentration! Water beetles typically exemplify this scenario. If we assume a uniform temperature of 20°C , and if we assume a beetle's environmental water is at equilibrium with the atmosphere so that the O_2 partial pressure in the water is 0.21 atm, the O_2 concentration in the water is about 0.3 mmol/L (calculated from Equation 22.3 using the value for A already mentioned). Air is dramatically richer in O_2 than water is under most circumstances, as discussed later. Specifically, atmospheric air at 20°C , with an O_2 partial pressure of about 0.21 atm (see Figure 22.1), has an O_2 concentration of about 8.6 mmol/L. Let's consider a beetle that

FIGURE 22.3 The function of a water beetle's bubble as a gill: O_2 levels in the atmosphere, water, and bubble gas—and O_2 diffusion. The upper value in each box is the partial pressure of O_2 , and the lower value is the O_2 concentration. The beetle acquires each bubble from the atmosphere. Here the beetle is assumed to have used 50% of the O_2 originally in its bubble. The volume of the bubble is assumed to stay constant as O_2 is withdrawn; this is approximately true because the principal gas in the bubble, N_2 , tends to remain in the bubble even as O_2 is used. Temperature is 20°C everywhere. See the text for further explanation.

grabbed a fresh bubble from the atmosphere a while ago and has removed 50% of the O_2 from its bubble (Figure 22.3). The partial pressure of O_2 in this beetle's bubble gas will be about 0.1 atm, and the concentration of O_2 will be about 4.3 mmol/L (50% of the values in the atmospheric air). Diffusion will steadily transport O_2 from the environmental water into the beetle's bubble because the partial pressure of O_2 in the water, 0.21 atm, is far higher than the partial pressure in the bubble gas, 0.1 atm. The beetle's bubble, in other words, will act as a gill! This is true even though the *concentration* of O_2 in the beetle's bubble gas, 4.3 mmol/L, is far higher than the concentration in the water, 0.3 mmol/L. Oxygen will travel from high partial pressure to low partial pressure, as it always does, but in this situation involving both gas and liquid phases, it will move from low concentration to high concentration. Always, *equilibrium is attained with respect to any given gas when the partial pressure of the gas is uniform everywhere in a system.*

Although we will use the principles of gas diffusion in this book primarily to analyze O_2 and CO_2 , these principles apply to all substances that exist as gases under physiological conditions.⁵ Thus, for example, partial pressures govern the diffusion of gaseous anesthetics or gaseous poisons into and out of an animal's body.

⁵Water vapor (gaseous water) is a bit of a special case because, unlike other gases, it does not merely dissolve in aqueous solutions but can *become* liquid water or be generated from liquid water. It is addressed in Chapter 27.

The blood partial pressures of gases increase during diving because the air in a diver's lungs is at elevated pressure. A diver must correctly manage the increased blood partial pressures to dive safely.

FIGURE 22.4 The principles of gas diffusion are vital knowledge for scuba divers

Partial pressures also govern the diffusion of N_2 , a topic crucial for understanding the threat of decompression sickness in scuba divers (Figure 22.4) and dolphins (see Chapter 26). When a scuba diver is at any particular depth, his or her lungs are kept normally expanded by the operation of the scuba air regulator, which ensures that the air in the lungs is at a pressure equal to the ambient (environmental) water pressure at that depth. Suppose a diver is at a depth of 20 m, where the ambient water pressure is 3 atm. The total air pressure in the diver's lungs is then also 3 atm, and the partial pressure of N_2 in the lung air is 78% of the total, or 2.3 atm (assuming the diver's tanks are filled with ordinary air). If the diver remains at 20 m long enough for his or her blood to come to equilibrium with the lung air, the partial pressure of N_2 dissolved in the diver's blood will be 2.3 atm. This is not a problem as long as the diver stays at depth. However, the high N_2 partial pressure will force macroscopic bubbles to form in the diver's blood if he or she suddenly comes to the surface. The reason can be seen by imagining that an extremely minute, microscopic bubble forms in the blood (some authorities think such minuscule bubbles are always present within liquids). Let's assume the bubble contains only N_2 (a best-case scenario). Then, if the diver has come to the surface and is under 1 atm of pressure, the N_2 partial pressure in the minute bubble (gas in the gas phase) will be 1 atm. The partial pressure of N_2 dissolved in the diver's blood, however, is 2.3 atm. Thus N_2 will diffuse rapidly from the blood into the bubble, and the bubble will grow to macroscopic size. You can get an excellent visual image of this process by watching the formation of CO_2 bubbles within a recently opened bottle of pop or beer, a situation that adheres to the same physical laws. Bubbles in the blood are extremely dangerous (see Chapter 26), and their formation must be prevented. Standard practice in scuba diving is to avoid staying too long at depth. Suppose, however, that a diver has been at 20 m for such a long time that his or her blood N_2 partial pressure is 2.3

atm. Before surfacing, the diver must have adequate diving skills to come partway to the surface and remain there until the blood N_2 partial pressure falls to a safe level.

The equation for the *rate* of gas diffusion is similar in form to the equation for the rate of solute diffusion presented in Chapter 5 (see page 102). Consider a fluid system (consisting of a gas phase, liquid phase, or both) in which a gas, such as O_2 , is at a relatively high partial pressure, P_1 , in one region and a relatively low partial pressure, P_2 , in another. Think of an imaginary plane that is perpendicular to the direction of diffusion between the two regions. Let J be the rate of net movement of gas through the plane, per unit of cross-sectional area. Then

$$J = K \frac{P_1 - P_2}{X} \quad (22.4)$$

where X is the distance separating P_1 and P_2 and K is a proportionality factor that is often called the **Krogh diffusion coefficient**. As you will see, the rate of diffusion J is directly proportional to the difference in partial pressures but is inversely proportional to the distance separating the two partial pressures (see Table 5.1). The diffusion coefficient K depends on the particular diffusing gas, the temperature, and the ease with which the gas is able to pass through the particular material separating the regions of different partial pressure. If the two regions of interest are separated by a layer of tissue (e.g., a gill epithelium), K is termed the **gas permeability** of the tissue.

Gases diffuse far more readily through gas phases than through aqueous solutions

The ease with which gases diffuse is far greater when they are diffusing through air than through water. The Krogh diffusion coefficient (K) for O_2 , for example, is about 200,000 times higher in air than in water at 20°C ! One way to see the enormous implications of this difference is to consider O_2 diffusing between two regions that have a particular difference in O_2 partial pressure (i.e., a particular value for $[P_1 - P_2]$ in Equation 22.4). If the diffusion is occurring through air rather than water, the length of the diffusion path can be 200,000 times longer and still have the same rate of O_2 transport.

An interesting application of these principles is provided by analyzing the O_2 supply to mice in underground burrows, or the O_2 supply to eggs of sea turtles buried in beach sand. If the soil or sand is dry and porous, O_2 is often supplied chiefly or entirely by diffusion through the soil or sand, that is, diffusion through the network of minute gas-filled spaces among the soil or sand particles. There are virtually countless different paths—countless “angles of approach”—by which diffusion can occur from the atmosphere to the underground animals or eggs through the soil or sand. When transport along all these paths is summed, diffusion through the gas-filled spaces in soil or sand often proves adequate to meet O_2 needs. This is true, however, *only* if the spaces among the soil or sand particles are *gas-filled*. If the spaces become water-filled, the rate of O_2 diffusion drops by a factor of about 200,000—a circumstance that can have drastic consequences for the underground animals or eggs (Figure 22.5).

Diffusion through water—according to a commonly used rule of thumb—can meet the O_2 requirements of living tissues only if the distances to be covered are about *1 millimeter* or less (Box 22.1)! This rule has many important applications. A dramatic application

FIGURE 22.5 Replacement of air with water in the interstitial spaces of beach sand can cause anoxia in a sea turtle nest because diffusion is far slower through water than through air Female loggerhead sea turtles (*Caretta caretta*) come ashore to lay their eggs on ocean beaches. They bury the eggs about 40 cm deep in the sand, cover them, and leave. The eggs are dependent on O_2 diffusion through the sand to obtain O_2 during the long period (50–70 days) they require to become mature enough to hatch. The nest described here—which contained 117 eggs—was positioned unusually close to the surf’s edge, and the sand overlaying the nest became submerged under water when the eggs were about 54 days old. O_2 partial pressure in the nest was measured at regular time intervals with a fiberoptic probe permanently implanted in the nest. O_2 was sensed with a fluorescent dye on the tip of the probe. When activated by a light pulse sent down the fiberoptic cable, the dye fluoresced in an O_2 -dependent fashion. (Data kindly provided by Nathan A. Miller.)

concerns the consequences of liquid accumulation in a person’s lungs: Just a small accumulation of body fluids in the terminal air spaces of a person’s lungs immediately creates a dire medical emergency because of the small diffusion distance that is tolerable with water present.

The difference between air and water in the ease of diffusion of CO_2 is less than that for O_2 , but still substantial. The Krogh diffusion coefficient for CO_2 at 20°C is about 9000 times greater in air than in water.

Gas molecules that combine chemically with other molecules cease to contribute to the gas partial pressure

Only gas molecules that exist as free gas molecules contribute to the partial pressure of a gas. This may seem an odd point to stress until you realize that, especially in body fluids, gas molecules often undergo chemical reactions. Molecules of O_2 in the blood of a person or coral-reef worm, for example, combine chemically with hemoglobin or hemoglobin-like pigments, and those molecules of O_2 then *do not* contribute to the partial pressure of O_2 in the blood. Only O_2 molecules that are free in solution contribute to the partial pressure. Similarly, CO_2 molecules added to blood—or to an environmental liquid such as seawater—may react with H_2O to yield chemical forms such as HCO_3^- (bicar-

BOX 22.1 DIFFUSION THROUGH TISSUES CAN MEET O₂ REQUIREMENTS OVER DISTANCES OF ONLY 1 MILLIMETER OR LESS

August Krogh (1874–1949), one of the great names in respiratory physiology, was the first to quantify the distance over which the simple diffusion of O₂ through tissues might meet the O₂ requirements of life. Oxygen diffuses less rapidly through animal tissues than through pure water, and Krogh assumed, on the basis of the evidence available in his lifetime, a rate of one-third the rate in water. As his model, he considered a spherical cell with a rate of O₂ consumption of 0.1 mL O₂ /g·h (relatively low) and an O₂ partial pressure of about 0.21 atm at the surface (relatively high). He calculated that diffusion of O₂ through such a cell would meet the O₂ demands of all its parts only if the cell radius were no greater than 0.9 mm! Modern recalculations come up with similar results. Thus Krogh's major conclusion still stands: Diffusion from a high-partial-pressure source through the aqueous medium of tissue can be expected to supply the ordinary O₂ requirements of aerobic catabolism over only short distances—approximately 1 mm or less.

Over truly minute distances, such as the distance across a cell membrane, diffusion

transport is very fast. However, the rate of diffusion falls as distance increases (see Table 5.1), and in general, for O₂ transport to occur at a rate sufficient to supply the needs of tissues at distances greater than about 1 mm, convective transport—transport by a moving fluid, such as circulation of blood—needs to supplement diffusion.

The larvae of bony fish—some of which are the smallest of all vertebrate animals—present important examples of the application of these principles. The young of some species are so immature at hatching that they lack an effective circulatory system. Thus their interior tissues must receive O₂ from their body surfaces largely by diffusion. As a young larva grows, diffusion becomes less and less certain to be able to meet all its O₂ needs because the increasing thickness of the larva's body means that its deepest tissues are positioned farther from its body surface. In a 3-week-old larval anchovy (illustrated), the gills are far from fully developed and circulatory development is still

A 3-week-old larva of the anchovy *Engraulis mordax*, common along the West Coast of the United States The O₂ demand of the larva is met primarily by diffusion. The larva's average body radius is about 0.6 mm and approaching the maximum that calculations for the species indicate is compatible with uptake of O₂ by diffusion, yet the circulatory and gill-breathing systems remain immature. (Graham 1990 provides a more complete discussion; after Kramer and Ahlstrom 1968.)

incomplete, yet the thickness of the body is close to the maximum over which diffusion can meet O₂ needs. As a larval fish develops through such a transition phase—a stage at which its convective-transport mechanisms are required but still immature—it is particularly vulnerable to dying if it finds itself in low-O₂ water.

bonate ions). Only the molecules of CO₂ that are free in solution as unchanged CO₂ molecules contribute to the partial pressure of CO₂.

One noteworthy implication of these principles is that if you know the partial pressure of a gas in an aqueous solution and you use the absorption coefficient (*A*) to calculate the concentration of the gas in the solution from the partial pressure (see Equation 22.3), the concentration you obtain is that of gas free in solution as unchanged gas molecules. Any gas that is present in chemically combined form (or chemically altered form) is not included in the concentration calculated in this way.

A second noteworthy implication is that *only the gas molecules that are free in solution as unchanged gas molecules affect the direction and rate of gas diffusion* because only those gas molecules affect the partial-pressure gradient. This point is exceedingly important in many situations, one of which is the dynamics of O₂ uptake by an animal's blood as the blood flows through the gills or lungs. Let's consider an animal with hemoglobin in its blood. When O₂ diffuses from the environment into the animal's blood, the O₂ molecules that combine with hemoglobin do not increase the blood's partial pressure of O₂. Thus the hemoglobin-combined O₂ molecules do not interfere with further O₂ diffusion into the blood. To illustrate with an extreme case, suppose that all the O₂ that diffuses into an animal's blood over a period of time combines with hemoglobin. In this case, the blood O₂ partial pressure stays constant, and if the environmental O₂ partial pressure also stays constant, the difference of partial pressure driving diffusion stays constant as well. The rate of O₂ diffusion will then remain undiminished even as more and more O₂ enters the blood.

SUMMARY Diffusion of Gases

- Gases always diffuse from regions of high partial pressure to regions of low partial pressure and at a rate that is proportional to the difference in partial pressure. A gas is at equilibrium in a system when its partial pressure is uniform throughout.
- Diffusion occurs much more readily through air than water. Specifically, the Krogh diffusion coefficient is 200,000 times greater for O₂ and 9000 times greater for CO₂ in air than in water (at 20°C).
- When gas molecules undergo chemical combination, they cease to contribute to the partial pressure of the gas in question and thus no longer affect the direction or rate of diffusion of the gas.

Convective Transport of Gases: Bulk Flow

As earlier stated, besides diffusion, the second major mechanism of respiratory gas transport is convection. **Convective gas transport**—also called **transport by bulk flow**—occurs when a gas mixture or an aqueous solution *flows* and gas molecules in the gas or liquid are carried from place to place by the fluid flow. The transport of O₂ by blood flow in an animal's circulatory system provides an example.

Convective gas transport is typically *far faster* than gas diffusion because convection (bulk flow) moves gas molecules in a deterministic, forced fashion rather than depending on random molecular movements. The two principal processes by which animals set fluids in motion to transport gases are breathing and

BOX 22.2 INDUCTION OF INTERNAL FLOW BY AMBIENT CURRENTS

Animals are sometimes able to take advantage of ambient air currents (winds) or water currents in such ways that the currents induce fluid flow through their bodies or through structures they build. Prairie dogs, for example, construct their burrow systems in such a way that wind flowing *parallel* to the ground surface is forced to rise and fall as it blows across some burrow openings but not others. Because of Bernoulli's principle, the pressure exerted at some burrow openings is lower than at others as a result. Wind blowing parallel to the ground surface thus induces flow of air through the burrows—renewing O₂ supplies far underground. For a more thorough discussion of this effect and other, similar cases of internal flow induced by ambient currents, see **Box Extension 22.2**.

Black-tailed prairie dog (*Cynomys ludovicianus*)

the pumping of blood. Both cost metabolic energy. The reward an animal gets for making the metabolic investment is that it is able to speed the transport of O₂ and CO₂ from place to place.

Convection does not always require muscular effort from an animal. Ambient winds and water currents, in fact, often move O₂ and CO₂ from place to place in the environments of animals in ways that are helpful, as when global-scale water currents renew the O₂ supplies of the deep sea. Sometimes, ambient winds and water currents even induce internal flow within animals or animal-built structures (**Box 22.2**).

The precise effects of fluid flow on gas transport depend in part on the geometry of the flow. Two geometries of importance are depicted in **Figure 22.6**. One is **unidirectional flow** through a tube, such as the flow of blood through a blood vessel. The second is **tidal flow** (back-and-forth flow) in and out of a blind-ended cavity, such as occurs in the lungs of mammals. To exemplify how the rate of convective gas transport can be calculated, let's use as a model the simple case of O₂ transport by the unidirectional flow of a fluid through a tube (see **Figure 22.6a**) when there is no exchange of gases across the walls. This sort of model applies, for example, to O₂ transport through the arteries of animals because arteries basically act as conduits, neither adding O₂ to the blood passing through them nor removing O₂. In this case,

$$\text{Rate of convective gas transport} = C_T F \quad (22.5)$$

where C_T represents the *total* concentration of gas in the fluid (including both gas that is chemically combined [e.g., O₂ combined with hemoglobin] and gas that is free in solution) and F represents

the rate of fluid flow.⁶ As the equation makes clear, the rate of convective gas transport can be increased by increasing the concentration or the flow rate. Mammals and some other animals with very high demands for O₂ have evolved favorable modifications of *both* of these properties to enhance the rate of convective O₂ transport by the flow of blood through their arteries. The high concentration of hemoglobin in mammalian blood enables each volume of blood to carry 50 times more O₂ than it could carry in simple solution, and the intense work done by the mammalian heart propels blood through the arteries at very high rates (e.g., 5 L/min through the systemic aorta of an adult person during rest, and 35 L/min in trained athletes during high exertion).

Gas transport in animals often occurs by alternating convection and diffusion

Although in tiny animals O₂ may be able to move as fast as is needed from the environment to all parts of the body by diffusion (see **Box 22.1**), exclusive reliance on diffusion is not possible in animals that are larger than 2–3 g, or even in many animals that are smaller than that. The reason is *distance*. In most animal body plans, diffusion of O₂ within the body occurs through liquid media—body fluids and tissues. This fact constrains what diffusion can accomplish because diffusion through liquid media is inherently slow. It is so slow that it can meet transport needs only over very short distances. For aquatic animals, even O₂ transport to the gills from the environment must occur through a liquid medium, and thus again, diffusion can suffice only if the distances to be covered are very short. Animals that face these diffusion limitations typically employ convective transport (bulk flow) to solve the problem.

In animals that employ convective transport, diffusion and convection typically alternate as O₂ makes its way from the environment to the mitochondria. During this alternation, diffusion meets the needs for gas transport over short distances, whereas convective transport is employed for the long hauls. An apt example is provided by O₂ transport from the atmosphere to the mitochondria in a person (**Figure 22.7**). The first step in this transport is that O₂ must travel a distance of about 0.5 m from the atmosphere to minute air passageways deep in the lungs. For this transport to occur at an adequate rate, convection must be employed. Thus we breathe, moving large masses of air rapidly (by bulk flow)

⁶ F is used here as a general symbol for the rate of fluid flow. According to established convention in circulatory and respiratory physiology, the fluid flow rate would be symbolized by Q if the fluid were a liquid (e.g., blood) or V if it were a gas (e.g., air).

FIGURE 22.6 Two types of convective transport Arrows depict bulk flow of fluid.

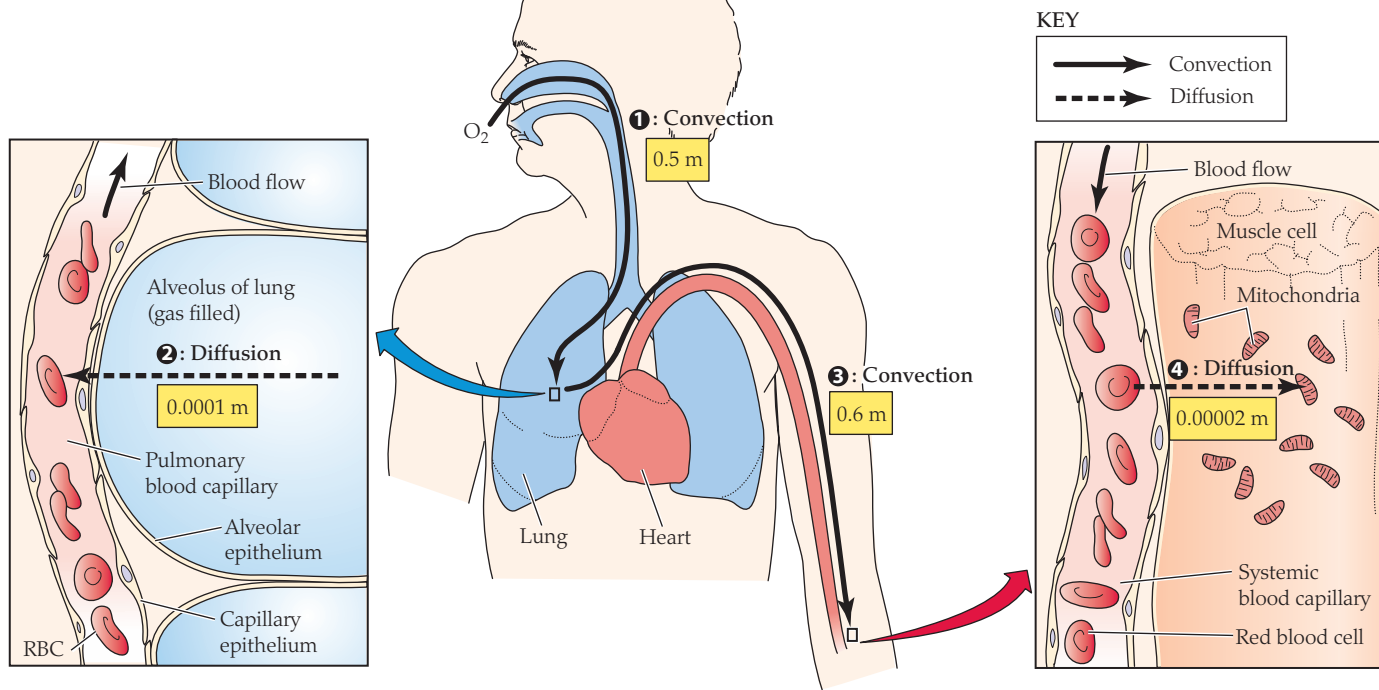

FIGURE 22.7 Convection (bulk flow) and diffusion alternate in transporting O_2 from the atmosphere to the mitochondria in a person. Four steps are recognized; the distance covered in each step is shown in meters: ① Convective transport by movement of inhaled air from the atmosphere to the depths of the lung. ② Diffusion across a gas-filled alveolar end sac (including alveolus), then through the alveolar epithelium and the epithelium of a pulmonary blood capillary, and finally

into a red blood cell (RBC), where O_2 combines with hemoglobin. Only the final 0.000006 m of this step requires diffusion through tissue or liquid; the initial 0.000094 m is covered by diffusion through gas. ③ Convective transport by the circulation of the blood. ④ Diffusion from an RBC in a systemic blood capillary to a mitochondrion in a muscle cell. Mitochondria are actually much smaller relative to the muscle cell than shown.

over long distances (step ① in Figure 22.7). Oxygen then moves by diffusion over the next 0.0001 m of distance; in this step (step ②), the O_2 crosses the minute alveolar end sacs deep in the lungs and the two epithelia (alveolar and capillary) that separate the lung air from the blood. The next long haul is the movement of O_2 from the lungs to the systemic tissues (step ③). Transport to a muscle in the forearm, 0.6 m from the lungs, is an example. This transport must be by convection—in this case, the circulation of the blood. Finally, O_2 must travel 0.00002 m from blood within systemic blood capillaries into mitochondria within tissue cells (step ④). This last step occurs by diffusion.

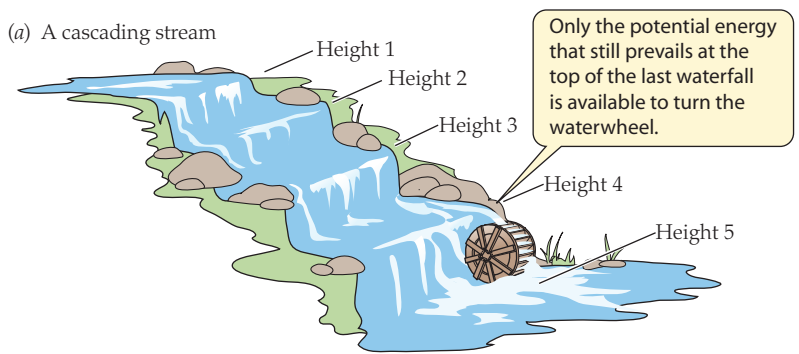

The Oxygen Cascade

The concept of the **oxygen cascade** is an especially informative way to summarize the transport of O_2 from the environment to the mitochondria of an animal. In everyday language, a *cascade* is a series of steep waterfalls along a stream. Suppose that a waterwheel (or turbine) is positioned at the base of a cascade, as shown in Figure 22.8a. The force available to turn the waterwheel is that available when the water drops from height 4 to height 5. The water starts at height 1 as it enters the cascade, but gradually, as it flows through the cascade, it drops from height 1 to 2, and then from height 2 to 3, and so forth, so that the final fall of the water—which provides the actual force to turn the waterwheel—is only from height 4 to height 5. The *oxygen cascade* is analogous to such a water cascade. To construct an oxygen cascade, one plots the O_2 partial pressure at successive steps along the path between

an animal's environmental source of O_2 and its mitochondria, as shown in Figure 22.8b. Because O_2 is not subject to active transport, the partial pressure always drops with each step, and thus the plot resembles the hydraulic analog we have discussed, a cascading mountain stream.

Why is the *partial pressure* plotted in an oxygen cascade? The answer to this question is an essential concept for having a proper understanding of the physiology of O_2 transport. The mitochondria of an animal are where O_2 is ultimately used, and—as seen in step ④ of Figure 22.7— O_2 enters the mitochondria by diffusion at a rate that depends on the difference in O_2 partial pressure between the blood in systemic capillaries and the mitochondria themselves. Just as a waterwheel on a stream requires water of a certain height immediately upstream to function, the mitochondria in each cell require a certain partial pressure of O_2 in the capillary blood near the cell surface if they are to receive O_2 fast enough by diffusion to meet their O_2 needs. From this perspective, the entire point of the O_2 -transport system in an animal is to maintain an adequately high O_2 partial pressure at cell surfaces throughout the body. With each step along the oxygen cascade, the O_2 partial pressure drops. The partial pressure at the cell surfaces must nonetheless be kept high enough for O_2 to diffuse to the mitochondria at an adequate rate.

Let's now review in greater detail the particular oxygen cascade shown in Figure 22.8b: the cascade in healthy, resting people at sea level. The first step, the transport of O_2 from the ambient air to the gas in the alveolar end sacs in the lungs, occurs by convection, as we have seen. When people breathe in their normal way, the drop in O_2 partial pressure during this step is from about 0.2 atm in the

(b) The oxygen cascade in people

ambient air⁷ to about 0.13 atm in alveolar gas. The second step of the O₂ cascade, the transport of O₂ across the alveolar sacs and through the epithelia separating the alveolar gas from the blood, occurs by diffusion. Its rate therefore depends on the difference in O₂ partial pressure between the alveolar gas and the blood. In healthy lungs, a partial-pressure difference of about 0.007 atm is sufficient to cause O₂ to diffuse at the rate required. Lungs damaged from smoking or disease often require a larger partial-pressure difference, which might mean that the blood partial pressure is lower than normal. The third step of the cascade is the convective step between arterial blood and the blood in systemic blood capillaries. Whereas the arterial blood has an O₂ partial pressure of about 0.12 atm, the partial pressure in the capillaries averages about 0.09 atm.⁸ The average partial pressure in the capillaries is dynamically determined by the rate at which blood flow brings O₂ to the capillaries and the rate at which diffusion into tissues removes O₂ from them.

The final step of the oxygen cascade is the “payoff” of O₂ transport: the diffusion-mediated transport of O₂ from the blood in systemic capillaries to the mitochondria in surrounding cells,

⁷We say “about 0.2 atm” here because in the real world, air has a variable content of water vapor (see Chapter 27). In the open atmosphere, the gas other than water vapor (the “dry air”) is always 20.95% O₂. However, this gas is diluted when water vapor is present, lowering the overall O₂ percentage and O₂ partial pressure.

⁸This step and the next are actually more complex than portrayed here, as discussed in Chapter 24, because O₂ diffuses out of capillaries all along their lengths. The “capillary partial pressure” is thus not a single number, but drops from a relatively high value at the arterial ends of capillaries to a lower value at the venous ends.

FIGURE 22.8 The concept of the physiological oxygen cascade is based on an analogy with a cascade along a mountain stream (a) In a cascading stream, water loses potential energy each time it falls lower. (b) In a person, the O₂ partial pressure drops with each step in oxygen transport. In (a), the height numbers refer to sequentially lower heights along the stream’s path; kinetic energy is ignored but would have to be taken into account for a full physical analysis. In (b), the numerical values are representative values for a healthy, resting individual at sea level; the partial pressure depicted for the mitochondria is estimated rather than measured and (as would be true during rest at sea level) is higher than the minimum required for unimpaired aerobic catabolism. The scales at the right show O₂ partial pressure in kilopascals (kPa) and millimeters of mercury (mm Hg).

driven by the difference in O₂ partial pressure between the blood and the mitochondria. The reason the O₂ partial pressure in the mitochondria is lower than that in the capillary blood is that the mitochondria constantly draw down the partial pressure in their vicinity by chemically consuming O₂, converting it to water. For aerobic catabolism to be unimpaired, the *mitochondrial* partial pressure cannot be allowed to fall below about 0.001 atm. The *capillary* O₂ partial pressure must therefore be kept sufficiently higher than 0.001 atm for diffusion to occur at a rate equal to the rate of mitochondrial O₂ consumption. Keeping the capillary O₂ partial pressure from slipping below this required value, as already stressed, is the key task of all the O₂-transport processes. In healthy people resting at sea level (see Figure 22.8b), the average capillary O₂ partial pressure is well above the minimum value required, providing a wide margin of safety. However, during strenuous exercise, as we shall see in upcoming chapters, all the systems responsible for O₂ delivery may need to operate near their limits if they are simply to keep the capillary partial pressure above the minimum value required.

Expressing the Amounts and Partial Pressures of Gases in Other Units

Up to now, to keep units of measure simple while we have developed the principles of gas transport, we have always expressed the amounts of gases in moles and the partial pressures in atmospheres. Most of the alternative units in use are very straightforward. Amounts, for example, are sometimes expressed in grams, and for any given gas there is simply a proportional relation between moles and grams (1 mole weighs 1 gram molecular weight). Similarly, all the units of pressure in use are simply proportional to each other.⁹

⁹The units of measure for pressure, although all proportional to one another, can present vexing problems at present because several disparate systems of units exist, and different branches of physiology have progressed to different degrees in adopting SI units. Moreover, in the United States (although not elsewhere), there has been great resistance in everyday life to abandoning old-fashioned units of measure such as millimeters of mercury (mm Hg) and pounds per square inch (psi). The basic SI unit of pressure is the pascal (Pa)—equal to a newton per square meter (N/m²). This is such a tiny pressure that nearly always in physiology, the kilopascal (kPa) is the SI unit used. The millimeter of mercury (mm Hg), although now being left behind, has seen extensive use in physiology for many decades; it is the pressure exerted by a column of mercury 1 mm high under standard gravitational acceleration. Another old unit used often in physiology for many decades is the torr (Torr), which is essentially identical to a millimeter of mercury. 1 kPa ≈ 7.5 mm Hg. Also, 1 kPa ≈ 0.01 atm. An atmosphere (atm) is 760 mm Hg or about 101 kPa.

TABLE 22.1 The usual maximum concentration of O₂ in air, freshwater, and seawater at three temperatures

The concentrations listed are for air at sea level and for fully aerated freshwater and seawater equilibrated with such air. In other words, the O₂ partial pressure is 0.21 atm in all cases. For the most part, actual O₂ concentrations in natural environments are either as high as shown or lower (because of O₂ depletion by organisms).

	Concentration of O ₂ (mL O ₂ at STP/L) at specified temperature		
	0°C	12°C	24°C
Air	210	200	192
Freshwater	10.2	7.7	6.2
Seawater ^a	8.0	6.1	4.9

^a The values given are for full-strength seawater having a salinity of 36 g/kg.

What can be confusing is that amounts of gases are often expressed as volumes of gases. The amount of a gas in moles is simply proportional to the volume of the gas if the volume is expressed at **standard conditions of temperature and pressure (STP)**, meaning a temperature of 0°C (273 K) and a pressure of 1 atm (101 kPa; 760 mm Hg). This relation is so simple that it does not even vary among gases; for essentially all gases, 1 mole occupies 22.4 L at STP. The reason that volumetric expressions can get confusing is that the volume occupied by a given molar amount of gas depends on temperature and pressure (see Equation 22.1). Because of this dependency, if we are thinking about a gas that is at a temperature and pressure different from 0°C and 1 atm, the gas has *two* volumes of potential interest. One is the volume the gas actually occupies under the conditions where it exists. The other is its volume at STP. Suppose, for example, that we are studying the lung gas of a person who is standing at a location where the barometric pressure is 740 mm Hg and we are concerned about 0.0446 mole of O₂ in the lung gas. In the lungs, where this gas is at a temperature of 37°C and a pressure of 740 mm Hg, the O₂ occupies a volume of 1170 mL. However, this same quantity of O₂ occupies only 1000 mL at STP. Appendix C provides more detail on these calculations. When gas volume is used as a way of expressing the absolute amount of a gas (the molar quantity of the gas), the volume at STP is the volume used, because it is this volume that bears an unvarying, one-to-one relation to the number of moles.

Another aspect of volumes that can be confusing arises from the common practice, among biologists, of expressing the amount of gas *dissolved in an aqueous solution* as a volume of gas at STP. Let's illustrate. Suppose that a liter of an aqueous solution has dissolved in it an amount of O₂ that, in gaseous form, would occupy 2 mL at STP. Biologists then often say that the concentration of O₂ in the solution is "2 mL O₂/L." Except for the units used, this expression is no different from saying that there is a certain number of moles dissolved per liter. What can be confusing is that the gas occupies the stated volume only if it is *removed* from solution and placed at STP. When the gas is *actually in* solution, it essentially does not occupy any volume at all.

The Contrasting Physical Properties of Air and Water

Air and other gas phases differ dramatically from water and aqueous solutions in many physical properties that are of critical

importance for the physiology of the respiratory gases. We have already stressed that gases diffuse much more readily through air than through water. Other properties—such as density and viscosity—also differ dramatically between air and water.

Water is much more dense and viscous than air. At 20°C, for example, the density of water (about 1 g/mL) is more than 800 times higher than the density of sea-level air (about 0.0012 g/mL). The viscosity of water is 35 times higher than that of air at 40°C and more than 100 times higher at 0°C. Because of water's greater density and viscosity, water-breathing animals must generally expend more energy than air-breathing ones to move a given volume of fluid through their respiratory passages.

Dramatic differences also typically exist between air and water in natural environments in the amounts of O₂ they contain per unit of volume (Table 22.1). Ordinary atmospheric air is about 21% O₂, as we have seen. This means that if air is at sea level and at 0°C, it contains 210 mL of O₂, measured at STP, per liter. Warming the air lowers its absolute concentration of O₂ a little because gases expand and become more rarefied when they are heated, but even at 24°C, atmospheric air at sea level contains 192 mL of O₂ (measured at STP) per liter.¹⁰ The amounts of O₂ per liter in water are dramatically lower because they depend on the *solubility* of O₂ in water, and O₂ is not particularly soluble. If freshwater at 0°C is equilibrated with atmospheric air at sea level so that the partial pressure of O₂ in the water is identical to that in the atmosphere (0.21 atm), the water dissolves 10.2 mL of O₂ per liter. Seawater, because of its salinity, dissolves less O₂ under the same conditions (see Table 22.1). Both freshwater and seawater dissolve less O₂ as they are warmed because the solubility of O₂ decreases as temperature increases. Overall, as is dramatically evident in Table 22.1, *the maximum O₂ concentration likely to occur in bodies of water is 5% or less of the concentration in air at sea level*. One way to appreciate the quantitative significance of these numbers is to consider a hypothetical terrestrial or aquatic animal that is trying to obtain a liter of O₂ by completely extracting the O₂ from a volume of its environmental medium. At 0°C, this animal would need to process 4.8 L of air, 98 L of freshwater, and 125 L of seawater!

¹⁰ Air at 24°C contains 210 mL of O₂ per liter when the volume of O₂ is measured at 24°C. However, the air is less dense than air at 0°C and thus contains less mass of O₂ per liter than air at 0°C. This effect of temperature is removed by correcting to STP. The O₂ that occupies 210 mL at 24°C will occupy only 192 mL at STP.

Water actually presents animals with a *combination* of properties that together make water a far more difficult place to acquire O_2 than air. First, each liter of water is typically more costly than a liter of air to pump during breathing because of the relatively high density and viscosity of water. Second, each liter of water has a lower O_2 reward to provide (see Table 22.1). Together, these considerations mean that a water-breathing animal must often work much harder than an air-breathing one to obtain a given quantity of O_2 , which means that in the water-breather, a greater fraction of the O_2 taken up must be dedicated to obtaining more O_2 . Although in resting people, the cost of ventilating the lungs with air is 1–2% of the total metabolic rate, in resting fish, the cost of ventilating the gills with water is probably near 10% of the total metabolic rate.¹¹ The dramatic differences in the physical properties of air and water also undoubtedly help explain why the highest absolute metabolic rates in the animal kingdom are found in air breathers: insects, mammals, and birds. A high absolute rate of O_2 uptake is far more feasible in air than in water.

Respiratory Environments

When we consider the respiratory environments of animals in nature, biotic processes are as important as physical effects in determining the concentrations and partial pressures of O_2 and CO_2 . The processes at work in a portion of a terrestrial or aquatic environment are diagrammed in **Figure 22.9**. The animals and plants living there exert strong influences on the local concentrations and partial pressures of O_2 and CO_2 . During the day, with adequate sunlight, photosynthetic organisms add O_2 to the air or water and extract CO_2 . Animals, bacteria, and fungi remove O_2 and add CO_2 , and at night the photosynthetic organisms do the same. Any portion of the environment, as the figure shows, exchanges O_2 and CO_2 with neighboring regions by way of diffusion and convection (breezes or water currents). Diffusion always tends to equalize partial pressures across boundaries, and convection usually does so as well (by physical mixing). Thus, in any portion of the environment, it is common to find that the resident organisms collectively raise or lower the O_2 partial pressure relative to that in neighboring regions, whereas diffusion and convection simultaneously tend to even out the partial pressure from place to place. The relative strengths of these processes determine whether the O_2 partial pressure in the portion of interest becomes different from, or remains similar to, the partial pressures in neighboring regions.

In open environments on land, because breezes are ubiquitous and diffusion occurs relatively rapidly in air, the fractional composition of dry air is virtually uniform from place to place, both at sea level and over the altitudinal range occupied by animals. Oxygen, for example, represents 20.95% of the volume of dry air just about everywhere. When the concentrations and partial pressures of gases vary from place to place in open-air environments, they do so principally because of altitude (see Figure 1.13); at 4500 m (14,800 ft)—one of the highest altitudes where human settlements occur—the concentration and the partial pressure of O_2 are only about 60% as high as at sea level because the air (while still 21% O_2) is under less pressure. In contrast to open terrestrial environments,

¹¹ Measurement of the value for fish has proved challenging, and a wide range of values have been reported in the experimental literature. The value of 10% is often cited as a “best guess” of the average.

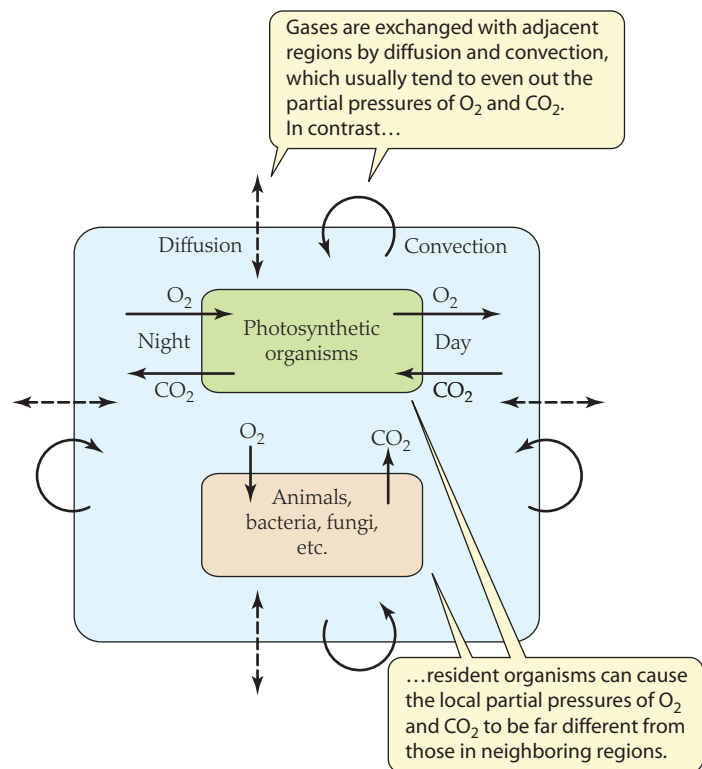

FIGURE 22.9 The processes that affect the partial pressures of O_2 and CO_2 within a portion of a terrestrial or aquatic environment. The outer box (blue) symbolizes a portion of the natural world.

in secluded ones, such as underground burrows or tunnels in wood, the metabolic activities of resident organisms often draw down the local concentration and partial pressure of O_2 and increase the level of CO_2 . These local changes are possible in secluded places because convective mixing with the open atmosphere is restricted in such places.

Regional differences in the concentrations and partial pressures of O_2 and CO_2 are far more common in aquatic environments than in terrestrial ones because in water the processes that act to even out gas levels are weaker than in air. With the evening-out processes less effective, local biotic processes are readily able to modify local gas levels. Thus, even in a completely unobstructed body of water such as a lake, the concentrations and partial pressures of gases often vary considerably from place to place (see Figure 1.14). In secluded aquatic environments populated by organisms having substantial O_2 demands, O_2 partial pressures approaching zero can readily occur.

Study Questions

1. Explain in your own words why the oxygen cascade is presented as a cascade of partial pressures.
2. Plot the rate of O_2 consumption of a fish as a function of water temperature (see Figure 10.9 if you need help). Then, based on information from this chapter, plot the O_2 concentration of fully aerated water as a function of water temperature. Why do physiologists sometimes say that high water temperatures create a “respiratory trap” for fish, a “trap” in which the fish are caught between two conflicting trends?
3. A team of investigators is out on a boat on a lake on a marvelous, sunny summer day, and they are taking water samples from various depths in the lake so as to construct a plot of dissolved

O₂ concentration versus depth, similar to the plot in Figure 1.14. When the investigators bring up a water sample from a depth of 20 m, why is it imperative that they measure its dissolved O₂ concentration immediately, rather than letting it sit on the deck for 5 minutes? (Hint: Look at Figure 22.2.)

4. In the sediments at the bottoms of ponds and lakes, there is often absolutely no O₂ at depths of 0.5 cm or more, even if the water above is rich in O₂. How is this possible?
5. The absorption coefficient of O₂ in seawater at 0°C is 1.7 mmol/L. What is the concentration of O₂ if the O₂ partial pressure is 0.1 atm? Express your answer first in mmol/L, then in mL/L.
6. Archimedes' principle states that when an object is immersed in a fluid, it is buoyed up by a force equal to the weight of the fluid displaced. Assume (slightly incorrectly) that tissue has the same density as water. Using Archimedes' principle, explain why the gill filaments of aquatic animals typically flop into a drooping mass in air even though they float near neutral buoyancy in water. How do these differences between air and water affect the ability of gills to function in gas exchange?
7. For a biologist, what are the three or four most important things to know about gas solubility?
8. Compare and contrast diffusion and convection. In what way do they "alternate" in the O₂ transport system of a mammal?
9. The hemoglobin in mammalian blood is usually thought of simply as increasing the amount of O₂ that can be carried by each liter of blood. However, in a lecture on hemoglobin, a respiratory physiologist made the following statement: "The presence of hemoglobin in the blood also makes possible the rapid uptake of O₂ by the blood as it flows through the lungs." Explain the lecturer's point.
10. When a water beetle is placed in a laboratory situation where the atmosphere is pure O₂ and the water that the beetle is in is equilibrated with the atmosphere, after the beetle obtains a new bubble from the atmosphere, it cannot stay under water for nearly as long as it can when the atmosphere is ordinary air. This is true because the bubble does not operate effectively as a gill. Explain. Assume (almost accurately) that CO₂ added to the bubble diffuses quickly out of the bubble into the surrounding water. (Hint: What is the partial pressure of O₂ in the water and in the bubble?)
11. Helicopters have been used to move young salmon from lake to lake for purposes of aquaculture in remote areas such as Alaska. From the viewpoint of the behavior of dissolved gases, why is it important for helicopters used in this way to stay at very low altitudes? (Hint: After fish were transported at altitudes where the total ambient pressure was 0.9 atm, high percentages suffered disease or death because of gas bubble formation in various tissues.)

External Respiration: The Physiology of Breathing

Tunas represent one of the pinnacles of water breathing. If they lived on land, where they could be readily observed, they would be classed metaphorically with wolves, African hunting dogs, and other strong, mobile predators. Judging by the length of time spent in motion, tunas are actually more mobile than any terrestrial predator. Using their red swimming muscles, they swim *continuously*, day and night, at speeds of one to two body lengths per second; some species cover more than 100 km per day during migrations.¹ Tunas thus rank with the elite endurance athletes among fish, the others being salmon, mackerel, billfish, and certain sharks. To meet the O₂ demands of their vigorous lifestyle, tunas require a respiratory system that can take up O₂ rapidly from the sea and a circulatory system that can deliver O₂ rapidly from the gills to tissues throughout the body. They are, in fisheries ecologist John Magnuson's memorable phrase, "astounding bundles of adaptations for efficient and rapid swimming."

Tunas breathe with gills, as do most fish. Their gills are hardly average, however. Instead, tuna gills are exceptionally specialized for O₂ uptake, illustrating a general principle in the study of respiration: that a single type of breathing system may exhibit a wide range of evolutionary refinements in various species. Based on studies of yellowfin tuna and skipjack tuna, the gills of a tuna have about eight times more surface area than the gills of a rainbow trout—a relatively average fish—of equal body size. If the gas-exchange membranes of the gills of a small, 1-kg (2.2-pound) tuna were flattened, they would form a square measuring 1.3 m on each side. The gill membranes of tunas are also exceptionally thin: Whereas the average distance between blood and water is about 5 μm in a rainbow trout's gills, it is 0.6 μm in the gills of a skipjack or yellowfin tuna. Compared with average fish, tunas have evolved gills that present an extraordinarily large surface of extraordinarily thin membrane to the water for gas exchange.

Most fish, including rainbow trout, drive water across their gills by a pumping cycle that is powered by their buccal and opercular muscles (discussed later in this chapter). Some species are adept at alternating between this mechanism of ventilating their gills and another mechanism termed **ram ventilation**. During ram ventilation, a fish simply holds its mouth open while it swims powerfully forward, thereby "ramming" water into its buccal cavity and across its gills; in this way, the swimming muscles assume responsibility for powering the flow of water across the gills. During their evolution, tunas completely abandoned the buccal–opercular pumping mechanism and became *obligate ram ventilators*, a distinction they share with just a few other sorts of fish. As obligate ram ventilators, they have no choice regarding how much of their time they spend swimming. They must swim continuously forward, or they suffocate! Physiologists debate whether ram ventilation is intrinsically superior as a way of moving water across the gills. Less debatable is the fact that tunas achieve extraordinarily high rates of water flow using ram ventilation. During routine cruising, a small, 1-kg skipjack or yellowfin tuna drives about 3.6 L of water across its gills per minute; this is seven times the resting flow rate in a 1-kg rainbow trout, and twice the maximum rate of the trout.

¹Burst speeds, which are powered relatively anaerobically by the white swimming muscles, are 12–15 body lengths per second.

Throughout the animal kingdom, species that depend on vigorous endurance exercise for survival—such as tunas—must be able to acquire oxygen rapidly Although water is not a particularly rich source of O₂, tunas have gills and breathing processes that enable them to live as highly active predators. This is a southern bluefin tuna (*Thunnus maccoyii*).

FIGURE 23.1 Generalized features of animal gas exchange O_2 and CO_2 move between the environmental medium and the internal tissues of an animal across a gas-exchange membrane.

Fundamental Concepts of External Respiration

In all animals, the systems used to exchange respiratory gases with the environment can be diagrammed as in [Figure 23.1](#). A **gas-exchange membrane** or **respiratory exchange membrane**—a thin layer of tissue consisting typically of one or two simple epithelia—separates the internal tissues of the animal from the environmental medium (air or water).² **External respiration** or **breathing**—the topic of this chapter—is the process by which O_2 is transported to the gas-exchange membrane from the environmental medium and by which CO_2 is transported away from the membrane into the environmental medium. **Ventilation** is bulk flow (convection) of air or water to and from the gas-exchange membrane during breathing. Ventilation does not always occur because breathing can occur by diffusion rather than convection.

Oxygen always crosses the gas-exchange membrane by diffusion, as stressed in Chapter 22. This means that for O_2 to enter an animal from the environment, the partial pressure of O_2 on the inside of the gas-exchange membrane *must* be lower than that on the outside. The fact that O_2 enters animals by diffusion explains why the area and thickness of the gas-exchange membrane play critical roles in O_2 acquisition. The rate of diffusion across a membrane increases in proportion to the area of the membrane. Furthermore, according to the fundamental diffusion equation (see Equation 22.4), the rate of diffusion across a membrane increases as the thickness of the membrane decreases. These physical laws explain why an expansive, thin gas-exchange membrane is a great asset for animals such as tunas that must acquire O_2 at high rates. As for CO_2 , diffusion is the exclusive mechanism by which it crosses the gas-exchange membrane in some animals (e.g., humans); in others, however, although diffusion is the principal CO_2 transport mechanism, active transport also occurs. Active transport of CO_2 (as HCO_3^-) is best documented in freshwater animals (see [Figure 5.15](#)).

Usually, just a single part of an animal is identified by name as a “breathing organ.” Other parts may participate in gas exchange

with the environment, however. Let’s briefly consider some examples that illustrate the range of possibilities. In mammals and tunas, most of the body surface—the skin—is of very low permeability to gases. Therefore, just the identified breathing organs—the lungs and gills—take up almost all O_2 and void almost all CO_2 . In a typical adult frog, by contrast, the skin is rather permeable to gases; O_2 and CO_2 are exchanged to a substantial extent across the skin as well as the lungs, and therefore the identified breathing organs—the lungs—are not the *only* breathing organs. Similarly, some fish breathe with their stomachs as well as their gills, sea stars breathe with their tube feet as well as their gills (branchial papulae), and some salamanders, lacking lungs, breathe only with their skin.

In organs that are specialized for external respiration, the gas-exchange membrane is typically thrown into extensive patterns of invagination or evagination, which greatly increase the membrane surface area. For physiologists, *gills* and *lungs* are generic labels that refer to two such patterns ([Figure 23.2](#)). **Gills** are respiratory structures that are evaginated from the body and surrounded by the environmental medium. **Lungs**, by contrast, are respiratory structures that are invaginated into the body and contain the environmental medium. The adjective **branchial** refers to structures or processes associated with gills, whereas **pulmonary** refers to those associated with lungs.

Although exceptions occur, water breathing is usually by gills, whereas air breathing is usually by lungs. The comparative method strongly indicates that lungs are adaptive for terrestrial life (see [Figure 1.18](#)). One advantage of lungs on land is that their finely divided elements receive structural support by being embedded in the body. The finely divided elements of gills project into the environmental medium. This is not a problem in water because there, the fine, evaginated gill processes are supported by the water’s substantial buoyant effect.

Gills can be *external* or *internal* (see [Figure 23.2](#)). **External gills** are located on an exposed body surface and project directly into the surrounding environmental medium. **Internal gills** are enclosed within a superficial body cavity. Whereas external placement permits ambient water currents to flow over the gills, internal placement usually requires an animal to use metabolic energy to ventilate them. Internal placement has its advantages nonetheless. When the gills are internal, the enclosing structures physically protect them and may help canalize the flow of water across the gills in ways that enhance the efficiency or control of breathing.

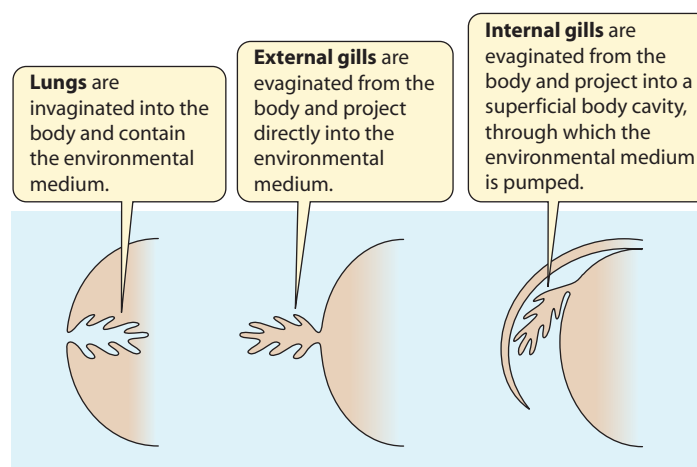

FIGURE 23.2 Three types of specialized breathing structures

²“Membrane” is used here in an entirely different way than when speaking of a cell membrane or intracellular membrane. The gas-exchange membrane is a tissue formed by one or more layers of cells.

Ventilation of lungs, gills, or other gas-exchange membranes may be *active* or *passive*. Ventilation is **active** if the animal creates the ventilatory currents of air or water that flow to and from the gas-exchange membrane, using forces of suction or positive pressure that it generates by use of metabolic energy (as by contracting muscles or beating cilia). Ventilation is **passive** if *environmental* air or water currents directly or indirectly induce flow to and from the gas-exchange membrane (see Box 22.2). Active ventilation, although it uses an animal's energy resources, is potentially more reliable, controllable, and vigorous than passive ventilation. Active ventilation may be **unidirectional**, **tidal (bidirectional)**, or **nondirectional**. It is unidirectional if air or water is pumped over the gas-exchange membrane in a one-way path. It is tidal if air or water alternately flows to and from the gas-exchange membrane via the same passages (see Figure 22.6); mammalian lungs illustrate tidal ventilation. Ventilation is nondirectional if air or water flows across the gas-exchange membrane in many directions; animals with external gills that they wave back and forth in the water exemplify nondirectional ventilation.

In air-breathing animals with lungs, the lungs are usually ventilated. Some lungs, however, exchange gases with the environment entirely by diffusion and are termed **diffusion lungs**. Some insects and spiders, for example, are believed to breathe with diffusion lungs. Within a diffusion lung, the air is still, and O_2 and CO_2 travel the full length of the lung passages by diffusion.

A **dual breather**, or **bimodal breather**, is an animal that can breathe from either air or water. Dual breathers often have at least two distinct respiratory structures, which they employ when breathing from the two media. Examples include certain air-breathing fish (with both lung- and gill-breathing) and amphibians (with both lung- and skin-breathing).

SUMMARY Fundamental Concepts of External Respiration

- Oxygen always crosses the gas-exchange membrane by diffusion. This means that O_2 enters an animal only if the O_2 partial pressure on the outside of the gas-exchange membrane is higher than that on the inside.
- Breathing organs are categorized as gills if they are evaginated structures that project into the environmental medium. They are lungs if they are invaginated structures that contain the medium.
- Ventilation is the forced flow (convection) of the environmental medium to and from the gas-exchange membrane. It is categorized as active if an animal generates the forces for flow using metabolic energy. Ventilation may be unidirectional, tidal, or nondirectional.

Principles of Gas Exchange by Active Ventilation

Active ventilation is very common, and its analysis involves several specialized concepts that apply to a variety of animals. Here we discuss the principles of active ventilation.

When an animal ventilates its breathing organ (e.g., gills or lungs) directionally—either unidirectionally or tidally—a discrete current of air or water flows to and from the gas-exchange membrane. The rate of O_2 uptake by the breathing organ then depends on (1) the

volume flow of air or water per unit of time and (2) the amount of O_2 removed from each unit of volume:

$$\text{Rate of } O_2 \text{ uptake (mL } O_2/\text{minute)} = V_{\text{medium}} (C_I - C_E) \quad (23.1)$$

where V_{medium} is the rate of flow (L/minute) of the air or water through the breathing organ, C_I is the O_2 concentration of the inhaled (inspired) medium (mL O_2 /L medium), and C_E is the O_2 concentration of the exhaled (expired) medium. The difference ($C_I - C_E$) represents the amount of O_2 removed from each unit of volume of the ventilated medium. The *percentage* of the O_2 available in the inhaled medium that is removed is $100(C_I - C_E)/C_I$. This ratio—known as the **oxygen utilization coefficient**, **oxygen extraction coefficient**, or **oxygen extraction efficiency**—expresses how thoroughly an animal is able to use the O_2 in the air or water it pumps through its lungs or gills.

To illustrate these calculations, consider a fish for which the water entering the mouth contains 6 mL O_2 /L, the water exiting the gills contains 4 mL O_2 /L, and the rate of ventilation is 0.5 L/minute. According to Equation 23.1, the fish's rate of O_2 uptake is $0.5 \text{ L/minute} \times 2 \text{ mL } O_2/\text{L} = 1 \text{ mL } O_2/\text{minute}$. Moreover, its oxygen utilization coefficient is 33%—meaning that the fish is removing 33% of the O_2 from each volume of water it pumps and is allowing the other 67% to flow out with the exhaled water. Tunas are especially efficient in using the O_2 in the water they drive over their gills. Whereas rainbow trout use 33%, yellowfin and skipjack tunas use 50–60%.

The O_2 partial pressure in blood leaving a breathing organ depends on the spatial relation between the flow of the blood and the flow of the air or water

The O_2 partial pressure in the blood leaving a breathing organ can in many ways be considered the best single measure of the breathing organ's effectiveness. This is clear from the oxygen cascade concept (see Figure 22.8b): An animal with a high O_2 partial pressure in the blood leaving its breathing organ is particularly well poised to maintain an O_2 partial pressure in its mitochondria that is sufficiently high for aerobic catabolism to proceed without being O_2 -limited. Animals are believed to control mitochondrial O_2 partial pressure in ways that limit production of reactive oxygen species (see Box 8.1). The existence of such controls does not change the fact that a sufficiently high mitochondrial O_2 partial pressure depends on having a sufficiently high O_2 partial pressure in the blood leaving the breathing organs.

Breathing organs with different designs exhibit inherent differences in the blood O_2 partial pressure they can maintain. These differences depend on the spatial relation between the flow of blood and the flow of the air or water. The differences are not absolute, because in all designs, the blood O_2 partial pressure is affected by additional factors besides spatial flow relations. Nonetheless, the flow relations between the blood and the air or water have great importance.

To explore the implications of various designs, let's start by considering tidally ventilated breathing organs, such as the lungs of mammals (Figure 23.3). Tidally ventilated breathing organs are distinguished by the fact that the medium (air in this case) next to the gas-exchange membrane is never fully fresh. The explanation is that such breathing organs are never entirely emptied between breaths. Consequently, when an animal breathes in, the fresh medium inhaled mixes—inside the breathing organ—with stale medium left behind by the previous breathing cycle, and because

FIGURE 23.3 Tidal gas exchange: O_2 transfer from the environmental medium to the blood in a tidally ventilated lung Because a tidally ventilated lung is never fully emptied, fresh medium mixes in the lung with stale medium. Numbers are O_2 partial pressures in arbitrary units: The blood arriving at the breathing organ is arbitrarily assigned a value of 0, whereas the atmosphere is arbitrarily assigned a value of 100.

of this mixing, the O_2 partial pressure of the medium next to the gas-exchange membrane is lower—often much lower—than the partial pressure in the outside environment. The O_2 partial pressure in the blood leaving the breathing organ is lower yet (see Figure 23.3), because a partial-pressure gradient must exist between the medium next to the gas-exchange membrane and the blood for O_2 to diffuse from the medium into the blood. Characteristically, in tidally ventilated structures, the O_2 partial pressure of the blood leaving the breathing organ is *below* the O_2 partial pressure of the *exhaled* medium.

When ventilation is unidirectional rather than tidal, the two most obvious relations that can exist between the flow of the medium and the flow of the blood are *cocurrent* and *countercurrent*. In the cocurrent arrangement (Figure 23.4a), the medium flows along the gas-exchange membrane in the same direction as the blood, resulting in **cocurrent gas exchange**. In the countercurrent arrangement (Figure 23.4b), the medium and blood flow in opposite directions, and **countercurrent gas exchange** occurs. *Concurrent* is sometimes used as a synonym of *cocurrent*. Thus, *cocurrent gas exchange* may also be called *concurrent gas exchange*.

In an organ that exhibits cocurrent gas exchange, when O_2 -depleted afferent³ blood first reaches the gas-exchange membrane, it meets fresh, incoming medium, as shown at the *left* of Figure 23.4a. Then, as the blood and medium flow along the exchange membrane in the same direction, they gradually approach equilibrium with each other at an O_2 partial pressure that is intermediate between their respective starting partial pressures. When the blood reaches the place where it leaves the exchange membrane, its final exchange of O_2 is with medium that has a partial pressure considerably

³Recall that *afferent* means “flowing toward”; in this case it refers to blood flowing toward the gas-exchange membrane. *Efferent* means “flowing away” and refers to blood flowing away from the gas-exchange membrane.

(a) Cocurrent gas exchange

(b) Countercurrent gas exchange

FIGURE 23.4 Cocurrent and countercurrent gas exchange: Two modes of O_2 transfer from the environmental medium to the blood when ventilation is unidirectional The upper diagram in each case depicts the flow of medium and blood along the gas-exchange membrane. Numbers are O_2 partial pressures in arbitrary units, as specified in the caption of Figure 23.3. The blood reaches a higher O_2 partial pressure when the exchange is countercurrent because the blood exchanges with fresh medium just before leaving the gas-exchange membrane. Cocurrent exchange is sometimes termed concurrent exchange.

below that of the environmental medium. Cocurrent gas exchange therefore resembles tidal exchange, in that the O_2 partial pressure of blood leaving the breathing organ cannot ordinarily rise above the partial pressure of *exhaled* medium.

In an organ that exhibits countercurrent gas exchange, when O_2 -depleted afferent blood first reaches the gas-exchange membrane, it initially meets medium that has already been substantially deoxygenated, as shown at the *right* of Figure 23.4b. However, as the blood flows along the exchange surface in the direction opposite to the flow of medium, it steadily encounters medium of higher and higher O_2 partial pressure. Thus, even as the blood picks up O_2 and its partial pressure rises, a partial-pressure gradient favoring further uptake of O_2 is maintained. The final exchange of the blood is with fresh, incoming medium of high O_2 partial pressure. Countercurrent exchange is thus an intrinsically more effective mode of exchange than either tidal or cocurrent exchange. One way to see this clearly is

FIGURE 23.5 Cross-current gas exchange: A third mode of O_2 transfer from the environmental medium to the blood when ventilation is unidirectional Numbers are O_2 partial pressures in arbitrary units, as specified in the caption of Figure 23.3. The afferent blood vessel breaks up into many vessels that “cross” the path followed by the medium; each of these vessels makes exchange contact with just a limited part of the structure through which the medium is flowing. These vessels then coalesce to form a single efferent vessel. Cross-current exchange is intermediate between cocurrent and countercurrent exchange in its intrinsic gas-transfer efficiency.

to note that the blood O_2 partial pressure created by countercurrent exchange is characteristically *much higher than the partial pressure in exhaled medium*; in principle, the O_2 partial pressure of the blood leaving the breathing organ might even approach equality with the O_2 partial pressure in *inhaled* medium. Moreover, if you compare Figures 23.4a and b, you will see that the O_2 partial pressure of the medium falls more—and that of the blood rises more—in 23.4b: Countercurrent exchange achieves a more complete transfer of O_2 from the medium to the blood than cocurrent (or tidal) exchange under comparable conditions.

When ventilation is unidirectional, a third possibility is **cross-current gas exchange**. In this type of exchange, the blood flow breaks up into multiple streams, each of which undergoes exchange with the medium along just part of the path followed by the medium (Figure 23.5). Some blood therefore undergoes gas exchange exclusively with O_2 -rich medium (although other blood exchanges with O_2 -poor medium). Cross-current exchange permits the O_2 partial pressure of the mixed blood leaving the breathing organ to be higher than that of exhaled medium, but it does not permit as high a blood O_2 partial pressure as countercurrent exchange under comparable circumstances.

The modes of exchange between the blood and the medium can be ranked in terms of their intrinsic ability to create a high O_2 partial pressure in the blood leaving the breathing organ (corresponding to their intrinsic efficiency in transferring O_2 from the medium to the blood): *Countercurrent exchange is superior to cross-current exchange, and cross-current exchange is superior to cocurrent or tidal exchange*. As already noted, however, this ranking is not absolute because additional factors affect the ways in which real breathing organs function in real animals.

The relative changes in the partial pressures of O_2 and CO_2 depend dramatically on whether air or water is breathed

Thus far we have discussed only O_2 in the blood leaving the gas-exchange surface. What about CO_2 ? The most important pattern in blood CO_2 partial pressure is a distinction between water and air breathers. *In water breathers, the partial pressure of CO_2 in the blood leaving the breathing organs is always similar to the CO_2 partial*

pressure in the ambient water, regardless of whether gas exchange is tidal, cocurrent, countercurrent, or cross-current. If the ambient water is well aerated and near zero in CO_2 , the blood is also near zero. For example, in fish in aerated water, the partial pressure of CO_2 in blood leaving the gills is typically about 0.3 kPa (2 mm Hg). In sharp contrast, *in air breathers, the partial pressure of CO_2 in the blood leaving the breathing organs is usually well above the CO_2 partial pressure in the ambient air*. In mammals and birds, for example, the partial pressure of CO_2 in blood leaving the lungs is more than ten times the corresponding value in fish; it is 5.3 kPa (40 mm Hg) in humans, for example! When vertebrates and invertebrates emerged onto land in the course of evolution, the level of CO_2 in their blood and other body fluids shifted dramatically upward.

The reason for these patterns is that during breathing, the extent to which the CO_2 partial pressure of the respired medium changes relative to the change in its O_2 partial pressure is sharply different between water breathers and air breathers. This difference arises from the different physical and chemical properties of water and air, not from the properties of the animals.

The key property of water and air applicable to these questions is the **capacitance coefficient** (β)—defined, for any particular gas, to be the change in total gas concentration per unit of change in gas partial pressure. In air, O_2 and CO_2 have the same capacitance coefficient because both adhere identically to the universal gas law (see Equation 22.1). In water, however, the capacitance coefficient for CO_2 is at least 23 times that for O_2 , in part because CO_2 is much more soluble than O_2 (each gas has a chemically specific solubility in water; see page 571). To see the implications, let’s assume that in the course of an animal’s metabolism, the number of moles of CO_2 produced is equal to the number of moles of O_2 consumed.⁴ Then, as the respired medium—air or water—passes over the gas-exchange membranes of the animal, the concentration of CO_2 in the air or water is raised by the same amount as the concentration of O_2 is lowered.

In air, the capacitance coefficients of O_2 and CO_2 are identical. Therefore, because the CO_2 concentration in respired air is raised during breathing by the same amount as the O_2 concentration is lowered, the air’s CO_2 partial pressure is raised by the same amount as its O_2 partial pressure is lowered. The green line in Figure 23.6 shows this relation graphically. The blue dot marks the partial pressures in fresh, atmospheric air (the inhaled air). The green line shows how the partial pressures of CO_2 and O_2 vary jointly in exhaled air. When an air breather lowers the O_2 partial pressure of the respired air to any given extent, it raises the partial pressure of CO_2 in the respired air to about the same extent.

In water, the capacitance coefficient of CO_2 is far greater than that of O_2 . This means that in water, although the CO_2 concentration of the respired water is raised by the same amount as the O_2 concentration is lowered, the CO_2 partial pressure is raised much less than the O_2 partial pressure is lowered. The black line in Figure 23.6 depicts this relation graphically. An animal breathing water *never* raises the partial pressure of CO_2 in respired water by much, even if it removes *all* the O_2 . As the orange areas in Figure 23.6 show, the arterial CO_2 partial pressure is typically only 0.1–0.6 kPa (1–4 mm Hg) in water breathers, whereas it is far higher, 4.0–5.4 kPa (30–40 mm Hg), in air breathers.

⁴This is a useful first approximation, although the actual relation depends on the types of foodstuffs being catabolized in the cells (see Table 7.2).

FIGURE 23.6 Air breathers and water breathers: Simultaneous values for the CO₂ partial pressure and O₂ partial pressure in the exhaled air or water The blue dot shows values for natural fresh air and for water aerated with fresh air. As air or water is subjected to gas exchange, its composition of dissolved gases shifts toward the upper left along the green line (air breathers) or black line (water breathers). The scales of partial pressure on the axes are shown in two systems of units, the SI system (kPa) and a traditional system (mm Hg)—as will often be the case in this chapter. The footnote on page 578 (right column) discusses the relations of the units used to express partial pressure. The green and black lines were calculated assuming the capacitance coefficient for CO₂ to be about 30 times that for O₂ in water (and equal to that for O₂ in air) and assuming a respiratory quotient (ratio of CO₂ production to O₂ consumption) of 0.9. Atmospheric air typically contains water vapor and therefore has a partial pressure of O₂ that is a bit lower than the value (159 mm Hg) in dry air. (After Scheid and Piiper 1997.)

SUMMARY Principles of Gas Exchange by Active Ventilation

- The oxygen utilization coefficient during breathing is the percentage of the O₂ in inhaled medium that an animal removes before exhaling the medium.
- The four major types of gas exchange that can occur during directional ventilation can be ranked in terms of their inherent ability to establish a high O₂ partial pressure in blood exiting the breathing organ. Countercurrent gas exchange ranks highest. Cross-current gas exchange ranks second. Cocurrent and tidal gas exchange rank third.
- Because of the different capacitance coefficients of air and water, air breathers typically raise the CO₂ partial pressure in air they breathe to roughly the same extent as they lower the O₂ partial pressure. Water breathers, however, do not elevate the CO₂ partial pressure in water they breathe to any great extent. Air breathers consequently tend to have much higher blood CO₂ partial pressures than water breathers.

Introduction to Vertebrate Breathing

The vertebrates living today are usually thought of, in a rough way, as representing an evolutionary sequence. In actuality, of course, today's fish were not the progenitors of today's amphibians, and today's nonavian reptiles were not the progenitors of today's mammals and birds. Thus, when we think of the sequence from fish to mammals and birds, caution is always called for in thinking of it as an evolutionary sequence. Comparisons among today's animals nonetheless often provide revealing insights into trends that occurred during evolution. Before we start our study of breathing in the various vertebrate groups, an overview of general trends will help place the individual vertebrate groups in a larger context.

The total surface area of the gas-exchange membrane is typically an allometric function of body size among species within any one group of phylogenetically related vertebrates. The allometric relation differs, however, from one group to another, as seen in [Figure 23.7a](#). Most groups of fish, the amphibians, and the reptiles other than birds have roughly similar allometric relations. This means, for example, that the total gill area of a fish of particular body size is roughly similar to the total lung area of an amphibian or reptile of the same size, suggesting that when vertebrates emerged onto land, there was not immediately much of a change in the area of the gas-exchange surface in their breathing organs. Mammals and birds, however, exhibit a dramatic step upward in the area of gas-exchange surface in their lungs (see [Figure 23.7a](#)). The mammals and the birds are independently evolved. Thus these two groups independently evolved lungs with markedly enhanced gas-exchange surface areas—probably in association with the evolution of homeothermy. As we saw in Chapter 10, homeothermy increases an animal's metabolic rate by a factor of at least four to ten. Thus lungs with an enhanced ability to take up O₂ and void CO₂ are required by homeothermic animals. Remarkably, tunas—noteworthy for being extremely active fish, as discussed at the opening of this chapter—have gill surface areas that approximate the lung surface areas of equal-sized mammals and birds!

The fact that mammals and birds have exceptionally large gas-exchange surface areas does not mean that they have large lungs compared with reptiles or amphibians. In fact, the opposite is often true. For example, if a lizard, snake, or turtle and a rodent of the same body size are compared, the lung volume of the reptile is likely to be at least five times greater than that of the rodent. Yet the surface area of the gas-exchange membrane is likely to be ten times greater in the rodent than in the reptile! The explanation for the high gas-exchange surface area in the lungs of a mammal or bird is that the lungs of these animals are extraordinarily densely filled with branching and rebranching airways. The lungs of nonavian reptiles and amphibians, in contrast, typically have parts that are simply like balloons: little more than a sheet of tissue surrounding an open central cavity. Even the parts of their lungs that are subdivided are much less elaborately subdivided than mammalian or avian lungs. Thus, whereas the lungs are large in a reptile compared with a rodent, they provide the reptile with a comparatively small area of gas-exchange membrane.

The thickness of the barrier between the blood and the environmental medium also shows significant evolutionary trends in the major vertebrate groups. In most fish, the sheet of gill tissue between blood and water is roughly 5–10 μm thick. Vertebrate lungs uniformly have a much reduced barrier between blood and

(a) Area of the gas-exchange membrane vs. body size

(b) Thickness of the gas-exchange membrane vs. body size

FIGURE 23.7 Total area and thickness of the gas-exchange membrane in the gills or lungs of vertebrates as functions of body size The lines for mammals and birds in both (a) and (b) and those for amphibians and reptiles other than birds in (a) are for many species (e.g., about 40 species of mammals, ranging in size from shrews to horses). The lines for fish in (a) are for various-sized individuals of single species. The thickness in (b) is the average distance between the blood and the water or air. (After Perry 1990.)

air (Figure 23.7b). Mammals tend to have a thinner sheet of tissue between blood and air than lizards, crocodilians, or other nonavian reptiles. Birds have a dramatically thinner barrier yet, roughly 0.2 µm. Tunas, which are dramatically specialized for O₂ uptake compared with most fish, have a blood–water barrier in their gills that is similar in thickness to the blood–air barrier in mammals.

The skin varies widely in its role as a gas-exchange site in vertebrates (Figure 23.8). Some fish and most reptiles have evolved skins that permit little O₂ or CO₂ exchange. In contrast, the skin can be responsible for 25% or more of gas exchange in other fish, in certain snakes and turtles, and in many amphibians; in the lungless salamanders, which not only lack lungs but have an epidermis that is vascularized (highly unusual), 100% of gas exchange occurs across the skin. Most mammals and birds resemble humans (see Figure 23.8) in relying almost entirely on their lungs. Among terrestrial vertebrates, the role of the skin in breathing is related to the skin’s desiccation resistance. Groups of terrestrial vertebrates, such as mammals and birds, that are well defended against water loss through their skin tend to make little use of cutaneous breathing, whereas groups, such as frogs and salamanders, that are poorly defended against cutaneous water loss tend to engage in significant cutaneous breathing. Modifications that render the skin poorly permeable to water (see page 745) also make it poorly permeable to O₂ and CO₂.

FIGURE 23.8 The percentage of O₂ and CO₂ exchange that occurs across the skin in vertebrates The exact extent of skin breathing within a species often depends on environmental conditions (e.g., temperature). (After Feder and Burggren 1985.)

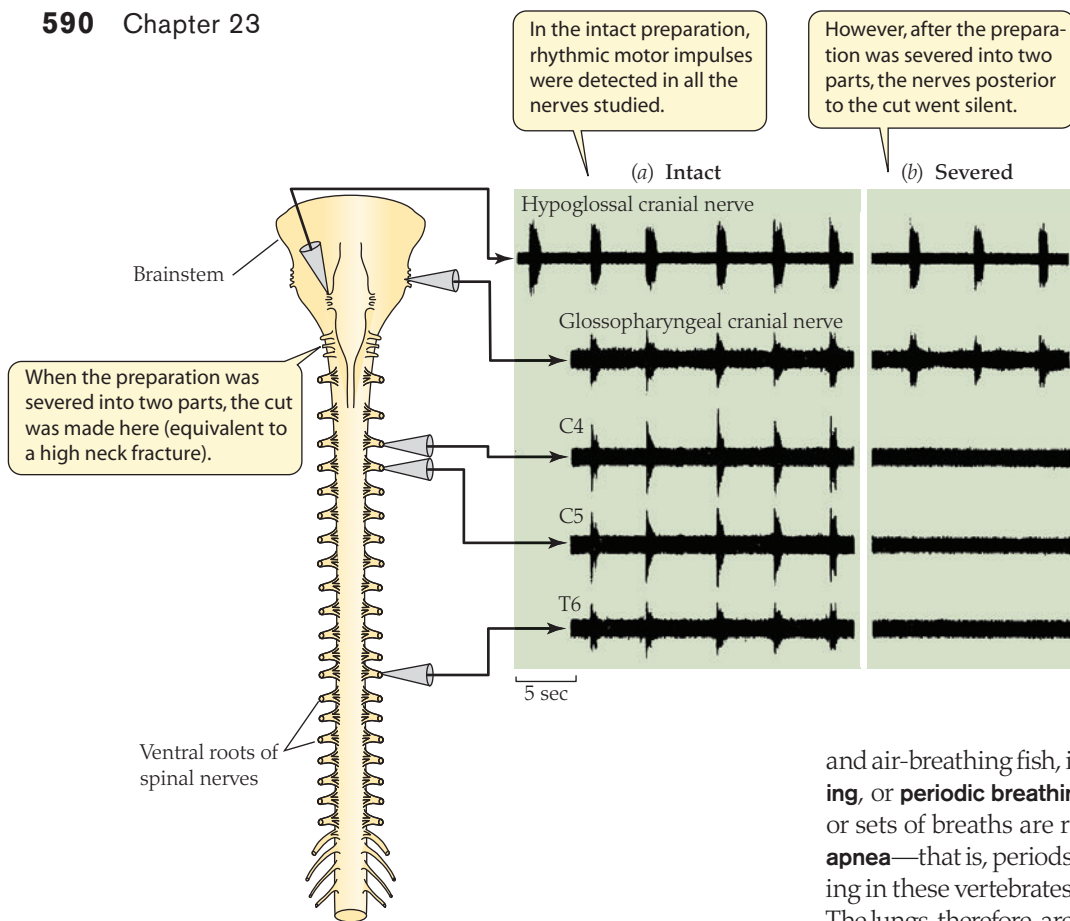

FIGURE 23.9 A central pattern generator in the brainstem originates motor nerve impulses that produce the breathing rhythm An *isolated* portion of the central nervous system of a neonatal rat, cut free from all connections with the rest of the animal, was used for this study. It included the brainstem and spinal cord. Recording electrodes were attached to two cranial nerves and the ventral roots of three spinal nerves: cervical nerves 4 and 5 (C4, C5) and thoracic nerve 6 (T6). Records show electrical activity as a function of time. (From Feldman et al. 1988.)

The control of the active ventilation of the gills or lungs is the final subject that deserves mention in introducing vertebrate breathing. Of central importance is the control of the rhythmic muscle contractions that produce breathing movements, such as our own inhalation and exhalation movements. The muscles responsible for breathing movements in all vertebrates are skeletal muscles. They therefore require stimulation by motor neurons for *each and every contraction* they undergo. The breathing rhythm originates in sets of neurons that form central pattern generators (see Chapter 19); in a process called **rhythmogenesis**, these sets of neurons initiate rhythmic outputs of nerve impulses (action potentials) that travel to the breathing muscles and stimulate them into rhythmic patterns of contraction. The central pattern generators for breathing in all vertebrates are believed to be located in the brainstem: in the medulla, and sometimes other associated parts, of the brain. Although these central pattern generators are affected by outside influences, they are absolutely essential for creating the breathing rhythm. Accordingly, if a vertebrate's spinal cord is severed just posterior to the brainstem, breathing stops instantly, because the neuronal outputs from the brainstem are unable to travel to the breathing muscles by way of spinal nerves. Experiments that illustrate these vital points have been carried out on the type of prepara-

tion shown at the left in **Figure 23.9**, consisting of the brainstem and spinal cord of a young rodent, isolated from the rest of the body. The medulla of the brain, isolated in this preparation from any sensory neuronal input, endogenously generates rhythmic bursts of ventilation-driving motor-neuron impulses that are detectable in multiple cranial and spinal nerves (see **Figure 23.9a**). However, if the spinal cord is severed (see **Figure 23.9b**), the spinal nerves posterior to the injury go silent, paralyzing the ventilatory muscles they service.⁵

Humans and most other mammals exhibit **continuous breathing**, meaning that each breath is followed promptly by another breath in a regular, uninterrupted rhythm. Birds and most fish also usually display continuous breathing. Lizards, snakes, turtles, crocodylians, amphibians, and air-breathing fish, in contrast, usually exhibit **intermittent breathing**, or **periodic breathing**, defined to be breathing in which breaths or sets of breaths are regularly interrupted by extended periods of **apnea**—that is, periods of no breathing. During intermittent breathing in these vertebrates, each period of apnea follows an inspiration. The lungs, therefore, are inflated during apnea. The glottis—the opening of the airways into the buccal cavity—is closed during apnea in the groups of vertebrates that display intermittent breathing. Because of this glottal closure, the inspiratory muscles can relax during the apnea without causing air to be expelled from the lungs.

SUMMARY Introduction to Vertebrate Breathing

- The gill surface area of most fish of a given body size is similar to the lung surface area of amphibians and nonavian reptiles of the same size. Compared with the latter groups, mammals and birds have much more lung surface area—helping to meet their far higher needs for gas exchange. The barrier between the blood and the air or water in the breathing organs is notably thin in mammals and thinnest in birds.
- The skin can account for 25% or more of gas exchange in some fish, turtles, and other nonavian reptiles, and up to 100% in some amphibians. The skin is a minor contributor to gas exchange, however, in mammals and birds.
- The breathing muscles of vertebrates are skeletal muscles activated by motor nerve impulses. The breathing rhythm originates in a central pattern generator in the brainstem.

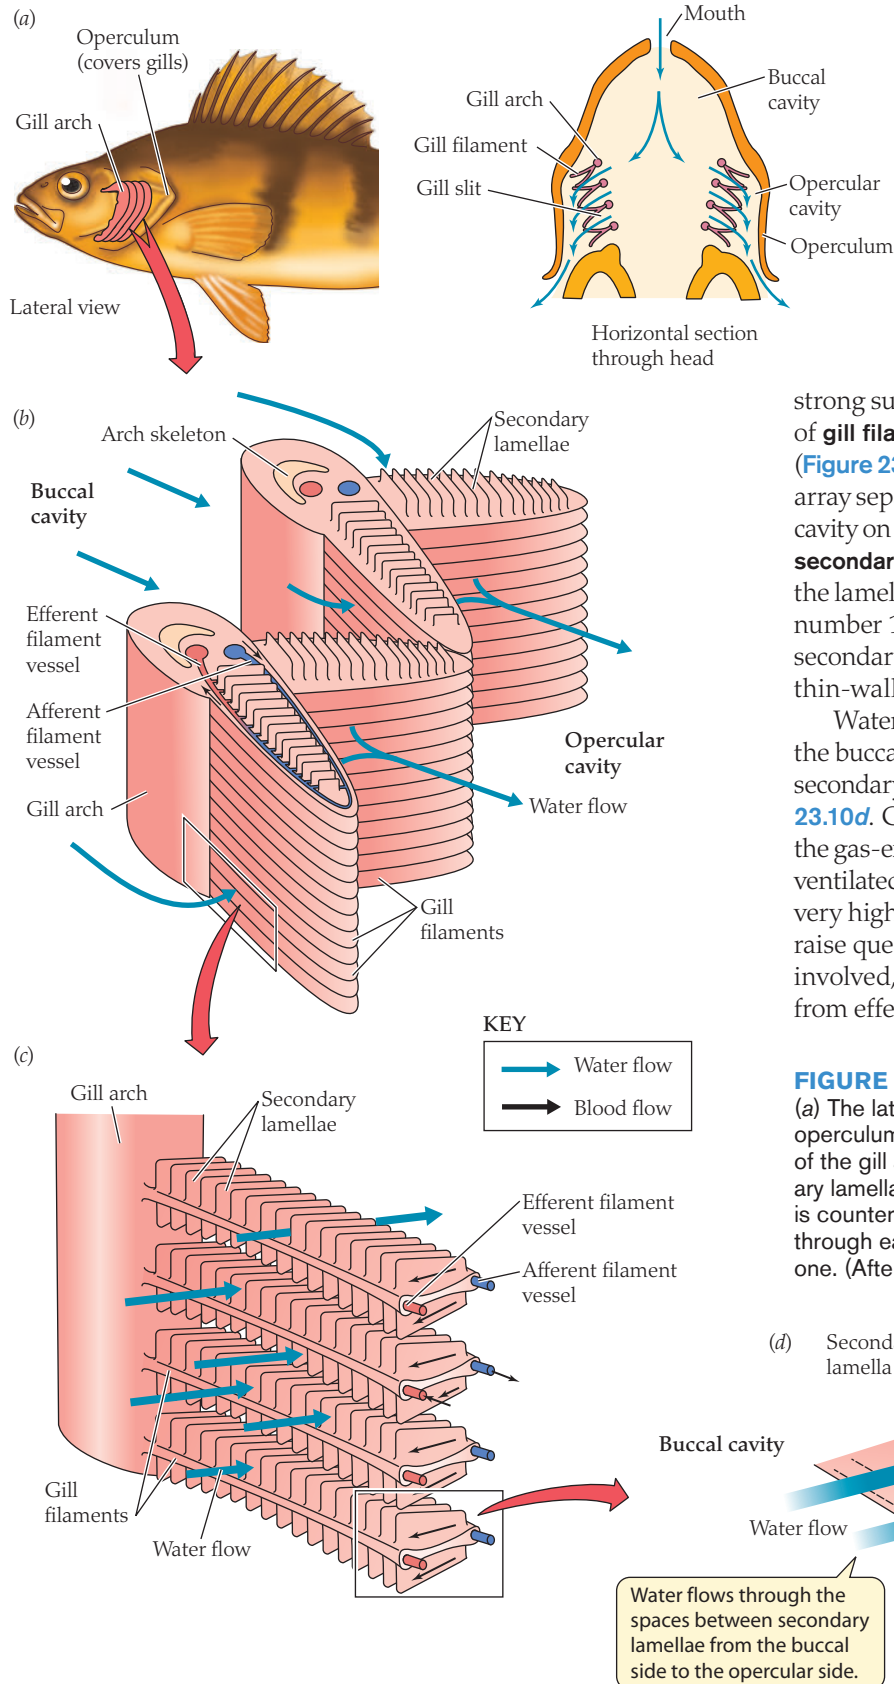

Breathing by Fish

Many fish start life as larvae that breathe only by diffusion of gases across their general body surfaces (see **Box 22.1**). Because fish lar-

⁵More information on rhythmogenesis is presented later in this chapter in the discussion of mammals.

vae are tiny and lack specialized breathing organs, it can be easy to disregard these early stages in the study of breathing. However, gas-exchange insufficiencies are sometimes responsible for mass deaths of larvae. Thus the physiology of early diffusion-respiration

stages can be of great importance ecologically and evolutionarily. As a young fish grows, its body becomes too thick for diffusion to suffice (see Box 22.1). At the same time, its gills develop and mature—as does its circulatory system, which is required for O_2 from the gills to reach the rest of its body.

For our study of gill breathing, we focus here on teleosts, the principal group of bony fish. The buccal cavity of a teleost communicates with the environment not only by way of the mouth but also by way of lateral pharyngeal openings, the **gill slits**. The gills are arrayed across these lateral openings, and a protective external flap, the **operculum**, covers the set of gills on each side of the head. Looking in detail at the structure of the gill apparatus, there are four **gill arches** that run dorsoventrally between the gill slits on each side of the head (Figure 23.10a); the arches, which are reinforced with skeletal elements, provide strong supports for the gills proper. Each gill arch bears two rows of **gill filaments** splayed out laterally in a V-shaped arrangement (Figure 23.10b); collectively, the rows of filaments form a corrugated array separating the buccal cavity on the inside from the opercular cavity on the outside. Each gill filament bears a series of folds, called **secondary lamellae**, on its upper and lower surfaces (Figure 23.10c); the lamellae run perpendicular to the long axis of the filament and number 10–40 per millimeter of filament length on each side. The secondary lamellae—which are richly perfused with blood and are thin-walled—are the principal sites of gas exchange.

Water flows along the surfaces of the secondary lamella from the buccal side to the opercular side. Conversely, blood within the secondary lamellae flows in the opposite direction, as seen in Figure 23.10d. Countercurrent gas exchange, therefore, can occur along the gas-exchange membranes. The percentage of O_2 extracted from ventilated water by resting teleosts has been reported to range from very high values of 80–85% down to 30% or less; the latter values raise questions about the exact nature of gas exchange in the fish involved, because the values are lower than would be expected from effective countercurrent exchange.

FIGURE 23.10 The branchial breathing system in teleost fish (a) The lateral view shows the orientation of the gill arches under the operculum. (b and c) Consecutive enlargements show the structure of the gill array. (d) An enlarged view of a filament and three secondary lamellae, showing that blood flow within the secondary lamellae is countercurrent to water flow across them. Blood flows in a sheet through each secondary lamella, as seen in the section of the foremost one. (After Hill and Wyse 1989.)

Gill ventilation is usually driven by buccal–opercular pumping

In general, water flow across the gills of a teleost fish is maintained almost without interruption by the synchronization of two pumps: a **buccal pressure pump**, which develops positive pressure in the buccal cavity and thus forces water from the buccal cavity through the gill array into the opercular cavity, and an **opercular suction pump**, which develops negative pressure in the opercular cavity and thus sucks water from the buccal cavity into the opercular cavity. The relative dominance of the two pumps varies from species to species; here, we take a generalized view. We look first at the action of each pump separately and then at the integration of the pumps over the breathing cycle. It will be important to remember throughout that water flows from regions of relatively high pressure to ones of relatively low pressure.

THE BUCCAL PRESSURE PUMP The stage is set for the buccal pressure pump to operate when a fish fills its buccal cavity with water by depressing the floor of the cavity while holding its mouth open. The lowering of the buccal floor increases the volume of the buccal cavity, thereby decreasing buccal pressure below ambient pressure and causing an influx of water. The mouth is then closed, and the buccal pump enters its positive-pressure phase. The fish raises the floor of the buccal cavity during this phase. This action increases the buccal pressure above ambient pressure and drives water from the buccal cavity through the gills into the opercular cavities. Thin flaps of tissue, which act as passive valves, project across the inside of the mouth opening from the upper and lower jaws. During the refilling phase of the buccal cycle, when buccal pressure is below ambient, these flap valves are pushed inward and open by the influx of water through the mouth. During the positive-pressure phase, however, the flap valves are forced against the mouth opening on the inside and help to prevent water from exiting the buccal cavity through the mouth.

THE OPERCULAR SUCTION PUMP A teleost fish is able to expand and contract its opercular cavities by lateral movements of its opercula and other muscular actions. Running around the rim of each operculum is a thin sheet of tissue that acts as a passive valve, capable of sealing the slitlike opening between the opercular cavity on the inside and the ambient water on the outside. The negative-pressure phase—suction phase—of the opercular pump occurs when the opercular cavity is expanded. At this time, the pressure in the cavity falls below the pressures in the buccal cavity and the ambient water. The negative pressure in the opercular cavity sucks water from the buccal cavity into the opercular cavity through the gill array. Water would also be sucked in from the environment were it not for the action of the opercular rim valve, which is pushed medially against the fish's body wall by the higher ambient pressure, sealing the opercular opening and preventing influx of ambient water. After its sucking phase, the opercular pump enters its discharge phase. The cavity is contracted, raising the pressure inside to be higher than ambient pressure; this pressure difference forces the rim valve open and discharges water through the opercular opening.

INTEGRATION OF THE TWO PUMPS PRODUCES NEARLY CONTINUOUS, UNIDIRECTIONAL FLOW The temporal integration of the buc-

FIGURE 23.11 The breathing cycle in teleost fish Plus (+) and minus (-) symbols indicate pressures *relative to ambient pressure*. The buccal and opercular pumps are represented by pistons. Blue arrows represent water flow. Arrows through the gill array indicate water flow over the gills. Stages 2 and 4 are transitional and short in duration. (After Hughes 1961; Moyle 1993.)

cal and opercular pumps is diagrammed in **Figure 23.11**. In stage 1, the buccal cavity is being refilled. Expansion of the buccal cavity produces a pressure below ambient; therefore, if the buccal pump were the only pump, flow of water through the gills from the buccal side would not occur at this time, and in fact, there would be backflow through the gills into the buccal cavity because of the lowered buccal pressure. It is during stage 1, however, that the opercular pump is in its sucking phase. The pressure in the opercular cavity is reduced to a level far below buccal pressure, and water is drawn through the gills from the buccal cavity. Stage 2 is a short transition period in which the opercular pump is completing its sucking phase and the buccal pump is beginning its pressure phase. In stage 3, the opercular pump is in its discharge phase, and the pressure in the opercular cavity is elevated. However, because the buccal pump is simultaneously in its pressure phase, the buccal pressure exceeds opercular pressure, and water again flows through the gills from the buccal cavity. Only in stage 4, which occupies just a short part of the breathing cycle, is the pressure gradient in the direction favoring backflow of water through the gills. In all, therefore, the two pumps are beautifully integrated to produce almost continuous, unidirectional flow across the gills: The opercular pump sucks while the buccal pump is being refilled, and the buccal pump develops positive pressure while the opercular pump is being emptied.

Many fish use ram ventilation on occasion, and some use it all the time

When a swimming fish attains a speed of 50–80 cm/s or greater, its motion through the water, if it holds its mouth open, can itself elevate the buccal pressure sufficiently to ventilate the gills at a rate adequate to meet O₂ requirements. Many fast-swimming teleost fish, in fact, cease buccal–opercular pumping when they reach such speeds and employ ram ventilation, which in theory lowers the metabolic cost of ventilation. Tunas, mackerel, dolphinfish, bonitos, and lamnid sharks swim continuously and use ram ventilation all the time. In the tunas, at least, ram ventilation is obligatory, as already mentioned, because the buccal–opercular pumping mechanisms have become incapable of producing a sufficiently vigorous ventilatory stream.

Decreased O₂ and exercise are the major stimuli for increased ventilation in fish

Fish are capable of as much as 30-fold changes in their rates of gill ventilation by buccal–opercular pumping. One potent stimulus to increase the rate of ventilation is a decrease in the partial pressure of O₂ in the environment or blood, detected by chemoreceptor cells in the gills. Exercise also is a potent stimulus of ventilation in fish. Sometimes, fish increase ventilation in response to increases in the external or internal partial pressure of CO₂. Carbon dioxide, however, is overall a relatively weak ventilatory stimulus in fish—in sharp contrast to mammals, in which ventilation is extremely sensitive to elevated CO₂. The question arises as to why CO₂ plays different roles in the two groups. The answer probably lies in the different capacitance coefficients of CO₂ in water and air (see page 587). Put loosely, for a water breather, although O₂ can be difficult to acquire, CO₂ is easy to excrete. Water breathers never increase the CO₂ partial pressure by much in the water passing over their gills (see Figure 23.6); therefore, CO₂ is unlikely to be a sensitive indicator of their ventilatory status.

Changes in the rate of ventilation are not the only means employed by fish to adjust gill O₂ exchange. Some fish, for example, exhibit *lamellar recruitment*, by which they adjust the proportion of the secondary lamellae that are actively perfused with blood. Whereas only about 60% of lamellae may be perfused at rest, 100% may be perfused during exercise or exposure to reduced O₂.

Several hundred species of bony fish are able to breathe air

Many species of bony fish have evolved mechanisms for tapping the rich O₂ resources of the air. Nearly 400 species of air-breathing fish are known, especially in freshwater. Most retain functional gills and are dual breathers, acquiring O₂ from both water and air. The extent to which these fish rely on the atmosphere depends on several factors. They typically increase their use of air as the level of dissolved O₂ in their aquatic habitat falls. They also tend to resort increasingly to air breathing as the temperature rises, because high temperatures elevate their O₂ needs. Notably, air-breathing fish typically void most of their CO₂ into the water—across their gills or skin—even when relying on the atmosphere for most of their O₂. The traditional view of the adaptive value of air breathing is that it arose in groups of fish living over evolutionary scales of time in O₂-poor waters, as a means of solving the problem of O₂ shortage in the water (see page

21). A new hypothesis, discussed in Chapter 25, is that air breathing sometimes arose as a means of oxygenating the heart.

Some air-breathing fish lack marked anatomical specializations for exploiting the air. American eels (*Anguilla rostrata*) are examples. They sometimes come out onto land in moist situations, and they then meet about 60% of their O₂ requirement by uptake across their skin and 40% by buccal air gulping. Their gills, which are quite ordinary, are probably the primary site of O₂ uptake from the air they gulp.

In most air-breathing fish, some part or branch of the alimentary canal has become specialized as an air-breathing organ. The specialized region varies greatly among species—reflecting the fact that air breathing has evolved independently more than 20 times. The specialized region is always highly vascularized, and its walls may be thrown into extensive patterns of evagination or invagination. In some species the buccal cavity is specialized for air breathing—as is true in electric eels (*Electrophorus electricus*), which have vast numbers of vascular papillae on the walls of their buccal cavity and pharynx. The opercular cavities form air-breathing organs in some species; mudskippers (*Periophthalmus*), for example, breathe air using expanded gill chambers lined with vascularized, folded membranes. Many air-breathing species employ so-called *suprabranchial chambers*, situated in the dorsal head above the gills; in some catfish (*Heteropneustes*) dramatic tubular diverticula extend from the head structures into half the length of the body. Quite a few air-breathing fish employ vascularized portions of the stomach to breathe. Others, notably species of armored catfish (family Callichthyidae), employ the intestine; in these, half or more of the intestinal length is highly vascularized and devoted to breathing from air that is swallowed and later expelled via the anus. The swim bladder (gas bladder) is used as an air-breathing organ by many fish. The “tinkering” aspect of evolution (see page 9) is nowhere better illustrated than in the fantastic diversity of body parts that fish have diverted from old functions to the task of getting O₂ from the atmosphere.

The air-breathing organs of fish are most often inflated by buccal pumping. A fish takes air into its buccal cavity, then closes its mouth and compresses the buccal cavity. In this way, air is driven into its stomach, swim bladder, or other air-breathing structure.

A potential problem for air-breathing fish is that O₂ taken up from the atmosphere may be lost to O₂-poor water across their gills! This possibility probably helps explain why the gills of these animals are often reduced in comparison with those of other fish. In extreme cases, the gills are so atrophied that air breathing is obligatory—as is true of electric eels, which drown if they cannot obtain air. Many air-breathing fish have also evolved specialized circulatory shunts by which oxygenated blood can bypass the gas-exchange surfaces of their gills, thereby limiting O₂ loss across the gills.

Of all air-breathing fish, the six species of **lungfish (dipnoans)** (Figure 23.12a) have received the most attention because they are believed to be the modern fish that most closely resemble the ancestral fish that gave rise to terrestrial vertebrates. The walls of the lungs of lungfish (Figure 23.12b) are thrown into complex arrays of interconnected folds—with the folds arranged roughly in tiers from low folds to high folds—resembling the walls of many amphibian lungs. The air-breathing organs of lungfish came to be called *lungs*—and the fish themselves were named *lungfish*—because their air-breathing organs have often been viewed as being “particularly homologous” to the lungs of terrestrial vertebrates. Many

(b) The inner wall of a lungfish lung

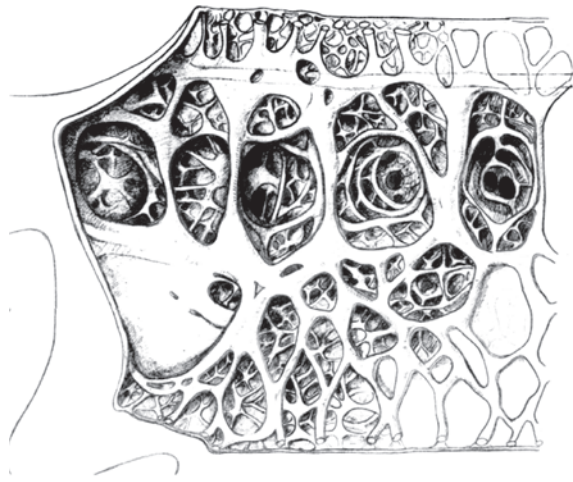

FIGURE 23.12 Lungfish and their lungs This figure features African lungfish (genus *Protopterus*); two other genera of lungfish occur in South America and Australia. (a) *Protopterus dolloi*. (b) The inner wall of part of a lung of *Protopterus aethiopicus*. The respiratory surface area of the lung is greatly enhanced by a complex pattern of vascularized folds. The side compartments in the wall of the lung open to a central cavity that runs the length of the lung. The cavity communicates anteriorly with a short pulmonary canal leading to the esophagus. (b from Poll 1962.)

morphologists now conclude, however, that swim bladders could just as justifiably be called lungs by this standard. To a physiologist, all invaginated breathing organs are lungs (see Figure 23.2), and thus all of the air-breathing organs of fish are lungs.

SUMMARY Breathing by Fish

- The secondary lamellae are the principal sites of gas exchange in fish gills. Countercurrent gas exchange occurs in the lamellae.
- Water flow across the gills is essentially unidirectional. It is driven by a buccal pressure pump and an opercular suction pump that act in an integrated rhythm, so that the buccal pump drives water across the gills when the opercular pump is being emptied of water and the opercular pump sucks water across the gills while the buccal pump is being refilled with water.

- Some fish turn to ram ventilation when swimming fast enough. Others, such as tunas, are obligate ram ventilators and must swim all the time to avoid suffocation.
- A lowered O_2 partial pressure in the blood is a more potent stimulus for increased ventilation in fish than an elevated CO_2 partial pressure.
- Most of the 400 or so species of air-breathing fish have an air-breathing organ that is derived from the buccal cavity, opercular cavity, stomach, or intestines—or one that originates as an outpocketing of the foregut (e.g., swim bladder).

Breathing by Amphibians

Amphibians, of all the vertebrate groups, mix water and air breathing to the greatest extent. Many move from an aquatic environment to a terrestrial one during their individual development, and many are dual breathers as adults.

The gills of aquatic amphibian larvae (tadpoles) are of different origin and structure than the gills of adult fish. They develop as outgrowths of the integument of the pharyngeal region and project into the water from the body wall (Figure 23.13a). The gills are external in all young amphibian larvae; in salamander larvae they remain so, but in the larvae of frogs and toads (anurans), an outgrowth of the integument, termed the *operculum* (different from the bony operculum of a fish) soon encloses the gills in a chamber that opens to the outside posteriorly. Ventilation of the gills enclosed in the opercular cavity is accomplished by buccal pumping. The gills of amphibians are generally lost at metamorphosis, but external gills remain throughout life in certain aquatic salamanders, such as mudpuppies (*Necturus*).

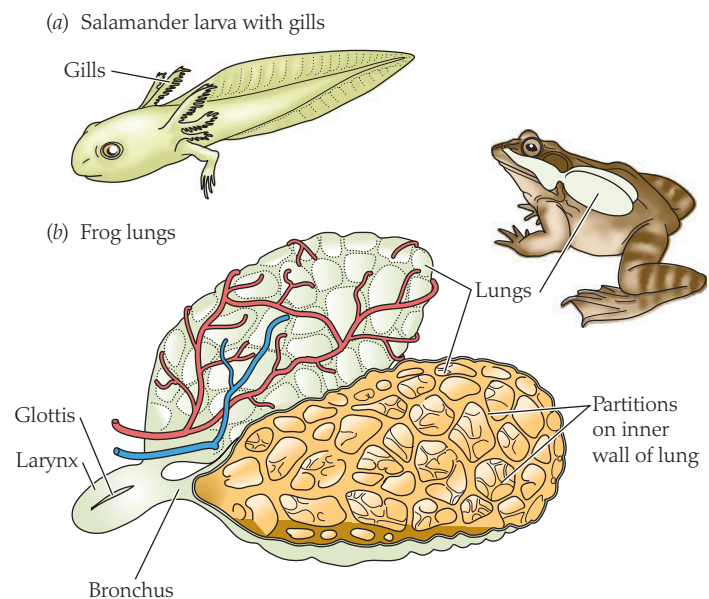

FIGURE 23.13 Breathing organs of amphibians (a) The external gills of a 3-week-old salamander larva (*Ambystoma maculatum*). (b) The lungs of a frog (*Rana temporaria*). The dorsal half of one lung has been cut off to reveal the compartmentalization of the inner wall by interconnected folds in multiple tiers. Modern amphibians lack a trachea; their lungs connect almost directly to the pharynx. (b after Poll 1962.)

FIGURE 23.14 The three major steps in the ventilatory cycle of an adult bullfrog (*Lithobates catesbeianus*) Until recently this species was named *Rana catesbeiana*. (After Gans 1970.)

Mudpuppies ventilate their gills by waving them back and forth in the water and increase the frequency of these movements in response to decreased O_2 or increased temperature.

In most amphibians, paired lungs develop from the ventral wall of the pharynx near the time of metamorphosis. Each lung is classed as **unicameral** (*uni*, “one”; *cameral*, “chamber”) because it is a single sac with an open, undivided central cavity that provides access to any side compartments that may be formed by the folding of the walls. The lungs of many adult amphibians are simple, well-vascularized sacs; their internal surface area is increased little, if at all, by folding, and in this respect they are less well developed than the lungs of lungfish. The inner walls of the lungs of frogs and toads are often more elaborate; they may be thrown into complex patterns of interconnected folds in multiple tiers, giving them a honeycombed appearance (Figure 23.13b).

Lunged amphibians fill their lungs by buccopharyngeal pressure. This basic mechanism is presumably carried over from their piscine ancestors and, as mentioned earlier, is often employed by amphibian larvae to ventilate their gills. In frogs, although several patterns differing in detail have been reported, the essentials of the buccopharyngeal pressure pump are uniform. Air is taken into the buccal cavity through the nares or mouth when the pressure in the cavity is reduced by lowering its floor. Then, when the floor of the buccal cavity is raised with the mouth closed and the nares at least partially sealed by valves, the increase in pressure forces air into the lungs. The inflation of the lungs elevates the air pressure within them. Thus the lungs would discharge upon opening of the mouth or nares were it not for the glottis (see Figure 23.13b), which is closed by muscular contraction after inhalation. A period of apnea (no breathing), with the lungs inflated, then follows (i.e., breathing is intermittent). The nares are opened during the apneic period, and a frog often pumps air in and out of its buccal cavity through its nares at that time by raising and lowering the floor of the buccal cavity, termed *buccopharyngeal pumping*. Then the glottis is opened, and air from the lungs is exhaled.

Exhalation in a frog results in part from elastic recoil of the expanded lungs and may also be promoted by contraction of muscles in the walls of the lungs and body wall. Exhalation is described as having both **passive** and **active** components. In the study of the forces that drive lung volume changes, *passive* means “not involving contraction of muscles” and refers to forces developed by simple elastic rebound. *Active*, by contrast, refers to forces developed by muscular contraction.

The bullfrog (*Lithobates catesbeianus*) provides a well-studied specific example of the pulmonary breathing cycle. A bullfrog fills its buccal cavity in preparation for inflation of its lungs *before* it empties its lungs; to do so, with its glottis closed, it inhales air, which mostly comes to lie in a posterior depression of the buccal floor (step 1, Figure 23.14). Next (step 2), the glottis is opened, and pulmonary exhalant air passes in a coherent stream across the dorsal part of the buccopharyngeal cavity to exit through the nares. The fresh air in the depression of the buccal floor is then driven into the lungs when the buccal floor is raised with the nares closed (step 3). An important effect of the buccopharyngeal pumping between breaths is that it washes residual pulmonary exhalant air out of the buccal cavity, so that when the next pulmonary ventilatory cycle begins, the buccal cavity is filled with a relatively fresh mixture.

Gills, lungs, and skin are used in various combinations to achieve gas exchange

A central question in amphibian respiratory physiology is how the total gas exchange of an individual is partitioned among the available gas-exchange sites: the gills, lungs, and skin. Bullfrogs, to continue with them as an example, start their lives without lungs, and when they are living at 20°C as aquatic tadpoles, their gills and skin each account for about half of their O_2 and CO_2 exchange (Figure 23.15). As bullfrog tadpoles mature and their lungs become functional, their lungs gradually assume primary responsibility for their O_2 uptake. In adulthood, the lungs take up most O_2 . The

FIGURE 23.15 The development of external respiration in the bullfrog (*Lithobates catesbeianus*) Shown are the percentages of O_2 uptake and CO_2 excretion that occur across the gills, lungs, and skin of bullfrogs as they develop from tadpoles to adults. The animals were studied at 20°C and had free access to well-aerated water and air. (After Burggren and West 1982.)

lungs, however, do not play a large role in CO_2 exchange at any age; instead, when the gills are lost at metamorphosis, the skin increases its role in eliminating CO_2 (see Figure 23.15). The pattern seen in adult bullfrogs at 20°C —that the lungs are primarily responsible for O_2 uptake, whereas the skin eliminates most CO_2 —is common in amphibian adults at such temperatures.

Some species of frogs in temperate regions of the world hibernate at the bottoms of ponds and lakes during winter. All their O_2 and CO_2 exchange is then across their skin. One reason the skin can suffice under these circumstances is that the hibernating animals have very low needs for O_2 and CO_2 exchange because of their low body temperatures and seasonal metabolic depression. The relatively high permeability of the skin is also important: Whereas it increases rates of dehydration on land, it makes underwater breathing by adults possible.

Breathing by Reptiles Other than Birds

When we consider the lizards, snakes, turtles, and crocodylians, an important first point to make is that in most of them, the lungs take up essentially all O_2 and eliminate essentially all CO_2 . The skin of reptiles is generally much less permeable than amphibian skin, meaning that it protects far better against evaporative dehydration, but it does not readily allow the respiratory gases to pass through.

The simplest type of reptilian lung—seen in most lizards and snakes—is unicameral (single chambered); it is a saclike structure with an open central cavity. Unicameral lungs are sometimes well perfused with blood throughout, but sometimes they are well perfused only at the anterior end and are balloonlike at the posterior end (Figure 23.16a). In the well-perfused parts where O_2 and CO_2 are principally exchanged with the blood, the walls are thrown into a honeycomb-like pattern of vascularized folds, increasing their surface area (Figure 23.16b,c). Air flows in and out of the central cavity during breathing, but gas exchange between the central cavity and the depths of the honeycomb-like cells on the walls is probably largely by diffusion.

A major evolutionary advance observed in several groups of non-avian reptiles is that, in each lung, the main lung cavity has become subdivided by major septa into numerous smaller parts, forming a **multicameral**—multiple-chambered—lung, as seen in Figure 23.16d.

FIGURE 23.16 Lizard lungs (a) Freshly dissected unicameral lungs from an African plated lizard (*Gerrhosaurus* sp.). Blood trapped within the tissue is responsible for the red color. The highly localized presence of blood at the cranial (anterior) ends of the lungs reflects the fact that virtually all perfusion takes place within the cranial portions of the lungs in some species with unicameral lungs. (b) A drawing of the gross internal structure of the unicameral lung of another type of lizard, the green lizard (*Lacerta viridis*). (c) Scanning electron micrograph of the lung wall of a tegu lizard (*Tupinambis nigropunctatus*), showing the honeycomb-like pattern of vascularized partitions. Magnification: 25 \times . (d) Gross internal structure of the highly developed multicameral lung of a monitor lizard (*Varanus exanthematicus*). (a courtesy of Tobias Wang; b and d courtesy of Hans-Rainer Duncker, reprinted from Duncker 1978; c courtesy of Daniel Luchtel and Michael Hlastala.)

A multicameral lung can provide a great deal more surface area of gas-exchange membrane per unit of lung volume than a unicameral lung because the septa between lung chambers, not just the outer walls, can develop elaborate, highly folded gas-exchange surfaces. The multicameral type of lung occurs in monitor lizards (see Figure

(a) Unicameral lungs of a plated lizard

Some unicameral lungs are perfused with blood principally at just the cranial (anterior) end.

(d) The elaborate, multicameral lung of a monitor lizard

A bronchus allows air to flow to the multiple chambers of this type of lung.

23.16d), reptiles noted for their dramatically active ways of life and relatively high aerobic competence. It is also found in crocodylians and turtles. These groups all resemble each other in their septation, in that—when viewed in three dimensions—each lung is divided into three rows of chambers, with four or more chambers in each row. A noteworthy evolutionary development in the multicameral lung is the appearance of a cartilage-reinforced tube (*bronchus*) that runs lengthwise through the lung (see Figure 23.16d). This tube allows air to flow to all of the multiple chambers in the lung.

The lungs in nonavian reptiles are filled principally or exclusively by *suction* (also termed *aspiration*) rather than by buccal pressure: Air is drawn into the lungs by an expansion of the lung volume, which creates a subatmospheric pressure within the lung chambers. This mode of ventilation represents a major evolutionary transition from the earlier buccal-pressure-filled lungs of air-breathing fish and amphibians. It is a transition that is carried forward to the mammals and birds, which also employ suction to fill their lungs. Because suction is created by the action of thoracic and abdominal muscles, not by buccal muscles, the evolution of suction ventilation freed the buccal cavity from one of its ancient functions, allowing it to evolve in new directions without ventilatory constraints.

Suction is developed in the lungs of reptiles in two different ways. In one sort of breathing cycle, seen in at least some snakes, thoracic and abdominal expiratory muscles compress the lungs to a volume smaller than their passive relaxation volume during the exhalation of air; suction for inhalation is then developed when the lungs later rebound elastically to larger size. In the other sort of breathing cycle, seen in lizards and some crocodylians, inspiratory muscles actively create suction in the lungs during inhalation by expanding the lungs to a size larger than their passive relaxation volume; then, when the muscular activity stops, the lungs rebound elastically, becoming smaller, and the elastic rebound contributes to exhalation.

Lizards provide an instructive example to study in more detail. Unlike modern amphibians, lizards have well-developed ribs. Running over and between the ribs on each side of the body are **intercostal muscles** (*costa*, “rib”) that—by means of their contractions—can expand or contract the volume enclosed by the rib cage. When a resting lizard inhales, certain of its intercostal muscles are activated and expand the rib cage, a mechanism sometimes called the **costal suction pump**. After the inflation of the lungs has occurred, the glottis is closed and the inspiratory muscles relax. The inhaled air is then held in the lungs for several seconds to several minutes of apnea, while often the buccal cavity is ventilated by buccopharyngeal pumping, thought generally to aid olfaction. Exhalation then occurs, followed quickly by another inhalation.

Recent research has demonstrated that when lizards are walking or running, some of their intercostal muscles help produce the back-and-forth flexions of the body that are so characteristic of lizard locomotion. This involvement of the intercostals in locomotion can interfere with their ability to develop ventilation forces. Some, but not all, species of lizards overcome this problem by using buccal pressure to help fill their lungs while they are walking or running.

Sea turtles and some crocodylians exhibit the most structurally elaborate lungs seen in the nonavian reptiles. In one of these two groups, a major, unexpected discovery has recently been reported. In each lung of an American alligator (*Alligator mississippiensis*), the bronchus branches complexly, and running between certain of those branches are many tiny gas-exchange tubes. Evidence indicates that

the gas-exchange surfaces in these tubes in the alligator lung are not ventilated tidally as are the gas-exchange surfaces in all other nonavian reptiles studied. Instead, air flows through these tubes in one direction during both inhalation and exhalation. As we will see, unidirectional flow of this sort is well known in birds. As this new discovery is explored further, it may strongly influence theories of bird evolution.

Breathing by Mammals

Mammals and birds possess the most elaborate lungs of all animals. Their lungs are independently evolved and built on very different principles. The extreme intricacy of mammalian lungs is illustrated by the plastic cast of a person’s airways shown in **Figure 23.17**.

The lung system of an adult human consists of 23 levels of airway branching. The *trachea* first branches to form two major airways, the *primary bronchi* (singular *bronchus*), that enter the two lungs (see Figure 23.17). Each primary bronchus then branches and rebranches dendritically (as a tree branches) within the lung, giving rise to *secondary* and *higher-order bronchi* of smaller and smaller diameter, and then to ever-smaller fine tubes known as *bronchioles*. At the outer limits of this branching tree of airways, 23 branches from the trachea, the final bronchioles end blindly in **alveolar ducts** and **alveolar sacs**, the walls of which are composed of numerous semispherical outpocketings, each called an **alveolus**

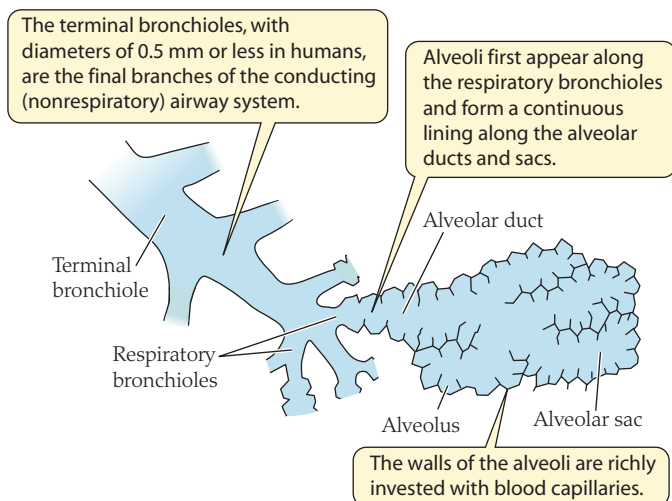

FIGURE 23.17 The airways in human lungs To visualize the lung passages, the airways were injected with white plastic. Similarly, the arteries were injected with red plastic. After the plastic hardened, the tissue was removed, leaving just the plastic to mark the airways and arteries. Only the airways and arteries of relatively large diameter are preserved with this technique. Thus the airway system and arterial system branch far more finely than seen here. Note that the arteries tend to branch in parallel with the airways.

(a) The finest airways of the mammalian lung, ending in alveoli

(b) Scanning electron micrograph of an alveolar region in a human lung

FIGURE 23.18 Respiratory airways of the mammalian lung

(a) Longitudinal section of the final branches of the airways in a mammalian lung, showing respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli. (b) Scanning electron micrograph of a 0.4-mm² area of a human lung, showing alveolar ducts (D) and alveoli (A). (a after Hildebrandt and Young 1960; b courtesy of Ewald Weibel.)

(*alveolus*, “hollow cavity”) and collectively termed **alveoli** (Figure 23.18). There are about 300 million alveoli in the lungs of a human adult; they vary in size but average about 0.25 mm in diameter. The alveoli make up a total area of gas-exchange membrane of 120–140 m²! The floor of an 80-student classroom is likely to have a similar area. Thus, by virtue of elaborate branching, a highly vascularized interface between air and blood that is the size of a large classroom floor is fit within the compact volume occupied by our lungs.

The trachea and bronchi and all but the last few branches of bronchioles in a mammal’s lungs are not much involved in gas exchange; they are thus known as the **conducting airways** and are said to constitute the **anatomical dead space** of the lungs. They are lined with a relatively thick epithelium and do not receive a particularly rich vascular supply. Gas exchange between air and blood occurs in the **respiratory airways** of the lungs (see Figure 23.18a), which consist of *respiratory bronchioles* (the last two or three branches of bronchioles), *alveolar ducts* (through-passages lined with alveoli), and *alveolar sacs* (end sacs lined with alveoli). The walls of the respiratory airways are composed of a single layer of thin, highly

flattened epithelial cells and are richly supplied with blood capillaries. The alveoli constitute most of the gas-exchange surface. In them, blood and air are separated by just two thin epithelia (the alveolar and capillary epithelia) and a basement membrane in between. The total average diffusive thickness of these structures is only 0.3–0.6 μm. Recent research indicates that type IV collagen in the basement membrane is critical for imparting sufficient mechanical strength to these very thin structures that they do not usually rupture, despite being exposed to considerable physical stresses.

The total lung volume is employed in different ways in different sorts of breathing

When mammals breathe at rest, they do not come close to inflating their lungs fully when they inhale, and they do not come close to deflating their lungs fully when they exhale. Thus a wide margin exists for increasing the use of total lung volume. The **tidal volume** is the volume of air inhaled and exhaled per breath. In resting young men, the volume of the lungs at the end of inhalation is about 2900 mL, whereas that at the end of exhalation is about 2400 mL. Thus the *resting tidal volume* is about 500 mL (Figure 23.19). The maximal volume of air that an individual can expel beyond the resting expiratory level is termed the resting **expiratory reserve volume**. In healthy young men, it is about 1200 mL; that is, of the 2400 mL of air left in the lungs at the end of a resting exhalation, 1200 mL can be exhaled by maximal expiratory effort, but 1200 mL (termed the *residual volume*) cannot be exhaled at all (see Figure 23.19). The maximal volume of air that can be inhaled beyond the resting inspiratory level is the resting **inspiratory reserve volume**. In healthy young men, it is about 3100 mL; thus the total lung volume at the end of a maximal inspiratory effort is about 6000 mL (see Figure 23.19). Using the terminology developed here, when mammals increase their tidal volume above the resting level, they do so by

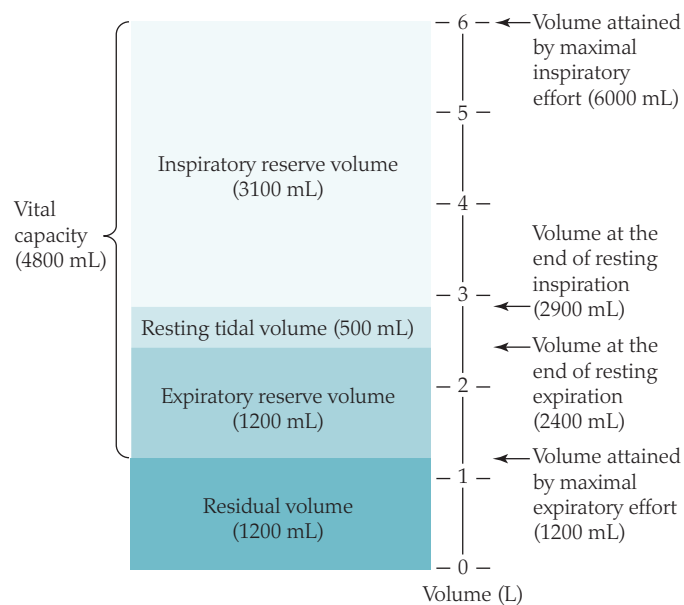

FIGURE 23.19 Dynamic lung volumes in healthy young adult men

The lung volumes shown include the anatomical dead space as well as the respiratory airways. The inspiratory and expiratory reserve volumes shown are the reserves available during resting breathing. The residual volume is the volume remaining in the lungs after maximal expiratory effort. Values shown are averages for 70-kg men.

using parts of their inspiratory and expiratory reserve volumes. The maximal possible tidal volume, sometimes termed **vital capacity**, is attained by fully using both reserves and thus is the sum of the resting tidal volume and the resting inspiratory and expiratory reserve volumes: about 4800 mL in young men. The vital capacity of humans tends to be increased by physical training, but advancing age and some diseases tend to decrease it.

The gas in the final airways differs from atmospheric air in composition and is motionless

The gas in the alveoli, which is the gas that undergoes exchange with the blood, differs dramatically in composition from atmospheric air in all mammals. The most fundamental reason is that the alveolar sacs form the blind ends of tidally ventilated airways that are never fully emptied. To see the implications of this anatomical fact, consider a resting person. At the end of a resting exhalation, the lungs contain 2400 mL of stale air, about 170 mL of which is in the anatomical dead space (the conducting airways). When the person then inhales, the stale air in the anatomical dead space is the first to move deeper into the lungs, into the respiratory airways; thus the entire 2400 mL of stale air is in the respiratory airways after inhalation. Of the 500 mL of fresh atmospheric air inhaled during a resting breath, about 330 mL passes through the anatomical dead space and enters the respiratory airways; the other 170 mL—the last of the air to be inhaled—simply fills the anatomical dead space and is later exhaled, unused. All things considered, at the end of a resting inhalation, the gas in the respiratory airways consists of a mix of 2400 mL of stale air and 330 mL of fresh atmospheric air. Accordingly, the O_2 partial pressure in the alveoli is bound to be far below the atmospheric O_2 partial pressure, and the CO_2 partial pressure in the alveoli is far above the atmospheric partial pressure. Another significant property that arises from these quantitative realities is that the gas partial pressures in the alveoli do not change much between inhalation and exhalation. Using the values for resting humans, only about 12% of the air in the respiratory airways at the end of an inhalation is fresh, whereas 88% is carried over from previous breaths. The large carry-over from breath to breath helps impart stability to the gas composition deep in the lungs.

The exact partial pressures of gases that prevail in the alveoli depend *dynamically* on the *rate* at which fresh air is brought into the depths of the lungs and the *rate* of gas exchange with the blood. Ventilatory control systems (to be discussed later) ordinarily adjust the rate of ventilation relative to the rate of gas exchange with the blood so that certain set-point partial pressures of O_2 and CO_2 are maintained in the alveolar gas. In humans near sea level, the partial pressure of O_2 in alveolar gas is nearly always about 13.3 kPa (100 mm Hg), and that of CO_2 is about 5.3 kPa (40 mm Hg). There are some data that indicate that these values vary with body size among species of mammals, and a partial explanation for this pattern would be the regular relation between breathing rate and body size. Small-bodied mammals take many more breaths per minute than large-bodied ones (see Chapter 7). Correlated with this potentially greater influx of fresh air relative to lung volume, mammals smaller than humans may have consistently higher values for the alveolar partial pressure of O_2 than humans (e.g., 14.5 kPa measured in rats). Conversely, mammals larger than humans may have lower values than humans (e.g., 10 kPa in horses).

The gas occupying the final respiratory airways of a mammal is essentially motionless (Figure 23.20). This unexpected property

FIGURE 23.20 Mechanisms of gas transport in the final branches of mammalian lungs during inhalation Although gases are drawn by convection (bulk flow) into the finest bronchioles, the gases in the alveolar sacs and alveoli are motionless. Therefore, O_2 must travel by diffusion across the final (minute) stretches of distance it must cover to reach the gas-exchange membrane, and CO_2 must diffuse in the opposite direction. (After Weibel 1984.)

is still another consequence of the anatomical fact that the alveolar sacs are the blind ends of a tidally ventilated airway system. During inhalation, convective air movement carries air rapidly down the trachea and through the various bronchi. As the air flows ever deeper into the lungs, however, it slows, because the collective volume of the airways rapidly increases as the airways branch into greater and greater numbers. Convective airflow ceases before the air reaches the alveolar sacs.

Because the gas in the blind ends of the airways is motionless, O_2 and CO_2 transport through that gas must occur by diffusion (see Figure 23.20). The layer of motionless gas is very thin (recall, for instance, that human alveoli average only 0.25 mm in diameter). Therefore, diffusion across the motionless layer of gas can readily occur fast enough for rates of O_2 and CO_2 exchange between the lung air and the blood to be adequate (see Table 5.1). This happy situation is contingent, however, on the alveoli being filled with gas, not water. If the alveoli become filled with body fluid, rates of diffusion sharply plummet. That is why any disease that causes even a minute chronic accumulation of body fluid within the airways is a mortal threat.

The power for ventilation is developed by the diaphragm and the intercostal and abdominal muscles

Unlike other vertebrates, mammals have a true **diaphragm**: a sheet of muscular and connective tissue that completely separates the thoracic and abdominal cavities (see Figure 1.18). The diaphragm is dome-shaped, projecting farther into the thorax at its center than at its edges. Contraction of the diaphragm tends to flatten it, pulling the center away from the thorax toward the abdomen. This movement increases the volume of the thoracic cavity, resulting in expansion of the lungs and inflow of air by suction.

The **external** and **internal intercostal muscles** that run obliquely between each pair of adjacent ribs are also important in ventilation.

Contraction of the external intercostals rotates the ribs anteriorly and outward, expanding the thoracic cavity. The contractile filaments of the internal intercostals run (roughly speaking) perpendicular to those of the externals, and in general their contraction rotates the ribs posteriorly and inward, decreasing the volume of the thoracic cavity. You can easily demonstrate the action of these muscles on yourself by consciously expanding and contracting your rib cage while monitoring your ribs with your fingers.

To fully understand ventilation, it is essential to recognize that the lungs and thoracic wall together form an elastic system. Much like a hollow rubber ball with a hole on one side, they assume a certain equilibrium volume, known as their **relaxation volume**, if they are free of any external forces. For the volume of the lungs to deviate from the relaxation volume, muscular effort must be exerted. In adult human males, the relaxation volume of the lungs, measured as the volume of gas they hold at relaxation, is about 2400 mL. This volume is the same as that of the lungs after a resting exhalation (see Figure 23.19): The lungs and thorax are in their relaxed state after a resting exhalation.

Inhalation in humans at rest is active (meaning that it entails muscular effort). During inhalation, the lungs are *expanded to greater than their relaxation volume* by contraction of the diaphragm, external intercostal muscles, and anterior internal intercostals. Mammals do not close the glottis during ordinary breathing. Thus inhalation continues only as long as the inspiratory muscles contract. Exhalation in resting humans is largely or completely passive (meaning that it does not entail muscular effort). When the inspiratory muscles cease to contract at the end of inhalation, lung volume *returns elastically to its passive equilibrium state: the relaxation volume*.

When mammals exercise, they typically increase not only their tidal volume but also their breathing frequency. Additional muscular activity is required, therefore, both to amplify changes in lung volume during each breath and to hasten the inspiratory and expiratory processes. In people, the external intercostal muscles assume a greater role in inhalation during exercise than they do during rest; whereas expansion of the rib cage by these muscles during quiet breathing is of relatively minor importance compared with the action of the diaphragm, expansion of the rib cage by the external intercostals during heavy exertion accounts for about half of the inspiratory increase in lung volume. Active forces also contribute to exhalation

FIGURE 23.21 The likely fountainhead of breathing A 1-mm-thick slice of the medulla of a nestling mouse produces electrical signals that, judging from their patterns, control the rhythm of ordinary breathing and sighs. Each recording shows electrical activity as a function of time. The recordings presented here have been integrated to remove random noise, explaining why they are smoother than those in Figure 23.9. (After Lieske et al. 2000.)

in people during exercise. The most important muscles in exhalation are the internal intercostals, which actively contract the rib cage, plus the muscles of the abdominal wall, which contract the abdominal cavity, forcing the diaphragm upward into the thoracic cavity. These muscles hasten exhalation during exercise and may also compress the lungs beyond their relaxation volume, thereby enhancing tidal volume by use of some of the expiratory reserve volume.

Although all mammals tend to use the same basic groups of muscles for ventilation, the relative importance of the muscle groups varies. In large quadrupeds, for example, movements of the rib cage tend to be constrained, and the diaphragm bears especially great responsibility for ventilation.

The control of ventilation

A KEY SITE OF ORIGIN OF THE VENTILATORY RHYTHM IS THE PRE-BÖTZINGER COMPLEX The location of the specific neurons that are most important for rhythmogenesis—generation of the breathing rhythm—is now well established. These neurons are found in a bilaterally arrayed pair of neuron clusters within the ventrolateral medulla of the brainstem, called the **pre-Bötzinger complex**. Thin medullary tissue slices containing the pre-Bötzinger complex—slices that are entirely isolated from the rest of the body—endogenously produce neural outputs that control the routine breathing rhythm and that evidently also play roles in controlling sighs and gasps (Figure 23.21). A question that remains is whether the central pattern generator in the pre-Bötzinger complex can, in itself, produce the fully formed rhythmogenesis observed in intact animals. Current evidence indicates it must interact with one or more additional, nearby central pattern generators to achieve this.

VENTILATION IS MODULATED BY CHEMOSENSATION OF CO₂, H⁺, AND O₂ As briefly mentioned earlier, the partial pressures of O₂

and CO_2 in alveolar gas are ordinarily held at set-point levels under a wide range of functional states. In humans at rest, for example, the alveolar O_2 partial pressure is 13.3 kPa (100 mm Hg), and the CO_2 partial pressure is 5.3 kPa (40 mm Hg). These partial pressures remain the same during light to moderately intense exercise. Only during heavy exertion do the gas partial pressures in the alveoli deviate more than slightly from the resting values. To explain the stability of alveolar gas composition, ventilatory controls based on chemosensation of CO_2 , H^+ , and O_2 are critical, although they are not the only important controls of ventilation.

Controls based on sensation of CO_2 and H^+ are the most potent chemosensory controls in mammals. When the concentration of CO_2 in the blood or other body fluids rises or falls, the concentration of H^+ typically increases or decreases in parallel (see page 640).⁶ The blood concentrations of *both* CO_2 and H^+ are independently sensed by

⁶ CO_2 has been aptly termed a “gaseous acid” because it reacts with H_2O to form carbonic acid (H_2CO_3), which then dissociates to form H^+ and HCO_3^- . The changes in H^+ concentration are sometimes expressed as changes in pH. When H^+ concentration increases, pH decreases, and vice versa.

chemosensitive neural zones near the ventral surface of the medulla. A deviation of either concentration from its normal level potently influences breathing, and because CO_2 and H^+ concentrations tend to vary together, they often exert synergistic effects. Ventilation increases or decreases so as to bring the concentrations of CO_2 and H^+ back toward normal—a negative feedback system. For example, if the CO_2 concentration of the blood is elevated, ventilation is increased, resulting in a greater rate of CO_2 exhalation. The potency of these effects is illustrated by the fact that an increase of just 0.5 kPa (4 mm Hg) in a person’s arterial partial pressure of CO_2 —from 5.3 to 5.8 kPa (40 to 44 mm Hg)—will cause the volume of air ventilated per minute to approximately *double*. During high-intensity exercise, as discussed in Chapter 8, production of lactic acid by anaerobic glycolysis often increases the H^+ concentration of the blood, in addition to the effects of CO_2 on H^+ . Ventilatory drive caused by this acidification sometimes is so potent that it gives athletes a sense of profound discomfort because of the intensity of their breathing.

Detection of hypoxia—low tissue O_2 —is a particularly active area of research at present (Box 23.1). Blood hypoxia in mammals

BOX 23.1 LOW O_2 : DETECTION AND RESPONSE

Animals detect low O_2 levels—and respond to them—at two different scales. The elaborateness of these mechanisms reflects the extreme importance of O_2 . Because most animals are fundamentally aerobic, O_2 levels that are unusually low mean trouble.

One scale of response to low O_2 is that of the whole body: the scale of organ systems. This is the scale discussed in the accompanying text. The O_2 partial pressure in the circulating blood is monitored, and responses—such as increased ventilation—are elicited to keep the blood O_2 partial pressure from falling. These responses help to protect the animal’s cells from experiencing hypoxia.

The second scale is intracellular, in cells throughout the body. These responses are elicited if the rate at which the circulatory and breathing systems supply O_2 fails to keep pace with the rate of mitochondrial O_2 utilization—resulting in cellular hypoxia. **Hypoxia-inducible factors 1 and 2 (HIF-1 and HIF-2)** are the most central players in these responses. They are closely related transcription factors, which bind with *hypoxia-response elements* (regions) of DNA to activate gene transcription. HIF-1 is an ancient molecule, identified in invertebrates as well as in all groups of vertebrates. HIF-1 and HIF-2 increase in concentration in a cell when the cell experiences hypoxia, and they affect the transcription of dozens or hundreds of target genes, which have been identified through transcription profiling (transcriptomics) (see Chapter 3). HIF-1 and HIF-2 are different in their effectiveness in activating various genes in a tissue. Moreover, their target genes differ to some extent from

Formation and action of HIF-1

tissue to tissue within a single species, and they also differ among species. Overall, HIF-1 and HIF-2 have extremely broad ranges of potential action. Many of their actions require the participation of additional transcription factors or coactivators. In vertebrates, they increase erythropoiesis, synthesis of glucose transporters, synthesis of enzymes of anaerobic glycolysis, and synthesis of a form of mitochondrial cytochrome oxidase that is particularly efficient in using O_2 . Besides these effects and many others, they also promote *angiogenesis*, the development of new blood capillaries. The increase in capillaries shortens the average distance between tissue cells and capillaries, thereby aiding O_2 diffusion into the cells.

The basic manner in which the intracellular concentrations of these transcription factors are regulated is exemplified in the figure using HIF-1. A complete HIF-1 molecule consists of

α and β subunits. The β subunits are present regardless of O_2 level. Moreover, the α subunits are constantly being synthesized and tagged (ubiquitinated) for breakdown. When the O_2 level in a cell decreases, breakdown of α subunits is inhibited. Therefore, the concentration of α subunits rises, and more HIF-1 molecules are formed by dimerization of α and β subunits. Various agents in addition to O_2 help control the half-life of the α subunits.

The two scales of response to low O_2 mentioned at the start in fact interact. As already indicated, for example, the HIF-1 and HIF-2 systems play central roles in controlling the secretion of the hormone *erythropoietin*, which controls the rate of production of red blood cells. In this way, HIF-1 and HIF-2 help control the O_2 -carrying ability of each unit of volume of blood, which is a major factor at the scale of organ systems.

BOX 23.2 MAMMALS AT HIGH ALTITUDE

With Notes on High-Flying Birds

The environment at high montane altitudes is challenging in many respects. It can be cold, windy, dehydrating, and high in ultraviolet radiation. The most immediate challenge for a mammal or bird at high elevation, however, is to meet the O_2 demands of its cells, because the source of O_2 —the atmosphere—is rarefied. This low level of O_2 cannot be escaped. People can escape cold temperatures by building dwellings and animals can do so by building nests, but the low level of O_2 in the ambient air at high altitude exists everywhere, including in a dwelling or nest. Here we discuss several dimensions of this challenge; other aspects are discussed in Boxes 8.3 ($\dot{V}_{O_{2max}}$) and 24.5 (blood and circulation).

Permanent human settlements occur at 3500–4500 m (11,500–15,000 ft) on the Andean and Tibetan Plateaus. The people in these settlements have ordinary resting and maximal rates of O_2 consumption compared with members of the general population at sea level, and they lead active lives—despite the fact that the atmospheric O_2 partial pressure is only 60–65% as high as at sea level.

Evolutionary adaptation, based on natural selection and gene-frequency changes, has probably occurred in the high-altitude populations in the Andes and Tibet. These populations, which began independently, have existed now for 10,000–20,000 years—representing hundreds of generations. Recent research has established beyond doubt that the Andean and Tibetan populations differ in striking ways in their physiological attributes at high altitude.

When a person born and reared at low altitude ascends the high mountains, his or her functional traits change over time as acclimatization occurs. However, such a person may never acquire a close physiological resemblance to people born and reared at high altitude.

From what we have said thus far, you can see that for analyzing people at high altitude, we need to distinguish three groups: newly arrived lowlanders, acclimatized lowlanders, and native highlanders. Moreover, we need to recognize distinct populations of native highlanders. Among other mammals, many species resemble humans in being predominantly of lowland distribution, and they therefore—at least in principle—present the same complexities. By contrast, wild populations of some species, such as llamas, are limited to high altitudes.

In the study of mammals that have principally lowland distributions—including humans—a major theme is that exposure to high altitudes may sometimes trigger responses that evolved for reasons other than adaptation to high altitude. Consider a population living at low altitude. Tissue hypoxia—a state of too little O_2 in the tissues—will arise inevitably in individuals of such a population from time to time either (1) in subparts of the body because of regional differences in O_2 delivery and use or (2) throughout the body because of blood loss or anemia. Accordingly, de-

Oxygen cascades of people at sea level and high altitude Two groups of native male Peruvians were studied at their altitudes of residence. (Data from Torrance et al. 1970.)

fenses against tissue hypoxia will evolve. Such defenses are well known in modern lowland populations, as we discuss later in this box and in Box 24.5. When individuals from such a lowland population go to high altitude, their whole body is subjected to hypoxia because of the new environment. This hypoxia caused by high altitude may trigger responses that evolved to defend against episodes of hypoxia occurring at low altitudes, and those responses may be detrimental (maladaptive) at high altitude. We must be alert to the possibility that some of the responses seen at high altitude may be misplaced responses!

is detected principally by chemoreceptive bodies outside the central nervous system: the **carotid bodies** and **aortic bodies**. There are two carotid bodies (each measuring about 0.5 cm in humans), positioned along the two common carotid arteries, near where each branches to form internal and external carotids. The carotid bodies receive blood flow from the carotid arteries and relay sensory information on the blood O_2 partial pressure to the brainstem via the glossopharyngeal nerves. Although humans have only O_2 -sensing carotid bodies, dogs, cats, and many other mammals also have O_2 -sensing aortic bodies, located along the aortic arch.

Both the carotid and aortic bodies, being richly perfused with blood from major arteries, are in excellent positions to monitor arterial O_2 partial pressure. Ordinarily the arterial O_2 partial pressure must fall far below normal before ventilation is reliably stimulated. Sensation of CO_2 and H^+ by the medulla is therefore paramount in regulating ventilation under usual resting conditions. In humans, if the arterial O_2 partial pressure falls below 7–8 kPa (50–60 mm Hg) (as compared with a normal arterial value

of ~12.7 kPa [~95 mm Hg]), marked stimulation of ventilation occurs. Sensation of O_2 partial pressure is thus of key importance in ventilatory regulation at high altitude (Box 23.2) and under other conditions (e.g., some disease states) in which the O_2 partial pressure is substantially reduced. The carotid and aortic bodies become more sensitive to lowered O_2 when the blood concentration of CO_2 or H^+ is elevated.

VENTILATION IS ALSO MODULATED BY CONSCIOUS CONTROL, LUNG MECHANOSENSORS, AND DIRECT EFFECTS OF EXERCISE The most obvious type of modulation of ventilation in humans is conscious control. We can temporarily stop breathing by choosing to stop. There are, in addition, other types of control besides the chemosensory ones.

One well-understood set of controls is based on mechanoreceptors in the lungs, which sense stretch or tension in the airways. Information from these receptors is relayed via sensory neurons to the brainstem, where signals for inhalation tend to be inhibited by

BOX 23.2 (continued)

Let's now look at some of the information available on high-altitude physiology. The figure depicts the oxygen cascades of native lowland Peruvians living at sea level and of native Peruvian highlanders at 4500 m in the Andes. You'll notice that despite the large drop in *ambient* O₂ partial pressure at 4500 m, the *venous* partial pressure of the highlanders is reduced only a little. Comparing the two populations, the venous O₂ partial pressure is *conserved*. To understand why this occurs, physiologists study all the steps in the oxygen cascade (see Figure 22.8). From inspection of the figure, you can see that the conservation of venous O₂ partial pressure in the Andean highlanders results from significant reductions in two of the partial pressure drops (steps) of the oxygen cascade. The drop in partial pressure between ambient air and alveolar gas is about 4.3 kPa (32 mm Hg) at high altitude and therefore is much smaller than the drop at sea level, 5.7 kPa (43 mm Hg); and the drop between arterial blood and mixed venous blood is about 1.5 kPa (11 mm Hg) at high altitude, versus 7.3 kPa (55 mm Hg) at sea level. Discussion of the arterial-to-venous drop is a topic in blood-gas transport and is discussed later (see Box 24.5). Here, we examine *lung function* and *systemic tissue physiology*.

One of the most important defenses marshaled by lowland humans at high altitude is **hyperventilation**, defined to be an increase in the rate of lung ventilation associated with any given rate of O₂ consumption. When lowlanders first ascend to high altitude, a prompt (acute) increase in their rate of ventilation occurs; this increase is probably activated principally by the reduction in their arterial O₂ partial

pressure, sensed by the carotid bodies. As lowlanders pass their first days at high altitude, their rate of ventilation becomes even higher, evidently because of an increasing physiological sensitivity of the breathing control mechanisms to hypoxic stimulation. The hyperventilation observed in lowlanders accelerates the flux of fresh air to their lungs and clearly helps them maintain a relatively high O₂ partial pressure in their alveolar gas despite the fact that they are breathing rarefied air. Nonetheless, based on the information available, hyperventilation gradually subsides if lowlanders spend extended lengths of time at altitude. Among native highlanders, Tibetans and Andeans differ strikingly. Tibetan highlanders exhibit marked hyperventilation; at a given O₂ demand, their ventilation rate is roughly twice that of people residing at sea level. For them, hyperventilation is permanent! Andean highlanders exhibit less of a hyperventilation response. Hyperventilation is not essential for life at high altitude; adjustments elsewhere in the oxygen cascade can substitute for it. Most species of mammals at high altitude, however, display hyperventilation.

Although processes such as hyperventilation (and others discussed in Box 24.5) help keep O₂ partial pressures in the systemic blood capillaries from falling excessively at high altitude, capillary O₂ partial pressures do in fact decline. In the people at sea level in the figure, blood enters the systemic capillaries at an arterial O₂ partial pressure of about 12.5 kPa (94 mm Hg) and exits at a mixed venous O₂ partial pressure of about 5.2 kPa (39 mm Hg). In the people at 4500 m, blood enters at a much lower partial pressure, 5.9 kPa (44 mm Hg), and exits at a modestly lower one, 4.4

kPa (33 mm Hg). Thus the O₂ partial pressure in the capillaries—which drives O₂ diffusion to the mitochondria in cells—is, on average, reduced at high altitude, a common circumstance in mammals. Great interest is focused at present on how the tissues of mammals accommodate to this condition. Investigations of various species point to off-setting *tissue-level adjustments* that sometimes occur, either as a consequence of acclimatization or as a result of adaptive evolution.

Genomic scientists are trying to identify genes that have been subject to natural selection in native highland populations. These studies have recently hit pay dirt in finding that genes in the hypoxia-inducible factor HIF-2 signaling pathway (see Box 23.1) have been subject to strong positive natural selection in Tibetan highlanders during the approximately 20,000 years since the Tibetan Plateau was colonized with permanent human settlements. These genes may prove to affect HIF-2 signaling in ways that aid life at high altitude, such as by controlling red blood cell production in advantageous ways (see Box 24.5). **Box Extension 23.2** discusses elevated pulmonary blood pressure in humans at high altitude, specific tissue-level adjustments, HIF involvement, and llamas as examples of native highland mammals. It also addresses high-flying birds, especially the bar-headed goose.

lung expansion and excited by lung compression. Certain of these mechanosensory responses are known as the *Hering-Breuer reflexes*.

During exercise, there are clearly controls operating in addition to chemosensory ones. Whereas these other controls are important, they are not well understood. As already stressed, the arterial partial pressures of O₂ and CO₂ remain little changed from resting values during light to moderate exercise. This stability results *because* the ventilation rate increases in tandem with the metabolic rate. However, arterial gas partial pressures are far too stable during light to moderate exercise to *account* for observed increases in ventilation on the basis of the simple chemosensory negative feedback systems we have discussed up to here; for example, whereas an increase of about 0.5 kPa (4 mm Hg) in the arterial CO₂ partial pressure is required to bring about a doubling of ventilation rate, the measured CO₂ partial pressure during exercise may not be elevated to that extent even when ventilation has reached 10–15 times the resting rate! In addition to controls mediated by gas partial pressures, there is increasing evidence for the existence of controls that are

initiated in direct association with the muscular movements of exercise. These controls are postulated to take two forms: First, parts of the brain that initiate motor signals to the exercising muscles might simultaneously initiate stimulatory signals to the breathing centers. Second, sensors of movement or pressure in the limbs might stimulate the breathing centers based on the vigor of the limb activity they detect. One persuasive piece of evidence for these sorts of controls is that when people suddenly begin to exercise at a moderate level, a marked increase in their ventilation rate is evident within just *one or two breaths*; this response is far too rapid to be mediated by changes in the chemical composition of the body fluids. Another piece of evidence is that in many species of mammals, breathing movements and limb movements are synchronized during running.

BOTH TIDAL VOLUME AND BREATHING FREQUENCY ARE MODULATED BY CONTROL SYSTEMS The overall rate of lung ventilation depends on two properties: the tidal volume, V_T , and the frequency

of breaths, f , usually expressed as the number of breaths per minute. The product of these is the **respiratory minute volume**:

$$\text{Respiratory minute volume} = \frac{V_T}{(\text{mL}/\text{min})} \times \frac{f}{(\text{breaths}/\text{min})} \quad (23.2)$$

To illustrate, resting humans have a tidal volume of about 500 mL and breathe about 12 times per minute. Thus their respiratory minute volume is about 6 L/min.

Both tidal volume and breathing frequency are increased during exercise and during other states that increase the rate of metabolism. Humans and other mammals, however, cannot maximize both of these variables simultaneously because the time needed for one breathing cycle tends to increase as the tidal volume increases. Nonetheless, during vigorous exercise, trained athletes are able to maintain a tidal volume of at least 3 L while breathing at least 30 times per minute. In this way, their respiratory minute volume can reach greater than 100 L/min—more than 15 times the resting value.

The **alveolar ventilation rate**, typically expressed as the **alveolar minute volume**, is defined to be the rate at which new air is brought into the alveoli and other *respiratory* airways. This rate is important because the air that reaches the respiratory airways is the air that can undergo gas exchange with the blood. The alveolar minute volume is calculated by subtracting the volume of the anatomical dead space, V_D , from the tidal volume and multiplying by the breathing frequency:

$$\text{Alveolar minute volume} = (V_T - V_D) \times f \quad (23.3)$$

Another property of importance relating to the respiratory airways is the fraction of all inhaled air that reaches them. This fraction—calculated by dividing the alveolar minute volume (Equation 23.3) by the total minute volume (Equation 23.2)—is $(V_T - V_D)/V_T$.

From the expression just described, you can see that—with V_D assumed to be constant—the fraction of air reaching the respiratory airways increases as the tidal volume increases. This fact helps resolve a paradox. When the overall ventilation rate is increased, the oxygen utilization coefficient increases. Although humans, for example, use about 20% of the O_2 in the air they breathe when their tidal volume is 500 mL, they use about 30% when their tidal volume is 2000 mL. How is this possible if, as we have often emphasized, the control systems typically keep the alveolar O_2 partial pressure constant? The paradox is resolved by recognizing two aspects of gas exchange. First, air that reaches the respiratory airways always gives up about the same fraction of its O_2 (accounting for the constancy of alveolar O_2 partial pressure). Second, however, a greater proportion of all the air that is breathed actually enters the respiratory airways as the tidal volume increases.

In species of different sizes, lung volume tends to be a constant proportion of body size, but breathing frequency varies allometrically

If we look at the full range of mammals, ranging in size from shrews to whales, there is a strong inverse (and allometric) relation between breathing frequency and body size. We breathe about 12 times per minute at rest. A mouse breathes 100 times per minute! This dramatic effect is a logical consequence of several facts. First, lung volume tends, on average, to be a relatively constant fraction of total body volume: Lung volume in liters averages about 6% of body weight in kilograms. Second, resting tidal volume tends consistently to

be about one-tenth of lung volume or 0.6% of body weight. Third, related to these points, when mammals of all sizes are at rest, the amount of O_2 they obtain per breath is approximately a constant proportion of their body weight. However, as emphasized in Chapter 7, the resting weight-specific rate at which mammals metabolically consume O_2 increases allometrically as body size decreases. If the O_2 demand per unit of body weight in a small mammal is greater than that in a large mammal, and yet the small animal obtains about the same amount of O_2 per breath per unit of weight, then the small animal must breathe more frequently.

Pulmonary surfactant keeps the alveoli from collapsing

The alveoli may be thought of as aqueous bubbles because their gas-exchange surfaces are coated with an exceedingly thin water layer. If the alveoli were composed only of water, they would follow the physical laws of simple aqueous bubbles. One such law is that the tendency of a bubble to collapse shut increases as its radius decreases.⁷ Thus, during exhalation, there is a risk that as the radius of an alveolus decreases, the alveolus might collapse shut by emptying entirely into the airways of the lung. This possibility may sound like a remote conjecture from a physics book. In fact, however, until this application of physics to biology was appreciated, thousands of human babies died every year because of bubble physics, as we discuss soon.

The alveoli in normal lungs do not behave as simple aqueous bubbles because of the presence of a complex mixture of metabolically produced lipids and proteins called **pulmonary surfactant** (*surfactant*, “surface active agent”). About 90% of pulmonary surfactant is lipids, mostly phospholipids (amphipathic molecules, as seen in Chapter 2). Pulmonary surfactant is synthesized by specialized pulmonary epithelial cells, which secrete the lipoprotein complex as vesicles. After secretion, phospholipids from the vesicles associate with the surface of the thin water layer that lines each alveolus, where they radically alter the surface-tension properties of the water. Their overall effect is to reduce the surface tension below that of pure water. This effect in itself helps prevent alveoli from collapsing shut because the tendency of bubbles to collapse decreases as their surface tension decreases (explaining why soap bubbles linger longer than bubbles of pure water). The most profound effect of pulmonary surfactant, however, is that it gives the alveoli a *dynamically variable surface tension*. With surfactant present, as an alveolus enlarges, its surface tension increases, an effect that impedes further enlargement and helps prevent the alveolus from expanding without limit. Conversely, as an alveolus decreases in size, its surface tension decreases, helping to prevent any further decrease in size. Surfactant, therefore, helps keep all alveoli similar in size.

Infants born prematurely sometimes lack adequate amounts of pulmonary surfactant. Their alveoli therefore lack the protections of surfactant, and many collapse shut during each exhalation. The infants then must inhale with sufficient force to reopen the alveoli. The process is tiring and damages the alveoli. Death rates were very high until therapies based on knowledge of pulmonary surfactant were introduced.

⁷ This is an implication of Laplace’s Law, which—applied to bubbles—states that $P = 2T/r$, where r is the radius of a bubble, P is the pressure difference between the inside and outside of the bubble, and T is the tension in the walls of the bubble. If everything is considered constant except P and r , the pressure difference required to keep a bubble open is seen to increase as the radius r decreases.

The use of knockout mice and other genomic methods is leading to rapid advances in understanding of the surfactant proteins. One of them, *protein B*, is now known to be essential for life, evidently because it plays indispensable roles in controlling the distribution of surfactant lipids.

Pulmonary surfactants that share basic chemical similarities have been reported from the lungs of all groups of terrestrial vertebrates, lungfish, and some other air-breathing fish. Thus the pulmonary surfactants have a long evolutionary history, dating back at least to the origins of vertebrate air breathing. The roles of pulmonary surfactants in animals other than mammals are incompletely known but are gradually being better understood.

SUMMARY Breathing by Mammals

- The lungs of mammals consist of dendritically branching airways that end blindly in small, thin-walled, well-vascularized outpocketings, the alveoli. The airways exhibit 23 levels of branching in the human adult lung, giving rise to 300 million alveoli. The airways in a mammalian lung are categorized as conducting airways, where little gas exchange with the blood occurs, and respiratory airways, where most gas exchange with the blood takes place.
- Because of the blind-ended structure of the mammalian lung, the gas in the alveoli always has a substantially lower O_2 partial pressure and higher CO_2 partial pressure than atmospheric air.
- Contraction of the diaphragm is a principal force for inhalation in mammals, especially large quadrupeds. External intercostal muscles may contribute to inhalation; internal intercostal muscles and abdominal muscles may contribute to exhalation. Inhalation occurs by suction as the lungs are expanded by contraction of inspiratory muscles. At rest, exhalation occurs passively by elastic rebound of the lungs to their relaxation volume when the inspiratory muscles relax.
- The breathing rhythm in mammals originates in a central pattern generator in the pre-Bötzinger complex in the medulla of the brainstem.
- The most potent chemosensory stimulus for increased ventilation in mammals is a rise in blood CO_2 partial pressure and/or H^+ concentration, sensed in the medulla. The blood O_2 partial pressure, ordinarily a less influential factor in controlling ventilation, is sensed by the carotid bodies along the carotid arteries (humans) or by carotid and aortic bodies (certain other mammals). The control of ventilation during exercise involves stimuli generated in association with limb movement as well as chemosensory controls.
- Pulmonary surfactant, a surface tension-reducing mix of lipids and proteins, makes a critical contribution to maintaining the proper microscopic conformation of the lungs in all air-breathing vertebrates.

Breathing by Birds

The lungs of birds, although they are logical derivatives of the types of lungs thought to exist in the common ancestors of birds and mammals, differ in fundamental structural features from the lungs of mammals and all other modern vertebrates except certain crocodylian reptiles (see page 597). The structural difference between avian and mammalian lungs inevitably invites compari-

son. Are avian lungs functionally superior to mammalian lungs? Some authorities conclude that the designs of the lungs in birds and mammals are “different but equal”—that is, equal in their gas-exchange ability. Other authorities conclude that the lungs of birds are in fact superior organs of gas exchange. As evidence, they point to the fact that bird lungs have relatively large surface areas for gas exchange and thin gas-exchange membranes (see Figure 23.7). They also point to the fact that some birds, such as certain geese, cranes, and vultures, can *fly*—not just mope around and survive—near or above the altitude of Mt. Everest. The design of the bird lung, in comparison with the mammalian lung, may be an advantage at high altitude, in part because (as we will see) cross-current gas exchange prevails in the bird lung instead of tidal exchange. High-flying birds are discussed in Box Extension 23.2.

A bird’s trachea bifurcates to give rise to two primary bronchi, which enter the lungs. Here the similarity to mammals ends. The primary bronchus that enters each lung *passes through* the lung, being known as the **mesobronchus** within the lung. Two groups of branching **secondary bronchi** arise from the mesobronchus. One group, which arises at the anterior end of the mesobronchus, spreads over the ventral surface of the lung. The other group originates toward the posterior end of the mesobronchus and spreads over the dorsolateral lung surface. For simplicity, we call these the *anterior* and *posterior* groups of secondary bronchi, although they are formally termed the *medioventral* and *mediodorsal* groups, respectively. Also for simplicity, each group is represented as just a single passageway in **Figure 23.22a**.

The anterior and posterior secondary bronchi are connected by a great many small tubes, 0.5–2.0 mm in internal diameter, termed **tertiary bronchi** or **parabronchi** (four are shown in Figure 23.22a). As depicted in **Figure 23.23**, each parabronchus gives off radially along its length an immense number of finely branching **air capillaries**. The air capillaries are profusely surrounded by blood capillaries and are the sites of gas exchange. They are only 3–14 μm in diameter (large birds tending to have diameters greater than those of small birds), and collectively they form an enormous gas-exchange surface amounting to 200–300 mm^2/mm^3 of tissue in the parabronchial walls. Air flows through the central lumen of each parabronchus, but exchange between the central lumen and the surfaces of its air capillaries is probably largely by diffusion. The parabronchi, air capillaries, and associated vasculature constitute the bulk of the lung tissue of a bird.

A bird’s **air sacs**, which are part of the breathing system, are located *outside* the lungs and occupy a considerable portion of the thoracic and abdominal body cavities (**Figure 23.24**). Usually, there are nine air sacs, divisible into two groups. The *anterior air sacs* (cervical, anterior thoracic, and interclavicular) connect to various anterior secondary bronchi. The *posterior air sacs* (abdominal and posterior thoracic) connect to the posterior portions of the mesobronchi. (Each mesobronchus terminates at its connection with an abdominal air sac.) The air sacs are thin-walled, poorly vascularized structures that play little role in gas exchange between the air and blood. Nonetheless, as we will see, they are essential for breathing.

The structures of the lung described thus far are present in all birds, and their connections with the air sacs are similar in all birds. These lung structures are collectively termed the **paleopulmonary system**, or simply **paleopulmo**. Most birds, in addition, have a more

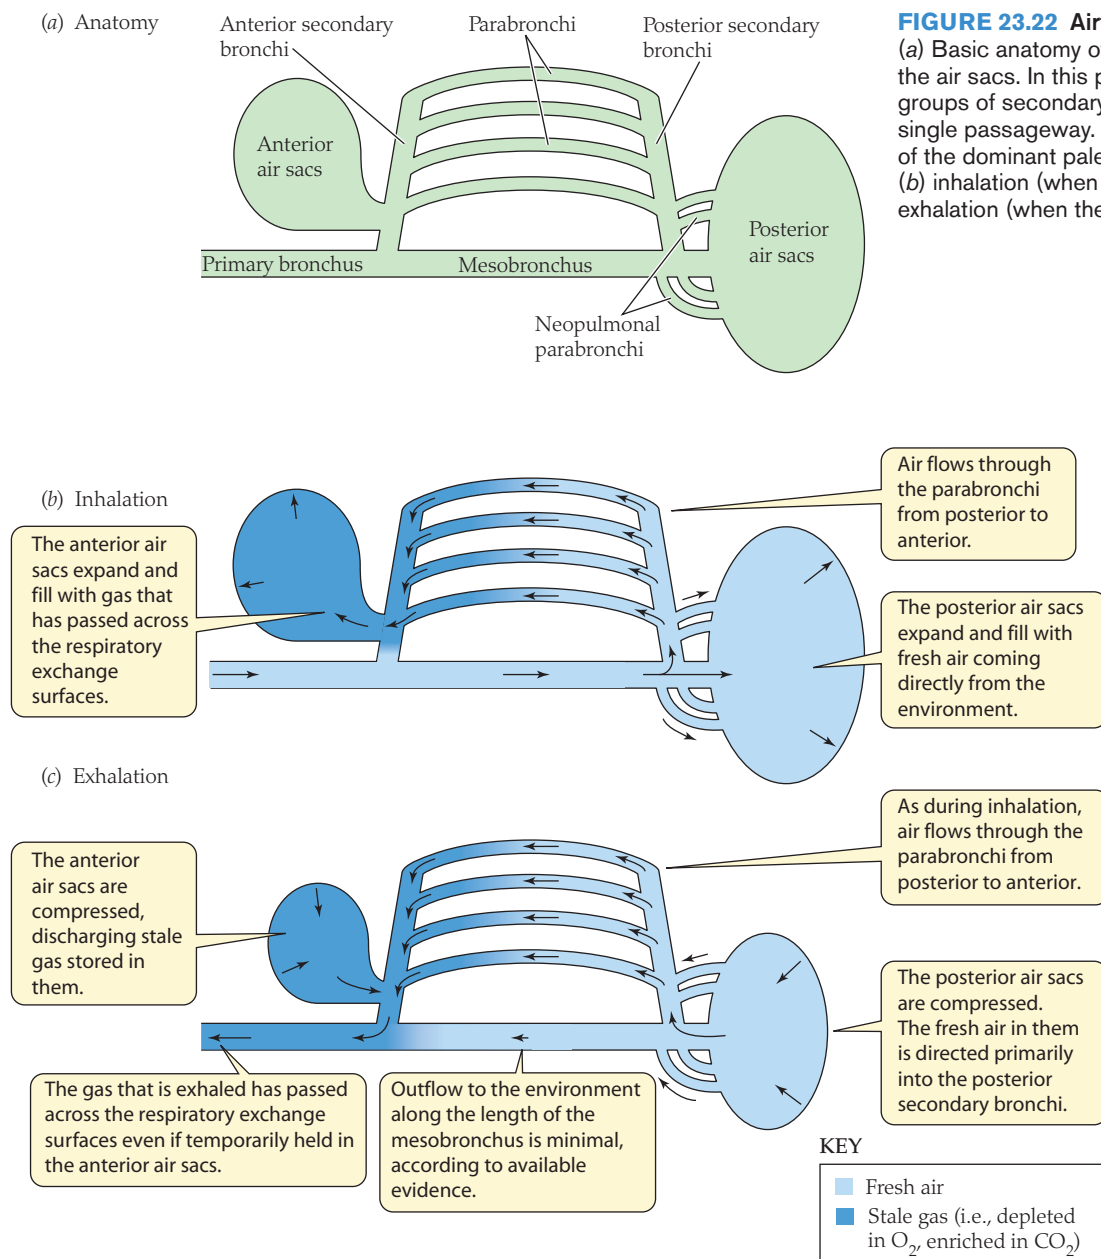

FIGURE 23.22 Airflow in the lungs and air sacs of birds (a) Basic anatomy of the avian lung and its connections with the air sacs. In this presentation, the anterior and posterior groups of secondary bronchi are each represented as a single passageway. The tubes labeled *parabronchi* are those of the dominant paleopulmonary system. (b, c) Airflow during (b) inhalation (when the air sacs undergo expansion) and (c) exhalation (when the air sacs undergo compression).

or less extensively developed system of respiratory parabronchial tubes—termed the **neopulmonary system**—running directly between the posterior air sacs and the posterior parts of the mesobronchi and posterior secondary bronchi (see Figure 23.22a). The neopulmonary system is especially well developed in songbirds. The paleopulmonary system, nonetheless, is always dominant.

Ventilation is by bellows action

Avian lungs are compact, rigid structures. Unlike mammalian lungs, they undergo little change in volume over the course of each breathing cycle. The air sacs, by contrast, expand and contract substantially and, like bellows, suck and push gases through the relatively rigid airways of the lungs. To a dramatic extent relative to mammalian ventilation, this avian process is an energetically inexpensive way to move air.

The part of the rib cage surrounding the lungs themselves is relatively rigid. During inhalation, other parts of the rib cage (es-

pecially those posterior to the lungs) are expanded by contraction of internal intercostal muscles and certain other thoracic muscles, and the sternum swings downward and forward. These movements enlarge all the air sacs by expanding the thoracoabdominal cavity. Some of the external intercostals and abdominal muscles compress the thoracoabdominal cavity and air sacs during exhalation. Resting birds typically breathe at only about one-half or one-third the frequency of resting mammals of equivalent body size, but the birds have greater tidal volumes.

Air flows unidirectionally through the parabronchi

Air flows unidirectionally through the parabronchi of the paleopulmonary system. To see how this occurs, we must describe the movement of air during both inhalation and exhalation. During inhalation, both the anterior and posterior sets of air sacs expand. Suction, therefore, is developed in *both* sets of air sacs, and *both* receive gas. As depicted in Figure 23.22b, air inhaled from the at-

mosphere flows through the mesobronchus of each lung to enter the posterior air sacs and posterior secondary bronchi. Simultaneously, the air entering the posterior secondary bronchi is drawn anteriorly through the parabronchi by suction developed in the expanding anterior air sacs. Three aspects of the events during inhalation deserve emphasis. First, the posterior air sacs are filled with relatively fresh air coming directly from the environment. Second, the anterior air sacs are filled for the most part with stale gas that has passed across the respiratory exchange surfaces in the parabronchi. Finally, the direction of ventilation of the parabronchi in the paleopulmonary system is from posterior to anterior.

During exhalation, both sets of air sacs are compressed and discharge gas. As shown in [Figure 23.22c](#), air exiting the posterior air sacs predominantly enters the posterior secondary bronchi to pass anteriorly through the parabronchi. This air is relatively fresh, having entered the posterior sacs more or less directly from the environment during inhalation. Gas exiting the parabronchi anteriorly, combined with gas exiting the anterior air sacs, is directed into the mesobronchus via the anterior secondary bronchi and exhaled. Recall that the anterior air sacs were filled with stale gas from the parabronchi during inhalation. Thus the exhaled gas is mostly gas that has passed across the respiratory exchange surfaces.

FIGURE 23.24 The air sacs of a goose and their connections to the lungs Air sacs are blue, lungs are light orange. All the air sacs are paired, except the single interclavicular sac. (After Brackenbury 1981.)

Three aspects of the expiratory events deserve emphasis: First, the relatively fresh air of the posterior air sacs is directed mostly to the parabronchi. Second, the gas that is exhaled from the lungs has largely passed across the respiratory exchange surfaces. Finally, air flows through the parabronchi of the paleopulmonary system from posterior to anterior, just as it does during inhalation.

One of the greatest remaining questions in the study of avian lungs is *how* air is directed along its elaborate (and in some ways counterintuitive) paths through the paleopulmonal system and air sacs. Passive, flaplike valves appear to be entirely absent. Active, muscular valves could be present, but evidence for their existence is at best circumstantial. Most present evidence suggests that the complex architecture of the lung passages creates aerodynamic conditions that direct air along the inspiratory and expiratory paths without need of either passive or active valves.

Ventilation of the neopulmonal system is incompletely understood. Probably, however, airflow through many of the neopulmonal parabronchi is bidirectional (see Figure 23.22*b,c*).

As discussed in **Box 23.3**, birds face unique challenges at hatching because of their lungs, which at that point must take over full responsibility for gas exchange.

The gas-exchange system is cross-current

When the unidirectional flow of air through the paleopulmonal parabronchi in the lungs of birds was first discovered, countercurrent exchange between the blood and air was quickly hypothesized. Soon, however, this hypothesis was disproved by clever experiments, which showed that the efficiency of gas exchange between air and blood is not diminished if the direction of airflow in the parabronchi is artificially reversed. Morphological and functional studies have now shown convincingly that blood flow in the respiratory exchange vessels of the circulatory system occurs in a cross-current pattern relative to the flow of air through the parabronchi (see Figure 23.23*c*).

BOX 23.3 BIRD DEVELOPMENT: FILLING THE LUNGS WITH AIR BEFORE HATCHING

The lungs of both mammals and birds initially develop in a fluid-filled condition. Young animals of both groups therefore face the problem of filling their lungs with air so as to be able to breathe when they are born or hatched. When mammals are born, they are able to fill their lungs sufficiently to survive by inflating them suddenly with their first breath from the atmosphere (all nonavian reptiles do likewise). Birds, however, cannot inflate their lungs in this way: The air capillaries in their lungs cannot be inflated suddenly out of a collapsed state because the lungs are relatively rigid and the air capillaries have extremely small diameters. Another obstacle to a sudden-inflation strategy for birds is that avian lungs probably will not work correctly unless *every* critical airway becomes gas-filled, because the pattern of airflow through the lungs is determined by complex aerodynamic interactions among the airways. Birds have thus evolved a way to *fill their lungs with air gradually* before the lungs become essential for breathing.

During most of a bird's development inside an egg, its breathing organ is a highly vascular chorio-allantoic membrane pressed against the eggshell on the inside. Oxygen and CO₂ pass between the atmosphere and the membrane by diffusion through gas-filled pores in the eggshell.

As an egg develops, it dehydrates by controlled loss of water vapor outward through the eggshell pores, a process that leads to the formation of a gas-filled space, the **air cell**, inside the egg at its blunt end. About 1–2 days before a young bird hatches, it starts to breathe from the air cell, inhaling and exhaling gas. During the ensuing hours until it hatches, the bird makes a *gradual* transition from gas exchange across its chorio-allantoic membrane to full-fledged pulmonary breathing. The air capillaries, in fact, undergo most of their pre-hatching development during this period. The airways and air capillaries in the lungs fill with gas and thus are already gas-filled by the time hatching begins and the chorio-allantoic membrane is left behind.

SUMMARY Breathing by Birds

- The lungs of birds are relatively compact, rigid structures consisting mostly of numerous tubes, running in parallel, termed parabronchi. Fine air capillaries, extending radially from the lumen of each parabronchus, are the principal sites of gas exchange. Air sacs, which are nonrespiratory, are integral parts of the breathing system.
- The lungs are ventilated by a bellows action generated by expansion and compression of the air sacs.
- Airflow through the parabronchi of the paleopulmonal system (the major part of the lungs) is posterior to anterior during both inhalation and exhalation. Cross-current gas exchange occurs.

Breathing by Aquatic Invertebrates and Allied Groups

Many small aquatic invertebrates, and some large ones, have no specialized breathing organs. They exchange gases across general body surfaces, which sometimes are ventilated by swimming motions or by cilia- or flagella-generated water currents. Many larvae and some adults also lack a circulatory system. Thus gases move within their bodies by diffusion or by the squishing of body fluids from place to place. To the human eye, these sorts of gas-exchange systems are confining. They suffice only if the animals are tiny (see Box 22.1) or have specialized body plans, such as those of flatworms and jellyfish. Most cells of a flatworm are near a body surface because the worm's body is so thin. Most cells of a jellyfish are near a

body surface because a jellyfish's body is organized with its active tissues on the outside and primarily low-metabolism, gelatinous tissue deep within.

Adults of the relatively advanced phyla of aquatic invertebrates typically have gills of some sort. The gills of the various major phyletic groups are often independently evolved. Thus, whereas they all are evaginated and project into the water (meeting the definition of gills), they vary widely in their structures and in how they are ventilated (**Figure 23.25**).

Molluscs exemplify an exceptional diversity of breathing organs built on a common plan

The phylum Mollusca nicely illustrates that within a phyletic group, a single basic sort of breathing apparatus can undergo wide diversification. In molluscs, outfolding of the dorsal body wall produces a sheet of tissue, the **mantle** (responsible for secreting the shell), that overhangs or surrounds all or part of the rest of the body, thereby enclosing an external body cavity, the **mantle cavity**. The gills of molluscs typically are suspended in the mantle cavity and

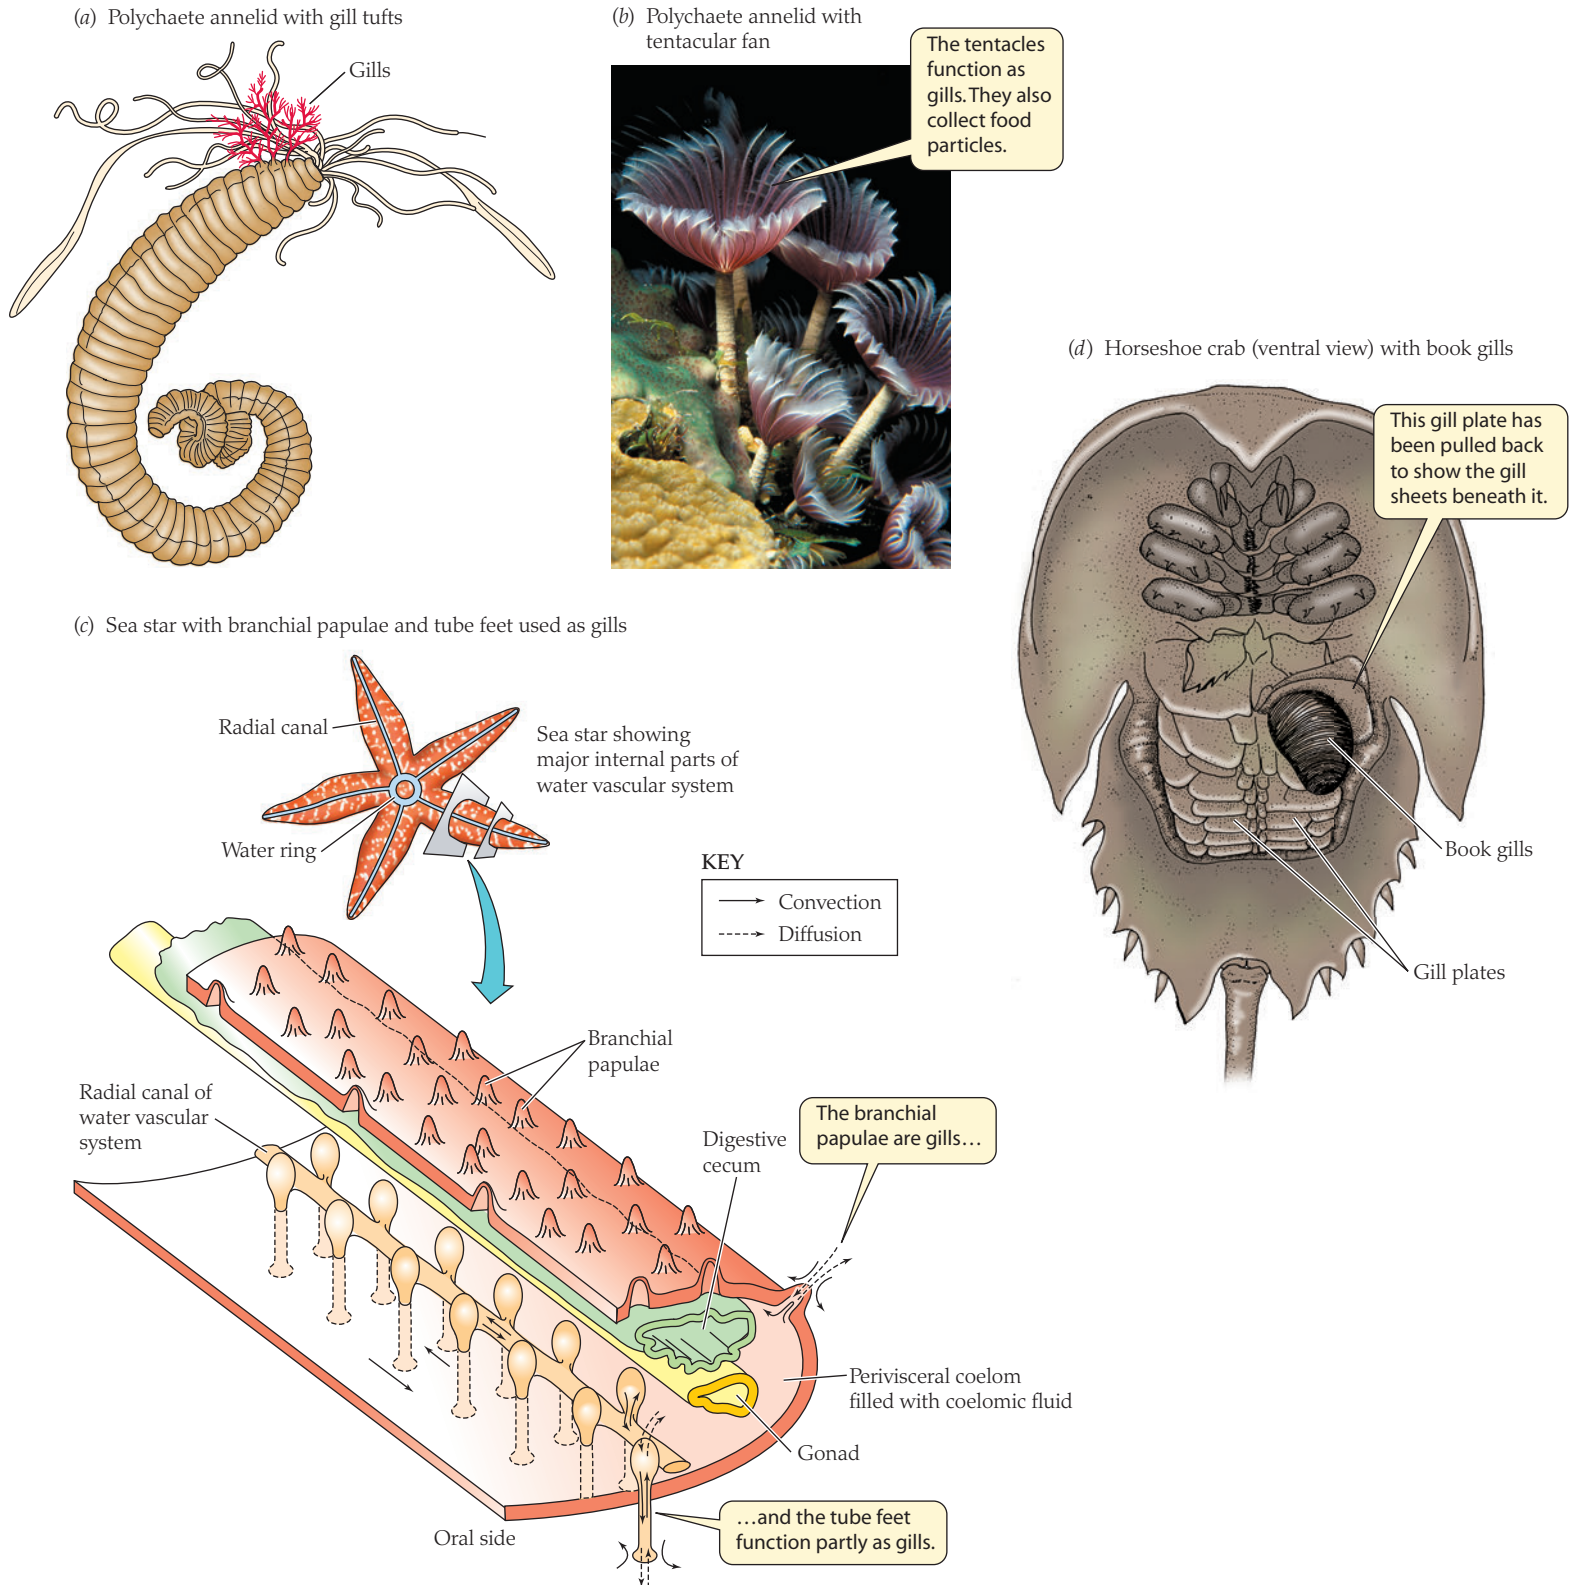

FIGURE 23.25 A diversity of gills in aquatic invertebrates

(a) This terebellid worm (*Amphitrite*), a type of marine annelid, lives inside a tube it constructs and can pump water in and out of the tube. (b) This fanworm, another type of marine annelid, also lives in a tube, but when undisturbed, it projects its well-developed array of pinnately divided tentacles into the ambient water. The tentacles are used for both feeding and respiratory gas exchange; they are ventilated by the action of cilia on the tentacles. (c) Sea stars bear many thin-walled, finger-like projections from their coelomic cavity, termed *branchial papulae* ("gill processes"), on their upper body surfaces; respiratory gases pass

between the coelomic fluid and ambient water by diffusion through the walls of the papulae. Similarly, gases diffuse between the coelomic fluid and ambient water through the tube feet and associated parts of the water vascular system. Cilia accelerate these processes by circulating fluids over the inner and outer surfaces of the papulae and tube feet. (d) Horseshoe crabs (*Limulus*) have unique *book gills*, consisting of many thin gill sheets arranged like pages of a book. The book gills are protected under thick *gill plates*, which undergo rhythmic flapping motions that ventilate the gills. (d after a drawing by Ralph Russell, Jr.)

thus are internal gills (see Figure 23.2). Certain of the aquatic snails provide a straightforward example. In them (Figure 23.26a), a series of modest-sized *gill leaflets* hangs in the mantle cavity and is ventilated unidirectionally by ciliary currents. Blood flow through the leaflets, in at least some cases, is opposite to the direction of water flow. Thus countercurrent gas exchange occurs.

One major modification of the gills in molluscs is the evolution of extensive *sheetlike gills* in the clams, mussels, oysters, and other lamellibranch (“sheet-gilled”) groups. In these groups, four gill sheets, or lamellae, composed of fused or semifused filaments, hang within the mantle cavity (Figure 23.26b). Cilia on the gill sheets drive incoming water through pores on the gill surfaces into water channels that run *within* the gill sheets; the water channels then convey the water to exhalant passages. The direction of water flow within the water channels is opposite to the direction of blood flow in the major gill blood vessels, meaning that countercurrent gas exchange can again occur. The specialized sheetlike gills of these molluscs represent, in part, an adaptation for feeding: As the abundant flow of incoming water passes through the arrays of pores leading to the interior water channels of the gill sheets, food particles suspended in the water are captured for delivery to the mouth (a type of suspension feeding; see page 141). In some (not all) molluscs with sheetlike gills, the food-collection function has become paramount: Respiratory gas exchange across general body surfaces suffices to meet metabolic needs. Thus the “gills” have become primarily feeding organs.

In the cephalopod molluscs—the squids, cuttlefish, and octopuses—it is not so much the gills that are specialized, but the mechanism of ventilation. The gills are feathery structures that follow the usual molluscan plan of being positioned in the mantle cavity (Figure 23.26c). They are ventilated, however, by muscular contraction rather than beating of cilia. Cephalopods swim by using muscular contractions of the mantle; they alternately suck water into the mantle cavity via incurrent openings and then drive it forcibly outward through a ventral funnel by mantle contraction, producing a jet-propulsive force. The gills are ventilated (in countercurrent fashion) by the vigorous flow of water used for propulsion. Some species move so much water for propulsion that they use only a small fraction of the O_2 in the water: 5–10%.

A final specialization worthy of note in molluscs is the evolution of the mantle cavity into a lung in the dominant group of snails and slugs that live on land, a group known aptly as the *pulmonates* (Figure 23.26d). In the terrestrial pulmonates, gills have disappeared, and the walls of the mantle cavity have become highly vascularized and well suited for gas exchange. Some species are thought to employ the mantle cavity as a diffusion lung, but others ventilate it by raising and lowering the floor of the cavity.

Decapod crustaceans include many important water breathers and some air breathers

In the decapod crustaceans—which include many ecologically and commercially important crabs, shrimps, lobsters, and crayfish—the head and thorax are covered with a continuous sheet of exoskeleton, the *carapace*, that overhangs the thorax laterally, fitting more or less closely around the bases of the thoracic legs. The carapace encloses two lateral external body cavities—the **branchial chambers**—in which the gills lie (Figure 23.27a). The gills arise from near the bases of the thoracic legs. Each gill consists of a central axis to which are attached many richly vascularized lamellar plates, filaments, or dendritically

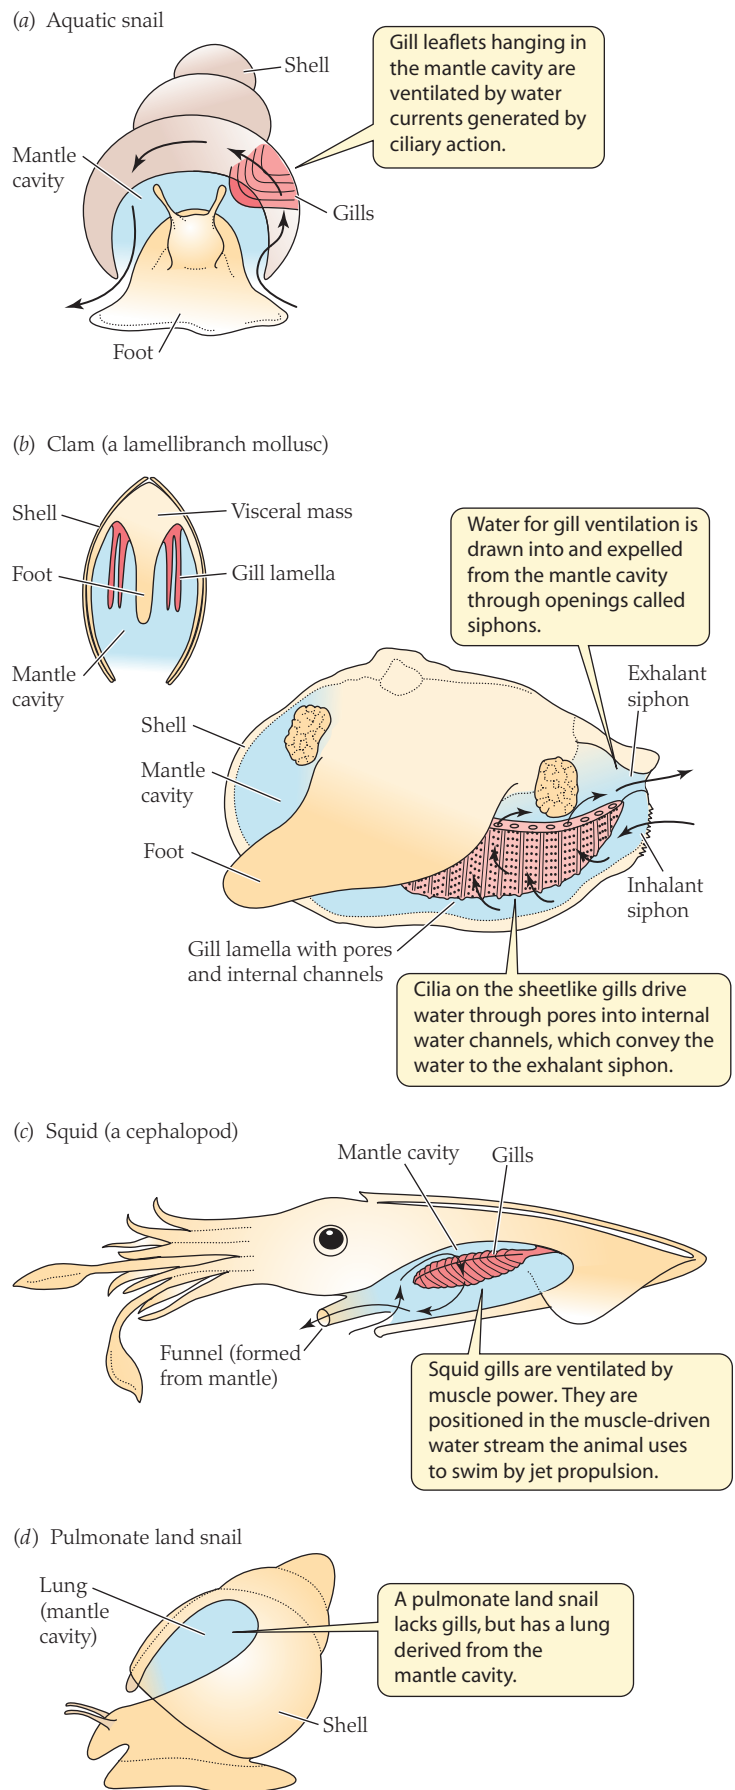

FIGURE 23.26 The diversification of the breathing system in molluscs

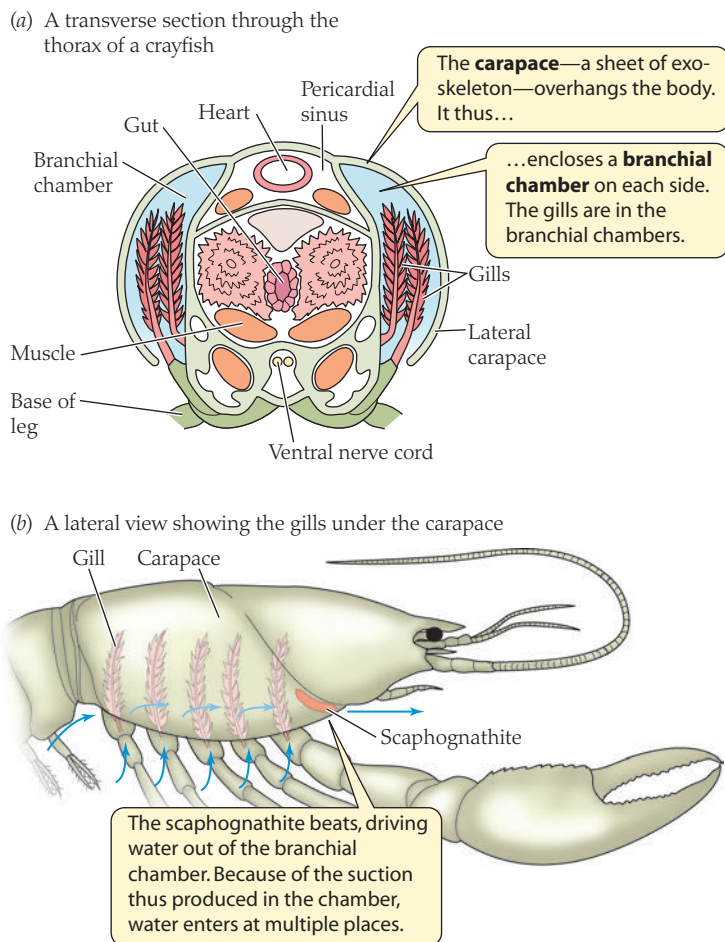

FIGURE 23.27 The gills and ventilation in a crayfish

branching tufts. The gill surfaces—like all the external body surfaces of crustaceans—are covered with a chitinous cuticle. The cuticle on the gills is thin, however, and permeable to gases.

Ventilation in crustaceans is always accomplished by muscular contraction, because the body surfaces of crustaceans lack cilia. In decapod crustaceans, each branchial chamber is ventilated by a specialized appendage—the *scaphognathite* or *gill bailer*—located toward its anterior end (Figure 23.27b). Beating of this appendage, under control of nerve impulses from a central pattern generator in the central nervous system, generally drives water outward through an anterior exhalant opening. Negative pressure is thus created within the branchial chamber, drawing water in at various openings. Ventilation is unidirectional, and countercurrent exchange may occur.

Some crabs and crayfish have invaded the land, especially in the tropics. All the semiterrestrial and terrestrial species retain gills, which are supported to some degree by their cuticular covering. One trend observed in semiterrestrial and terrestrial crabs is that the gills tend to be reduced in size and number by comparison with aquatic crabs. A second trend is that the branchial chambers tend to be enlarged (“ballooned out”), and the tissue⁸ that lines the chambers tends to be specialized by being well vascularized, thin, and thrown into folds that increase its surface area. These trends—the reduction of the gills and the development of lunglike branchial chambers—are strikingly parallel to those seen earlier in air-breathing fish and air-breathing (pulmonate) snails. The branchial chambers of crabs on land are

⁸This tissue is called the *branchiostegites*.

typically ventilated with air by beating of the scaphognathites. In the species that are semiterrestrial (amphibious), the gills are kept wet by regular trips to bodies of water. Recent evidence suggests that in these crabs, O_2 is chiefly taken up by the branchial-chamber epithelium, whereas CO_2 is chiefly voided across the gills. In fully terrestrial species of crabs, however, water is not carried in the branchial chambers, and the branchial-chamber epithelium may bear chief responsibility for exchange of both O_2 and CO_2 .

SUMMARY Breathing by Aquatic Invertebrates and Allied Groups

- The gills of various groups of aquatic invertebrates are often independently evolved. Wide variation thus exists in both gill morphology and the mode of gill ventilation.
- A single basic sort of breathing apparatus can undergo wide diversification within a single phyletic group. This general principle is illustrated by the molluscs, the great majority of which have breathing organs associated with the mantle and located in the mantle cavity. Whereas both aquatic snails and lamellibranchs employ ciliary ventilation, the gills are modest-sized leaflets in snails, but expansive sheets (used partly for feeding) in the lamellibranchs. Cephalopods, such as squids, ventilate their gills by muscular contraction. Most land snails lack gills and breathe with a lung derived from the mantle cavity.

Breathing by Insects and Other Tracheate Arthropods

The insects (Figure 23.28) have evolved a remarkable strategy for breathing that is entirely different from that of most metabolically active animals. Their breathing system brings the gas-exchange surface itself close to all cells. Thus, with some thought-provoking

FIGURE 23.28 A praying mantis, one of the largest existing insects To look at a praying mantis, one could imagine it breathing through its mouth. Nothing could be further from the truth.

exceptions, the cells of insects get their O_2 directly from the breathing system, and the circulatory system plays little or no role in O_2 transport. Insect blood, in fact, usually lacks any O_2 -transport pigment such as hemoglobin.

The body of an insect is thoroughly invested with a system of gas-filled tubes termed **tracheae** (Figure 23.29a,b). This system opens to the atmosphere by way of pores, termed **spiracles**, located at the body surface along the lateral body wall. Tracheae penetrate into the body from each spiracle and branch repeatedly, collectively reaching all parts of the animal (only major branches are seen in Figure 23.29). The tracheal trees arising from different spiracles typically join via large *longitudinal* and *transverse connectives* to form a fully interconnected tracheal system. The spiracles, which number from 1 to 11 pairs, are segmentally arranged and may occur on the thorax, abdomen, or both (but not the head). Usually they can be closed by spiracular muscles. Although tracheal breathing is best understood in insects, there are other tracheate arthropods: Most notably, certain groups of spiders and ticks have tracheal systems. Some spiders and other arachnids have *book lungs*, unique breathing organs that sometimes function in parallel with tracheal systems and sometimes are the sole breathing organs (Box 23.4).

The tracheae of an insect develop as invaginations of the epidermis and thus are lined with a thin cuticle. Typically, the cuticle is thrown into spiral folds, providing resistance against collapse. The tracheae become finer with increasing distance from the spiracles and finally give rise to very fine, thin-walled end-tubules termed **tracheoles**, believed to be the principal sites of O_2 and CO_2 exchange with the tissues. Tracheoles are perhaps 200–350 μm long and are believed to end blindly. They generally taper from a lumen diameter approximating 1 μm at their origin to 0.05–0.20 μm at the end. The walls of the tracheoles and the finest tracheae are about 0.02–0.2 μm thick—exceedingly thin by any standard (see Figure 23.7b).

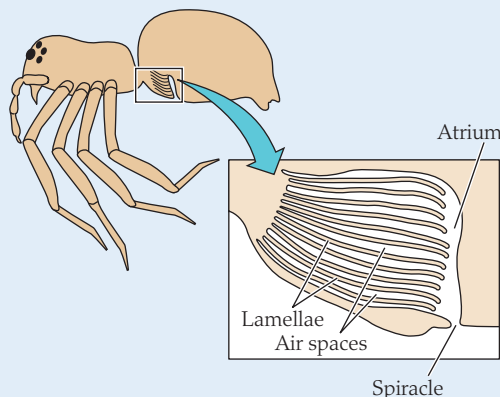

Although the layout of the tracheal system varies immensely among various species of insects, the usual result is that all tissues are thoroughly invested with fine tracheae and tracheoles. The degree of tracheation of various organs and tissues tends to vary directly with their metabolic requirements. For the most part, the tracheoles run between cells. However, in the flight muscles of many species, the tracheoles penetrate the muscle cells, indenting the cell membranes inward, and run among the individual myofibrils, in close proximity to the arrays of mitochondria. The average distance between adjacent tracheoles within the flight muscles of strong fliers is often about 3 μm . The nervous system, rectal glands, and other active tissues—including muscles besides the flight muscles—also tend to be richly supplied by the tracheal system, although intracellular penetration is not nearly as common as in flight muscles. In the epidermis of the bug *Rhodnius*, which has been carefully studied, tracheoles are much less densely distributed than in active flight muscles, but nonetheless, cells are usually within 30 μm of a tracheole. In other words, no cell is separated from a branch of the tracheal system by more than two or three other cells!

The terminal ends of the tracheoles are sometimes filled with liquid when insects are at rest. During exercise, or when the insects are exposed to O_2 -deficient environments, the amount of liquid decreases and gas penetrates farther into the tracheoles. This process facilitates the exchange of O_2 and CO_2 because of the greater ease of diffusion in gas than liquid.

Distensible enlargements of the tracheal system called **air sacs** are a common feature of insect breathing systems (Figure 23.29c) and may occur in the head, thorax, or abdomen. Some air sacs are swellings along tracheae, whereas others form blind endings of tracheae. Air sacs tend to be particularly well developed in active insects, in which they may occupy a considerable fraction of the body volume.

BOX 23.4 THE BOOK LUNGS OF ARACHNIDS

Some arachnids possess a novel type of respiratory structure, the **book lung**. Scorpions have only book lungs. Many species of spiders also have book lungs, but they may have systems of tracheae as well. The number of book lungs in an individual arachnid varies from a single pair (as in certain spiders) to four pairs (in scorpions). Book lungs are invaginations of the ventral abdomen, lined with a thin chitinous cuticle. Each book lung consists of a chamber, the atrium, which opens to the outside through a closable ventral pore, the spiracle (see figure). The dorsal or anterior surface of the atrium is thrown into many lamellar folds: the “pages of the book.” Blood streams through the lamellae, whereas the spaces among the lamellae are filled with gas. The lamellae commonly number into the hundreds, and the blood-to-gas distance across their walls is often less than 1 μm . Some book lungs may function as diffusion lungs, whereas others

A book lung The section shows the internal structure of a book lung in a two-lunged spider. (After Comstock 1912.)

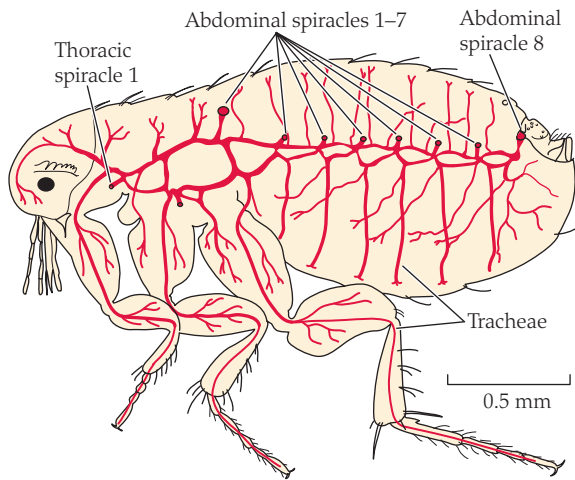

are clearly ventilated by pumping motions. They oxygenate the blood, which then carries O_2 throughout the body.

Diffusion is a key mechanism of gas transport through the tracheal system

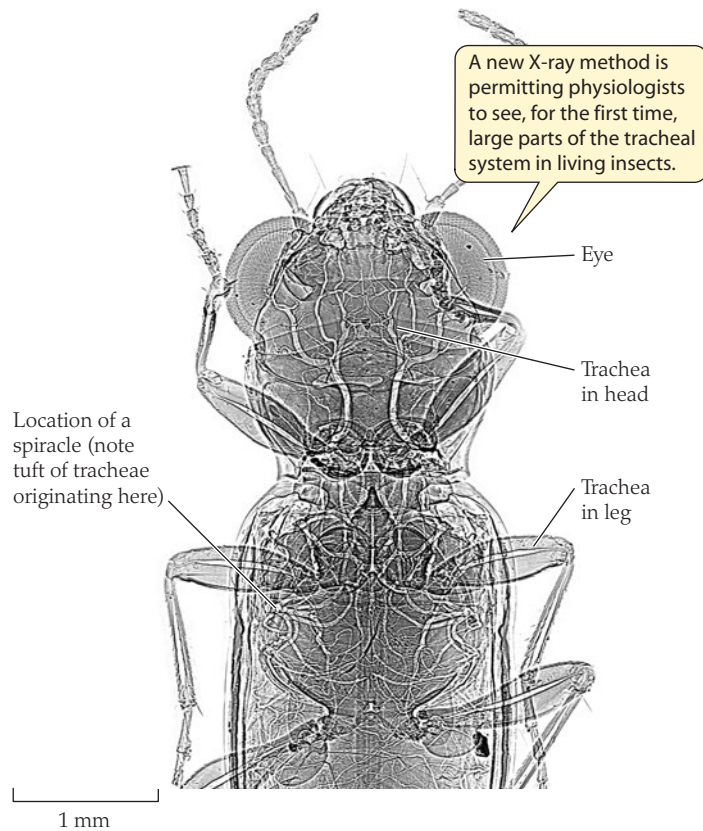

The traditional dogma has been that the tracheal system of most insects functions as a diffusion lung, meaning that gas transport through the system occurs solely by diffusion. This dogma is presently undergoing profound revision. Diffusion, nonetheless, seems likely to be an important gas-transport mechanism in subparts of the tracheal system in most or all insects and may be the sole transport process in some. Diffusion can occur fast enough to play this role because the tracheae are gas-filled.

Because of the importance of diffusion in insect breathing and because diffusion transport tends to be slow when distances are great, physiologists have long wondered whether insect body size is limited by the nature of the insect breathing system. A recent study using a new X-ray technique to

(a) Major parts of the tracheal system in a flea

(b) Tracheae in a carabid beetle

visualize the tracheal system (see Figure 23.29b) revealed that in beetles of different body sizes, the volume of the tracheal system is disproportionate to body size. In stark contrast to mammals, a greater proportion of body space is devoted to the breathing system in big beetles than in small ones. This trend could represent an evolutionary compensation for diffusion limitations in large-bodied insects, suggesting that large body size and tracheal breathing are at odds with each other.

When considering an individual insect, a question that arises is how the *rate* of diffusion can be varied to correspond to the insect's needs for O_2 . Although diffusion may sound like a process that is purely physical and therefore independent of animal needs, in fact

(c) Air sacs in the abdomen of a worker honeybee

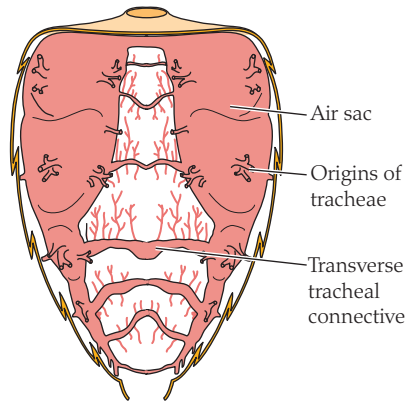

FIGURE 23.29 Insects breathe using a tracheal system of gas-filled tubes that—branching and rebranching—reach all tissues from the body surface (a) The principal tracheae in a flea in the genus *Xenopsylla*—an insect that has ten pairs of spiracles (two thoracic pairs and eight abdominal). (b) The tracheae in a tiny living adult carabid beetle in the genus *Notiophilus*, visualized by a cutting-edge technique, synchrotron X-ray phase-contrast imaging. (c) Air sacs and associated tracheae in the abdomen of a worker honeybee (*Apis*). Additional air sacs occur in the head and thorax. (a after Wigglesworth 1935; b from Socha et al. 2010; image courtesy of Jake Socha.)

its rate responds to an insect's metabolic needs because the animal's metabolism alters the partial pressures of gases. Suppose that an insect breathing by diffusion has an adequate rate of O_2 transport when (1) the atmospheric O_2 partial pressure is at the level marked ❶ in Figure 23.30a and (2) the O_2 partial pressure at the inner end of its tracheal system is at the level marked ❷. If the insect suddenly increases its rate of O_2 consumption, its end-tracheal O_2 partial pressure will fall because of the increased rate of O_2 removal from the tracheae. This decline in the end-tracheal partial pressure will increase the difference in partial pressure between the two ends of the tracheal system and thus accelerate diffusion. Suppose that the difference in partial pressure between level ❶ and level ❸ (see Figure 23.30a) is sufficient for O_2 to diffuse fast enough to meet the insect's new metabolic need. The end-tracheal partial pressure will then fall to level ❸ and stabilize. In this way, the rate of diffusion will automatically rise to meet the insect's O_2 need.

Of course, there are limits to the ability of the process just described to increase the rate of O_2 diffusion. The end-tracheal O_2 partial pressure must itself remain sufficiently high for O_2 to diffuse from the ends of the tracheae to the mitochondria in cells. If an insect's oxygen cascade follows line ❶-❷-❹ in Figure 23.30b when the insect has a low rate of cellular O_2 use, it might follow line ❶-❸-❺ when the insect's rate of O_2 use is raised. The mitochondrial O_2 partial pressure would then be very low, and a further increase in the rate of O_2 diffusion might not be possible while keeping the mitochondrial O_2 level adequate.

Some insects employ conspicuous ventilation

Conspicuous (macroscopic) ventilation of the tracheal system occurs in some large species of insects at rest and is common among active insects. Grasshoppers and locusts, for example, are easily seen to pump their abdomens, and abdominal pumping occurs also in bumblebees, ants, and some other insects. The abdominal pumping motions alternately expand and compress certain of the tracheal airways, either causing tidal ventilation or causing air to be sucked in via certain spiracles and expelled via others, flowing unidirectionally through parts of the tracheal system in between. Air sacs, when present (as they are in grasshoppers and bumblebees, for example), commonly act as bellows during such muscular pumping movements; they may be compressed to only 25–50% of their full size during each cycle of compression. A mechanism of

FIGURE 23.30 Insect oxygen cascades assuming oxygen transport by diffusion These diagrams represent purely a thought exercise; scaling of O_2 partial pressure on the y axis is not linear, and resistance to diffusion is assumed constant. (a) A drop in the O_2 partial pressure at the inner end of the tracheal system from level 2 to level 3 will speed diffusion through the tracheal system by increasing the difference in partial pressure from one end to the other. (b) For the rate of diffusion to the mitochondria to be accelerated, the difference in partial pressure between the inner end of the tracheal system and the mitochondria must be increased—as well as the difference between the ambient air and the inner tracheae. Eventually, no further increase in the rate of diffusion will be possible because the mitochondrial partial pressure will become too low.

conspicuous tracheal ventilation that is important in many insects during flight is **autoventilation**: ventilation of the tracheae supplying the flight muscles *driven by flight movements*.

Physiologists have generally hypothesized that conspicuous ventilation forces flow of air to occur only in major tracheae, with diffusion being the principal mode of gas transport through the rest of the tracheal system. According to this hypothesis, the function of conspicuous ventilation is essentially to *reduce the path length for diffusion* by moving air convectively to a certain depth in the tracheal system.

Microscopic ventilation is far more common than believed even a decade ago

A revolution is underway in the understanding of microscopic ventilation: forced air flow that occurs on such fine scales that it is impossible to detect without use of technology. Probably the most dramatic recent discovery is that when microscopic X-ray videos are made of various insects—such as beetles, crickets, and ants—the major tracheae in the head and thorax are observed to undergo cycles of partial compression and relaxation, a process named *rhythmic tracheal compression*. These pulsations occur every 1–2 s

and are substantial: Each compression reduces the volumes of the tracheae to 50–70% of their relaxed volumes. These microscopic cycles of tracheal compression probably move gases convectively. They may be particularly important for O_2 delivery to the head and brain, recognizing that tracheae to the head connect to the atmosphere at thoracic spiracles and thus may be long.

Similar X-ray studies have revealed that in some insects under some conditions, tracheae undergo massive rhythmic collapsing movements during which they completely empty and refill. This is observed, for example, in some moth caterpillars exposed to hypoxia.

One of the first sorts of evidence for microscopic ventilation was the discovery and analysis of **discontinuous gas exchange** in diapausing pupae⁹ of moths some decades ago. The hallmark and defining feature of discontinuous gas exchange is that CO_2 is released to the atmosphere in dramatic, intermittent bursts, although the rate of O_2 uptake from the atmosphere is relatively steady. This pattern of CO_2 release arises in large part from spiracular control. In the periods between one burst of CO_2 release and the next, the spiracles are closed or partly closed, and CO_2 produced by metabolism *accumulates in body fluids* by dissolving and reacting to form bicarbonate (HCO_3^-). Because O_2 is removed from the tracheal airways by metabolism during these periods, but the CO_2 produced by metabolism temporarily accumulates in the body fluids rather than in the airways, a partial vacuum—a negative pressure—can potentially develop in the airways. When this occurs, atmospheric air can be sucked in convectively on an inconspicuous, microscopic scale when the spiracles open or partly open. Investigators have directly assessed in several species whether inward suction of air actually occurs, and it does in some (not all) of the species tested. No one knows the depth to which air is drawn, but it travels by convection at least through the spiracles and into the major tracheae. Discontinuous gas exchange is known today to occur widely in quiescent or resting insects, plus certain ticks, mites, and spiders.

In addition to the forms of microscopic ventilation we have already discussed, several other types have been reported during the last 20 years. These include processes named “miniature ventilation pulses” in grasshoppers and tiny “Prague cycles” of CO_2 release in beetles. Moreover, some authorities have become convinced by calculations that continuous respiration must often involve alternating periods of diffusion and convection gas transport through the spiracles of insects.

According to the old dogma, insects that were not conspicuously pumping their abdomens or ventilating in other conspicuous ways were breathing entirely by diffusion. The evidence is now overwhelming that convective phenomena are widely employed by visibly motionless insects, but many mysteries remain regarding the exact interplay of convection and diffusion in the tracheal system.

Control of breathing

A vulnerability of the insect respiratory system is that it can permit rapid evaporative loss of body water. The gas in the tracheal airways is humid—ordinarily saturated with water vapor—and when the spiracles are open, only a minute distance separates the humid tracheal gas from the atmosphere. Outward diffusion of water vapor can accordingly be rapid. Insects commonly solve this problem by keeping their spiracles partly closed—or by periodi-

⁹Diapause is a programmed resting stage in the life cycle.

cally opening and closing them—whenever compatible with their needs for O₂ and CO₂ exchange. If the spiracles of resting insects are experimentally forced to remain fully open all the time, the rate of evaporative water loss increases 2–12 times, demonstrating the importance of keeping them partly closed.

In insects using diffusion transport, it is common for the spiracles to be opened more fully or frequently as the insects become more active. The greater opening of the spiracles facilitates O₂ transport to the tissues, although it also tends to increase evaporative water loss. Insects that ventilate their tracheal systems by abdominal pumping or other conspicuous mechanisms are well known to increase their rates of ventilation as they become more active.

What is the chemosensory basis for spiracular control? The most potent stimulus for opening of the spiracles in insects is an increase in the CO₂ partial pressure and/or H⁺ concentration of the body fluids. A decrease in the O₂ partial pressure in the body fluids may also stimulate spiracular opening but typically offers far less potent stimulation. In these respects, the control of the spiracles in insects resembles the control of pulmonary ventilation in mammals.

Aquatic insects breathe sometimes from the water, sometimes from the atmosphere, and sometimes from both

Many insect species live underwater in streams, rivers, and ponds during parts of their life cycles. The aquatic life stages of some of these species lack functional spiracular openings and obtain O₂ by taking up dissolved O₂ from the water using superficial arrays of fine tracheae. These insects often have dense proliferations of fine tracheae under their general integument. Many have **tracheal gills**: evaginations of the body surface that are densely supplied with tracheae and covered with just a thin cuticle—a remarkable parallel with the evolution of ordinary gills in numerous other groups of aquatic animals. Tracheal gills may be positioned on the outer body surface or in the rectum. The tracheal system remains gas-filled. Oxygen diffuses into the tracheal airways from the water across the walls of the tracheal gills or other superficial tracheae. Thereafter, the gas-filled tracheal system serves as the path of least resistance for the O₂ to move throughout the body.

Other aquatic insects have evolved alternative ways of interfacing their tracheal breathing systems with the ambient water or air: ways based on retaining functional spiracles. Insects of this sort breathe from external gas spaces. There are three distinctive ways in which they do so, however. The simplest to understand is the system used by insects such as mosquito larvae, which hang at the water's surface and have their functional spiracles localized to the body region that contacts the atmosphere. Such insects breathe from the atmosphere, much in the way that terrestrial insects do.

A second strategy employed by aquatic insects with functional spiracles is to carry a conspicuous bubble of gas captured from the atmosphere. Many water beetles, for example, carry a conspicuous bubble either under the wings or at the tip of the abdomen (see opening photo of Chapter 22). Their functional spiracles open into the bubble and exchange O₂ and CO₂ with the gas in the bubble. As explained previously (see Figure 22.3), a remarkable attribute of a bubble like this is that it *acts as a gill*: Dissolved O₂ from the water diffuses into the bubble. Thus the insect is able to remove much more O₂ from the bubble than simply the amount captured from the atmosphere. A conspicuous bubble gradually shrinks, a process that decreases its

surface area and impairs O₂ diffusion into the bubble because the rate of diffusion depends on bubble surface area. A bubble of this sort must therefore be periodically renewed with air from the atmosphere.

The third strategy employed by aquatic insects with functional spiracles is certainly the most unexpected. It is also a type of bubble breathing, but a very different type. In some aquatic insects, parts of the body surface are covered extremely densely with fine water-repelling hairs; the bug *Aphelocheirus aestivalis*, for example, has 2–2.5 million of these hairs per square millimeter! Such densely distributed water-repelling hairs on the body surface trap among themselves a thin, almost invisible film of gas *that cannot be displaced*. This film of gas, known as a **plastron**, is incompressible and permanent. Thus its surface area remains constant, and it can serve as a gill (an air space into which O₂ diffuses from the water) for an indefinite period. Some plastron-breathing aquatic insects remain submerged continuously for months!

SUMMARY Breathing by Insects and Other Tracheate Arthropods

- Insects and many arachnids breathe using a tracheal system that connects to the atmosphere by way of spiracles on the body surface and ramifies throughout the body so that gas-filled tubes bring O₂ close to all cells.
- The modes of gas exchange through the tracheal system include diffusion, conspicuous ventilation (such as abdominal pumping and autoventilation), and several forms of microscopic ventilation.
- Aquatic insects may lack functional spiracles and breathe using superficial tracheal beds. Alternatively, they may have functional spiracles and breathe from the atmosphere, large bubbles, or plastrons.

Study Questions

1. Lungs ventilated with water occur in some animals—most notably sea cucumbers—but are rare. Why would water lungs be unlikely to be favored by natural selection? Give as many reasons as possible.
2. In Chapter 1 we discussed François Jacob's question of whether evolution is more like tinkering or engineering. Jacob's view is that tinkering is a far better analogy than engineering. How could the evolution of air breathing in fish be used to argue for the validity of the tinkering analogy?
3. Outline the differences among the three most sophisticated lungs found in modern animals: the mammalian lung, the avian lung, and the insect tracheal system.
4. Suppose a mammal's tidal volume is 2 L, its tracheal volume is 80 mL, its anatomical dead space volume is 350 mL, and its breathing frequency is 9 breaths per minute. What is its alveolar minute volume?
5. When researchers first discovered that airflow through a bird's paleopulmonal parabronchi is unidirectional, the question arose as to whether gas exchange is countercurrent, cocurrent, or cross-current. Some ingenious investigators carried out experiments in which they measured the efficiency of gas exchange between air and blood in duck lungs when parabronchial airflow was in its normal direction and when the direction of parabronchial airflow was artificially reversed. The efficiency did not change. How is this evidence *against* countercurrent and cocurrent gas exchange? How is this evidence *for* cross-current exchange?

6. What is the evidence that the breathing rhythm in mammals originates in the brainstem?
7. Explain mechanistically how hyperventilation alters the oxygen cascade of an animal.
8. Arthropods are distinguished by having an exoskeleton and lacking external cilia. How do these traits of the phylum affect the breathing structures and ventilation modes of arthropods?
9. Why do fish suffocate when taken out of the water and placed in air, whereas mammals suffocate if the air in their alveoli is replaced with water?
10. In your own words, explain how a person's pulmonary oxygen utilization coefficient can increase as the person's rate of ventilation increases even though the composition of alveolar gas is held constant by negative feedback controls.
11. Insects of giant size compared with today's insects are found in the fossil record. There were times in the past when the atmospheric concentration of O₂ was 1.5 times today's concentration. Some investigators hypothesize that insect gigantism was permitted by high O₂ levels. Explain why this hypothesis is plausible.

Transport of Oxygen and Carbon Dioxide in Body Fluids (with an Introduction to Acid-Base Physiology)

A developing mammalian fetus receives oxygen and voids carbon dioxide by means of a close juxtaposition of its own blood vessels with those of its mother's circulatory system in the placenta. The fetus's heart pumps blood through the umbilical cord to the placenta, where that blood picks up O_2 that its mother's blood has brought there from her lungs. The now-oxygenated fetal blood returns to the fetus through the umbilical cord and is circulated to all the parts of the body of the fetus. By 10 weeks after conception, a human fetus already has hemoglobin-rich blood. At that age, the amount of hemoglobin per unit of volume in the fetus's blood has reached 50% of the adult concentration and is increasing rapidly, so that it will be about 80% of the adult value at 20 weeks of age.

In the placenta, O_2 must cross from the mother's blood to the fetus's blood by diffusion through tissues separating the two circulatory systems. The detailed way in which this occurs remains a topic of active research. The basic options for the mode of gas transfer are countercurrent gas exchange, cross-current gas exchange, and cocurrent (concurrent) gas exchange—the same options we discussed in Chapter 23 (pages 586–587) for the transfer of O_2 between fluid streams. The mode of gas transfer in the human placenta remains uncertain for two reasons. First, experiments cannot be done on human fetuses. Second, other species of placental mammals exhibit such wide diversity in the morphology and physiology of their placentas that researchers are not certain which animal model would best reveal how the human placenta works. Enough is known about placental physiology in several mammalian species to make clear, however, that—contrary to expectation—substantial impediments to O_2 transfer from maternal to fetal blood often exist in mammalian placentas.¹ Placentas are emphatically not like lungs, in which high rates of air and blood flow and minutely thin intervening membranes result readily in dramatic blood oxygenation.

An important reason a human fetus can in fact obtain enough O_2 from its placenta is that the fetus produces a different molecular form of hemoglobin from the one its mother produces. This is also true in many other species of placental mammals that have been studied. For reasons we discuss principally later in this chapter, fetal hemoglobin has a higher affinity for O_2 than adult hemoglobin does. This greater affinity has two important, interrelated consequences. First, the *difference* in affinity between the maternal and fetal hemoglobins means that O_2 has a chemical tendency to leave the lower-affinity hemoglobin of the mother to bind with the higher-affinity hemoglobin of the fetus. Second, the *high absolute affinity* of fetal hemoglobin means that it can become well oxygenated even if the O_2 partial pressure in the fetal blood remains relatively low, as it typically does.

¹The placental O_2 partial pressure is strikingly low during the first trimester of human intrauterine development, for example. To explain this unexpected state, one hypothesis is that the low partial pressure helps limit formation of reactive oxygen species (see Box 8.1), which might be particularly damaging to the early developmental stages.

This human fetus obtains oxygen (O_2) by pumping blood along its umbilical cord to the placenta, where its blood picks up O_2 from its mother's blood Hemoglobin plays a major role in the acquisition and transport of O_2 by the fetus. In the mother, O_2 taken up in her lungs combines with hemoglobin in her red blood cells and is carried by blood flow to the placenta in that form. In the placenta, the fetus's hemoglobin combines with O_2 that is released from the mother's hemoglobin. The O_2 combined with fetal hemoglobin is then carried, by the circulation of the fetus's blood, from the placenta into the body of the fetus, where the O_2 is used.

The hemoglobins are one of several types of **respiratory pigments** or **oxygen-transport pigments** that animals have evolved. The defining property of the respiratory pigments is that they undergo *reversible combination with molecular oxygen* (O_2). Thus they can pick up O_2 in one place, such as the lungs of an adult or the placenta of a fetus, and release the O_2 in another place, such as the systemic tissues² of the adult or fetus. All the types of respiratory pigments are *metalloproteins*: proteins that contain metal atoms, exemplified by the iron in hemoglobin. In addition, all are strongly colored at least some of the time, explaining why they are called *pigments*.

The most straightforward function of the respiratory pigments is to increase the amount of O_2 that can be carried by a unit of volume of blood. Although O_2 dissolves in the blood plasma³ just as it dissolves in any aqueous solution (see Chapter 22), the solubility of O_2 in aqueous solutions is relatively low, meaning that the amount of O_2 that can be carried in dissolved form per unit of volume is not high. When a respiratory pigment is present in the blood, however, the blood can carry O_2 in two ways: in chemical combination with the pigment as well as in simple solution. Therefore, a respiratory pigment increases the **oxygen-carrying capacity** of blood, meaning the total amount of O_2 that can be carried by each unit of volume. In some cases, the increase is very large. For example, when the blood of an adult person leaves the lungs, it contains almost 200 mL of O_2 per liter of blood in chemical combination with hemoglobin and about 4 mL of O_2 per liter in solution. Thus the blood's concentration of O_2 is increased about 50-fold by the presence of hemoglobin. This means, among other things, that the heart can work far less intensely; roughly calculated, the circulation of a liter of actual human blood delivers the same amount of O_2 as would the circulation of 50 liters of blood without hemoglobin.

Multiple molecular forms of hemoglobin occur, as already exemplified by the contrast between fetal and maternal hemoglobins. Not only may one species have multiple molecular forms, but different species have different forms. Thus the word *hemoglobin* refers to a family of many compounds, not just a single compound. To emphasize this fact, we refer to these compounds as *hemoglobins* (plural) rather than just *hemoglobin* (singular). All the hemoglobins—plus a great diversity of other globin proteins—are coded by genes of a single ancient gene family. Natural selection and other processes have modified the genes in this gene family over evolutionary time, giving rise to the great diversity of hemoglobins and other globin proteins in modern organisms.

Hemoglobins have several functions; that is, their functions are not limited just to increasing the blood's oxygen-carrying capacity. Blood hemoglobins, for example, play important roles as *buffers* and participate in blood CO_2 transport as well as O_2 transport. Moreover, specialized hemoglobins are found *within* muscle cells or nerve cells (neurons), where they often *facilitate diffusion of O_2* into the cells and potentially serve as *intracellular storage depots for O_2* . Fast-breaking research indicates also that hemoglobins within some muscle cells serve in intricate ways both to *synthesize and break down intracellular nitric oxide (NO)*, which in turn potently *controls mitochondrial respiration* (mitochondrial O_2 consumption and ATP production) in the muscle

²The **systemic tissues** are all tissues other than the tissues of the breathing organs.

³The **plasma** of the blood is the aqueous solution in which the cells are suspended. Operationally, plasma is obtained by removing all cells from blood (e.g., by centrifugation).

cells. This chapter emphasizes the role of hemoglobins in blood O_2 transport but touches on the other functions as well.

One could aptly say that a revolution is currently underway in the study of the respiratory pigments. The driving forces in this revolution are molecular sequencing, genomics, applications of advanced chemical analysis, and phylogenetic reconstruction. For instance, because of the availability of relatively cheap molecular sequencing tools, it is becoming routine—as it has not been before—to know the entire amino acid sequences of respiratory-pigment molecules that are being compared. Genomics facilitates the widespread search for respiratory-pigment molecules and has led to the discovery of new ones.

A final introductory point worth noting is that when hemoglobins or other respiratory pigments combine with O_2 , they are said to be **oxygenated**, and when they release O_2 , they are **deoxygenated**. They are not said to be *oxidized* and *reduced*. The reason for these distinctions is that the process by which a respiratory pigment combines with O_2 is not chemically equivalent to oxidation. During the oxygenation of a hemoglobin molecule, for example, although electrons are partially transferred from iron atoms in the hemoglobin molecule to the O_2 , the transfer is not complete, as it would be in full-fledged oxidation. In fact, if a hemoglobin molecule accidentally becomes truly oxidized (so that its iron atoms are converted from their ordinary ferrous state to the ferric state), the molecule (now called *methemoglobin*) loses its ability to combine with O_2 ! The prefixes **oxy-** and **deoxy-** are used to specify the oxygenated and deoxygenated states of respiratory-pigment molecules. Hemoglobin, for example, is called **oxyhemoglobin** when it is combined with O_2 (oxygenated) and **deoxyhemoglobin** when it is not combined with O_2 (deoxygenated). Respiratory pigments change color when they are oxygenated and deoxygenated, and measures of these color changes can be used to monitor the oxygenation and deoxygenation of blood (**Box 24.1**).

The Chemical Properties and Distributions of the Respiratory Pigments

Four chemical categories of respiratory pigments are recognized: **hemoglobins**, **hemocyanins**, **hemerythrins**, and **chlorocruorins**. The prefix *hemo-* is from the Greek for “blood,” explaining its use in the names of three of the pigment categories. Like the hemoglobins, the other categories are groups of related compounds, not single chemical structures.

Many of the important chemical properties of the respiratory pigments resemble the properties of the enzyme proteins we studied in Chapter 2. The parallels are so great, in fact, that biochemists have occasionally dubbed the respiratory pigments “honorary enzymes.” The point of mentioning these parallels is not to suggest that respiratory pigments are enzymes; in terms of their principal functions, they are *not*. The point, instead, is to highlight that, based on your knowledge of enzyme proteins, you will find that you already know a great deal about the molecular features of respiratory pigments.

When a hemoglobin molecule, for example, combines with O_2 , it does so at *defined binding sites*, resembling the way in which enzymes combine with their substrates at defined binding sites. Moreover, the combination of the O_2 -binding sites with O_2 is *highly specific* and occurs by *noncovalent, weak bonding* (see Box 2.1), just as enzyme–substrate binding is specific and noncovalent. Accordingly, O_2 is a *ligand* of he-

BOX 24.1 ABSORPTION SPECTRA OF RESPIRATORY PIGMENTS

The hemoglobins and other respiratory pigments—like all pigments—differentially absorb various wavelengths of light. The pattern of absorption by a pigment when expressed as a function of wavelength, is known as an **absorption spectrum** (plural *spectra*). The absorption spectrum of a specific respiratory pigment (e.g., human hemoglobin) changes with the oxygenation or deoxygenation of the pigment, as shown in the accompanying figure. These changes are qualitatively evident to our eyes: We know, for example, that oxygenated hemoglobin (bright red) differs in color from deoxygenated hemoglobin (purple-red). By using quantitative light-absorption measurements, the percentage of heme groups that are oxygenated in blood can be determined. This is the principle behind the finger probes—known as *pulse oximeters*—that are used to monitor arterial blood oxygenation in hospital patients. **Box**

Extension 24.1 explains how a pulse oximeter measures the percentage of oxygenated heme groups in arterial blood and why it is called a “pulse” oximeter.

Absorption spectra for fully oxygenated and fully deoxygenated human hemoglobin To measure absorption, light of each wavelength is passed through a hemoglobin solution of defined concentration and optical path length (in the case shown here, the concentration was 1 mM, and the light path through the solution was 1 cm long). The fraction of the incoming photon energy that fails to pass through the solution is measured. From the data, one calculates the *extinction coefficient*, which is a measure of the absorption of the light by the hemoglobin: A high extinction coefficient signifies high absorption. (After Waterman 1978.)

moglobin, based on the definition of “ligand” we developed in Chapter 2. When a hemoglobin molecule combines with O_2 , it undergoes a change in its molecular conformation (shape) that is analogous to the conformational change an enzyme molecule undergoes when it combines with its substrate; the ability of a hemoglobin molecule to *flex* in this way is an essential attribute of its function, just as molecular flexibility is critical for enzyme function. One of a hemoglobin molecule’s most important properties is its *affinity* for O_2 , meaning the ease with which it binds with the O_2 molecules it encounters; thus a hemoglobin molecule (like an enzyme) is characterized in part by *how readily* it binds with its primary ligand.

A hemoglobin molecule also has specific sites at which it combines with *ligands other than O_2* . Using the same terminology we used in Chapter 2 in connection with enzymes, such ligands (e.g., H^+ and CO_2) are *allosteric ligands* or *allosteric modulators*, because when they bind with their specific sites on a hemoglobin molecule, they affect the ability of the hemoglobin to bind with its primary ligand, O_2 . Allosteric ligands, for example, can potentially affect a hemoglobin molecule’s affinity for O_2 . Within a hemoglobin molecule, just as in an enzyme molecule, allosteric ligands exert their effects *at a distance*; that is, the binding sites for allosteric ligands on a hemoglobin molecule are separate from the O_2 -binding sites, and when allosteric ligands affect O_2 binding, they do so by modifying the conformation and flexibility of the molecule as a whole.

Hemoglobin molecules are usually *multisubunit proteins*; that is, each whole molecule consists of two or more proteins bonded together by noncovalent bonds. Multisubunit hemoglobins have an O_2 -binding site on each subunit and thus have multiple O_2 -binding sites. In common with multisubunit enzymes that exhibit cooperativity among substrate-binding sites, multisubunit hemoglobin molecules exhibit *cooperativity among their O_2 -binding sites*, meaning that binding of O_2 to any one site on a molecule affects how readily

the other sites bind O_2 .⁴ These interactions among O_2 -binding sites themselves occur at a distance; the various O_2 -binding sites on a molecule are separate and distinct, and they influence each other by effects that are relayed through the structure of the protein, rather than by direct site-to-site effects.

The points we have made using hemoglobin as an example apply to the other categories of respiratory pigments as well. Thus, in the study of all respiratory pigments, it is helpful to keep these points in mind.

Despite sharing many key properties with enzymes, however, the respiratory pigments differ from enzymes in a major way: *They do not modify their primary ligand*. After they combine with O_2 , they later release O_2 .

Hemoglobins contain heme and are the most widespread respiratory pigments

The chemical structures of all hemoglobin molecules share two features. First, all hemoglobins contain **heme** (Figure 24.1a), which is a particular metalloporphyrin containing iron in the ferrous state (ferrous protoporphyrin IX). Second, the heme is noncovalently bonded to a protein known as a **globin** (Figure 24.1b). The combination of heme with globin accounts for the name *hemoglobin*. Oxygen binds at the heme site at a ratio of one O_2 molecule per heme. In all hemoglobin molecules, the heme is identical. The multiple molecular forms of hemoglobin differ in their protein (globin) structures (and in the numbers of unit molecules of hemoglobin that are linked together).

Biochemical studies reveal that small changes in the protein structure of a hemoglobin molecule can cause highly significant alterations in the functional properties of the molecule. There are, to illustrate, more than 100 known mutant forms of human

⁴In the terminology developed in Chapter 2, this is *homotropic* cooperativity. See page 45 for more on cooperativity within multisubunit proteins.

FIGURE 24.1 The chemical structure of hemoglobin (a) The structure of heme: Ferrous iron is complexed with protoporphyrin. The positions assigned to double and single bonds in the porphyrin ring are arbitrary because resonance occurs. (b) A single heme-globin complex. The specific molecule shown is myoglobin (muscle hemoglobin) taken from the muscle of a whale. The structure of the globin protein includes eight segments in which the amino acid backbone of the protein (seen spiraling inside the cylindrical outline) forms a helix. The outer, cylindrical part of the drawing shows the major contours of the globin structure. (c) A tetrameric hemoglobin molecule of the sort found in mammalian red blood cells. In adults, each tetramer consists of two α -globins, two β -globins, and a total of four heme groups. (b,c after Dickerson and Geis 1983.)

hemoglobin. Each human globin protein consists of more than 140 amino acids, and most of the mutant forms differ from the normal form in just one of those amino acids. Nonetheless, many mutant forms differ markedly from the normal form in their functional properties; they may differ in their affinity for O_2 or in other key properties, such as their solubility or structural stability.

The blood hemoglobins of vertebrates are almost always four-unit (tetrameric) molecules (Figure 24.1c) that can bind a total of four O_2 molecules. The molecular weight of each unit molecule is typically about 16,000–17,000 daltons (Da). Thus the four-unit blood hemoglobins have molecular weights of approximately 64,000–68,000 Da. Two types of globins, termed α and β , are found in adult blood hemoglobins. The ancestral genes for the two types originated by gene duplication about 500 million years ago. Each molecule of adult blood hemoglobin consists of two α units and two β units. The human α -globin contains 141 amino acids,

whereas the human β -globin contains 146 amino acids. Although other species are also described as having α - and β -globins, the particular chemical structures of those globins vary from species to species. Relatively huge hemoglobin molecules are found in the blood of some invertebrates, as we will soon see.

Animals sometimes have hemoglobins inside muscle cells or inside the cells of other tissues besides blood. Such hemoglobins typically differ from blood hemoglobins in their chemical structure. The muscle hemoglobins, termed **myoglobins** (*myo*-, “muscle”), of vertebrates provide apt examples. Occurring in the cytoplasm of muscle fibers (muscle cells), they tend to be especially abundant in cardiac muscle fibers and in the slow oxidative (SO) class of skeletal muscle fibers (see page 195). When present at high concentrations, they impart a reddish color to the tissue; “red” muscles are red because of myoglobins. Unlike blood hemoglobins, vertebrate myoglobins appear always to be single-unit (monomeric) molecules (see Figure 24.1b). They also have distinctive globins. In adult humans, for example, the globin of myoglobin is of different structure than the α - or β -globins.

In addition to varying spatially—from tissue to tissue—within an animal, the chemical nature of hemoglobin often also changes temporally over the life cycle. For example, as we have already seen, the blood hemoglobin of fetal mammals is often different from that of the adults of their species. In humans, fetuses synthesize α -globin (as adults do) and γ -globin, which differs from the β -globin synthesized by adults (Figure 24.2); each fetal blood-hemoglobin

FIGURE 24.2 Human developmental changes in the types of globins synthesized for incorporation into blood hemoglobins Each blood-hemoglobin molecule consists of four globin units plus four O_2 -binding heme groups (see Figure 24.1c). In early embryos, the principal globins synthesized are α -globin, ϵ -globin, and ζ -globin; *embryonic hemoglobins* are made up of principally of these globins (e.g., one common form consists of two α -globin and two ϵ -globin units). By about 8 weeks after conception, α -globin and γ -globin are the principal globins synthesized, and most hemoglobin molecules are *fetal hemoglobin* molecules consisting of two α -globin and two γ -globin units. Following birth, synthesis of γ -globin ebbs, whereas that of β -globin increases, so that by 20 weeks of postnatal age, the blood hemoglobin is predominantly *adult hemoglobin* consisting of α - and β -globins. The dashed part of the β -globin curve is postulated rather than empirical. (After Wood 1976.)

molecule consists of two α -globin and two γ -globin subunits. Earlier in development, as Figure 24.2 shows, still different globins are expressed.

Although the adult blood hemoglobin of many animals (e.g., humans and most other mammals) is of essentially uniform composition, in many species of poikilothermic vertebrates and invertebrates, the blood of adults normally consists of mixes of two, three, or even ten or more chemically different forms of hemoglobin. A relatively simple example is provided by the blood hemoglobin of the sucker fish *Catostomus clarkii*, which consists of about 80% of one major type of hemoglobin and 20% of another. When multiple chemical forms of hemoglobin occur in a species, the forms sometimes differ substantially in their O_2 -binding characteristics. Possession of multiple blood hemoglobins may thus permit a species to maintain adequate O_2 transport over a broader range of conditions than would be possible with only a single hemoglobin type.

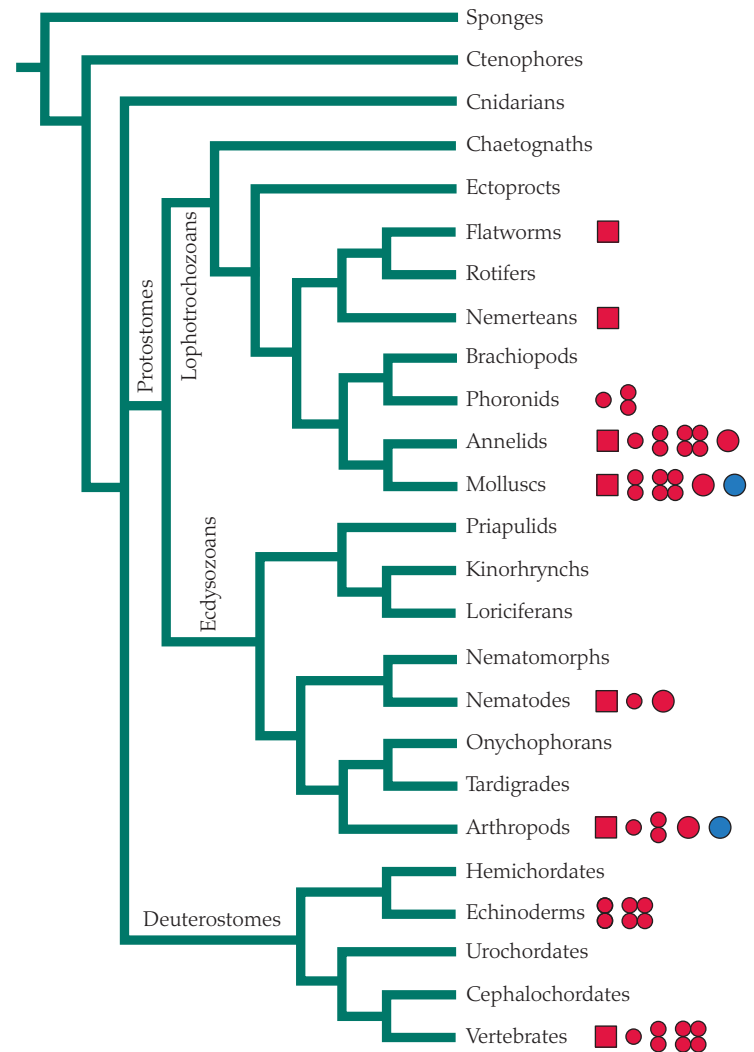

THE DISTRIBUTION OF HEMOGLOBINS Hemoglobins are the most widely distributed of the respiratory pigments, being found in at least nine phyla of animals (Figure 24.3) and even in some protists and plants. They are the only respiratory pigments found in vertebrates, and with a few interesting exceptions (see Chapter 3), all vertebrates have hemoglobin in their blood. The blood hemoglobins of vertebrates are always contained in specialized cells, the **red blood cells (erythrocytes)**, discussed in Box 24.2.

Among the invertebrates, the distribution of hemoglobins is not only wide but sporadic. Hemoglobins may occur within certain subgroups of a phylum but not others, and even within certain species but not other closely related species. Sometimes, among

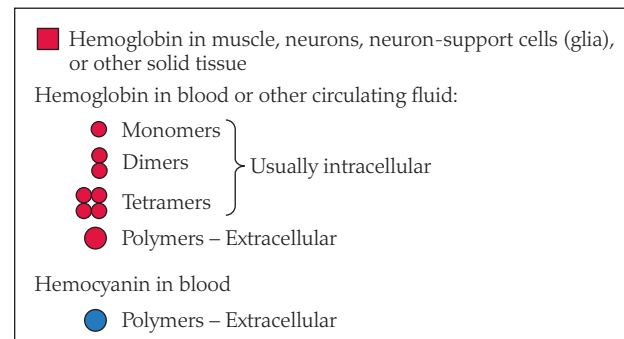

all the members of a large assemblage of related species, only an isolated few possess hemoglobins. The evolution of the wide but sporadic distribution of hemoglobins certainly provokes curiosity. According to the prevailing view at present, the hemoglobin gene family originated even before animals did, and therefore genes of the family are potentially present in all evolutionary lines of animals. The genes are sometimes fully functional and expressed in modern animals, and sometimes not—accounting for the hemoglobin distribution observed.

The circulating hemoglobins of invertebrates may be found in blood, or they may occur in other moving fluids, such as coelo-

FIGURE 24.3 The distribution of the two major respiratory pigments—hemoglobins and hemocyanins—in animals A red square indicates that hemoglobins occur in solid tissues such as muscle or nerve tissues. Red circles indicate that hemoglobins occur in circulating body fluids. A single small red circle indicates the presence in circulating body fluids of hemoglobins consisting of one unit molecule of heme plus globin: hemoglobin monomers. A pair or four-some of small red circles symbolizes hemoglobin dimers or tetramers, respectively. A large red circle indicates polymeric hemoglobins of high molecular weight, consisting of many joined unit molecules. The polymeric hemoglobins are always extracellular—dissolved in the circulating fluid. The monomeric, dimeric, and tetrameric forms of hemoglobin, with few exceptions, are intracellular—contained within circulating cells such as erythrocytes. A large blue circle indicates polymeric hemocyanins of high molecular weight dissolved in the blood; this is the only circumstance in which hemocyanins occur. In each group labeled here as having hemoglobin or hemocyanin, not all species in the group have it; nor does each species with hemoglobin necessarily have all the chemical forms of hemoglobin shown. In vertebrates, for example, although most have blood hemoglobin, icefish do not (see Chapter 3); and the monomeric and dimeric forms of blood hemoglobin occur only in cyclostome fish, with tetrameric forms being found in all other vertebrates that have blood hemoglobin. Similarly, whereas some arthropods and molluscs have hemoglobins as symbolized here, the majority lack them. Some echiurid worms have tetrameric circulating hemoglobins and/or hemoglobins in solid tissues. The preponderance of current opinion is that the echiurids are annelids (and thus not separately represented in this diagram); however, until recently the echiurids were viewed as a separate phylum. This summary is not exhaustive. (Hemoglobin data from Terwilliger 1980; cladogram after Sadava et al. 2008.)

KEY

BOX 24.2 BLOOD CELLS AND THEIR PRODUCTION

The red blood cells (erythrocytes, RBCs) of vertebrates vary in size, shape, and other properties. Mammals have relatively small RBCs, usually 4–10 μm in diameter; human RBCs, for example, average 7.4 μm . Some other groups of vertebrates have distinctly larger RBCs; the oval RBCs of frogs and toads, for example, average 23 \times 14 μm in their major dimensions. A significant difference between the RBCs of mammals and those of other vertebrates is that the mature RBCs of mammals are essentially devoid of cell organelles; they have no nucleus, mitochondria, or ribosomes. The RBCs of all other vertebrates, and all the respiratory pigment-containing blood cells of invertebrates that have been studied, are nucleated, emphasizing how distinctive mammalian RBCs are in this regard. One way of expressing the blood's content of RBCs is as the **hematocrit**, defined to be the percentage of total blood volume occupied by the RBCs. The normal hematocrit for people at sea level is 42–45%.

The process by which the body makes RBCs is called **erythropoiesis**. Because RBCs have relatively short life spans, they are continually being replaced. The rate of turnover seems to be particularly rapid in mammals, possibly because mature mammalian RBCs—lacking a nucleus and ribosomes—lack any ability to repair proteins. The average human RBC lasts 4 months. We replace almost 1% of our RBCs every day, meaning that we make about 2 million new RBCs per second! The principal site of erythropoiesis in adult mammals is the soft interior of the bones, the **bone marrow**.

Erythropoiesis is under endocrine control. In mammals, the principal control is exerted by a glycoprotein hormone, **erythropoietin**. When low- O_2 conditions are detected in the body, erythropoietin is secreted in increased amounts and accelerates erythropoiesis. The control of mammalian erythropoietin secretion has become a favored system for study of the control of gene expression. The kidneys are the principal site of erythropoietin secretion in adult mammals. Molecular probes for eryth-

ropoietin messenger RNA (mRNA) have now established that erythropoietin is synthesized by secretory cells in *interstitial tissue* located between adjacent nephron tubules in the cortex of the kidneys. Hypoxia—a low level of O_2 —in the kidneys causes increased transcription of the erythropoietin gene in the secretory cells, thereby increasing formation of mRNA for synthesis of erythropoietin. The erythropoietin then travels in the blood to the bone marrow, where it stimulates production of RBCs.

Upregulation of the erythropoietin gene by hypoxia is mediated by the transcription factor *hypoxia-inducible factor 1 (HIF-1)*, discussed in Box 23.1. This transcription factor, now known to be enormously significant in responses to hypoxia throughout the animal kingdom, in fact was discovered through studies of the regulation of the erythropoietin gene. HIF-1 plays multiple regulatory roles, including the upregulation of pathways that aid iron delivery to the bone marrow when erythropoiesis is stimulated.

mic fluids. Sometimes, as in vertebrates, these hemoglobins are contained within cells and thus categorized as *intracellular*. The intracellular hemoglobins of invertebrates are always of relatively low molecular weight (~14,000–70,000 Da); structurally, they are generally one-, two-, or four-unit molecules. On the other hand, the blood hemoglobins of some invertebrates are dissolved in the blood plasma and thus categorized as *extracellular*. Earthworms (*Lumbricus*), for example, have hemoglobin dissolved in their blood plasma, which when held to the light is wine red and clear—quite unlike vertebrate bloods, which are opaque because of their high concentrations of red blood cells. The extracellular, dissolved hemoglobins of invertebrates are—almost always—relatively huge, multiunit molecules, having molecular weights of 0.2–12 million Da. There are 144 O_2 -binding sites *on each molecule* of earthworm (*Lumbricus*) hemoglobin!

The concentration of blood hemoglobin in some invertebrates changes so dramatically from one environment to another that the animals change color. Water fleas (*Daphnia*), for example, have little hemoglobin and are pale when they have been living in O_2 -rich waters. However, if they are placed in O_2 -poor waters, they increase their levels of hemoglobin within days and become bright red (see Figure 24.20).

Hemoglobins—usually single-unit molecules—are found widely in solid tissues of invertebrates, not only in muscles but also in certain other tissues. Both muscle and nerve hemoglobins occur, for example, in a wide variety of molluscs and annelids; the nerve hemoglobins may be present in neurons per se or in support cells (glia), but either way, they sometimes impart a striking pinkish or red color to the ganglia or nerves. Although insects usually lack circulating respiratory pigments, large numbers of insect species have hemoglobins in the fat body or parts of the tracheal system.

Such hemoglobins in some backswimmer bugs, for example, store O_2 for release to the tracheae during diving.

Copper-based hemocyanins occur in many arthropods and molluscs

Hemocyanins are found in just two phyla—the arthropods and the molluscs (see Figure 24.3)—but clearly rank as the second most common class of respiratory pigments. In turning to the hemocyanins, we encounter a minor problem that they share with the chlorocruorins and hemerythrins: The names given to these compounds provide no clue to their chemical structures. Hemocyanins do not contain heme, iron, or porphyrin structures. The metal they contain is copper, bound directly to the protein. The arthropod and mollusc hemocyanins exhibit consistent structural differences and are clearly of separate evolutionary origin. Thus they are distinguished as “arthropod hemocyanins” and “mollusc hemocyanins.” Each O_2 -binding site of a hemocyanin contains two copper atoms; thus the binding ratio is one O_2 molecule per two Cu. In both phyla, hemocyanins are invariably found dissolved in the blood plasma, not in cells, and are typically large molecules (4–9 million Da in molluscs, 0.5–3 million Da in arthropods) that have numerous O_2 -binding sites. The number of binding sites per molecule is as high as 160 in some cases. Although hemocyanins are colorless when deoxygenated, they turn bright blue when oxygenated. Species that have high concentrations of hemocyanins are dramatically blue-blooded!

The molluscs that possess hemocyanins include the squids and octopuses (cephalopods), many chitons and gastropods (snails and slugs), and a relatively small subset of bivalves. Hemocyanins are not present in most bivalve molluscs (clams, scallops, and the like); indeed, bivalves usually lack circulating respiratory pigments of any

kind. Groups of arthropods in which hemocyanins are important include the decapod crustaceans (crabs, lobsters, shrimps, and crayfish), the horseshoe crabs, and the spiders and scorpions. Even some (relatively primitive) insects have recently been discovered to have hemocyanins. Hemocyanins are never found within muscle or other solid tissues. Certain molluscs that have blood hemocyanins have hemoglobins in their muscles, neurons, or gills.

Chlorocruorins resemble hemoglobins and occur in certain annelids

Chlorocruorins, also sometimes called “green hemoglobins,” occur in just four families of marine annelid worms, including the fan worms and feather-duster worms that are so popular with aquarists. Chlorocruorins are always found extracellularly, dissolved in the blood plasma. They have close chemical similarities to the extracellular hemoglobins found dissolved in the blood plasma of many other annelids. Like the extracellular hemoglobins, they are large molecules, with molecular weights of close to 3 million Da, composed of unit molecules consisting of iron-porphyrin groups conjugated with protein. They bind one O₂ per iron-porphyrin group. The chlorocruorins differ from hemoglobins in the type of iron porphyrin they contain.⁵ This difference gives the chlorocruorins a distinctive and dramatic color. In dilute solution, they are greenish. In more concentrated solution, they are deep red by transmitted light but greenish by reflected light.

Iron-based hemerythrins do not contain heme and occur in three or four phyla

Hemerythrins have a distribution that is puzzling because it is both limited and far-flung, encompassing three or four phyla. Circulating hemerythrins occur in a single family of marine annelid worms (the magelonids), in the sipunculid worms (which have been a separate phylum but might be annelids), in many brachiopods (lamp shells), and in some species of the small phylum Priapulida. Despite their name, hemerythrins do not contain heme. They do contain iron (ferrous when deoxygenated), bound directly to the protein. Each O₂-binding site contains two iron atoms, and there is one such site per 13,000–14,000 Da of molecular weight. In some instances (including, for example, some annelids that lack circulating hemerythrin), single-unit hemerythrins, known as myohemerythrins, occur within muscle cells. Better known are the circulating hemerythrins, which are always located intracellularly, in blood or coelomic cells, and typically have molecular weights of 40,000–110,000 Da; many are octomers, having eight O₂-binding sites per molecule. Hemerythrins are colorless when deoxygenated but turn reddish violet when oxygenated.

⁵The porphyrin differs from heme in that one of the vinyl chains (—CH=CH₂) on the periphery of the protoporphyrin ring in heme (see Figure 24.1a) is replaced with a formyl group (—CHO).

SUMMARY The Chemical Properties and Distributions of the Respiratory Pigments

- The four chemical classes of respiratory pigments are all metalloproteins. They bind reversibly with O₂ at specific O₂-binding sites associated with the metal atoms in their molecular structures.

- In hemoglobins, the unit molecule consists of heme bonded with protein (globin). The heme structure—an iron (ferrous) porphyrin—is identical in all hemoglobins. The globin, however, varies widely among species and among different molecular forms of hemoglobin within any single species.
- Hemoglobins are the most common and widespread respiratory pigments, occurring in at least nine phyla. Virtually all vertebrates have blood hemoglobin. The blood-hemoglobin molecules of vertebrates are usually tetramers consisting (in adults) of two α -globin and two β -globin unit molecules; they always occur in red blood cells. Although many invertebrates also have hemoglobins in blood cells, some invertebrates have hemoglobins dissolved in their blood plasma.
- Hemocyanins are the second most common of the respiratory pigments in animals. They contain copper and turn bright blue when oxygenated. There are two types of hemocyanins, which are of separate evolutionary origin: arthropod hemocyanins (occurring in crabs, lobsters, crayfish, horseshoe crabs, spiders, and some other arthropods) and mollusc hemocyanins (occurring in squids, octopuses, many snails, and some other molluscs). Hemocyanins are always dissolved in the blood plasma.
- Chlorocruorins, which are similar to hemoglobins, occur in only four families of marine annelid worms, and are always dissolved in the blood plasma.
- Hemerythrins are non-heme, iron-containing respiratory pigments that have a limited and scattered distribution, occurring in three or four different invertebrate phyla.

The O₂-Binding Characteristics of Respiratory Pigments

A key tool for understanding the function of a respiratory pigment is the *oxygen equilibrium curve*. In a body fluid containing a respiratory pigment, there is a large population of O₂-binding sites. Human blood, for example, contains about 5.4×10^{20} heme groups per 100 mL. The combination of O₂ with each individual O₂-binding site is *stoichiometric*: One and only one O₂ molecule can bind, for example, with each heme group of a hemoglobin or with each pair of copper atoms in a hemocyanin. However, in blood, where there are great numbers of O₂-binding sites, all sites do not simultaneously bind with O₂ or release O₂. Instead, the fraction of the O₂-binding sites that are oxygenated varies in a *graded* manner with the O₂ partial pressure. The **oxygen equilibrium curve**, also sometimes called the **oxygen dissociation curve**, shows the functional relation between the percentage of binding sites that are oxygenated and the O₂ partial pressure (Figure 24.4a).

The respiratory pigment in the blood of an animal is said to be **saturated** if the O₂ partial pressure is high enough for all O₂-binding sites to be oxygenated. Accordingly, the percentage of binding sites that are oxygenated is often termed the **percent saturation**. The blood's *oxygen-carrying capacity*, an important property mentioned earlier, is the amount of O₂ carried per unit of volume at saturation. Ordinary human blood, for example, has an oxygen-carrying capacity of about 20 mL O₂ per 100 mL of blood and actually has that concentration of O₂ when saturated.⁶ The volume of gas carried

⁶Gas volumes are always expressed at standard conditions of temperature and pressure (see Appendix C) unless otherwise stated. Such volumes are proportional to molar quantities, as discussed in Chapter 22.

(a) Percentage of heme groups oxygenated as a function of O_2 partial pressure

(b) Blood O_2 concentration as a function of O_2 partial pressure

FIGURE 24.4 A typical oxygen equilibrium curve for human arterial blood presented in two different ways (a) The percentage of heme groups oxygenated as a function of the O_2 partial pressure. (b) The total blood O_2 concentration—including both hemoglobin-bound and dissolved O_2 —as a function of the O_2 partial pressure; the portion of the total O_2 present as dissolved O_2 is plotted at the bottom. Normal arterial values of CO_2 partial pressure, pH, and temperature are assumed. In humans, as in other animals, significant individual variation occurs. (After Roughton 1964; b assumes an O_2 concentration of 20 vol % at 16 kPa.)

per 100 volumes of blood is often termed the **volumes percent (vol %)** of gas. In that system of units, the oxygen-carrying capacity of ordinary human blood is 20 vol %.

The oxygen equilibrium curve can be presented in two ways. Figure 24.4a—showing the *percentage of oxygenated binding sites* (the *percent saturation*) as a function of O_2 partial pressure—exemplifies one of these. The alternative presentation, seen in **Figure 24.4b**, shows the *blood O_2 concentration* as a function of the O_2 partial pressure. To calculate this alternative form of the curve from the first form, one needs merely to convert the percentage of oxygenated

binding sites at each partial pressure into the corresponding blood O_2 concentration. For most purposes, this conversion can be carried out by use of the oxygen-carrying capacity: The O_2 concentration at each partial pressure is the oxygen-carrying capacity multiplied by the percentage of oxygenated binding sites.⁷

An oxygen equilibrium curve that shows the percentage of oxygenated binding sites on the respiratory pigment, such as Figure 24.4a, directly reflects the function of the respiratory pigment. Because most O_2 in the blood is typically carried in combination with the respiratory pigment, the shape of that oxygen equilibrium curve (see Figure 24.4a) determines the shape of the curve that shows O_2 concentration as a function of partial pressure (see Figure 24.4b). This explains why the curves in Figure 24.4a and b have the same shape. However, blood also contains O_2 dissolved in the blood plasma. The amount of dissolved O_2 per unit of blood volume simply follows the principles of gas solution discussed in Chapter 22 (see Equation 22.3). Therefore, it is proportional to the O_2 partial pressure, producing a straight-line relation, as seen at the bottom in Figure 24.4b. Comparing the O_2 bound to the respiratory pigment and the dissolved O_2 , the former typically dominates, as it does in Figure 24.4b.

Later in this chapter, we will see that the O_2 -binding properties of respiratory pigments are often affected by temperature, pH, and other properties of the blood chemical environment. We will also discuss the reason for the sigmoid shape of the oxygen equilibrium curve (see Figure 24.4). Before we consider those factors, however, it is important to understand the basic elements of respiratory-pigment function in living animals and to appreciate the interpretive value of oxygen equilibrium curves. To these ends, and recognizing that refinements will later be needed, let's look at the fundamentals of O_2 transport by our own blood.

Human O_2 transport provides an instructive case study

To understand the uptake of O_2 by the blood in a person's lungs, it is important to recall from Chapter 23 that breathing maintains the O_2 partial pressure in the alveolar gases of our lungs at about 13.3 kPa (100 mm Hg). Blood arriving at the alveoli has a lower O_2 partial pressure. Thus O_2 diffuses into the blood from the alveolar gas, raising the blood O_2 partial pressure as the blood passes through the lungs. As the blood O_2 partial pressure rises, at each partial pressure the hemoglobin in the blood takes up the amount of O_2 that is dictated by its oxygen equilibrium curve (see Figure 24.4).⁸

If, in the lungs, the O_2 partial pressure of the blood were to rise to the alveolar partial pressure, 13.3 kPa (100 mm Hg), we can see from Figure 24.4 that the hemoglobin in the blood would become virtually saturated with O_2 . In fact, mixed blood leaving the lungs is at a somewhat lower O_2 partial pressure: 12.0–12.7 kPa (90–95 mm Hg) in a person at rest. This lower partial pressure hardly affects the blood O_2 content, however, because as shown by the oxygen equilibrium curve, there is a plateau in the relation between the blood O_2 concentration and the O_2 partial pressure at these high partial pressures; provided the blood O_2 partial pressure is high enough to be in the plateau region, hemoglobin will be almost saturated with

⁷For exacting work, the dissolved O_2 , discussed in the next paragraph, has to be calculated separately from the pigment-bound O_2 and the two amounts added.

⁸Hemoglobin also plays an important role in *speeding* the uptake of O_2 by the blood, as discussed in Chapter 22 (see page 575).

FIGURE 24.5 Oxygen delivery by human blood at rest and during vigorous exercise The oxygen equilibrium curve shown is that for human arterial blood (see Figure 24.4b). The thickened, shaded areas on the curve show representative ranges of blood O₂ concentration and O₂ partial pressure in the lungs (blue), the systemic tissues during rest (green), and the systemic tissues during vigorous exercise (red). The vertical purple arrows to the right show how much O₂ is delivered to the tissues by each 100 mL of blood during rest and exercise. All values are semi-quantitative; the intent of this diagram is conceptual rather than literal. Tissue values are mixed venous blood values. Effects of pH and other variables of the blood-hemoglobin milieu are not included.

O₂ regardless of the partial pressure. The alveolar O₂ partial pressure could even vary a bit, and still, because of the plateau—a property of the hemoglobin—the blood leaving the lungs would remain almost entirely saturated. The close “matching” of the saturation partial pressure of hemoglobin and the alveolar partial pressure represents a striking evolutionary coadaptation: *The hemoglobin molecule has evolved O₂-binding properties that suit it to oxygenate well at the O₂ partial pressures maintained in the lungs by the breathing system.*

After leaving the lungs, blood flows to the left side of the heart and is pumped to the systemic tissues. To understand the events in the systemic tissues, it is crucial to recall that in the mitochondria, O₂ is continually being combined with electrons and protons to form H₂O. By this process, O₂ molecules are removed from solution, and the O₂ partial pressure in and around the mitochondria is lowered. Blood arriving in capillaries of systemic tissues from the lungs has a high O₂ partial pressure; O₂ thus diffuses from the blood to the mitochondria (see Figure 22.7). During this diffusion, dissolved O₂ leaves the blood, and the O₂ partial pressure of the blood falls. As this occurs, hemoglobin releases (unloads) O₂, thereby making hemoglobin-bound O₂ available to diffuse to the mitochondria. The oxygen equilibrium curve (see Figure 24.4) is a key to understanding the unloading of O₂ from hemoglobin: As the blood O₂ partial pressure falls, the amount of O₂ released from hemoglobin at each O₂ partial pressure is dictated by the curve.

Knowing that hemoglobin leaves the lungs in a virtually saturated condition, we can calculate its yield of O₂ to the systemic tissues by obtaining a measure of its degree of saturation after it has passed through the systemic tissues. The simplest way to obtain this measure is to determine the degree of saturation in blood drawn from the great veins leading back to the heart; such blood is termed **mixed venous blood** because it represents a mixture of the venous blood coming from all parts of the body. In people at rest, the O₂ partial pressure of mixed venous blood is about 5.3 kPa (40 mm Hg). From the oxygen equilibrium curve (see Figure 24.4b), we can see that blood at this partial pressure contains about 15 mL of O₂/100 mL. Recalling that arterial blood contains about 20 mL of O₂/100 mL, we see that the O₂ content of the blood falls by about 5 mL of O₂/100 mL when the blood circulates through the systemic tissues in humans at rest. In other words, as shown by the “Rest” arrow in Figure 24.5, about 5 mL of O₂ is released from each 100 mL of blood. The release of O₂ from the blood is often expressed as the **blood oxygen utilization coefficient**, defined to be the *percentage* of arterial O₂ that is released to the systemic tissues. In people at rest, recognizing that arterial blood contains about 20 mL of O₂/100 mL and that about 5 mL of O₂/100 mL is released to the tissues, the oxygen utilization coefficient is about 25%. That is, only one-fourth of the O₂ brought to the systemic tissues in the arterial blood is actually used at rest.

THE SIGNIFICANCE OF MIXED VENOUS O₂ PARTIAL PRESSURE

The O₂ partial pressure of mixed venous blood represents an average of the O₂ partial pressures of blood leaving the various systemic tissues. It thus allows us to gauge the blood’s *overall* drop in O₂ partial pressure during circulation through all tissues combined. It does not necessarily reflect, however, the drop in partial pressure as the blood flows through any particular tissue; blood entering a particular tissue at a partial pressure of 12.7 kPa (95 mm Hg) might exit at a partial pressure that is either higher or lower than the mixed venous partial pressure. The mixed venous partial pressure is, in fact, a *weighted* average of the O₂ partial pressures of blood leaving the various tissues. It is weighted according to the rate of blood flow through each tissue; tissues with high rates of blood flow influence the mixed venous partial pressure more than those with low rates of flow do.

THE DETERMINANTS OF A TISSUE’S VENOUS O₂ PARTIAL PRESSURE

The O₂ partial pressure to which the blood falls in its passage through a particular tissue is not a static property of that tissue. Instead, it is a dynamic and changing property. It depends on the rate of blood flow through the tissue, the arterial O₂ partial pressure, the amount of hemoglobin per unit of blood volume, and the tissue’s rate of O₂ consumption. To illustrate, if the rate of blood flow through a tissue decreases while all the other relevant factors remain unchanged, each unit of blood volume will have to yield more O₂ in its passage through the tissue, and therefore the venous partial pressure will decline. Similarly, an increase in the rate of O₂ consumption by a tissue will cause a decrease in the tissue’s venous partial pressure. The venous partial pressures normally seen in people at rest result from the set of conditions that ordinarily prevail at rest.

DELIVERY OF O₂ DURING EXERCISE As discussed in Chapter 23, controls on breathing tend to keep the alveolar O₂ partial pressure stable, near 13.3 kPa (100 mm Hg), as people exercise more and

more intensely. During vigorous exercise, however, the *blood* O_2 partial pressure reached in the lungs tends to decline from the resting blood partial pressure. There are several potential reasons for this decline. One is that blood passes through the pulmonary circulation faster as the intensity of exercise increases, thus decreasing the time available for equilibration between the alveolar gas and blood. The relative flatness of the oxygen equilibrium curve at high O_2 partial pressures again comes to the rescue (see Figure 24.4). Even if the blood passing through the lungs reaches a partial pressure of only 11 kPa (80 mm Hg)—which is often the case during intense exercise—the drop in the O_2 content of the arterial blood is modest. For simplicity, we treat the O_2 content of the arterial blood as a constant as we discuss exercise in more detail.

The modest utilization of blood O_2 at rest leaves a large margin to increase utilization during exercise. As we have seen, only about 25% of the O_2 carried by the systemic arterial blood is used when people are at rest. The remaining amount, the amount of O_2 in mixed venous blood, is called the **venous reserve**. During exercise, more O_2 is withdrawn from each unit of blood as the blood passes through the systemic tissues, and the venous reserve becomes smaller.

A highly significant attribute of blood O_2 transport during rest is that the mixed venous O_2 partial pressure, averaging 5.3 kPa (40 mm Hg), is low enough to be *below the plateau* displayed by the oxygen equilibrium curve at high partial pressures (see the green-shaded part of the curve in Figure 24.5). During exercise, therefore, when the venous O_2 partial pressure declines below the resting value, it does so on the *steep* part of the oxygen equilibrium curve (Figure 24.6). Consequently, relatively small decreases in the venous O_2 partial pressure result in relatively large increases in the yield of O_2 from the blood. To illustrate, recall first that at rest, a drop in partial pressure from an arterial value of 12.0–12.7 kPa (90–95 mm Hg) to the resting venous value of 5.3 kPa (40 mm Hg)—a total drop of 6.7–7.4 kPa (50–55 mm Hg)—causes release of about 5 mL of O_2 from each 100 mL of blood. A further drop of just 2 kPa (15 mm Hg) to a venous partial pressure of 3.3 kPa (25 mm Hg) causes the blood to release another 5 mL of O_2 from each 100 mL of blood, thus *doubling* the O_2 yield (see Figure 24.6). Moreover, a still further drop of just 1.3 kPa (10 mm Hg) to a venous partial pressure of 2 kPa (15 mm Hg) *triples* the yield of O_2 from the blood! This steep release of O_2 is a consequence of the binding characteristics of the hemoglobin molecule, as we will discuss later in this chapter.

How great is the actual O_2 delivery during exercise in mammals? Over a wide range of exercise states, the O_2 partial pressure of blood leaving the working skeletal muscles is about 2.7 kPa (20 mm Hg) in humans and also in several other species on which measurements have been made. This value is about 2.7 kPa (20 mm Hg) lower than the resting value. With this reduction in partial pressure, the amount of O_2 released from each volume of blood is increased (compared with rest) by a factor of about 2.5. Thus the oxygen utilization coefficient for blood flowing through the working skeletal muscles is about 65%. We have said that a partial pressure of about 2.7 kPa (20 mm Hg) prevails in the blood leaving the muscles over a wide *range* of exercise states; that is, even as the muscles work harder and demand more O_2 , in this range little change occurs in their venous partial pressure or in the amount of O_2 they obtain from each unit of blood volume. This stability of

FIGURE 24.6 As the O_2 partial pressure of blood falls, less and less of a drop in partial pressure is required to cause unloading of 5 mL of O_2 from each 100 mL of blood. Each green horizontal arrow depicts the drop in O_2 partial pressure required to cause the unloading depicted by the red vertical arrow to its right. The oxygen equilibrium curve shown is that for human arterial blood (see Figure 24.4b).

venous partial pressure occurs because the *rate of blood flow* to the muscles is adjusted: As the O_2 demand of the muscles rises, their rate of blood flow increases in parallel, enabling them to draw O_2 from an enhanced volume of blood per unit of time. Of course, the rate of blood flow cannot increase indefinitely. Once it is maximized, further increases in a muscle's intensity of work result in further decreases in the venous O_2 partial pressure. Indeed, during extreme exertion, the O_2 partial pressure of blood leaving some muscles may fall close to zero, signifying virtually complete deoxygenation of the blood (100% O_2 utilization).

As the O_2 partial pressure of blood in the systemic capillaries declines, there is a risk that the rate of O_2 diffusion from the blood to the mitochondria will become too low to support aerobic catabolism. The venous O_2 partial pressure below which aerobic catabolism becomes impaired is known as the **critical venous O_2 partial pressure**. It is approximately 1.3 kPa (10 mm Hg) in mammalian muscles. As we have seen, the rate of blood flow through muscles is usually increased sufficiently to maintain the venous O_2 partial pressure above this critical level over a wide range of exercise states. Human hemoglobin yields about 90% of its O_2 before the venous partial pressure falls below the critical level, as can be seen from the oxygen equilibrium curve (see Figure 24.4a). In this respect we see once more that the O_2 -binding properties of hemoglobin are closely integrated with other physiological features.

Let's now look briefly at *whole-body* O_2 utilization and O_2 delivery during exercise. Although blood draining active muscles may be rather thoroughly deoxygenated during heavy exercise, the partial pressure of *mixed* venous blood generally does not fall below 2.1–2.7 kPa (16–20 mm Hg) in humans, even during strenuous work, because blood from the exercising muscles mixes in the great veins with blood from other parts of the body in which O_2 utilization is not so great. The whole-body oxygen utilization coefficient therefore rises to a peak of about 60–75% during exercise—indicating that 2.5–3.0 times more O_2 is extracted from each volume of blood than

is extracted at rest (see Figure 24.5). In average young people, the rate of blood circulation can be increased to 4–4.5 times the resting level. These values, taken together, show that the total rate of O₂ delivery by the circulatory system can increase to 10–13 times the resting rate. Trained athletes often achieve still higher O₂ delivery rates, principally because endurance training increases the rate at which a person's heart can pump blood.

THE “MOLECULAR DESIGN” OF HUMAN HEMOGLOBIN We have seen in this section that (1) human hemoglobin is nearly saturated at the O₂ partial pressures that are maintained in the lungs by breathing; (2) the oxygen equilibrium curve of hemoglobin is nearly flat at pulmonary O₂ partial pressures, so that high oxygenation is ensured regardless of variation in pulmonary function; and (3) the oxygen equilibrium curve is shaped in such a way that 90% of the O₂ bound to hemoglobin can be released for use at blood partial pressures that are compatible with full mitochondrial function. These functional properties of human hemoglobin are consequences of its chemical structure, and its normal chemical structure is but one of thousands of possible structures. Many physiologists have concluded that the human hemoglobin molecule provides a particularly convincing example of “evolutionary molecular design.” Natural selection has produced a molecule with functional properties that are integrated in strikingly harmonious ways with the attributes of the organs that provide O₂ to the blood and draw O₂ from the blood.

A set of general principles helps elucidate O₂ transport by respiratory pigments

From our study of hemoglobin function in people, we can state four key principles that are useful for understanding the function of blood respiratory pigments in general:

1. To determine the extent of pigment oxygenation, ask first: What are the blood O₂ partial pressures established in the breathing organs? Then examine the oxygen equilibrium curve to determine the extent of pigment oxygenation at those partial pressures.
2. To determine the extent of pigment deoxygenation in systemic tissues, start by acquiring some knowledge of blood O₂ partial pressures in those tissues. The mixed venous O₂ partial pressure is a useful and easily measured indicator, although one must remember that it does not necessarily provide information on O₂ release in any *particular* tissue. After the O₂ partial pressure in the systemic tissues has been measured or estimated, examine the oxygen equilibrium curve to determine the extent of pigment deoxygenation in the systemic tissues.
3. To compute circulatory O₂ delivery, the rate of blood flow is as important as the yield of O₂ per unit of blood volume, because O₂ delivery is the product of flow rate and O₂ yield per unit of volume. Complexity is introduced by the fact that these two factors are not independent: The rate of blood flow helps to determine the venous O₂ partial pressure and thus the yield of O₂ per unit of blood volume.
4. The operational parameters of the O₂-transport system are strongly affected by exercise. They are also affected

by the environmental O₂ partial pressure and possibly other environmental conditions. Full understanding of the function of an O₂-transport system requires that animals be studied over a range of physiological and environmental conditions.

The shape of the oxygen equilibrium curve depends on O₂-binding site cooperativity

What determines the shape of the oxygen equilibrium curve? As we explore this question, vivid parallels to principles we addressed in the study of enzymes will again be evident. In Chapter 2 (see page 42), we saw that when the catalytic sites of a particular enzyme function independently of each other, a hyperbolic relation exists between enzyme activity and substrate concentration; when the sites exhibit cooperativity, however, a sigmoid relation occurs. Similarly, when the O₂-binding sites of a respiratory pigment function independently, the oxygen equilibrium curve is hyperbolic, but when they exhibit cooperativity, a sigmoid curve results.

Hyperbolic oxygen equilibrium curves are exemplified by the vertebrate myoglobins (Figure 24.7a). The vertebrate (and most invertebrate) myoglobins contain just one O₂-binding site (heme) per molecule. Thus their O₂-binding sites function independently of each other, and the chemical reaction between myoglobin and O₂ can be written simply as

where Mb is a molecule of deoxymyoglobin and MbO₂ is one of oxy-myoglobin. According to the principles of mass action (see page 45), increasing the partial pressure (and thus the chemical potential) of O₂ will shift this reaction to the right, increasing myoglobin oxygenation. Mass-action principles applied to such a simple chemical reaction also predict that the fraction of myoglobin molecules oxygenated will increase as a *hyperbolic* function of the O₂ partial pressure, as is observed.

Because vertebrate blood hemoglobins have four O₂-binding sites within each molecule, the opportunity exists for cooperativity. In fact, positive cooperativity occurs in these hemoglobins: Binding of O₂ at one or two of the O₂-binding sites on a molecule of blood hemoglobin alters the conformation of the molecule in ways that enhance the affinity of the remaining sites for O₂, meaning that a partially oxygenated molecule is more likely than an entirely deoxygenated one to bind additional O₂.⁹ The consequence is a sigmoid oxygen equilibrium curve, exhibiting a particularly steep relation between O₂ binding and O₂ partial pressure in the mid-range of O₂ partial pressures. Figure 24.8 presents oxygen equilibrium curves for the blood of 11 animal species, including 6 vertebrates that have four-unit hemoglobins and 5 invertebrates that have high-molecular-weight hemoglobins or hemocyanins with numerous O₂-binding sites. All the curves are sigmoid to some degree, indicating that intramolecular cooperativity occurs in all cases. The extent of cooperativity, which varies from one respiratory pigment to another, is usually expressed using a mathematical index called the **Hill coefficient** (*n*), named after A. V. Hill (1886–1977),

⁹Because the four O₂-binding sites are located within the four different protein subunits of the hemoglobin tetramer, the cooperativity displayed by the tetramer is often termed *subunit interaction*. It used to be termed *heme-heme interaction*, but this term has been dropped because the interaction between the O₂-binding sites is indirect, not directly between one heme and another.

(a) The oxygen equilibrium curve for human myoglobin

(b) Hypothetical respiratory pigments that differ in cooperativity

FIGURE 24.7 Respiratory pigments display hyperbolic or sigmoid oxygen equilibrium curves depending on whether they exhibit cooperativity in O_2 binding (a) The hyperbolic oxygen equilibrium curve of human myoglobin—a pigment that exhibits no cooperativity—compared with the sigmoid curve of human blood hemoglobin—a pigment that displays cooperativity. Both curves were determined under similar conditions: 38°C , pH 7.40. (b) Comparison of oxygen equilibrium curves for two hypothetical pigments that reach saturation at about the same O_2 partial pressure, but differ in whether they exhibit cooperativity. (a after Roughton 1964.)

a Nobel laureate. The coefficient is 1.0 for pigments that show no cooperativity (e.g., myoglobins) and reaches 6 or more in some high-molecular-weight pigments with very high cooperativity. Mammalian hemoglobins exhibit values of 2.4–3.0.

Cooperativity affects deoxygenation (unloading) of respiratory pigments as much as it affects their oxygenation (loading). During deoxygenation of a molecule that exhibits cooperativity, removal of O_2 from some of the O_2 -binding sites tends to decrease the affinity of the remaining sites for O_2 , thereby promoting even further deoxygenation. **Figure 24.7b** shows the consequences,¹⁰ using two

¹⁰Figure 24.6 also does so.

FIGURE 24.8 A diversity of blood oxygen equilibrium curves The blood oxygen equilibrium curves of 11 animal species vary in two ways. First, they vary in shape, a property that reflects the different molecular forms of the respiratory pigments in different species. Second, they vary in height, a property that reflects how much respiratory pigment is present per unit of blood volume (oxygen-carrying capacity). Species: bullfrog, *Lithobates catesbeianus* (until recently known as *Rana catesbeiana*); carp, *Cyprinus carpio*; common earthworm, the nightcrawler *Lumbricus terrestris*; giant earthworm, the 1-m-long South American earthworm *Glossoscolex giganteus*; iguana, *Iguana iguana*; lugworm, the seacoast annelid *Arenicola* sp.; mackerel, *Scomber scombrus*; octopus, the giant octopus *Enteroctopus dofleini* of the North American Pacific coast; spiny lobster, *Panulirus interruptus*; Weddell seal, *Leptonychotes weddelli*. (After Hill and Wyse 1989.)

hypothetical pigments that are similar in the O_2 partial pressure at which they become saturated, but differ in that one exhibits cooperativity whereas the other does not. If we assume that both pigments are initially fully oxygenated and ask how they behave during deoxygenation, it is clear that in the mid-range of O_2 partial pressures, the pigment showing cooperativity deoxygenates more readily, giving up more of its O_2 at any given O_2 partial pressure. In a sentence, whether a molecule of a respiratory pigment is loading or unloading, cooperativity enhances the *responsiveness* of the process to changes in the O_2 partial pressure within the mid-range of partial pressures.

Respiratory pigments exhibit a wide range of affinities for O_2

The respiratory pigments of various animals vary widely in how readily they combine with O_2 , a property known as their **affinity** for O_2 . Pigments that require relatively high O_2 partial pressures for full loading and that conversely unload substantial amounts of O_2 at relatively high partial pressures are said to have a relatively

FIGURE 24.9 How to measure P_{50}

low affinity for O_2 . Pigments that load fully at low partial pressures and consequently also require low partial pressures for substantial unloading are said to have a relatively **high affinity** for O_2 . Affinity for O_2 is an *inverse* function of the O_2 partial pressure required for loading: The *higher* the O_2 partial pressure required to load a pigment, the *lower* is the pigment's affinity for O_2 . The hemoglobins of humans and carp (see Figure 24.8) provide examples of pigments that differ in their affinity for O_2 . Human hemoglobin requires a far higher O_2 partial pressure to become saturated than carp hemoglobin, indicating that the human hemoglobin combines less readily with O_2 and has a lower affinity.

A convenient index of O_2 affinity is P_{50} (pronounced “P fifty”), defined to be the partial pressure of O_2 at which a pigment is 50% saturated. Figure 24.9 shows how P_{50} is measured. With Figure 24.9 in mind, a glance at Figure 24.8 reveals that human hemoglobin has a much higher P_{50} (≈ 3.5 kPa in arterial blood) than carp hemoglobin (≈ 0.7 kPa). *Affinity and P_{50} are inversely related: As P_{50} increases, O_2 affinity decreases.*

In the jargon of respiratory-pigment physiology, lowering the O_2 affinity is said to “shift the oxygen equilibrium curve to the right.” To explain, Figure 24.10 shows that a rightward shift (a shift from the blue to the red curve) reflects a higher P_{50} and therefore a lower O_2 affinity. Raising the O_2 affinity (decreasing the P_{50})—as would occur by shifting from the red to the blue curve—is said to “shift the curve to the left.”

FIGURE 24.10 A “shift to the right” Such a shift reflects decreased O_2 affinity.

The Bohr effect: Oxygen affinity depends on the partial pressure of CO_2 and the pH

In a body fluid or tissue containing a respiratory pigment, a decrease in the pH or an increase in the CO_2 partial pressure often causes the O_2 affinity of the respiratory pigment to decrease, thus shifting the oxygen equilibrium curve to the right. This effect, illustrated for the blood hemoglobins of humans and dogs in Figure 24.11, is known as the **Bohr effect** or **Bohr shift**,¹¹ in commemoration of Christian Bohr (1855–1911), the prominent Danish physiologist (and father of

¹¹In unusual cases, such as some species of molluscs and spiders, Bohr effects opposite to the usual direction, termed *reverse Bohr effects*, are observed.

(a) Human hemoglobin at various pH levels

(b) Dog hemoglobin at various CO_2 partial pressures

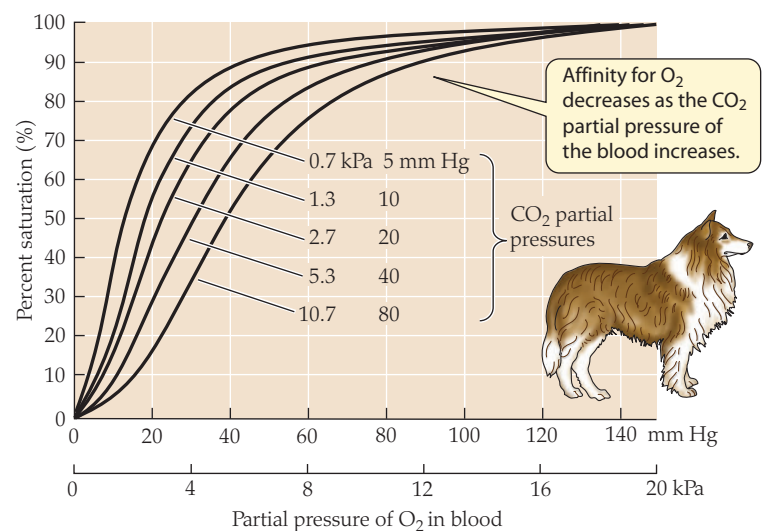

FIGURE 24.11 The Bohr effect: Affinity for O_2 decreases as pH decreases or CO_2 partial pressure increases (a) Oxygen equilibrium curves of human hemoglobin at three different pHs at $38^\circ C$. In resting humans, the normal pH of arterial blood is about 7.4, whereas that of mixed venous blood is about 0.04 unit less. (b) Oxygen equilibrium curves of dog hemoglobin at five different CO_2 partial pressures at $38^\circ C$. The data in part (b) are from the original work of Bohr and his coworkers. (After Roughton 1964.)

FIGURE 24.12 The Bohr effect typically enhances O₂ delivery in an animal The diagram shows oxygen equilibrium curves for arterial blood (A) and venous blood (V) in a hypothetical animal. The venous blood displays a reduced O₂ affinity because its CO₂ partial pressure and H⁺ concentration are higher than those in arterial blood. The magnitude of this Bohr shift is exaggerated for clarity. The three bold arrows show unloading under three different assumptions. The top of each arrow is the O₂ concentration of blood as it leaves the breathing organs; the bottom is the O₂ concentration of the blood as it leaves the systemic tissues. The numeric values next to the arrows are the volumes of O₂ delivered per 100 mL of blood.

Nobel laureate Niels Bohr) who led the discovery of the effect in 1904. Part of the reason that an increase in CO₂ partial pressure causes such a shift is that the pH of a solution tends to decline as its CO₂ partial pressure is increased.¹² However, CO₂ also exerts a direct negative effect on the O₂ affinities of some respiratory pigments, such as the blood hemoglobins of humans and other mammals. Recognizing that protons (H⁺ ions) and CO₂ itself can exert independent affinity-lowering effects, modern workers often distinguish two types of Bohr effects: a **fixed-acid Bohr effect**—which results from influences of the proton (H⁺) concentration on respiratory-pigment molecules—and a **CO₂ Bohr effect**—which results from the immediate influences of increased CO₂ partial pressure.

Species that show these effects vary widely in the *magnitudes* of the effects. One reason is that Bohr effects have probably evolved several times independently and thus have a different molecular basis in some animals than others. Even species with the same molecular mechanism often vary widely in details.

Protons exert their effects on O₂ affinity by combining with pigment molecules. Referring to hemoglobin (Hb) as a specific example, we can write the following *strictly conceptual* equation to summarize the effects of protons on O₂ affinity (the equation does not reflect the true stoichiometry of the reaction):

Increasing the H⁺ concentration tends to increase the combination of Hb with H⁺, thus shifting the chemical reaction in Equation 24.2 to the right and favoring dissociation of O₂. The H⁺ ions bind at sites on the hemoglobin molecules (e.g., at histidine residues) different from the O₂-binding sites. Thus H⁺ acts as an *allosteric* modulator of O₂ binding. CO₂ also combines chemically with pigment molecules and functions as an allosteric modulator in cases in which it exerts direct effects on affinity.

The Bohr effect often has adaptive consequences for O₂ delivery. The CO₂ partial pressure is generally higher, and the pH is generally lower, in the systemic tissues than in the lungs or gills. Because of this, a respiratory pigment that displays a Bohr effect shifts to

lower O₂ affinity each time the blood enters the systemic tissues and reverts back to higher O₂ affinity each time the blood returns to the breathing organs. The shift to lower affinity in the systemic tissues promotes release of O₂ because it facilitates deoxygenation. Conversely, the shift back to higher affinity in the breathing organs promotes uptake of O₂ by facilitating oxygenation. **Figure 24.12** illustrates the net effect of this shifting back and forth between two oxygen equilibrium curves as the blood flows between the breathing organs and systemic tissues. At any given O₂ partial pressures in the arterial and venous blood, more O₂ is delivered to the systemic tissues than would be if the pigment followed just one or the other equilibrium curve alone.

During exercise, the CO₂ partial pressure in the systemic tissues often rises above that prevailing during rest because of the increased production of CO₂. Furthermore, the pH in the systemic tissues often falls below the resting pH, not only because of the elevated CO₂ partial pressure but also because acid metabolites—such as lactic acid—often accumulate during exercise. These changes often augment the Bohr shift during exercise, thereby enhancing O₂ delivery to the active tissues.

Now it will be clear why we indicated earlier in this chapter that refinements would ultimately be needed to our initial analysis of O₂ delivery in humans. We based our earlier analysis on the arterial oxygen equilibrium curve alone (see Figure 24.4), whereas in reality, Bohr shifts occur as blood flows between the lungs and systemic tissues. In humans at rest, venous blood is slightly more acidic (pH 7.36) than arterial blood (pH 7.40). Moreover, the CO₂ partial pressure is higher in mixed venous blood than in arterial blood: about 6.1 kPa (46 mm Hg) in venous blood and 5.3 kPa (40 mm Hg) in arterial. Looking at Figure 24.11, you can see that these differences in pH and CO₂ partial pressure are sufficient to cause small but significant Bohr shifts of the oxygen equilibrium curve as blood flows between the lungs and systemic tissues.

To fully understand respiratory-pigment function, it is important that, before closing this section, we consider not only how pH can affect oxygenation, but also how oxygenation can affect pH. Let's return to the conceptual equation, Equation 24.2, that describes the reaction of H⁺ ions with respiratory pigments (assuming that a fixed-acid Bohr effect exists). Earlier, we stressed one perspective

¹²As already noted in Chapter 23, CO₂ has been aptly termed a “gaseous acid” because it reacts with H₂O to produce H⁺. The chemistry of these reactions is presented at length later in this chapter.

FIGURE 24.13 The Root effect in eels: Acidification lowers the oxygen-carrying capacity of hemoglobin Oxygen equilibrium curves are shown for the whole blood of eels (*Anguilla vulgaris*) at six different pH levels; the pH was adjusted at a constant temperature (14°C) by addition of lactic acid. Because the oxygen equilibrium curves include dissolved O₂, saturation of the hemoglobin is indicated when the slope of an oxygen equilibrium curve parallels the slope of the dissolved O₂ line. Experiments on some fish have shown that O₂ binding by hemoglobin is reduced at low pH even when the hemoglobin is exposed to an O₂ partial pressure of 140 atm (14,000 kPa)! (After Steen 1963.)

on this equation; namely, that an increase in H⁺ concentration will push the chemical reaction to the right, decreasing the tendency of pigment molecules to bind to O₂. Now we also stress that the equation has a complementary and equally important property: Removal of O₂ from pigment molecules will pull the chemical reaction to the right, causing the pigment molecules to take up H⁺ from their surroundings. When blood passes through the systemic tissues, metabolism tends to increase the H⁺ concentration of the blood solution. Simultaneously, however, because of the diffusion of O₂ out of the blood, respiratory-pigment molecules unload O₂ and thus bind with H⁺. This removal of free H⁺ from the blood, induced by the deoxygenation of the pigment molecules, limits the increase in the blood concentration of H⁺—and the decrease in blood pH—caused by the metabolic addition of CO₂ and H⁺.

The Root effect: In unusual cases, CO₂ and pH dramatically affect the oxygen-carrying capacity of the respiratory pigment

In some types of animals, because of distinctive properties of their respiratory pigments, an increase in the CO₂ partial pressure or a decrease in the pH of the blood not only causes a Bohr effect, but also reduces the amount of O₂ the respiratory pigment binds when saturated.¹³ The reduction in the amount of O₂ bound to the pigment at saturation (Figure 24.13) is termed the **Root effect**, after its discoverer. Root effects of sizable magnitude are not common. Among vertebrates, they are observed only in fish, principally teleost fish. Some molluscs also show either normal or reversed Root effects.

Root effects provide a mechanism by which the O₂ partial pressure of even well-oxygenated blood can be dramatically increased under the control of blood pH. To see this, consider the hemoglobin in the

blood of eels when it is fully loaded with O₂ (see Figure 24.13¹⁴). At a pH of 7.54, the hemoglobin is chemically combined with about 12.6 mL of O₂ per 100 mL of blood. Acidification to a pH of 7.35 lowers the O₂-binding capacity of the hemoglobin because of the Root effect, so that the hemoglobin can chemically combine with only about 9.4 mL O₂/100 mL. In this way O₂ is forced off the hemoglobin. The acidification from pH 7.54 to 7.35 forces the eel hemoglobin to unload 3.2 mL of O₂ into each 100 mL of blood! The O₂ released in this way goes into blood solution; it has no other immediate place to go. By dissolving, it dramatically elevates the blood O₂ partial pressure.

The Root effect is employed in various species of teleost fish to help create high O₂ partial pressures in two regions of the body: the swim bladder and the eyes. In both types of organs, the pH of well-oxygenated blood is lowered by a tissue-specific addition of lactic acid, which induces a rise in the blood O₂ partial pressure because of the Root effect. Moreover, in both types of organs, this rise in the blood O₂ partial pressure is *amplified* by a countercurrent vascular arrangement (a rete mirabile) that favors multiplication of the initial effect.¹⁵ The creation of high O₂ partial pressures helps inflate the swim bladder in many fish (swim-bladder gas is often principally O₂). The retinas of some fish are so poorly vascularized that they require high surrounding O₂ partial pressures to acquire enough O₂ to function properly. Recently, a convincing case has been made that, in the course of evolution, the first role of the Root effect in fish was oxygenation of the retina. Later, at least four different lines of fish independently evolved the use of the Root effect in O₂ secretion to inflate the swim bladder.

Thermal effects: Oxygen affinity depends on tissue temperature

The O₂ affinity of respiratory pigments is often inversely dependent on temperature (Figure 24.14). Increases in temperature decrease affinity, whereas decreases in temperature increase affinity (changes in temperature only rarely affect the O₂ content of blood at saturation, however). When humans or other mammals exercise, if the blood temperature in their exercising muscles exceeds the temperature in their lungs, thermal shifts in affinity will enhance O₂ delivery to the muscles in a manner much like that already described for the Bohr effect (see Figure 24.12). In total, therefore, unloading of O₂ to the exercising muscles will be promoted in a concerted manner by both temperature effects and Bohr effects, both of which independently tend to decrease the O₂ affinity of the respiratory pigment (and thereby facilitate O₂ unloading) when the blood passes through the muscles. Conversely to this happy state, temperature effects may become a problem in the hypothermic limbs of mammals in Arctic climates—a matter addressed in **Box 24.3** in relation to recent studies of a resurrected ancient protein, the hemoglobin of the woolly mammoth.

Organic modulators often exert chronic effects on oxygen affinity

Organic compounds synthesized by metabolism often play major roles as allosteric modulators of the function of respiratory pigments. In vertebrates, the principal compounds acting in this role are

¹⁴ Although Figure 24.13 will serve as a useful visual guide, note that—quantitatively—the lines in the figure include dissolved O₂ as well as the hemoglobin-bound O₂ being discussed in this paragraph.

¹⁵ The process of countercurrent multiplication is explained, in a different context, in Chapter 29 (see pages 766–767).

¹³ Some modern authorities view the Root effect as an exaggerated Bohr effect.

FIGURE 24.14 An increase in temperature typically causes a decrease in O_2 affinity. Oxygen equilibrium curves are shown for human blood at six different temperatures, with pH held constant at 7.4. These results show the pure effect of changes in temperature because of the constancy maintained in pH. The results, however, tend to understate the effects of temperature in many real-life situations because when the pH is not artificially controlled, a rise in blood temperature typically induces a decrease in blood pH, as discussed later in this chapter (see Figure 24.24), meaning that the immediate effects of temperature are often reinforced by thermally induced fixed-acid Bohr effects. The CO_2 partial pressure was held constant during the studies shown. (After Reeves 1980.)

organophosphate compounds within the red blood cells, which affect hemoglobin O_2 affinity. The organophosphate of chief importance in most mammals, including humans, is **2,3-bisphosphoglycerate**, which is synthesized in red blood cells from intermediates of glycolysis. This compound is sometimes called **BPG** or **2,3-BPG**, but more commonly, for historical reasons, the abbreviated name **2,3-DPG** (standing for 2,3-diphosphoglycerate) is used. The effect of 2,3-DPG is to reduce the O_2 affinity (raise the P_{50}) of the hemoglobin molecules with which it binds. As shown by the black line in Figure 24.15, he-

FIGURE 24.15 The normal P_{50} of human hemoglobin within red blood cells depends on a normal intracellular concentration of 2,3-DPG. There is usually about one 2,3-DPG molecule per hemoglobin molecule in human red blood cells. The temperature ($37^\circ C$), CO_2 partial pressure (5.3 kPa), and extracellular pH (7.4) were held constant during the measurements presented here. (After Duhm 1971.)

moglobin O_2 affinity is therefore a function of the 2,3-DPG concentration. The hemoglobin of humans and most other mammals is continuously exposed to and modulated by 2,3-DPG within the red blood cells. Thus, as stressed in Figure 24.15, the “normal” O_2 affinity of human hemoglobin in the red blood cells is in part a consequence of modulation by a “normal” 2,3-DPG concentration within the cells.¹⁶

In nonmammalian vertebrates, modulation of hemoglobin O_2 affinity by red blood cell organophosphates is also very common, although the specific phosphate compounds that bind with and allosterically affect hemoglobin vary from one taxonomic group to another and usually do not include 2,3-DPG. ATP and guanosine triphosphate (GTP) are generally the principal organophosphate modulators in fish. In birds, inositol pentaphosphate (IPP) and ATP are especially important. As in mammals, when organophosphates act as modulators in these other groups, their effect is to lower O_2 affinity.

Chronic changes in the concentration of organophosphate modulators in red blood cells serve as *mechanisms of acclimation or acclimatization* in many vertebrates. People with anemia, to mention one example, often exhibit a chronic increase in the concentration of 2,3-DPG in their red blood cells; the O_2 affinity of their hemoglobin is thereby lowered by comparison with the usual affinity. The resulting shift to the right in their oxygen equilibrium curve is not great enough to cause any substantial impairment of O_2 loading in their lungs, but it significantly facilitates O_2 unloading in their systemic tissues (Figure 24.16). Thus each molecule of hemoglobin, on average,

BOX 24.3 THE CHALLENGES OF REGIONAL HYPOTHERMIA AND THE RESURRECTION OF MAMMOTH HEMOGLOBIN

The extinct woolly mammoth (*Mammuthus primigenius*) was an abundant resident of Arctic and sub-Arctic environments—in sharp contrast to its extant relatives, the African and Asian elephants. Arctic mammals often permit tissue temperatures in their appendages to fall far below the temperature of the body core (see Chapter 10), raising the possibility that the affinity of hemoglobin may become so high as blood passes through the appendages that the appendage tissues are subjected to impaired O_2 offloading. Was this a problem for woolly mammoths? Researchers recently

resurrected the hemoglobin of woolly mammoths to try to find out, as discussed in **Box Extension 24.3**.

¹⁶Some mammals have hemoglobins that are not modulated by organophosphate compounds under ordinary physiological conditions. Included are some ruminants, cats, civets, and related species. Their hemoglobins, within the red blood cells, display functionally appropriate O_2 affinities without 2,3-DPG, and the red blood cells of adult animals of these types usually contain little 2,3-DPG.

FIGURE 24.16 A decrease in the O_2 affinity of hemoglobin can aid O_2 delivery to the systemic tissues when the O_2 partial pressure in the breathing organs remains high. Two human oxygen equilibrium curves, representing normal and reduced O_2 affinities, are shown. The loading O_2 partial pressure in the lungs is assumed to be 12.7 kPa (95 mm Hg), and the unloading O_2 partial pressure in the systemic tissues is assumed to be 5.3 kPa (40 mm Hg). The green vertical arrows show the changes in percent saturation at these two partial pressures caused by the shift from normal affinity to reduced affinity (for simplicity and clarity, other effects on affinity, such as Bohr effects, are ignored, and the reduction in affinity is exaggerated). The principles elucidated here apply to gill breathers as well as lung breathers. Note that a high O_2 partial pressure in the breathing organs is assumed.

delivers more O_2 from the lungs to the systemic tissues during each passage through the circulatory system. In anemic people, this effect helps offset the disadvantage of having a reduced amount of hemoglobin per unit of blood volume.

The arthropod hemocyanins are well known to be modulated by organic compounds. In many crustaceans, for example, O_2 affinity is elevated by increasing plasma concentrations of lactate ions (specifically L-lactate ions), which exert their effects by binding to specific allosteric sites on the hemocyanin molecules. When animals such as blue crabs (*Callinectes sapidus*) engage in exercise that produces lactic acid (see Chapter 8), the affinity-increasing effect of the lactate ions offsets the large affinity-decreasing effect of the acidification of their blood (Bohr effect), helping to ensure that their hemocyanin remains capable of fully loading with O_2 in the gills. Dopamine, trimethylamine, and urate are other known organic modulators in crustaceans.

Inorganic ions may also act as modulators of respiratory pigments

Concentrations of specific inorganic ions in blood cells or blood plasma sometimes allosterically modulate the O_2 affinity or other attributes of respiratory pigments. Recent research, for example, has revealed that in many ruminant mammals and certain bears, the concentration of Cl^- in the red blood cells is a critical allosteric modulator of hemoglobin function. The bicarbonate ion (HCO_3^-) is a modulator in crocodylians. The divalent ions Ca^{2+} and Mg^{2+} are important allosteric modulators of hemocyanin in crustaceans. Blue crabs (*Callinectes sapidus*) exposed to O_2 -poor waters, for example, increase their blood Ca^{2+} concentration, which raises the O_2 affinity of their hemocyanin.

SUMMARY The O_2 -Binding Characteristics of Respiratory Pigments

- The oxygen equilibrium curve of a respiratory pigment, which shows the relation between the extent of O_2 binding by the pigment and the O_2 partial pressure, is a key tool for interpreting respiratory-pigment function. An examination of the function of human hemoglobin allows the development of guidelines for analyzing O_2 transport (see the section titled “A set of general principles helps elucidate O_2 transport by respiratory pigments”).
- The shape of the oxygen equilibrium curve depends on the degree of cooperativity among O_2 -binding sites on respiratory-pigment molecules. When there is no cooperativity—as is the case when each molecule has only a single O_2 -binding site—the oxygen equilibrium curve is hyperbolic. The curve is sigmoid when molecules have multiple O_2 -binding sites that exhibit positive cooperativity. Hyperbolic curves are the norm for myoglobins; sigmoid curves are the norm for blood pigments.
- The Bohr effect is a reduction in O_2 affinity caused by a decrease in pH and/or an increase in CO_2 partial pressure. The Bohr effect typically enhances O_2 delivery because it promotes O_2 unloading in systemic tissues while promoting loading in the breathing organs.
- The Root effect, which occurs only rarely, is a substantial reduction of the oxygen-carrying capacity of a respiratory pigment caused by a decrease in pH and/or an increase in CO_2 partial pressure. In teleost fish it helps inflate the swim bladder and oxygenate the retina.
- Elevated blood temperatures often decrease the O_2 affinity of respiratory pigments.
- Organic molecules and inorganic ions frequently serve as allosteric modulators of respiratory-pigment function. 2,3-DPG (2,3-BPG) in the red blood cells of mammals, for example, acts on a long-term basis to decrease the O_2 affinity of the hemoglobin in the cells.

The Functions of Respiratory Pigments in Animals

It would be hard to exaggerate the diversity of functional properties found among animal respiratory pigments. The *oxygen affinity* (P_{50}) of respiratory pigments varies from less than 0.2 kPa to more than 7 kPa. *Cooperativity* (the Hill coefficient, n) varies from 1 to more than 6. The *concentration* of the respiratory pigment in an animal’s blood may be so low that the pigment merely doubles the oxygen-carrying capacity of the blood in comparison with the dissolved O_2 concentration; alternatively, a pigment may be so concentrated that it allows blood to carry 80 times more O_2 than can be dissolved. A respiratory pigment may or may not exhibit a *Bohr effect* or *temperature effect*. One pigment may be modulated by 2,3-DPG, another by ATP. With this diversity of properties, even when the respiratory pigments of various animals carry out a single function, they do so in a diversity of detailed ways.

Respiratory pigments, moreover, are presently known to carry out at least eight different functions—meaning that, overall, they have a very wide range of action. The functions are not mutually exclusive; often a single respiratory pigment carries out two or more functions simultaneously. Although we will cover only a few functions in any detail, all eight deserve recognition:

1. Respiratory pigments in blood (or other circulating body fluids) typically aid the *routine transport of O₂ from the breathing organs to the systemic tissues*. This is the function to which we have devoted most of our attention up to this point in the chapter.
2. Respiratory pigments in the blood of some invertebrates probably function primarily as *O₂ stores*, rather than participating in routine O₂ transport. The pigments that fit this description have very high O₂ affinities. Consequently, they hold so tightly to O₂ that they probably do not unload under routine conditions. Instead, they seem to release their O₂ when animals face severe O₂ shortages. In certain species of tube-dwelling marine worms, for example, O₂ bound to a high-affinity blood hemoglobin is believed to be unloaded primarily during periods when the worms do not breathe, when their tissue O₂ partial pressures fall very low.
3. Blood respiratory pigments often serve as major *buffers of blood pH* and thereby play key roles in blood acid–base regulation. As already mentioned (see Equation 24.2), this buffering is often of an “active” sort, in the sense that the affinity of the respiratory pigments for H⁺ changes as they unload and load O₂. The pigments tend to remove H⁺ from solution as they become deoxygenated and release H⁺ into solution as they become oxygenated. We return to this topic later in this chapter (e.g., see Figure 24.23).
4. Blood respiratory pigments often play critical roles in *CO₂ transport*, as we will also see later in the chapter.
5. Hemoglobins in the cytoplasm of muscle cells (myoglobins), or in the cells of other solid tissues, play two principal respiratory roles. First, they *increase the rate of O₂ diffusion through the cytoplasm of the cells*, a phenomenon that in muscle cells is called **myoglobin-facilitated O₂ diffusion**: At any given difference in O₂ partial pressure between the blood capillaries and the mitochondria of the cells, O₂ diffuses through the cytoplasm to the mitochondria faster if myoglobin is present. The second role played by hemoglobins within solid tissues is *O₂ storage for the tissues*. The myoglobin-bound O₂ store in skeletal muscles, for example, can be called upon at the start of sudden, vigorous muscular work to help sustain aerobic ATP production while circulatory O₂ delivery is still being accelerated to meet the heightened O₂ need.¹⁷
6. Sometimes, respiratory pigments *act as enzymes*, not in carrying out their roles in O₂ transport, but in other contexts. At least in mammals, for example, deoxymyoglobin and deoxyhemoglobin catalyze the local formation of the critically important signaling compound nitric oxide (NO) from nitrite in certain settings.
7. Respiratory pigments occasionally play *nonrespiratory transport roles*. In at least some species of worms that have symbiotic sulfur-oxidizing bacteria (see Figure 6.16), for example, the blood hemoglobin has sulfide-binding sites, and it transports S²⁻ as well as O₂ from the gills to the organ in which the bacteria live.
8. Finally, the fastest-breaking story in the contemporary study of respiratory pigments is the increasing recognition that at least in mammals, myoglobins are sometimes intimately involved in several *tissue functions other than O₂ supply*, especially the regulation of mitochondrial respiration, as addressed in [Box 24.4](#).

¹⁷This role is discussed at length in Chapters 8 and 20.

BOX 24.4 HEME-CONTAINING GLOBINS IN INTRACELLULAR FUNCTION: MYOGLOBIN REGULATORY AND PROTECTIVE ROLES, NEUROGLOBINS, AND CYTOGLOBINS

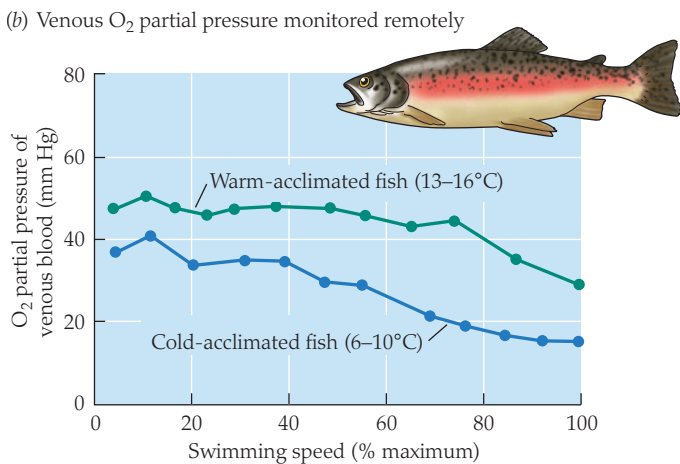

A revolution is underway in the understanding of the roles of globins in intracellular function. New roles of myoglobin are being documented or hypothesized. In addition, new intracellular globins—not known in the twentieth century—have been discovered.

Based on research using myoglobin knockout mice and other methods, researchers now hypothesize that in cardiac muscle and possibly other types of muscle, myoglobin plays a key role in the regulation of mitochondrial respiration, serves as a defense against reactive oxygen species (see Box 8.1), and helps control mitochondrial substrates. We say more here about just the first of these roles. Nitric oxide (NO) potently inhibits cytochrome oxidase (see Figure 8.3) and in this way serves as a key regulator of the rate of mitochondrial O₂ consumption and ATP synthesis in at

least certain muscles (notably cardiac). When O₂ is relatively abundant in a cell, myoglobin becomes oxygenated, forming oxymyoglobin (oxyMb). OxyMb breaks down NO, a process that prevents NO inhibition of cytochrome oxidase, thereby permitting the mitochondria to use O₂ to synthesize ATP when O₂ is available. Conversely, when O₂ is low in abundance in a cell, deoxymyoglobin (deoxyMb) forms. DeoxyMb acts as an enzyme that catalyzes NO synthesis; the NO inhibits cytochrome oxidase and thereby inhibits mitochondrial use of O₂ and ATP synthesis. In these ways, myoglobin is a principal player in regulating mitochondrial function to match the availability of O₂.

In 2000, a heme-containing globin expressed in the brain of humans and mice was discovered (based on genomics research) and named **neuroglobin (Ngb)**. Neuroglobins are now known to occur in most (possibly all)

vertebrates. They are intracellular and have been observed (usually at low concentration) in most brain neurons, peripheral neurons, the retina, some endocrine glands (e.g., adrenal), and the sperm-producing tissues of the testicles. The functions of neuroglobins are gradually being elucidated. They bind O₂ reversibly with high affinity (like myoglobins). Their chief function may be to act as O₂ stores for the central nervous system and retina. Animals genetically engineered to overexpress neuroglobins recover from strokes better than controls do, suggesting that the neuroglobin O₂ store helps protect neurons when their external O₂ supply is cut off. Neuroglobins might also function in antioxidant defense (see Box 8.1) or as sensors of metabolic stress. [Box Extension 24.4](#) discusses neuroglobin structure and another recently discovered set of globins, the cytoglobins.

Patterns of circulatory O₂ transport: The mammalian model is common but not universal

Circulatory O₂ transport in most animals qualitatively follows the pattern we described earlier for mammals (see Figure 24.5). This pattern has several major features, which, for example, can be seen in the O₂ transport physiology of rainbow trout (Figure 24.17). First, the blood respiratory pigment reaches near-saturation in the lungs or gills when the animals are living in well-aerated environments. Second, the respiratory pigment yields just a modest fraction of its O₂ to the systemic tissues during rest, meaning that venous blood in resting individuals is far from being fully deoxygenated. Third, the large resting venous O₂ reserve is used (i.e., venous blood becomes more deoxygenated) during exercise or other states of heightened metabolism. Thus increased tissue O₂ demands are met by increasing the amount of O₂ delivered per unit of blood volume, as well as by increasing the rate of blood flow.

Squids and octopuses are important examples of animals that follow a different pattern of circulatory O₂ transport, and thus illustrate that the pattern observed in mammals and fish is not universal. The squids and octopuses that have been studied have only a very small venous O₂ reserve when they are at rest: *Inactive* individuals use 80–90% of the O₂ available in their arterial blood (Figure 24.18). Thus, when the animals exercise, they have little room to increase unloading of O₂ from their hemocyanin, and they must meet their heightened O₂ demands almost entirely by increasing their circulatory rates. This pattern places high demands on their hearts and constrains

FIGURE 24.17 Blood O₂ transport in rainbow trout in relation to exercise (a) The lines show the average O₂ concentration of arterial and venous blood in trout (*Oncorhynchus mykiss*) at rest and swimming at various speeds in well-aerated water. The numbers above the arterial points show the average arterial percent saturation of the particular fish studied at each speed. As fish increase their speed from rest to maximal, they increase O₂ delivery per unit of blood volume about 2.5-fold. Trout also increase their rate of circulation about 3-fold. Thus the trout increase the total rate of O₂ delivery to their tissues about 7-fold. (b) The relation between venous O₂ partial pressure and swimming speed in trout acclimated to two temperatures. The data were gathered using cutting-edge technology that permitted remote and continuous measurement of the venous O₂ partial pressure in swimming fish. (a after Jones and Randall 1978; b after Farrell and Clutterham 2003.)

their ability to exercise, as we shall see in more detail in Chapter 25 (see Box 25.2). The inherently small venous O₂ reserve of the squids and octopuses also limits their ability to live in poorly aerated waters. If a squid or octopus ventures into O₂-poor waters and consequently can't oxygenate its arterial blood fully, it can't compensate to any great degree (as a fish can) by enhancing the deoxygenation of its venous blood, because the venous blood is already highly deoxygenated even

FIGURE 24.18 Blood O₂ delivery in an octopus: Even at rest, octopuses have almost no venous reserve The octopuses (*Enteroctopus doffeini*) studied were resting or only moderately active in well-aerated water. The three oxygen equilibrium curves correspond to three different blood CO₂ partial pressures (i.e., the hemocyanin exhibits a Bohr effect). All the data obtained on arterial blood fall within the dark purple area, whereas the data on venous blood fall within the light purple area. The two dots represent the approximate means for arterial and venous blood. (After Johansen and Lenfant 1966.)

in aerated waters. Squids and octopuses are notoriously intolerant of low- O_2 environments.

Regardless of the exact pattern of circulatory O_2 delivery an animal displays, the oxygen-carrying capacity of its blood—which depends on the amount of respiratory pigment per unit of blood volume—is a key determinant of how much O_2 can be delivered to its tissues. As already seen in Figure 24.8, animals display a wide range of oxygen-carrying capacities. The range of known values in animals that have blood respiratory pigments is from about 30–40 mL O_2 /100 mL of blood in some diving mammals to just 1–2 mL O_2 /100 mL in many crustaceans and molluscs. Among vertebrates, a rough correlation exists between metabolic intensity and the oxygen-carrying capacity of the blood; mammals and birds usually have carrying capacities of 15–20 mL O_2 /100 mL, whereas fish, amphibians, and nonavian reptiles usually have less hemoglobin per unit of volume and have carrying capacities of 5–15 mL O_2 /100 mL. Active species of fish such as tunas and lamnid sharks tend to have higher oxygen-carrying capacities than do related sluggish species. Animals with hemocyanin tend to have low oxygen-carrying capacities. Squids and octopuses exhibit the highest carrying capacities known for hemocyanin-containing bloods, and their carrying capacities are just 2–5 mL O_2 /100 mL (at or below the lower end of the range for fish). Animals with hemocyanin—which is always dissolved in the blood plasma, not contained in blood cells—probably cannot have much higher carrying capacities because the hemocyanin concentrations needed for higher capacities would make their blood too viscous to pump.

Individual animals can vary their oxygen-carrying capacity by raising or lowering the amount of respiratory pigment per unit of blood volume. The most common responses of this sort are long-term, occurring during acclimation or acclimatization to changed environments (to be discussed shortly). Some vertebrates, however, can acutely change their carrying capacity because they can remove red blood cells from their blood, store the cells, and quickly release them back into the blood. Horses, dogs, and some seals are well known to store massive quantities of red blood cells in their spleen when at rest. When the cells are needed during exercise, they are quickly released back into the blood under control of the sympathetic nervous system. Foxhounds, for example, can promptly increase their oxygen-carrying capacity from 16 to 23 mL O_2 /100 mL in this way.

Respiratory pigments within a single individual often display differences in O_2 affinity that aid successful O_2 transport

Two respiratory pigments often exist within one animal and pass O_2 from one to the other. Most commonly, this occurs in animals that have myoglobins. In these animals, the blood respiratory pigment (hemoglobin or hemocyanin) and the myoglobin act as a sort of “ O_2 bucket brigade”: The blood pigment carries O_2 from the lungs or gills to the muscles, and then passes the O_2 to the myoglobin in the muscle cells. This process is typically aided by differences in O_2 affinity. Specifically, the myoglobin typically has a higher O_2 affinity—a lower P_{50} —than the blood pigment; one can see in Figure 24.7a, for example, that the P_{50} of human myoglobin (about 0.8 kPa, 6 mm Hg) is far lower than that of human blood hemoglobin (about 3.5 kPa, 27 mm Hg). The higher O_2 affinity of the myoglobin means that it tends to load with O_2 at the expense

of unloading of the blood hemoglobin. Thus the difference in affinity promotes transfer of O_2 from the blood to the muscle cells.

Affinity relations also promote the transfer of O_2 from mother to fetus across the placenta in placental mammals. Generalizing across species, the P_{50} of fetal blood is typically less than the P_{50} of maternal blood by 0.4–2.3 kPa (3–17 mm Hg). Because the fetal blood has a higher O_2 affinity, it tends to oxygenate by drawing O_2 from the maternal blood. The relatively high affinity of the fetal blood also means that it is able to become relatively well oxygenated even if the O_2 partial pressure in the placenta is relatively low. Several specific mechanisms account for the differences in O_2 affinity between fetal and maternal bloods in various species. In humans and other primates, the difference occurs because the chemical structures of the fetal and maternal hemoglobins are different, as mentioned at the beginning of this chapter. One key effect of these structural differences is that the fetal hemoglobin is less sensitive to 2,3-DPG; because 2,3-DPG lowers affinity, the diminished sensitivity of fetal hemoglobin to 2,3-DPG raises its O_2 affinity. In some other species, such as dogs and rabbits, the hemoglobins in the fetus and mother are chemically the same; the reason the fetal affinity is higher is that fetal red blood cells have lower intracellular concentrations of 2,3-DPG than maternal red blood cells. In still other species of mammals, additional mechanisms of raising the fetal O_2 affinity are observed; ruminants, for example, have fetal forms of hemoglobin that are intrinsically higher in affinity than maternal hemoglobin, without 2,3-DPG modulation. The relatively high O_2 affinity of fetal hemoglobin is not necessarily the only factor that promotes O_2 transfer from the mother’s blood to the blood of the fetus. An extremely interesting additional factor is that often the loss of CO_2 from the fetal blood to the maternal blood induces a synchronous rise in fetal O_2 affinity and fall in maternal O_2 affinity because of Bohr effects in the two hemoglobins that have these opposing but reinforcing consequences!

Evolutionary adaptation: Respiratory pigments are molecules positioned directly at the interface between animal and environment

A dramatic property of the respiratory pigments is that they are molecules that, in a way, actually form part of the interface between an animal and its environment: They pick up O_2 from the environment and deliver it to cells deep within tissues. Moreover, evolution has produced hundreds of different molecular forms of the respiratory pigments. Because of these considerations, the respiratory pigments have long been regarded as prime subjects for the study of evolutionary molecular adaptation.

Such studies have revealed that often species that have long histories of existence in low- O_2 environments have evolved respiratory pigments with higher O_2 affinities than related species living in high- O_2 environments. This common pattern is well illustrated by the fish in Figure 24.8 and by other fish: Carp and catfish, which often inhabit waters low in O_2 , have average P_{50} values of 0.1–0.7 kPa (1–5 mm Hg)—meaning their hemoglobins load particularly well at low O_2 partial pressures—whereas mackerel and rainbow trout, which live in well-aerated waters, have far higher P_{50} values of 2.1–2.4 kPa (16–18 mm Hg).¹⁸ One reason goldfish survive the

¹⁸These measurements were made at approximately the same CO_2 partial pressures and temperatures.

FIGURE 24.19 The O_2 affinity of the hemoglobin in the whole blood of primates is a regular function of body size. Small-bodied species tend to exhibit lower O_2 affinity—and thus higher P_{50} —than large-bodied ones. (After Dhindsa et al. 1972.)

tender loving care of kindergarteners is that these members of the carp family have high-affinity hemoglobins that can load well in O_2 -poor water. Mammal species that live underground typically have evolved higher O_2 affinities than aboveground species of the same body size. Similarly, some species native to high altitudes have evolved higher O_2 affinities than lowland species (see Box 24.5).

Another thought-provoking evolutionary pattern that has been discovered is the relation between O_2 affinity and body size in groups of related species. In mammals and some other vertebrate groups, the O_2 affinity of blood hemoglobin tends to decrease as body size decreases: Small species have relative high P_{50} values and therefore relatively low O_2 affinities (Figure 24.19). Natural selection is hypothesized to have favored this pattern because of the inverse relation between weight-specific metabolic rate and body size (see Chapter 7). Arterial blood oxygenates similarly in all species of aboveground mammals near sea level because the O_2 partial pressure in the lungs is high enough in all such species to be on the plateaus of their oxygen equilibrium curves (where differences in affinity have little effect; see Figure 24.16). The lower-affinity hemoglobins in the smaller species unload O_2 to the tissues more readily, however. In this way, the lower affinity in the small species is hypothesized to help them meet their higher weight-specific O_2 needs.

Of course, it is exciting to find trends that make sense, but sometimes when physiologists have compared the O_2 affinities of related species, they have found no clear patterns, or even trends opposite to those expected. At present, a comprehensive predictive theory of affinity adaptation does not exist. An important reason is that when affinity is modified in the course of evolution, the changes can potentially affect both loading and unloading. Although a decrease in affinity, for example, could aid O_2 delivery by promoting O_2 unloading in the systemic tissues, it could potentially also diminish O_2 delivery by interfering with O_2 loading in the breathing organs. For sorting out these complexities, a crucial question is whether the O_2 partial pressure in the breathing organs is high enough to cause full oxygenation. To explain, consider a case in which arterial O_2 partial pressures are consistently high enough for respiratory pigments to be well oxygenated regardless of O_2 affinity. In this case, the principal

effect of low affinity is to promote unloading of O_2 in the systemic tissues, which augments O_2 delivery.¹⁹ You will recognize this argument. It is exactly why researchers think that small-bodied mammals living above ground near sea level can benefit by evolving relatively low affinities (see Figure 24.19). Conversely, consider a case in which arterial O_2 partial pressures are low enough that respiratory pigments can fall far short of being fully oxygenated in the breathing organs. In this case, a pigment with a high O_2 affinity might provide the greatest O_2 delivery to the systemic tissues because a high affinity could enable the blood to load much more fully in the lungs or gills.

The respiratory-pigment physiology of individuals undergoes acclimation and acclimatization

When individual animals are exposed chronically to reduced O_2 availability in their environments, they often respond with chronic alterations of their respiratory-pigment physiology. The most common response of this sort in both vertebrates and invertebrates is for the concentration of the respiratory pigment in the blood to be increased. Fish, for example, often increase the concentration of red blood cells in their blood when they live in poorly oxygenated waters.

In addition to the “quantitative strategy” of increasing the amount of respiratory pigment per unit of blood volume, animals also often modify the O_2 -binding properties of the pigments. Sometimes this is achieved by synthesizing different molecular forms. A dramatic example is provided by the water flea, *Daphnia*, a small, hemoglobin-synthesizing crustacean common in freshwater ponds. When *Daphnia* that have been living in O_2 -rich water are transferred into O_2 -poor water, hypoxia-inducible transcription factors (HIFs) are released and affect DNA transcription by modulating hypoxia response elements in the promoter regions for the globin genes (see Box 23.1). Multiple globin types can be synthesized, and after the transfer to O_2 -poor water, the mix of globins is modified. In fact, new mRNAs can appear within minutes, and new hemoglobin molecules—composed of different proportions of globin subunits than the preexisting molecules—can appear within 18 h. The new molecular forms of hemoglobin have a higher O_2 affinity than the preexisting ones. Thus, over the first 11 days in O_2 -poor water, the O_2 affinity rises (P_{50} falls) as the concentration of hemoglobin also rises (Figure 24.20)! Together, these changes give the *Daphnia* a greatly enhanced capability to acquire O_2 from their environment. The *Daphnia* also, as mentioned earlier, change color. Pale at the start, they turn brilliant red.

For modifying the O_2 -binding properties of respiratory pigments, perhaps a more common strategy is not to alter the molecular forms of pigments synthesized but to modulate preexisting types in advantageous ways. When fish, for example, are transferred from well-aerated to poorly aerated waters, they do not typically alter their hemoglobin types, but they often decrease the concentrations of ATP and GTP within their red blood cells over time. These chronic changes in the intracellular modulators of hemoglobin raise its O_2 affinity. Blue crabs, as noted earlier, chronically raise the concentration of Ca^{2+} in their blood when exposed to O_2 -poor waters, apparently by mobilizing Ca^{2+} from the exoskeleton; the effect is to raise the O_2 affinity of their hemocyanin. Box 24.5 discusses how mammals respond to the low atmospheric O_2 partial pressures of high altitudes.

¹⁹Figure 24.16, although it applies to changes in O_2 affinity within a species, illustrates this effect.

FIGURE 24.20 When water fleas are transferred to O₂-poor water, their O₂ transport system undergoes rapid acclimation because of altered gene expression. The water fleas (*Daphnia magna*) had been living in well-aerated water and were transferred at time 0 to water in which the O₂ partial pressure (3 kPa) was only 15% as high as in well-aerated water. The composition and concentration of their blood hemoglobin were then monitored for 11 days. The animals change color, as shown by the photographs. Symbols are means; error bars delimit \pm one standard deviation. (After Paul et al. 2004; photos courtesy of Shinichi Tokishita.)

Icefish live without hemoglobin

We now end our discussion of the transport of O₂ by respiratory pigments by recalling a group of unusual and puzzling vertebrates, the Antarctic icefish: animals that, although reasonably large, have no O₂ transport by blood hemoglobin because they have no hemoglobin in their blood. Of all vertebrates, the icefish—which we discussed at length in Chapter 3—are the only ones that lack blood hemoglobin as adults. As stressed earlier, their habitat is undoubtedly critical in permitting them to live without blood hemoglobin. The Antarctic seas tend to be consistently well aerated, and the temperature of the water is typically frigid (near -1.9°C) year-round. Because of the low temperature, the solubility of O₂ is relatively high, not only in the ambient water but also in the fish's blood. Despite the advantages of high O₂ solubility, the blood oxygen-carrying capacities of icefish (about 0.7 mL O₂/100 mL) are only about one-tenth as high as those of related red-blooded Antarctic fish (6–7 mL O₂/100 mL). The icefish circulate their blood exceptionally rapidly, evidently to compensate for the fact that each unit of blood volume carries relatively little O₂. They have evolved hearts that are dramatically larger than those of most fish of their body size; with each heartbeat, they therefore pump at least four to ten times more blood than is typical. In the microcirculatory beds of their tissues, they also have blood vessels that are of exceptionally large diameter. These large vessels allow rapid blood flow to occur with exceptionally low vascular resistance.

The O₂ affinity of hemoglobin dramatically rises (P_{50} falls) because of synthesis of new molecular forms while simultaneously...

...the total concentration of hemoglobin in the blood sharply increases to a new plateau.

environments often have evolved blood respiratory pigments with particularly high O₂ affinities.

- Respiratory-pigment physiology undergoes acclimation, as by changes in pigment amounts, synthesis of new molecular forms, or modulation of preexisting forms.

SUMMARY The Functions of Respiratory Pigments in Animals

- Respiratory pigments are diverse in their functional properties. The functions they can potentially perform include O₂ transport, facilitation of CO₂ transport, transport of substances other than respiratory gases, blood buffering, facilitation of O₂ diffusion through the cells of solid tissues such as muscle, and O₂ storage in blood or solid tissues.
- Blood respiratory pigments typically become well oxygenated in the breathing organs, and when animals are at rest, the respiratory pigments typically release only a modest fraction of their O₂ to the systemic tissues (25% in humans). During exercise, O₂ delivery is enhanced by increases in both the extent of pigment unloading and the rate of blood flow.
- The relative O₂ affinities of respiratory pigments are often critical for pigment function. When O₂ is transferred from one respiratory pigment to another in an individual animal—as when blood hemoglobin donates O₂ to myoglobin—it is usual for the pigment receiving the O₂ to have a higher O₂ affinity. Comparing related species, those with long evolutionary histories in O₂-poor

Carbon Dioxide Transport

Carbon dioxide dissolves in blood as CO₂ molecules, but usually only a small fraction of the carbon dioxide in blood is present in this chemical form (about 5% in human arterial blood). Thus the first step in understanding carbon dioxide transport is to discuss the other chemical forms in which carbon dioxide exists in blood. Because carbon dioxide can be present in multiple chemical forms, not just CO₂, we must distinguish the material from its exact chemical forms. We do this by speaking of “carbon dioxide” when we refer to the sum total of the material in all its chemical forms and by specifying the chemical form (e.g., CO₂) when we refer to a particular form.

When carbon dioxide dissolves in aqueous solutions, it undergoes a series of reactions. The first is hydration to form carbonic acid (H₂CO₃):

The second is dissociation of the carbonic acid to yield bicarbonate (HCO₃⁻) and a proton:

Bicarbonate can then dissociate further to yield carbonate (CO₃²⁻) and an additional proton. This final dissociation, however, occurs to only a small extent in the body fluids of most animals. Moreover, although carbonic acid is an important intermediate compound,

BOX 24.5 BLOOD AND CIRCULATION IN MAMMALS AT HIGH ALTITUDE

The study of blood O_2 transport in humans and other mammals at high altitude is, in its own particular way, one of the most intriguing chapters in the annals of evolutionary physiology. This is true because in the past 25 years, the blood responses of lowland people at high altitude have morphed from being touted as exceptional examples of *adaptation* to being cited as defining examples of *maladaptation*. A key reason for the change of perspective has been a gradual recognition of the important point discussed in Box 23.2 that responses of predominantly lowland species—such as humans—at high altitude may sometimes represent misplaced expressions of responses that evolved in lowland populations to meet lowland challenges. For example, when the low atmospheric O_2 partial pressure at altitude induces tissue hypoxia, the hypoxia might trigger responses—not necessarily advantageous at high altitude—that evolved to help with lowland anemia. As we discuss blood and circulation at high altitude, keep in mind a critical point emphasized in Box 23.2: *Lowland people and lowland species sojourning at high altitude need to be distinguished from native highland groups.**

If you think back to the oxygen cascade for people in the high Andes in Box 23.2, you will recall that when people—whether native lowlanders or highlanders—are exposed to the reduced atmospheric partial pressure of O_2 at high altitude, they do not experience an equal reduction in their venous O_2 partial pressure. The venous partial pressure, in fact, is reduced *far* less than the atmospheric partial pressure. A key reason for this conservation of venous O_2 partial pressure is blood O_2 transport. The drop in O_2 partial pressure between arterial and venous blood is much smaller at high altitude than at sea level (see Box 23.2). This smaller drop in O_2 partial pressure is important because it helps keep the O_2 partial pressure in the systemic tissues from falling too low.

The principal explanation for the reduced arteriovenous (a-v) drop in O_2 partial pressure at high altitude does not entail any special adaptations. Instead, the reduced a-v drop is simply a consequence of the shape of the mammalian oxygen equilibrium curve. Living at high altitude lowers the arterial O_2 partial pressure. Figure 24.6 illustrates the consequence:

When the arterial O_2 partial pressure is moved off the plateau of the equilibrium curve, there is a sharp reduction in the a-v drop in partial pressure required for the blood to yield any particular quantity of O_2 .

In the search for special high-altitude adaptations, three aspects of blood and circulation have been studied: (1) the oxygen-carrying capacity of the blood, (2) the hemoglobin O_2 affinity, and (3) the rate of blood circulation.

Regarding the oxygen-carrying capacity, when *lowland* people and some other species of *lowland* mammals go to high altitude, their oxygen-carrying capacities typically rise to well above sea-level values. Secretion of erythropoietin (see Box 24.2) is increased, causing an increase in the number of red blood cells (RBCs) per unit of blood volume: a state known as **polycythemia** (“many cells in the blood”). This change can be dramatic. For example, if lowland people go from sea level to 4000–5000 m, their oxygen-carrying capacity may increase from 20 to 28 mL O_2 per 100 mL of blood. This sort of response was long touted as a vivid illustration of adaptative phenotypic plasticity. By now, however, sufficient comparative data have accumulated that we can make the following statement with good confidence: Species of mammals (and birds) that are *native* to high altitudes do *not* have unusually high RBC concentrations or oxygen-carrying capacities. Moreover, among people, some native highland peoples—notably the Tibetan highlanders—do not exhibit the strong erythropoietin response shown by lowlanders and have oxygen-carrying capacities near those of lowlanders at sea level. Why is an elevated RBC concentration in general *not* favored at high altitude? Researchers now have evidence that an elevated RBC concentration can make the blood too viscous, placing a greater workload on the heart and sometimes interfering with regional blood flow. In an effort to carry out a direct test, researchers have medically removed RBCs from lowland people displaying high RBC concentrations at high altitude; some (but not all) studies of this sort have found that the subjects experienced either no change or an improvement in their ability to function. Overall, careful comparative studies have shown that evolution favors little or no increase in RBC concentration at high altitude. The response of lowland people probably evolved as a mechanism to correct blood loss or anemia near sea level and is a misplaced response—triggered erroneously—at high altitude.

With regard to O_2 affinity, *lowland* humans and some other *lowland* species undergo an increase in the concentration of 2,3-DPG in their RBCs at high altitude. When this change was first discovered, it was claimed to help prevent tissue hypoxia by lowering the O_2 affinity of hemoglobin and thus promoting O_2 unloading into the systemic tissues. By now we realize that this claim might not be even theoretically correct because it is myopically focused on just one part of the oxygen equilibrium curve and fails to consider effects on loading as well as unloading. More to the point, the collection of comparative data on many additional species now permits confidence in the following conclusion: Species of mammals (and birds) *native* to high altitudes typically have either ordinary O_2 affinities or particularly *high*—sometimes dramatically high— O_2 affinities (which help hemoglobin take up O_2 in the lungs). Thus, if lowland humans at high altitude have a reduced affinity, we must be wary of interpreting it as being beneficial. This topic is discussed further in **Box Extension 24.5**.

Regarding the rate of circulation, although an increase might at first seem logically to be expected at high altitude, cardiac output is not systematically elevated in humans or other mammals, either at rest or at any given level of exercise. An increase in circulatory rate is not a general attribute of high-altitude animals, and theoretical analyses discussed in Box Extension 24.5 clarify why. This said, researchers recently found that in the special case of Tibetan highlanders, circulatory rate is unusually high and a key to limiting tissue hypoxia.

In all, the study of blood and circulation at high altitude has a complex history, which we can see in retrospect got off on the wrong foot because researchers sometimes assumed uncritically that the responses of lowland humans must be beneficial. Taking a broad view, hemoglobin O_2 affinity is often particularly high in native highland mammals and birds, and this is the most convincing generality now known in the study of blood and circulation.

*Altitude physiology is discussed also in Boxes 8.3 and 23.2. Topics covered in Box 23.2 include the respiratory and tissue-level responses of mammals and the physiology of high-flying birds, especially the bar-headed goose—a species noted for migrating over the Himalayas.

it never accumulates to more than very slight concentrations. For most purposes, therefore, the reaction of CO_2 with water can be viewed simply as yielding HCO_3^- and protons:

Equation 24.5 emphasizes that carbon dioxide *acts as an acid* in aqueous systems because it reacts to produce H^+ ; as mentioned earlier, it has been aptly termed a “gaseous acid.”

The extent of bicarbonate formation depends on blood buffers

Although almost no bicarbonate is generated when CO_2 is dissolved in distilled water or a simple salt (NaCl) solution, bicarbonate is typically the dominant form in which carbon dioxide exists in the bloods of animals. To understand why—and to understand why there is more bicarbonate in some animal bloods than in others—we need to examine the factors that affect bicarbonate formation.

Suppose that we bring a liter of an aqueous solution—initially devoid of carbon dioxide—into contact with a gas that acts as a source of CO_2 , and that this gas remains at a constant CO_2 partial pressure regardless of how much CO_2 it donates to the solution. From Chapter 22, we know that after the solution comes to equilibrium with the gas, the concentration of carbon dioxide in solution in the form of CO_2 will be simply proportional to the CO_2 partial pressure. Thus the amount of CO_2 taken up in *dissolved* form by our liter of solution will depend simply on the principles of gas solubility. In contrast, the extent of bicarbonate formation is governed, not by the principles of solubility, but by the action of compounds that act as *buffers of pH*. In blood, these are the blood buffers. For our immediate purposes, the function of the buffers that deserves emphasis is that, under conditions when the concentration of H^+ is being driven upward, they are able to restrain the rise in concentration by removing free H^+ ions from solution (we’ll return to a fuller description of buffer function shortly).

How do blood buffers determine the amount of HCO_3^- formation? A straightforward way to see the answer is to return to the analysis of the solution mentioned in the last paragraph and apply the principles of mass action (see page 45) to Equation 24.5. According to the principles of mass action, the following equation holds true at equilibrium:

$$\frac{[\text{HCO}_3^-][\text{H}^+]}{[\text{CO}_2]} = K \quad (24.6)$$

where the square brackets signify the concentrations of the various chemical entities, and K is a constant. Because $[\text{CO}_2]$ is a constant at equilibrium in our solution at a given CO_2 partial pressure, and because K is also a constant, Equation 24.6 reveals that the amount of HCO_3^- formed per unit volume of solution depends inversely on the H^+ concentration. If $[\text{H}^+]$ is kept relatively low, $[\text{HCO}_3^-]$ at equilibrium will be relatively high, meaning that a lot of HCO_3^- will be formed as the system approaches equilibrium. However, if $[\text{H}^+]$ is allowed to rise to high levels, $[\text{HCO}_3^-]$ at equilibrium will be low, meaning little HCO_3^- will be formed. When carbon dioxide enters our solution from the gas and undergoes the reaction in Equation 24.5, the degree to which the H^+ made by the reaction is allowed to accumulate, driving $[\text{H}^+]$ up, is determined by the buffers in the solution. If the buffers are ineffective, the H^+ produced by the reaction will simply accumulate as free H^+ in the solution;

thus $[\text{H}^+]$ will rise rapidly to a high level, and the entire reaction will quickly reach an end point with little uptake of carbon dioxide and little formation of HCO_3^- . However, if the buffers are highly effective, so that most H^+ is removed from solution as it is formed, $[\text{H}^+]$ will stay low, and a great deal of carbon dioxide will be able to undergo reaction, causing a large buildup of HCO_3^- .

Let’s now speak about buffers in more detail. Buffer reactions are represented by the general equation

where X^- is a chemical group or compound that can combine reversibly with H^+ . When H^+ is added to a buffered solution, the buffer reaction is shifted to the left, removing some of the H^+ from free solution (as already stressed). However, if H^+ is extracted from a buffered solution, the reaction shifts to the right, releasing free H^+ from compound HX. In brief, a buffer reaction acts to stabilize $[\text{H}^+]$. Together, HX and X^- are termed a **buffer pair**. According to the principles of mass action, the following equation describes a buffer reaction at equilibrium:

$$\frac{[\text{H}^+][\text{X}^-]}{[\text{HX}]} = K' \quad (24.8)$$

where K' is a constant that depends on the particular buffer reaction and the prevailing conditions, notably temperature. The negative of the common logarithm of K' is symbolized **pK'**, just as the negative of the logarithm of $[\text{H}^+]$ is called pH. The *effectiveness* with which a particular buffer reaction (a particular buffer pair) is able to stabilize $[\text{H}^+]$ is greatest when half of the X^- groups are combined with H^+ and half are not; that is, the change in pH caused by the addition or removal of H^+ is minimized when $[\text{HX}] = [\text{X}^-]$. From Equation 24.8, it is clear that for $[\text{HX}]$ and $[\text{X}^-]$ to be equal, $[\text{H}^+]$ must equal K' ; that is, pH must equal pK'. Therefore, the buffering effectiveness of any given buffer reaction is greatest when the prevailing pH matches the pK' of the reaction. Applying this principle to the blood of an animal (it also applies to other solutions), we can say that the blood may contain an enormous variety of potential buffer pairs, but typically, *the buffer reactions that are important will be those with pK' values within one pH unit of the pH prevailing in the blood.*

The blood of mammals and most other vertebrates is highly effective in buffering the H^+ generated from CO_2 because the blood has a high concentration of effective buffer groups. These groups are found mostly on blood protein molecules, *especially hemoglobin!* Two types of chemical groups are particularly noteworthy as buffer groups because they are abundant and have appropriate pK' values: the terminal amino groups of protein chains and the imidazole groups found wherever the amino acid histidine occurs in protein structure. *The imidazole groups are the dominant buffering groups.* The buffering of human blood is so effective that when CO_2 undergoes the reaction in Equation 24.5, forming HCO_3^- and H^+ , the buffer groups remove more than 99.999% of the H^+ produced from free solution! This buffering permits a great deal of HCO_3^- to be formed. Thus the blood can take up a great deal of carbon dioxide.

Carbon dioxide transport is interpreted by use of carbon dioxide equilibrium curves

Blood equilibrium curves for carbon dioxide have interpretive value similar to that of oxygen equilibrium curves. To understand the use of carbon dioxide equilibrium curves, we must first establish the meaning of the **total carbon dioxide concentration** of the

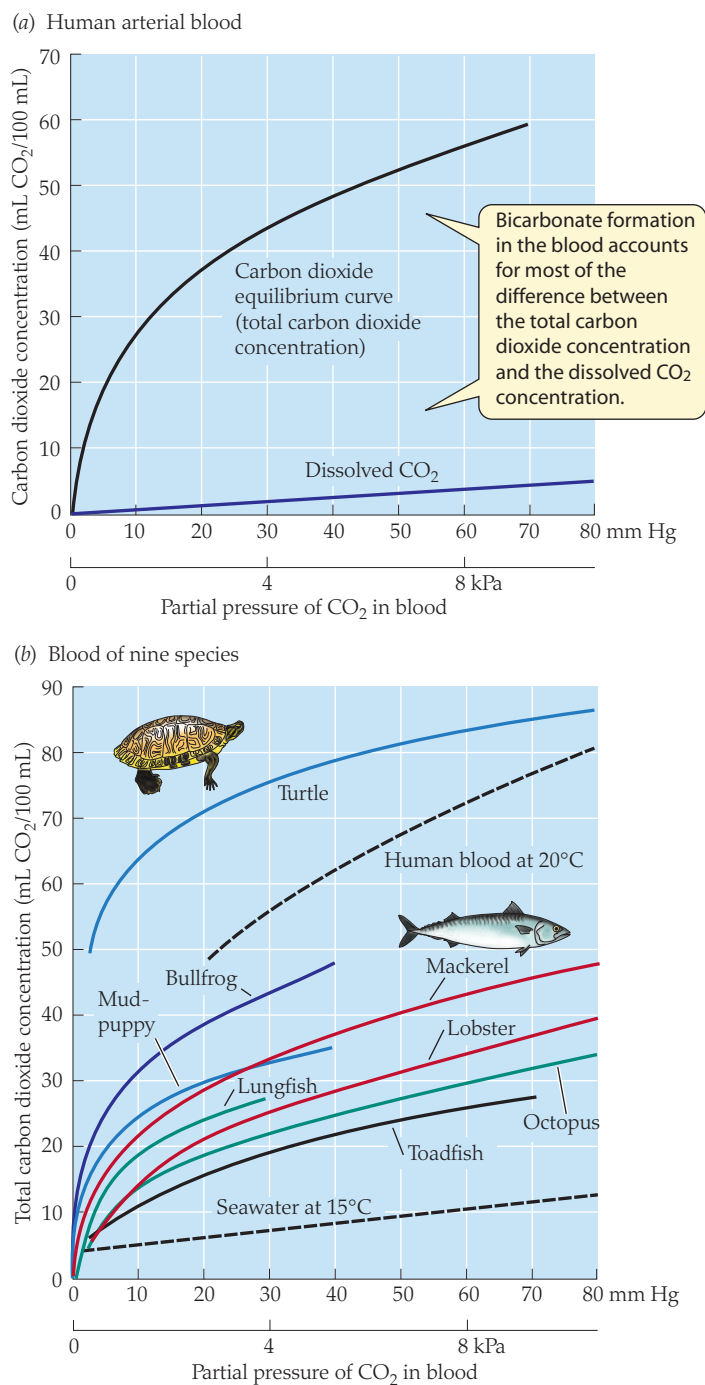

FIGURE 24.21 Carbon dioxide equilibrium curves (a) The carbon dioxide equilibrium curve of fully oxygenated human blood at normal body temperature. The portion of the total carbon dioxide concentration attributable to dissolved CO_2 is shown at the bottom. (b) Carbon dioxide equilibrium curves for oxygenated blood of nine species at 15–25°C. Because all curves were not determined at exactly the same temperature, some of the differences among curves may arise from temperature effects. Species: bullfrog, *Lithobates catesbeianus* (until recently known as *Rana catesbeiana*); lobster, *Panulirus vulgaris*; lungfish, *Neoceratodus forsteri*; mackerel, *Scorpaenopsis scorpaenoides*; mudpuppy, *Necturus maculosus*; octopus, *Octopus macropus*; toadfish, *Opsanus tau*; turtle, *Pseudemys floridana*. (After Hill and Wyse 1989.)

blood. Suppose that some blood is brought to equilibrium with an atmosphere containing no CO_2 , so that the CO_2 partial pressure of the blood is zero. Suppose that the blood is then exposed to an atmosphere containing CO_2 at some fixed, positive partial pres-

sure. And suppose that as the blood comes to equilibrium with the new atmosphere, we measure the total quantity of CO_2 it takes up, regardless of the chemical form assumed by the CO_2 in the blood. This quantity—the total amount of CO_2 that must enter each unit of blood volume to raise the blood CO_2 partial pressure from zero to any particular positive CO_2 partial pressure—is termed the blood's *total carbon dioxide concentration* at that partial pressure. A plot of the total carbon dioxide concentration as a function of CO_2 partial pressure is known as a **carbon dioxide equilibrium curve** or **carbon dioxide dissociation curve** (Figure 24.21a).

What determines the *shape* of the carbon dioxide equilibrium curve? In mammals, carbon dioxide exists in blood in three principal chemical forms, and thus the total carbon dioxide concentration has three components. Two, as we have already discussed, are dissolved CO_2 and HCO_3^- . The third is carbon dioxide that is directly chemically combined (in a reversible manner) with amino groups on hemoglobin and other blood proteins, forming **carbamate groups** ($-\text{NH}-\text{COO}^-$) (also called *carbamino groups*). The role of carbamate formation in types of animals other than mammals—vertebrate and invertebrate—remains debatable. Typically, in both mammals and other groups, the great preponderance of blood carbon dioxide is in the form of HCO_3^- ; 90% of the carbon dioxide in human blood, for example, is in that form. The shapes of the carbon dioxide equilibrium curves of animals are thus determined largely by the kinetics of HCO_3^- formation in their bloods. This means that the shapes depend on the blood buffer systems: the concentrations of buffer groups, their pK' values, and the extent to which they are loaded with H^+ from acids other than CO_2 .

A diversity of carbon dioxide equilibrium curves is found in the animal kingdom (Figure 24.21b). If we compare air-breathing and water-breathing animals, we find that they typically operate on substantially different parts of their carbon dioxide equilibrium curves. The reason, as discussed in Chapter 23 (see Figure 23.6), is that air breathers typically have far higher arterial CO_2 partial pressures than water breathers do. For example, the systemic arterial CO_2 partial pressure in resting mammals and birds breathing atmospheric air—being at least 3.3 kPa (25 mm Hg)—is far higher than that commonly observed in gill-breathing fish in well-aerated waters, 0.1–0.4 kPa (1–3 mm Hg). In air breathers, the CO_2 partial pressure of blood rises from a high arterial value to a still higher venous value as the blood circulates through the systemic tissues, meaning that the part of the carbon dioxide equilibrium curve that is used is the part at relatively high CO_2 partial pressures. In water breathers, by contrast, both the arterial and venous CO_2 partial pressures are relatively low; the part of the equilibrium curve that is used by water breathers is therefore the steep part at relatively low CO_2 partial pressures.

The Haldane effect: The carbon dioxide equilibrium curve depends on blood oxygenation

The carbon dioxide equilibrium curve of an animal's blood commonly changes with the state of oxygenation of the respiratory pigment (the O_2 -transport pigment) in the blood, a phenomenon named the **Haldane effect** after one of its discoverers. When a Haldane effect is present, *deoxygenation promotes CO_2 uptake by the blood, whereas oxygenation promotes CO_2 unloading*. Thus the total carbon dioxide concentration at any given CO_2 partial pressure is greater when the blood is deoxygenated than when it is oxygenated (Figure 24.22). The reason for the Haldane effect is that the buffering function of

FIGURE 24.22 The Haldane effect and its implications for human carbon dioxide transport. The principal graph (left) shows carbon dioxide equilibrium curves for fully oxygenated and essentially fully deoxygenated human blood, illustrating the Haldane effect. The inset (above) summarizes carbon dioxide transport in humans at rest. Point A represents arterial blood, which is fully oxygenated and has a CO_2 partial pressure of about 5.3 kPa (40 mm Hg). Point V represents mixed venous blood, which is about 70% oxygenated and has a CO_2 partial pressure of about 6.1 kPa (46 mm Hg). The arrows show the functional relation between total carbon dioxide concentration and CO_2 partial pressure as blood circulates through the body, becoming alternately arterial (A) and venous (V).

the respiratory pigments—which play major buffer roles—depends on their degree of oxygenation. Deoxygenation of a respiratory pigment alters its buffering function in such a way that it tends to take up more H^+ and lower the blood concentration of H^+ . According to Equation 24.6, this means that when a respiratory pigment becomes deoxygenated, more HCO_3^- can form, and the blood therefore reaches a higher total carbon dioxide concentration. This phenomenon is the necessary converse of the Bohr effect, as noted earlier (page 630).

The functional significance of the Haldane effect is illustrated in the inset of Figure 24.22 using CO_2 transport in resting humans as an example. Point A shows the total carbon dioxide concentration and CO_2 partial pressure in arterial blood, whereas point V shows the values in venous blood. The arrows between A and V represent the functional relation between total carbon dioxide concentration and CO_2 partial pressure in the body, where oxygenation changes simultaneously with the uptake and release of CO_2 . Note that the slope of this functional relation is steeper than the slope of any of the equilibrium curves in Figure 24.22 for blood at a fixed level of oxygenation (red and purple lines). Thus, when the CO_2 partial pressure shifts back and forth between its values in arterial and venous blood (A and V), the blood takes up and releases more CO_2 than would be possible without the Haldane effect. In this way, hemoglobin function simultaneously aids CO_2 transport and O_2 transport!

Critical details of vertebrate CO_2 transport depend on carbonic anhydrase and anion transporters

An important attribute of the hydration of CO_2 to form bicarbonate (Equation 24.5) is that it occurs relatively slowly in the absence of catalysis (requiring a minute or so to reach equilibrium). The native slowness of this reaction presents a potential bottleneck in the blood's ability to take up CO_2 as bicarbonate in the systemic tissues and release CO_2 from bicarbonate in the lungs. The enzyme **carbonic anhydrase (CA)** greatly accelerates the interconversion of CO_2 and HCO_3^- , thereby preventing this reaction from acting as a bottleneck.²⁰ The reaction is the only one known to be catalyzed in CO_2 transport.

²⁰When CO_2 is hydrated to form HCO_3^- by carbonic anhydrase catalysis, H_2CO_3 is not formed as an intermediate. Instead, the reaction proceeds by a pathway not involving H_2CO_3 formation.

The morphological location of CA has important consequences for CO_2 transport. In vertebrates, CA is found within the red blood cells but almost never free in the blood plasma. Sometimes CA is also found associated with the inner endothelial walls of blood capillaries, such as lung or skeletal muscle capillaries. A key point is that CA is both essential and localized.

With this in mind, let's discuss what happens when CO_2 from metabolism enters the blood in a systemic capillary (Figure 24.23). CO_2 diffuses readily into the red blood cells (possibly mediated in part by aquaporin AQP-1). There, it encounters CA and is quickly converted to HCO_3^- and H^+ . In fact, if there is no membrane-bound CA in the capillary walls or other CA outside the red blood cells, virtually all the reaction of CO_2 to form HCO_3^- and H^+ occurs inside the cells. Hemoglobin—the most important blood buffer—is immediately available inside the red blood cells to take up H^+ and thus play its critical role in promoting HCO_3^- formation. In fact, because hemoglobin is undergoing deoxygenation as CO_2 is added to the blood, hemoglobin develops a greater affinity for H^+ just as it is needed. The red blood cell membranes of nearly all vertebrates are well endowed with a transporter protein—a *rapid anion exchange protein* (often termed the **band 3 protein**)—that facilitates diffusion of HCO_3^- and Cl^- across the membranes in a 1:1 ratio. The HCO_3^- that is formed and buffered inside red cells thus tends to diffuse out into the plasma, so that the plasma ultimately carries most of the HCO_3^- added to the blood in the systemic capillaries. As HCO_3^- diffuses out of the red blood cells into the plasma, Cl^- diffuses into the cells from the plasma—a process called the **chloride shift**. In tissues that have a membrane-bound CA associated with the blood-capillary endothelium, such as the skeletal muscles of at least certain vertebrates, some rapid formation of HCO_3^- and H^+ occurs in the plasma, where the HCO_3^- must be buffered by plasma proteins. All these events occur in reverse when the blood flows through the lungs or gills.

The operations of these kinetic details govern the exact ways in which CO₂ is transported under any set of conditions. For example, from recent research, we know that the operations of the kinetic details differ during exercise and rest—a difference that may ultimately prove to be critical for a full understanding of exercise physiology.

FIGURE 24.23 The major processes of CO₂ uptake by the blood in a systemic blood capillary of a vertebrate. The red and purple molecules represent oxygenated and deoxygenated hemoglobin, respectively. Three elements of molecular structure are highlighted in each hemoglobin molecule: the O₂-binding site (symbolized Hb), an imidazole buffering group (Im), and an amino group (NH₂) that can participate in carbamate formation. The processes shown in this figure occur in reverse in the lungs or gills. Where the labels refer to the site of buffering, they are specifying where the H⁺ generated during bicarbonate production is taken up by buffering compounds. Carbamate formation occurs to a significant extent in mammals, but not necessarily in other vertebrates. Hb, hemoglobin; RBC, red blood cell; Pr, plasma proteins.

SUMMARY Carbon Dioxide Transport

- The carbon dioxide equilibrium curve, which shows the relation between the total carbon dioxide concentration of blood and the CO₂ partial pressure, is a key tool for analyzing carbon dioxide transport. In water breathers, the CO₂ partial pressures of both systemic arterial blood and systemic venous blood are typically low and on the steep portion of the carbon dioxide equilibrium curve. In air breathers, blood CO₂ partial pressures tend to be far higher and therefore on the flatter portion of the carbon dioxide equilibrium curve.
- Most carbon dioxide carried in blood is typically in the form of bicarbonate, HCO₃⁻. The extent of HCO₃⁻ formation depends on blood buffers and determines the shape of the carbon dioxide equilibrium curve. Because respiratory pigments are major blood buffers, they play major roles in carbon dioxide transport.
- The Haldane effect, which is in part the necessary converse of the Bohr effect, is an increase in the total carbon dioxide concentration of the blood caused by deoxygenation of the respiratory pigment. The Haldane effect aids carbon dioxide transport by promoting CO₂ uptake by the blood in the systemic tissues and CO₂ loss from the blood in the breathing organs.
- Rapid uptake of CO₂ by the blood or loss of CO₂ from the blood requires the action of carbonic anhydrase, an enzyme localized to certain places (e.g., red blood cells).

Acid-Base Physiology

The pH of the body fluids cannot vary far from normal levels without serious functional consequences. In humans, for instance, the normal pH of arterial blood at 37°C is about 7.4, and a person will lie near death if his or her pH rises to just 7.7 or falls to 6.8! Abnormal H⁺ concentrations inflict their adverse effects to a large extent by influencing the function of proteins. As buffer groups on a protein molecule take up or lose H⁺, the electrical charge of the whole molecule is rendered more positive or negative; beyond certain limits, these changes result in changes in molecular conformation or other properties that interfere with proper protein function. For the electrical-charge and ionization status of a protein molecule to remain within limits compatible with protein function, the pH must remain within parallel limits.

The neutral pH is defined to be the pH of pure water. By this definition, as shown in [Figure 24.24](#), the neutral pH varies with temperature, being higher at low temperatures than at high ones. In poikilotherms, the normal blood pH often varies with body temperature in parallel with the neutral pH. Specifically, a common pattern

FIGURE 24.24 Normal blood pH is a temperature-dependent variable

As the neutral pH varies with body temperature, blood pH—which is more alkaline than neutral—often varies in parallel; in species that follow this pattern, the blood pH tends to remain alkaline to a fixed extent. Data are shown for six poikilothermic species and for humans. Species differ in how alkaline their blood is relative to the neutral pH. (After Dejours 1981.)

is that, within a species, the blood pH is displaced by a relatively fixed amount to the alkaline side of the neutral pH, rising and falling with body temperature to maintain this fixed displacement (see Figure 24.24). A species that follows this pattern is said to maintain a *constant relative alkalinity* of blood pH. In a species of this sort, the pH inside cells, the intracellular pH, also parallels neutral pH (although intracellular pH and blood pH are different from each other).

In the early days of the study of acid–base physiology, studies of humans and other large mammals gave rise to the notion that the pH in any particular region of the body is always regulated at a single, invariant level (e.g., 7.4 in human arterial blood). We now realize that this type of pH regulation is a special case that occurs only in animals that maintain a constant deep-body temperature. In animals as a whole, the pH that is maintained by acid–base regulatory mechanisms—whether in the blood or inside cells—is more commonly a temperature-dependent variable.

What advantage might animals gain by increasing their pH as their body temperature falls? According to the leading hypothesis, the **alphastat hypothesis**, the changes in pH are a means of maintaining a *constant* state of electrical charge on protein molecules. The reason that changes in pH are required is that changes in temperature alter the chemical behavior of the buffer groups on protein molecules. Most importantly, as temperature falls, the pK' values of imidazole groups increase. This means that at reduced temperatures, imidazole groups increase their inherent tendency to combine with H^+ . If this change in chemical behavior were unopposed, more of the imidazole groups on proteins would be combined with H^+ at low temperatures than at high ones. Decreasing the H^+ concentration (raising the pH) at low temperatures serves to oppose the heightened tendency of the imidazole groups to take up H^+ . Accordingly, it helps prevent the proportion of positively charged groups on proteins from changing.

Acid–base regulation involves excretion or retention of chemical forms affecting H^+ concentration

When a process occurs that tends to cause a protracted increase in the amount of acid in the body of an animal, maintenance of the animal's temperature-dependent normal pH requires that other processes be set in motion that will either export acid from the body or increase the body's content of base. Conversely, if a disturbance occurs that decreases body acid, acid–base regulation requires a compensating uptake of acid or export of base. There are two competing “worldviews” of acid–base regulation.²¹ In our brief overview here, we adopt the simpler of the two, which focuses on adjustments in CO_2 , H^+ , and HCO_3^- .

The concentration of CO_2 in the body fluids of an animal can be raised or lowered to assist acid–base regulation. This is especially true

²¹The books by Davenport and Stewart in the References provide readable introductions to these two worldviews. For those who become interested in the strong ion difference approach, not covered here, the reference by Johnson et al. is also worthwhile.

in terrestrial animals, which (in contrast to aquatic ones) normally have relatively high blood partial pressures of CO_2 . Suppose that a person's blood becomes too acidic. One possible compensatory response is for the person to increase lung ventilation, thereby lowering the CO_2 partial pressure in the blood and other body fluids. Lowering the blood CO_2 partial pressure will pull Equation 24.5 to the left and thus lower the blood H^+ concentration. Slowing of lung ventilation, by contrast, can assist with acid–base regulation if the body fluids become too alkaline. The slowing of ventilation will promote accumulation of CO_2 in the body fluids and cause Equation 24.5 to be shifted to the right, providing more H^+ .

Animals often have the ability to exchange H^+ itself with the environment, and this ability also can be used for acid–base regulation. Because H^+ is not a gas, it must be transported in liquid solution. In terrestrial animals, responsibility for the export of H^+ from the body rests with the kidneys. Humans, for example, are routinely confronted with an excess of H^+ from their diet, and they void the excess principally in their urine; this urinary elimination of H^+ can be curtailed entirely, however, when appropriate. In aquatic animals, including both fish and crustaceans, H^+ is exchanged with the environment by the gill epithelium (see Box 5.2, for example).

Bicarbonate ions are also exchanged with the environment to assist acid–base regulation. The HCO_3^- exchanges are mediated principally by the kidneys in terrestrial animals but, it appears, principally by the gill epithelium in fish and crabs (see Box 5.2). Bicarbonate functions as a base. If retention of HCO_3^- in the body is increased, Equation 24.5 is shifted to the left, tending to remove H^+ from solution in the body fluids, making the body fluids more alkaline. Conversely, increased elimination of HCO_3^- tends to raise the H^+ concentration of the body fluids.²²

Disturbances of acid–base regulation fall into respiratory and metabolic categories

Disturbances of the pH of the body fluids are categorized as **acidosis** or **alkalosis**. Acidosis occurs when the pH of the body fluids is shifted to the acid side of an animal's normal pH at a given body temperature. Alkalosis is a shift in pH to the alkaline side of an

²²One way to view this effect of HCO_3^- elimination is to recognize that HCO_3^- originates from H_2CO_3 ; when HCO_3^- is eliminated, just the H^+ of H_2CO_3 remains in the body fluids, acidifying them.

animal's normal pH. Disturbances of pH are also classed as **respiratory** or **metabolic** according to their primary cause.

The *respiratory* disturbances of pH are ones that are brought about by an abnormal rate of CO₂ elimination by the lungs or gills. **Respiratory alkalosis** arises when the exhalation of CO₂ is abnormally increased relative to CO₂ production, causing the CO₂ partial pressure in the body fluids to be driven below the level needed to maintain a normal pH. Panting by mammals, for example, sometimes causes respiratory alkalosis (see page 262). **Respiratory acidosis** occurs when the exhalation of CO₂ is impaired and metabolically produced CO₂ therefore accumulates excessively in the body. Prolonged breath-holding, for example, can cause respiratory acidosis.

Whereas the blood property that is *initially* altered in *respiratory* disturbances of pH is the CO₂ partial pressure, *metabolic* disturbances of pH—by definition—initially alter the blood *bicarbonate* concentration. **Metabolic alkalosis** and **metabolic acidosis** both have numerous possible causes. Metabolic acidosis, for example, can result from excessive loss of HCO₃⁻ in gastrointestinal fluids during chronic diarrhea. Metabolic acidosis can also result from excessive addition of H⁺ to the body fluids, as when lactic acid is accumulated during vigorous exercise; the added H⁺ from lactic acid reacts with the pool of HCO₃⁻ in the body fluids, lowering the concentration of HCO₃⁻.

Animals typically respond to disturbances of pH by marshaling their acid–base regulatory mechanisms. Lung ventilation by human athletes performing work of ever-increasing intensity provides a striking and interesting example. When athletes are not accumulating lactic acid, they simply increase their rate of lung ventilation in parallel with their rate of CO₂ production. However, when athletes work intensely enough that they accumulate lactic acid, they increase their rate of lung ventilation more than their rate of CO₂ production. This disproportionate increase in ventilation, an example of *hyperventilation*, causes CO₂ to be exhaled from the body faster than it is being produced. The CO₂ partial pressure in the blood and body fluids is thereby lowered, helping to limit the degree of acidosis caused by the accumulation of lactic acid.

In the study of global climate change, a concern that has recently become a primary focus is ocean acidification. The atmospheric CO₂ partial pressure has risen by about 30% in the past century because of the burning of wood, coal, and petroleum. Because of the principles we have discussed in Chapter 22 and this chapter, the CO₂ partial pressure in the ocean has increased, driving Equation 24.5 to the right. Seawater is not buffered in a way that would significantly impede the rise in H⁺ concentration (see Figure 24.21), and animals are not always able to regulate processes that are affected by the consequent environmental acidification. For example, the acidification alters seawater Ca²⁺ chemistry in ways that tend to interfere with the synthesis of carbonate skeletal materials by reef corals and other marine animals.

SUMMARY Acid–Base Physiology

- The neutral pH varies with temperature, being higher at low temperatures than at high ones. In animals with variable body temperatures, the normal blood pH often varies in parallel with the neutral pH, being displaced in the alkaline direction to a constant extent (constant relative alkalinity).

- Acidosis and alkalosis are categories of acid–base disturbance. They occur, respectively, when the blood pH is to the acid or alkaline side of an animal's normal pH for the prevailing body temperature. Either sort of disturbance can be respiratory (originating because of changes in CO₂ loss by breathing) or metabolic (originating because of changes in the blood bicarbonate concentration).
- Within their range of acid–base regulation, animals correct chronic acid–base disturbances by modulating the elimination of CO₂, H⁺, and HCO₃⁻ in regulatory ways.

Study Questions

1. While touring a saltwater aquarium, suppose you see a striped bass, a hammerhead shark, an octopus, a feather-duster worm, and a lobster. What type of respiratory pigment would you expect to find in the blood of each?
2. One could say that a respiratory pigment with relatively low O₂ affinity is potentially disadvantageous for loading, but advantageous for unloading. Explain both parts of this statement.
3. In most species of mammals, the O₂ affinity of a fetus's blood hemoglobin is greater than that of its mother's blood hemoglobin. However, mammal species are not all the same in the *mechanism* that causes the affinities to be different. Specify three distinct mechanisms for the difference in affinity between fetal and maternal blood hemoglobin. Recall from Chapter 1 that François Jacob argued that evolution is analogous to tinkering rather than engineering. Considering the mechanism of the fetal–maternal difference in O₂ affinity, would you say that the evolution of the mechanism provides evidence for Jacob's argument? Explain.
4. Outline the ways in which mammalian hemoglobin *simultaneously* plays important roles in O₂ transport, CO₂ transport, and control of blood pH.
5. A fish swims from a body of cool water into a body of warm water. As its body temperature rises, its rate of O₂ consumption increases. The warm water, however, is likely to have a lower concentration of dissolved O₂ than the cool water because the solubility of O₂ in water decreases as temperature increases. These two factors taken together—an increase in the fish's rate of O₂ consumption and a decrease in the dissolved O₂ concentration of its environmental water—can make it difficult for the fish to obtain enough O₂ to meet its needs. The two factors can act as a two-pronged trap. Actually, however, the fish may face a three-pronged trap. How is the increase in temperature likely to affect the O₂ affinity of the fish's hemoglobin, and how could the effect on hemoglobin add even further to the challenge the fish faces? Does global warming pose concerns of this sort?
6. When fishing boats pull trawling nets through the water, many fish avoid being caught by vigorously swimming away. Others, after vigorous escape swimming, get caught, but later are released because they are not of legal size or are not the species desired. Fish that escape or are released sometimes die anyway. The accumulation of lactic acid from anaerobic work in such fish seems in certain cases to be a key factor in their deaths. How could a large lactic acid accumulation in a fish interfere with its ability to obtain enough O₂ to survive?
7. To study the chemical properties of the blood hemoglobin of a vertebrate, it might seem convenient to remove the hemoglobin from the red blood cells so that the hemoglobin is in simple aqueous solution. However, removing the hemoglobin from red blood cells often promptly alters its O₂-binding characteristics. Why?

8. Give an example of respiratory alkalosis and one of metabolic acidosis. In each case, explain how your example illustrates that type of acid–base disturbance.
9. As noted in this chapter, respiratory pigments that are dissolved in the blood plasma usually have very high molecular weights. The statement has been made that in animals with dissolved respiratory pigments, “the polymerization of unit respiratory-pigment molecules into high-molecular-weight polymers allows the blood solution to have a high oxygen-carrying capacity without having its osmotic pressure boosted to high levels by the presence of the respiratory pigment.” Explain. (Hint: Review in Chapter 5 how dissolved entities affect the colligative properties of solutions.)
10. Among related species (e.g., vertebrates), there is often a positive correlation between the oxygen-carrying capacity of blood and the height of the carbon dioxide equilibrium curve (the total carbon dioxide concentration at high CO₂ partial pressures). Why?
11. Studies have shown that reindeer and musk-ox, two Arctic mammals (see Chapter 11), have evolved hemoglobins that are unusually low in their sensitivity to temperature compared with the hemoglobins of most large mammals. The researchers who made this discovery hypothesized that a particularly low thermal sensitivity is required for hemoglobin to unload O₂ to an adequate extent in the distal parts of these animals’ legs, where tissue temperatures may be 25°C cooler than in the thorax (see Figure 10.32). Explain the rationale for this hypothesis. In answering, discuss how the temperature of the hemoglobin molecules changes as blood flows between the lungs and the legs in cold weather. If possible, design studies to test the hypothesis.

Circulation

When we look at the contours of the muscles of an athletic person, we can imagine that the muscles are a force unto themselves. The muscles, however, can be only as effective as their circulation permits them to be. For each cell in a muscle, the streaming of blood in nearby capillaries is a lifeline for resupply with O_2 and other necessities. Although a muscle may have a highly developed contractile apparatus, it is able to contract only with as much endurance and power as its rate of ATP production permits, and during sustained exertion, the capacity of a muscle to produce ATP is determined by the rate at which O_2 is brought to it by the circulation of the blood (see Chapter 9). In traditional human societies, in which food is gathered, shelter is built, and battles are fought with human muscles, the rate of O_2 supply to the muscles by the circulation can help determine whether a person and his family thrive or perish. In industrialized societies, the rate of O_2 supply to the muscles by the circulation helps determine whether a person can perform a job requiring hard manual labor, or be a successful basketball player or long-distance runner.

In addition to the transport of commodities such as O_2 , the circulatory system also performs other vital functions. Blood pressure is used to initiate the formation of urine. Blood pressure is also used to stiffen erectile tissues in both sexes during sexual intercourse. In men, the circulatory system of the testes plays a thermoregulatory role; the arteries and veins are arranged into a countercurrent heat exchanger (see page 259) that short-circuits heat from arterial blood flowing toward the testes into venous blood leaving them, thereby reducing heat flow into the testes and helping to keep them at the diminished temperature they require for sperm production. Vascular countercurrent heat exchangers also occur in the arms of both women and men and in the appendages of various other species of mammals. These arrays of blood vessels reduce energy costs by limiting heat losses from the body in chilly environments.

Ancient people undoubtedly were as aware as we are that when the body is cut, it oozes blood regardless of where the cut is made. This observation was the first sign that blood at high pressure streams through every region of tissue. The idea that the blood makes a round-trip through the body—the concept that it circulates—was first put forth by William Harvey in 1628. However, Harvey and his contemporaries could not possibly have understood the circulation as we do today, because blood capillaries were unknown in his time, and O_2 was not identified as a defined gas for another 150 years. From Harvey's time to the present, scientists have learned steadily more about the tasks that are accomplished by the circulation of the blood. As they have done so, the very word *circulation* has taken on a progressively different meaning. A generation after Harvey, early microscopists discovered that minute blood vessels just barely wider than red blood cells—the capillaries—weave among the cells of every tissue. Bleeding from every cut could then, finally, be understood, and the stage was set for biologists ultimately to realize that the blood brings needed substances to all cells. In

The heart circulates blood to every tissue and organ, sustaining all bodily strength

Until a few decades ago, some Nuba tribes lived in traditional ways apart from outside influence. The people did their work and fought their wars with human muscle—at intensities dependent on blood circulation. The young men, called *kaduma*, prized physical strength and music they plucked on lyres they made themselves. In the long evolutionary history of humankind, a life of this sort was undoubtedly common. (From Riefenstahl 1973.)

the nineteenth century, scientists demonstrated that the circulation of the blood brings O_2 to cells (see Box 7.1). In the twentieth century, hormones, antibodies, and immune cells were discovered, and the concept of the circulation of the blood was expanded to include their transport from one region of the body to another.

To define **circulation** today in a way that is relevant to all kinds of animals, two perspectives can be taken. From the perspective of mechanics, circulation is the pressure-driven bulk flow of a body fluid called **blood** through a system of tubular vessels or other passages that brings the fluid to all parts of the body. The system of vessels or other blood passages—plus the blood itself—is called the **circulatory system**. When we think of circulation, however, we usually do not think of it in only these mechanical terms. From a second perspective, circulation is defined by what it accomplishes. Thus, for us today, circulation is a pressure-driven bulk flow of fluid that rapidly transports O_2 , CO_2 , nutrients, organic wastes, hormones, agents of the immune system, heat, and other commodities throughout the body and that often provides a source of hydraulic pressure for organ function.

The *speed* of transport by the circulation is one of its most central and defining attributes. As we first saw in discussing Table 5.1, diffusion through aqueous solutions is too slow to transport commodities at biologically significant rates over distances exceeding 1 millimeter or so. Only very small animals, therefore, can depend on diffusion as their sole means of internal transport (see Box 22.1). Convective transport—transport by bulk flow of body fluids—is intrinsically far faster than diffusion. Consequently, as stressed in Chapter 22 (see Figure 22.7), animals larger than a millimeter or so generally require blood circulation (or some other form of bulk flow of body fluids) to move commodities from place to place in their bodies at adequate rates.

As we study the circulation, both of the defining perspectives we have identified will be important. Looking back at the man in our opening photograph, for example, one of our two key questions must be how his circulatory system itself works: How do his heart and vascular system function to bring blood to and from the cells in his head, feet, skeletal muscles, and all other parts of his body at the rate required, and how are these processes regulated? Our second key question must focus on consequences: What functions are accomplished by his circulation?

In humans and in most other animals, the transport of O_2 is by far the most pressing and urgent function performed by the circulation.¹ That is, of all the commodities that tissues require to be brought to them by the circulation of blood, O_2 is the one that, by far, they can least afford to have brought more slowly. This observation has both evolutionary and contemporary implications. In most types of modern animals, *metabolic intensity* and the *peak capacity of the circulatory system to transport O_2* are strongly correlated. These properties have likely coevolved over the course of evolutionary time, neither getting far ahead of the other because there would be few selective factors favoring a mismatch. Similarly, when we look at minute-by-minute variations in the circulatory function of individual animals, we find usually that tissue O_2 needs drive changes in blood-flow rates; the rate of blood flow rises and falls as the metabolic need for O_2 increases and decreases. These principles

explain why O_2 transport often receives paramount attention in the study of circulatory systems, even though circulation is essential for a great many functions.

Hearts

A logical starting point for study of the circulation is the hearts of animals. A **heart** is a discrete, localized pumping structure. Some animals that have a circulatory system lack a heart; in many annelid worms, for example, the blood is propelled through the circulatory system entirely by peristaltic contractions of blood vessels. Hearts are very common in circulatory systems, however, and often assume principal responsibility for driving the flow of blood through the blood vessels.

In some types of animals, such as arthropods, the heart is **single-chambered**, consisting of a single muscular tube or sac. In others, such as vertebrates, the heart is composed of two or more compartments through which blood passes in sequence, and thus is **multichambered**. Many types of animals, in addition to their principal heart, possess other hearts that assist with the pumping of blood through localized parts of the body. Such secondary or local hearts are called **accessory hearts** or **auxiliary hearts**.

The muscle tissue of a heart, composed of *cardiac muscle*, is known as the **myocardium** (*myo*, “muscle”; *cardium*, “heart”). **Cardiac muscle**, one of the major types of muscle, typically has distinctive structural and physiological properties in comparison with other types of muscle (e.g., skeletal muscle), as discussed in Chapter 20 (see Figure 20.19 and Table 20.3).

To study the morphology of a heart in detail, there is no more appropriate example than our own (Figure 25.1). The hearts of other mammals and of birds are similar. The left side of the human heart, which consists of two chambers—a weakly muscular **atrium** and a strongly muscular **ventricle**—receives freshly oxygenated blood from the lungs and pumps it to the systemic tissues of the body.² Blood arrives in the **left atrium** via the **pulmonary veins** that drain the lungs.³ It leaves the **left ventricle** via a single massive artery, the **systemic aorta**, which branches to send arterial vessels to the head, arms, abdomen, and all other body regions, even the myocardium itself. Passive valves, consisting of flaps of connective tissue covered with endothelial tissue, are positioned between the atrium and ventricle (the **left atrioventricular valve**) and between the ventricle and aorta (the **aortic valve**); these valves allow blood to flow freely in the correct direction but prevent it from flowing backward. After blood leaves the systemic aorta, it passes through the **systemic circuit**—the blood vessels that take blood to and from the systemic tissues—and ultimately returns in the great collecting veins (**venae cavae**; singular *vena cava*) to the heart, where it enters the **right atrium** and then the **right ventricle**. The function of the right side of the heart is to pump blood through the **pulmonary circuit**—the blood vessels that take blood to and from the lungs. The right ventricle propels blood into a large vessel, the **pulmonary trunk**, which divides to form the **pulmonary arteries** to the lungs. As in the left heart, passive flap valves prevent backward flow in the right heart; these valves are positioned between the atrium and

²The **systemic tissues** are all the tissues other than the tissues of the breathing organs.

³By definition, **veins** are vessels that carry blood toward the heart, and **arteries** are vessels that carry blood away from the heart.

¹Insects and other tracheate arthropods are dramatic exceptions to this statement, as discussed later in the chapter.

ventricle (the **right atrioventricular valve**) and between the ventricle and pulmonary trunk (the **pulmonary valve**). After blood has been oxygenated in the lungs, it returns to the left atrium.

The heart as a pump: The action of a heart can be analyzed in terms of the physics of pumping

During the beating cycle of any type of heart, the period of contraction is called **systole** (pronounced with a long *e*: *sis-tuh-lee*), and the period of relaxation is termed **diastole** (*dy-as-tuh-lee*). The heart is a pump, and we can understand its workings as a pump by analyzing pressure, flow, and volume during these periods. Here, as an example, we analyze the workings of the human left heart (left atrium and ventricle) shown in **Figure 25.2**.

At the time marked by the arrow at the bottom of Figure 25.2, ventricular systole begins. Whereas the pressure inside the ventricle was lower than that inside the atrium during the time just before the arrow, as soon as the ventricle starts to contract (marked by the arrow), the ventricular pressure rises abruptly to exceed the atrial pressure, causing the atrioventricular valve between the chambers to flip shut. For a brief interval of time (about 0.05 s), however, the ventricular pressure remains below the pressure in the systemic aorta, meaning that the aortic valve is not forced open. During this interval, therefore, both the inflow and outflow valves of the ventricle are shut. The volume of blood in the ventricle during this time is thus constant, and the interval is called the phase of **isovolumetric contraction** (“contraction with unchanging volume”) or **isometric contraction**. The contraction of the ventricle on the fixed volume of blood within causes the blood pressure inside the ventricle to rise rapidly. As soon as the ventricular pressure rises high enough to exceed the aortic pressure, the aortic valve flips open, and the blood in the ventricle accelerates extremely rapidly, gushing out into the

aorta (thus increasing aortic pressure). The opening of the aortic valve marks the start of the phase of **ventricular ejection**. Toward the end of this phase, the aortic pressure comes to exceed the ventricular pressure slightly, but ejection of blood into the aorta continues for a while—at a rapidly falling rate—because of blood momentum. Ultimately, the ventricle starts to relax. The ventricular pressure then falls rapidly away from the aortic pressure, and the aortic valve shuts. A period of **isovolumetric relaxation** follows, as ventricular pressure falls with both the inflow and outflow valves shut. When the ventricular pressure drops below the atrial pressure, the atrioventricular valve opens inward to the ventricle, and **ventricular filling** begins. Most filling of the ventricle occurs *before* atrial systole—that is, before the atrial muscle contracts; the motive force for this filling is the pressure built up by *accumulation* of pulmonary venous blood in the atrium. When atrial systole occurs, it forces some additional blood into the ventricle just before the next ventricular systole.

In thinking of any heart as a pump, its most important attribute is the volume of blood it pumps per unit of time, known as the **cardiac output**. (In the case of the mammalian or avian heart, the term *cardiac output* refers specifically to the output of the left ventricle into the systemic aorta unless stated otherwise.) The cardiac output is the product of the heart rate and the **stroke volume**, the volume of blood pumped per heart cycle:

$$\text{Cardiac output (mL/minute)} = \text{heart rate (beats/minute)} \times \text{stroke volume (mL/beat)} \quad (25.1)$$

The circulation must deliver O₂ to the myocardium

The myocardium of any heart (the “heart muscle”) performs sustained, vigorous work, and its cells therefore are especially dependent on a steady O₂ supply. In most vertebrates, the ventricular

FIGURE 25.2 The heart as a pump: The dynamics of the left side of the human heart The heart cycle is divided into five phases, labeled at the top and demarcated by the vertical lines that run through the diagram. The diagram shows the synchronous changes that occur in left ventricular blood pressure, systemic aortic blood pressure, left atrial blood pressure, ventricular volume, the rate of blood flow out of the ventricle, and the closing and opening of the atrioventricular and aortic valves in humans at rest. The arrow at the bottom marks the start of ventricular systole. The ECG (see top panel) is the electrocardiogram, discussed later in this chapter.

myocardium is second only to the brain in its reliance on aerobic catabolism and in the urgency with which it requires O_2 .

In mammals and birds, the ventricular myocardium is classified as **compact** because its muscle cells are packed closely together, much as cells are in other sorts of muscle. Blood passing through the *ventricular*

lumen—the open central cavity of the right or left ventricle—cannot flow directly among the myocardial muscle cells because of their close packing. The myocardium, therefore, is not oxygenated by the blood flowing through the heart lumen. Instead, the ventricular myocardium in mammals and birds is supplied with tissue blood flow and O_2 by a system of blood vessels called the *coronary circulation* (Figure 25.3a). **Coronary arteries** branch from the systemic aorta at its very beginning and carry freshly oxygenated blood to capillary beds throughout the myocardium; the blood then flows into **coronary veins**, which carry it out of the myocardium and into the right atrium. If a coronary artery becomes blocked, the part of the myocardium it supplies quickly deteriorates from O_2 deprivation, explaining why occlusions in the coronary arteries are extremely dangerous.

The original, evolutionarily primitive arrangement for oxygenation of the myocardium in vertebrates is believed to be that shown in Figure 25.3b. This arrangement is common today in teleost (bony) fish, amphibians, and nonavian reptiles. The ventricular myocardium is classified as **spongy** because the muscle tissue is thoroughly permeated by an anastomosing (branching and rejoining) network of open spaces. The blood that is passing through the lumen of the ventricle—ventricular *luminal* blood—flows among the spaces of the spongy tissue, and the myocardial cells obtain their O_2 from the luminal blood. A shortcoming of this arrangement, as we will see later in this chapter, is that luminal blood is not always well oxygenated.

In some fish—including salmonids, tunas, and sharks—as well as some amphibians and nonavian reptiles, the ventricular myocardium consists of an outer compact muscle layer and an inner spongy layer (Figure 25.3c). The compact layer is supplied by coronary blood vessels that receive freshly oxygenated blood. The spongy layer obtains O_2 from the luminal blood, although it may also receive branches of the coronary circulation. Recent studies, discussed later, have revealed that in hearts of this sort, the proportions of compact and spongy myocardium sometimes vary dramatically within a single species.

A fourth system that has been described for supplying the myocardium with O_2 occurs in the systemic heart of the octopus *Octopus vulgaris* (other octopuses may have a coronary artery system).⁴ Based on the evidence available, some of the blood flowing through the heart lumen of *O. vulgaris* enters a blood capillary system that carries it through the myocardium, whereupon it is collected into coronary veins on the surface of the heart (Figure 25.3d). The blood flowing through the lumen of the systemic heart of an octopus is freshly oxygenated, meaning that the myocardial cells ordinarily receive a relatively rich O_2 supply.

The electrical impulses for heart contraction may originate in muscle cells or neurons

The rhythmic contraction of a heart reflects a rhythmic depolarization of the cell membranes of its constituent muscle cells. As described in Chapter 20, the cell membranes of muscle cells are polarized electrically (inside negative, outside positive), but can become depolarized. Depolarization is the immediate stimulus for contraction.⁵ A key question about any heart is: Where does the impetus for the rhythmic depolarization of the muscle cells origi-

⁴In general, relatively little is known about myocardial O_2 supply in invertebrates.

⁵Cardiac muscle cells often exhibit specialized depolarization processes by comparison with neurons. These specializations help explain the distinctive contraction properties of cardiac muscle. See page 319 and Figure 12.23.

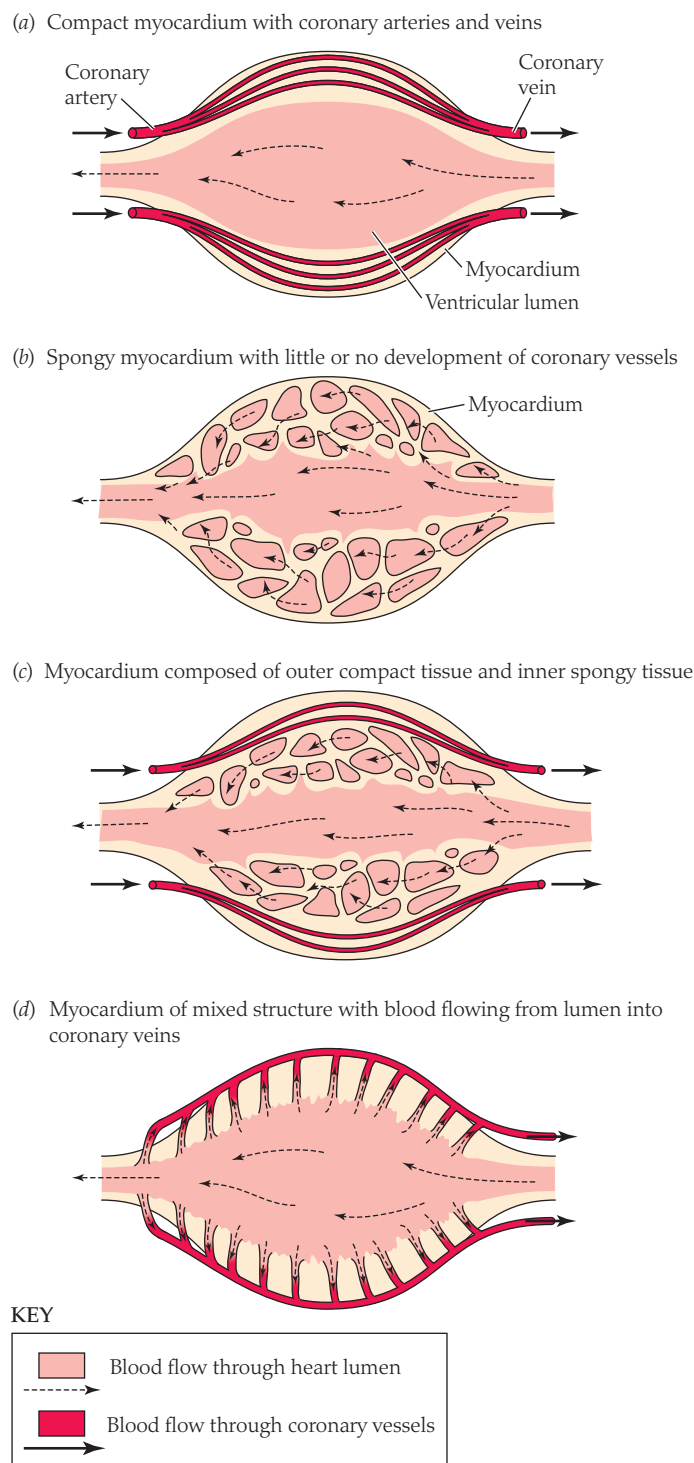

FIGURE 25.3 Four systems evolved by animals to supply O_2 to the myocardium The myocardium is sometimes supplied with O_2 by blood flowing through a coronary circulatory system, whereas sometimes it is supplied by blood flowing through the heart lumen. A major reason to be aware of this distinction is that, although blood pumped into coronary arteries is always well oxygenated, the blood flowing through the heart lumen may not be. Each drawing shows a stylized heart. (a) The compact myocardium of mammals and birds is supplied by coronary arteries and veins. (b) A fully spongy myocardium (e.g., characteristic of most teleost fish) is oxygenated mostly by luminal blood. (c) Sometimes, the ventricular myocardium consists of an outer, compact layer with a coronary circulation and an inner spongy layer (e.g., in salmonid fish, tunas, and sharks). (d) In some octopuses, such as *Octopus vulgaris*, blood flows from the lumen through the myocardium and into coronary veins.

each impulse to contract originates in neurons (nerve cells), and the heart is termed **neurogenic** (“beginning in neurons”). Let’s explore some of the attributes of myogenic and neurogenic hearts by looking at a classic example of each.

MYOGENIC HEARTS The hearts of vertebrates are myogenic. In almost all cases, they are innervated, but they continue to beat even if all nervous connections are stripped away.

An important feature of vertebrate heart muscle is that adjacent muscle cells are *electrically coupled*. This electrical coupling occurs at gap junctions (see Figure 2.7), which in humans and other mammals occur primarily at specialized regions of intercellular contact known as *intercalated discs*.⁷ Because adjacent cells are electrically coupled, depolarization of any one cell in the myocardium *directly* and *quickly* causes depolarization of neighboring cells. In turn, those cells induce their neighbors to depolarize, and so on. Thus, within large regions of the heart muscle, once depolarization is initiated at any point, it rapidly spreads—directly from muscle cell to muscle cell—to all cells in the region, leading all to contract together, as a unit (see Box 7.5).

Most or all of the muscle cells in a vertebrate heart possess an inherent ability to undergo rhythmic depolarization and contraction. Thus pieces of muscle cut from any part of the heart will beat. In the intact heart, of course, individual bits of heart muscle do not depolarize and contract on their own—at their own rhythms. Instead, all the cells in the myocardium are controlled by a particular group of specialized muscle cells: the pacemaker. In fish, amphibians, and nonavian reptiles, the pacemaker is located in the wall of the sinus venosus, the first heart chamber (see Figure 25.14b), or at the junction of the sinus venosus and atrium. In birds and mammals, in which the sinus venosus has become incorporated into the atrium, the pacemaker is located in the wall of the right atrium (Figure 25.4) and is known as the **sinoatrial (S-A) node (sinus node)**. The cells of the pacemaker are modified in comparison with most heart muscle cells; for example, they have a relatively poorly developed contractile apparatus. They are fundamentally muscle cells, however, meaning that the heart is myogenic. A critical attribute of the pacemaker cells is that they exhibit the highest frequency of spontaneous depolarization of all cells in the heart, and therefore are normally the first to depolarize at each heartbeat. By thus *initiating* a wave of depolarization that spreads throughout the heart, they *impose* their rhythm of depolarization on the heart as a whole.

nate? Do the muscle cells themselves spontaneously depolarize in a rhythmic manner? Or are they induced to depolarize by electrical impulses arriving from other cells? In either case, which are the cells that spontaneously depolarize and thus originate the impulses? A heart’s **pacemaker** is the cell or set of cells that spontaneously *initiates* the rhythm of depolarization in the heart.⁶

In some animals, each electrical impulse to contract originates in muscle cells or modified muscle cells; the hearts of such animals are described as **myogenic** (“beginning in muscle”). In other animals,

⁶See page 317 for discussion of the cellular physiology of pacemaker depolarization.

⁷Electrical coupling is discussed on page 329. Gap junctions are discussed on pages 39 and 329. Intercalated discs are illustrated in Figure 20.19.

The process by which depolarization spreads through the vertebrate heart or any other myogenic heart is known as **conduction**. Critical details of conduction in the mammalian heart depend on key structural features of the heart. The myocardium of the two atria of the heart is separated, for the most part, from the myocardium of the two ventricles by a layer of fibrous connective tissue across which myocardial cells are not electrically coupled by gap junctions and through which depolarization, therefore, cannot pass. In the mammalian heart, the one “electrical window” through this fibrous layer is provided by a **conducting system** composed of specialized muscle cells. As shown in Figure 25.4a, the conducting system starts with a group of cells in the right atrial wall known as the **atrioventricular (A-V) node**. Emanating from this node is a bundle of cells called the **atrioventricular bundle** (*common bundle, bundle of His*), which penetrates the fibrous layer and enters the *interventricular septum*—the wall of tissue that separates the right and left ventricles. Once in the septum, the atrioventricular bundle divides into right and left portions, the **bundle branches**, which travel along the right and left surfaces of the septum and connect

with systems of large, distinctive muscle cells, the **Purkinje fibers**, that branch into the ventricular myocardium on each side.

The conducting system of the mammalian heart has two key *functional* properties: (1) Depolarization enters and traverses the A-V node relatively slowly, and (2) depolarization spreads down the atrioventricular bundle, bundle branches, and systems of Purkinje fibers much more rapidly than it could travel through ordinary ventricular muscle. The implications of these properties become apparent when we consider the sequence of events during a heartbeat, shown in Figure 25.4b. Steps 1 and 2 show that once the sinoatrial (S-A) node initiates a heartbeat by depolarizing spontaneously, the depolarization spreads rapidly throughout the muscle of both atria, leading to atrial contraction. Spread into the ventricular muscle does not occur as rapidly, however, because it is dependent on activation of the conducting system, and the spread of depolarization into and through the initial part of the conducting system—the A-V node—is relatively slow (step 2). This slowness of depolarization of the A-V node is responsible for the sequencing of contraction: atrial contraction distinctly first, ventricular contraction distinctly second. Once the A-V node is activated, depolarization sweeps rapidly down the conducting system into the ventricles (step 3), precipitating wholesale ventricular depolarization and contraction (step 4). The rapid delivery of the depolarizing wave to far-flung parts of the ventricular tissue by the conducting system ensures that all parts of the ventricular myocardium contract approximately together.

NEUROGENIC HEARTS The defining feature of neurogenic hearts is that the rhythmic depolarization responsible for initiating the heartbeats originates in nervous tissue. The hearts of lobsters are

(a) The conducting system and sinoatrial node

(b) The initiation and spread of depolarization during a heartbeat

1 Depolarization begins in the S-A node and spreads outward through atrial muscle.

2 Although depolarization spreads rapidly throughout the atrial muscle, its spread into the A-V node is delayed. The depolarized atria start to contract.

3 Once the A-V node becomes depolarized, the depolarization spreads very rapidly into the ventricles along the conducting system. Atrial muscle starts to repolarize.

4 The nearly simultaneous depolarization of cells throughout the ventricular myocardium leads to forceful ventricular contraction.

The branches of the right and left bundle branches are in fact more elaborate than shown; traveling along the inner surfaces of the ventricles and across the ventricular cavities, they run to much of the inner wall of each ventricle. (b) The initiation and conduction of depolarization during a heartbeat. Box 7.5 shows actual images of the spread of depolarization in the surface layers of the ventricles. (a after Scher and Spach 1979; b after Rushmer 1976.)

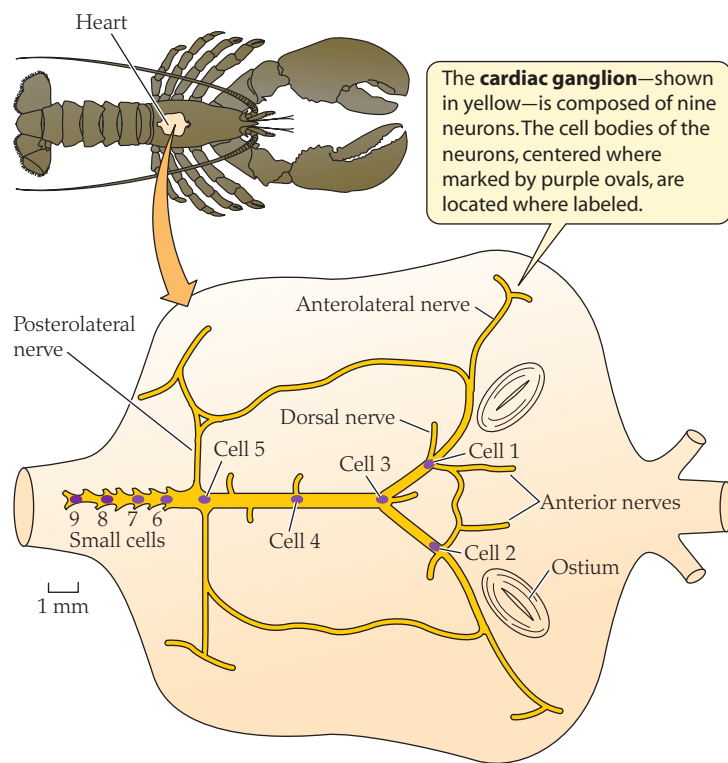

FIGURE 25.5 The neurogenic heart of a lobster and the cardiac ganglion that initiates and controls its contractions A dorsal view of the heart of the American lobster (*Homarus americanus*), showing the cardiac ganglion, which is positioned on the inside of the dorsal heart wall. Neuronal processes go out from each of the nine cell bodies in the ganglion and together form the structure of the ganglion. The posterior four neurons (numbers 6–9) are small, whereas the anterior five are large. Neuronal processes exit the ganglion to innervate the cells of the heart muscle. Regulatory neurons from the central nervous system enter the ganglion in the dorsal nerve. The ostia (slitlike openings through the heart wall) are discussed later in this chapter. (After Hartline 1967.)

well-documented examples. Each muscle cell in a lobster heart is innervated and typically contracts when and only when stimulated to do so by nerve impulses. As shown in **Figure 25.5**, a **cardiac ganglion** consisting of nine neurons is attached to the inside of the dorsal wall of the heart. The axonal processes of the five most anterior neurons (numbered 1–5) innervate the heart muscle. Those of the four posterior neurons (numbered 6–9) are confined to the ganglion and make synaptic contact with the five anterior neurons. One of the posterior neurons ordinarily assumes the role of pacemaker. This neuron functions as a cellular oscillator and central pattern generator (see Chapter 19): Periodically and spontaneously, it produces a train of impulses, which excite the other posterior neurons. The impulses from the posterior neurons activate the five anterior neurons, which in turn send trains of impulses to the muscle cells of the heart, causing the latter to contract approximately in unison. If the ganglion and heart muscle are dissected apart, the ganglion continues to produce bursts of impulses periodically, but the muscle ordinarily stops contracting! Other animals known or believed to have neurogenic hearts include other decapod crustaceans (e.g., crabs, shrimps, and crayfish), horseshoe crabs (*Limulus*), and spiders and scorpions.

A heart produces an electrical signature, the electrocardiogram

When a mass of heart muscle is *in the process* of being depolarized, such that some regions of cells are depolarized already and others await depolarization, a difference in electrical potential exists between the extracellular fluids in the depolarized regions of the muscle and those in the undepolarized regions (**Figure 25.6a**). A voltage difference of this sort within the heart muscle sets up ionic currents, not only in the muscle but also in the tissues and body fluids surrounding the heart. In this way, the voltage difference within the heart induces voltage differences elsewhere in the body, even between various parts of the external body surface. **Electrocardiograms (ECGs, EKGs)** are measurements over

time of voltage differences of this sort. They are recorded using extracellular electrodes, usually placed on the body surface. To record the elementary ECG⁸ of a person, a physician or nurse places electrodes on the skin of the person's two arms and left leg. The electrodes detect voltage differences on the skin surface that are induced by voltage differences within the heart muscle.

The ECGs of two species, human and octopus, are shown in **Figure 25.6b**. The waveforms in the human ECG are named with letters (**Figure 25.6c**). The **P wave** is produced by the depolarization of the myocardium of the two atria (= atrial contraction). The Q, R, and S waves, together known as the **QRS complex**, arise from the depolarization of the myocardium of the two ventricles (= ventricular contraction). Repolarization of the ventricles generates the **T wave**.⁹ **Figure 25.2** shows the relation of the ECG waveforms to mechanical events during the heart pumping cycle.

Heart action is modulated by hormonal, nervous, and intrinsic controls

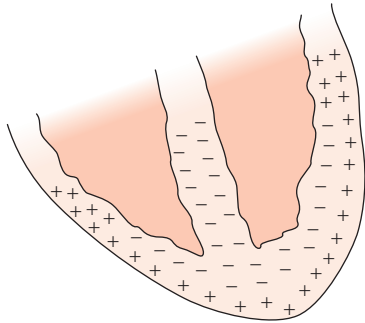

Heart action is subject to hormonal, nervous, and intrinsic controls. The controls we are typically most aware of are hormonal. When we are frightened and our heart pounds and races, the hormones epinephrine and norepinephrine, secreted by the adrenal medullary glands, are in part responsible for the heart stimulation we experience.

Nearly all hearts—whether myogenic or neurogenic—are innervated by neurons coming from the central nervous system, termed *regulatory neurons*. Some of these neurons stimulate increased heart action, whereas others are inhibitory. In the mammalian heart, both the sinoatrial node—the pacemaker—and the muscle cells of the myocardium are profusely innervated by the sympathetic and parasympathetic divisions of the autonomic nervous system. Sympathetic impulses delivered to the S-A node increase the frequency of spontaneous depolarization by the pacemaker cells (by affecting ion channel proteins) and thus raise the heart rate, whereas parasympathetic impulses exert opposite effects. Sympathetic impulses delivered to the cells of the myocardium markedly enhance the force and speed of their contraction, whereas parasympathetic impulses reduce the force and speed of contraction. When people exercise, sympathetic stimulation of the heart is increased. Most vertebrates are similar to mammals in that their hearts receive both sympathetic excitatory innervation and parasympathetic inhibitory

⁸More-advanced electrocardiograms used for detailed diagnostic purposes require the attachment of electrodes at numerous additional positions on the chest.

⁹The waveform produced by repolarization of the atria is typically not seen because it is obscured by the QRS complex.

innervation.¹⁰ In lobsters, the cardiac ganglion is innervated by both excitatory and inhibitory regulatory neurons; these neurons modulate both the frequency and intensity of the bursts of impulses generated by the ganglion and thus affect the heart rate and the force of heart contraction.

Intrinsic controls of heart action are controls that occur without the mediation of hormones or extrinsic neurons. The **Frank–Starling mechanism** refers to a vitally important intrinsic control of the

FIGURE 25.6 Electrocardiography (a) Relative electrical charges in the extracellular fluids of the human ventricular myocardium at an instant during passage of a wave of depolarization. The part of the ventricular myocardium lying nearest the ventricular chambers depolarizes first because it is the part supplied immediately by the branches of the conducting system (see Figure 25.4). (b) Electrocardiograms of a human and an octopus (*Eledone cirrhosa*) during three heartbeats. The human ECG was obtained using electrodes placed on the skin surface of the right arm and left leg. Electrodes attached to the surface of the ventricle (main body) of the systemic heart were used to record the octopus ECG. (c) A human ECG during one heartbeat with waveforms identified. (Octopus ECG after Smith 1981.)

vertebrate heart; namely, that stretching of the cardiac muscle tends to increase the force of its contraction by an effect at the cellular level. This mechanism plays an important role in enabling the heart to match its output of blood to its input. Consider, for example, what happens when the rate of blood flow into a heart chamber is increased. Because the heart chamber then tends to take in more blood in the time between beats, it becomes more stretched (distended) between beats. Because of the Frank–Starling mechanism, the heart muscle then intrinsically contracts more forcefully, which enhances ejection of blood—a response that tends to match heart output to the increased blood received. The Frank–Starling mechanism is important in all vertebrate hearts studied. It is particularly dramatic in its effects in fish hearts. Lobster hearts function similarly to vertebrate hearts in that they intrinsically increase both the rate and force of their contraction as they are stretched. The mechanism of this response in lobsters is, at least in part, quite different from that in vertebrates, however, because the cardiac ganglion is involved. Stretch induces the ganglion to fire more frequently and intensely.

SUMMARY Hearts

- The output of a heart, known as the cardiac output, depends on the heart rate and stroke volume.
- The cells in the heart muscle, the myocardium, must have means of receiving O_2 . In some hearts the myocardium is spongy, and blood flowing through the heart chambers flows through the spongy spaces, supplying O_2 to the cells. In other hearts, including those of mammals, the myocardium is compact and is supplied with blood and O_2 by means of coronary blood vessels.
- A heart is myogenic if the depolarization impulses required for heartbeats originate in muscle cells or modified muscle cells. A heart is neurogenic if the impulses originate in neurons. Vertebrate hearts are myogenic. Hearts of adult decapod crustaceans are neurogenic.
- In the mammalian heart, the sinoatrial node in the wall of the right atrium acts as pacemaker, initiating waves of depolarization. Conduction of a wave of depolarization from the atria to the ventricles occurs through the conducting system, which ensures both that the ventricles contract later than the atria and that the entire ventricular myocardium contracts approximately at once.
- When a part of the myocardium is in the process of contracting, voltage differences in the extracellular fluids develop between regions of muscle cells that have already undergone depolarization and regions that have not. These differences can be detected on the body surface. The electrocardiogram is a recording of such differences as a function of time.
- The rate and force of heart contraction are governed by nervous, endocrine, and intrinsic controls.

¹⁰ Some teleost (bony) fish are exceptions in that they have only parasympathetic inhibitory innervation. In hagfishes (primitive jawless fishes), the heart seems to lack any innervation.

Principles of Pressure, Resistance, and Flow in Vascular Systems

Having discussed the fundamental features of the hearts of animals, we now need to turn our attention to the perfusion of the vascular system. **Perfusion** refers to the forced flow of blood through blood vessels.

The **blood pressure** produced by the heart—or, in some animals, by other muscular activity—is the principal factor that causes blood to flow through the vascular system. What we mean by *blood pressure* is the amount by which the pressure of the blood exceeds the ambient pressure. Blood pressure is often expressed in *kilopascals (kPa)* by physiologists, but usually in *millimeters of mercury (mm Hg)* in medicine and related disciplines.¹¹ When we say that the blood pressure in a vessel in an animal is 10 kPa (= 75 mm Hg), this means that the pressure there is 10 kPa, or 75 mm Hg, higher than the pressure simultaneously present in the animal's surrounding environment.

In arteries, the blood pressure rises and falls over the heart cycle. The highest pressure attained at the time of cardiac contraction is termed the **systolic pressure**, whereas the lowest pressure reached during cardiac relaxation is the **diastolic pressure**. In young adult humans at rest, the systolic pressure in the systemic aorta is usually about 16 kPa or 120 mm Hg, and the aortic diastolic pressure is about 10 kPa or 75 mm Hg. When these pressures are measured for clinical reasons, the results are often expressed as a pseudo-ratio—for example, 120/75 (“120 over 75”). The **mean pressure** in an artery is obtained by averaging the pressure over the entire cardiac cycle; it usually does not equal the average of the two extreme pressures, systolic and diastolic, because the systolic and diastolic phases are not the same in duration. In resting young adults, the mean pressure in the systemic aorta is ordinarily about 12.7 kPa or 95 mm Hg.

In addition to the pressures produced dynamically by the beating of the heart, pressures resulting from *fluid-column effects* can also be important in circulatory systems. Any unobstructed vertical column of fluid exerts a pressure—termed a *hydrostatic* pressure—that increases as its height increases (Figure 25.7a). Because blood in the vessels of an animal forms fluid columns, fluid-column pressures are present in circulatory systems. The pressure produced by the beating of the heart is added (in an algebraic sense discussed in the next paragraph) to the fluid-column pressures that are present in arteries to determine the total arterial blood pressure. These relations are relevant for the clinical measurement of blood pressure. The pressure of interest during clinical measurement is that produced by the heart, unconfounded by fluid-column effects. The measurement device should therefore be in the same horizontal plane as the heart.

In a vertical column of blood, each 13 cm of height exerts about 10 mm Hg of pressure. At levels of the body below the heart, this hydrostatic fluid-column pressure adds to the pressure contributed by the heart; thus, in a person standing up, the blood pressure in arteries in the legs is far above that in the systemic aorta (Figure 25.7b). At levels of the body above the heart, some of the pressure developed by the heart is lost in simply supporting the fluid column of blood. Thus the blood pressure in the arteries of the neck and

head decreases by approximately 10 mm Hg for every 13 cm of height above the heart.¹²

Considering all the factors that could influence blood flow, how can we predict the *direction* of flow? Throughout most of this chapter, we will make simplifying assumptions so that we will be able to analyze blood flow based just on the pressures produced by the beating of the heart. However, it is important to be aware of a more general concept—the **total fluid energy** of the blood—that allows one to analyze blood flow in any situation, without simplifying assumptions.

Blood can possess three forms of energy that affect its flow, and the *total fluid energy* of the blood is the sum of these three forms, as shown in Figure 25.8. The first form of energy (labeled ① in Figure 25.8) is the pressure the blood is under because of the beating of the heart; this is a form of potential energy, which

¹¹Appendix A and footnote 9 on page 578 of Chapter 22 discuss the relations among these units.

¹²These same relations do not hold in any sort of simple fashion in veins because the veins, instead of being unobstructed, are obstructed by venous valves.

FIGURE 25.8 Total fluid energy: The true driving force for blood flow Kinetic energy is energy of motion. Potential energy is not motion but can produce motion.

means that it can produce motion, but is not motion itself. The second form of energy (❷) is the blood's energy of motion—its kinetic energy. The third form (❸) is the potential energy the blood possesses because of its position in Earth's gravitational field. *Blood always flows from where its total fluid energy is higher to where its total fluid energy is lower.*

Why be concerned with this complex concept? Actually, we have already encountered two situations in which the total fluid energy must be taken into account to explain the flow of blood. First, we saw in Figure 25.2 that toward the end of ventricular systole in the human heart, blood briefly continues to flow out of the left ventricle into the systemic aorta, even though the blood pressure in the ventricle (factor ❶ in the total fluid energy) has fallen below the pressure in the systemic aorta. If flow were governed only by simple pressure differences, blood would not flow out of the ventricle when the pressure in the ventricle is lower than that in the aorta. Blood in fact flows out of the ventricle at the end of ventricular systole, however, because at that time, the blood on the ventricular side of the aortic valve has a greater forward momentum—a greater kinetic energy (factor ❷)—than that on the aortic side. Thus the *total fluid energy*—the true driving force for blood flow—is higher in the ventricle than in the aorta.

The second case we have encountered that cannot be understood without taking account of total fluid energy is the flow of blood in arteries into our legs when we are standing up. Looking at Figure 25.7, you can see that at any given time, if one uses a simple pressure-measurement device to measure the existing pressure in the systemic aorta of a person standing up and the simultaneous pressure in the arteries in the lower legs, the pressure in the lower legs is perhaps 70–80 mm Hg *higher*.¹³ Thus, if pressure alone governed blood flow, blood would flow from the legs into the aorta, not the other way around. Here again, to understand the flow that actually occurs, one must analyze the total fluid energy. A simple pressure-measurement device confounds and confuses two distinct factors in the total fluid energy: the pressure produced by the beating of the heart (factor ❶) and the blood's potential energy of position in Earth's gravitational field (factor ❸). These factors become confounded by a simple pressure-measurement device because in parts of the body below the heart, high potential energy of position in the blood near the heart is recorded as high pressure in the blood below the heart. To analyze blood flow accurately, one must go back to the equation for total fluid energy and analyze its three components in an unconfounded way. The pressure produced by the heart (factor ❶) is slightly higher in the aorta than in the major leg arteries, and furthermore, the blood in the aorta has a greater potential energy of position (factor ❸) than that in the leg

arteries because it is at a greater elevation (put loosely, the blood in the aorta tends to “fall” into the legs). Considering all three factors, the *total fluid energy* is higher in the aorta, and therefore blood flows into the legs.

For many purposes, the analysis of blood flow can be usefully simplified by making two assumptions that in fact are often reasonably realistic: (1) Assume that the kinetic energy of the blood (factor ❷) does not vary from place to place within the system being analyzed. This assumption is often quite realistic. For example, in human arteries, kinetic energy accounts for a very small fraction of the total fluid energy (only 1–3% in the systemic aorta), and therefore little accuracy is lost by disregarding it. (2) Assume that the animal under study is in a horizontal posture. For a person or other animal lying on a horizontal surface, all blood is roughly in one horizontal plane, and one can therefore reasonably assume that potential energy of position (factor ❸) is equal everywhere. The horizontal posture is in fact the one usually used for experiments or analysis, and one can demonstrate that its use usually does not detract from the generality of conclusions reached.

With these simplifying assumptions made, blood flow can be analyzed using the pressure developed by the heart as the sole driving force.¹⁴ This is the approach we will use except in special cases.

The rate of blood flow depends on differences in blood pressure and on vascular resistance

Already in the nineteenth century, physiologists were seeking to understand the perfusion of blood vessels by analyzing the steady, nonturbulent flow of a simple liquid such as water through a horizontal, rigid-walled tube (Figure 25.9a). Their analyses led to insights that are still considered important today. The factors that determine the rate of flow (mL/minute) from one end of a tube to the other, they discovered, are the pressure at the entry to the tube (P_{in}), the pressure at the exit (P_{out}), the radius of the lumen of the tube (r), the tube length (l), and the viscosity of the liquid (η).¹⁵ The formula relating these quantities is named the **Poiseuille equation** or **Hagen–Poiseuille equation**, after Jean Poiseuille (1797–1869) and Gotthilf Hagen (1797–1884), who derived it:

$$\text{Flow rate} = (P_{in} - P_{out}) \left(\frac{\pi}{8} \right) \left(\frac{1}{\eta} \right) \left(\frac{r^4}{l} \right) \quad (25.2)$$

According to the Poiseuille equation, increasing the difference in pressure between the ends of a tube increases the rate of flow through the tube. Raising the viscosity of the fluid diminishes the rate of flow. The final term in the equation is an important geometric term: It shows that the rate of flow through a tube is a direct function of *the fourth power* of the radius of the lumen. Because of this relation, the rate of flow is extraordinarily sensitive to changes in the luminal radius. If water is flowing through a tube at a certain rate and the radius of the lumen is reduced to half of the starting radius, the rate of flow falls to $1/16$ of the original rate!

The Poiseuille equation, as mentioned, was derived to apply to simple liquids such as water flowing through unbranched,

¹⁴Under these simplifying assumptions, the total fluid energy is equal to the pressure developed by the heart—factor ❶ in Figure 25.8—because factors ❷ and ❸ do not apply. Thus blood flows from where the pressure developed by the heart is high to where it is low.

¹⁵We will describe viscosity shortly. For the moment, it refers to how syruplike a liquid is.

¹³The true value depends on how tall the person is.

rigid-walled tubes. Blood is not a simple liquid because it contains suspended cells, and blood vessels are not unbranched or rigid-walled. Nonetheless, the Poiseuille equation often proves to be a useful approximate model for understanding the flow of blood through blood vessels. From the Poiseuille equation, we see that *when muscles in the walls of a blood vessel change the radius of the vessel by contracting or relaxing, they exert profound (fourth power) control over the rate of flow through the vessel.*

Another equation that is useful for understanding the rate of steady blood flow through a horizontal system of blood vessels is

$$\text{Flow rate} = \frac{\Delta P}{R} \quad (25.3)$$

where ΔP is the difference in blood pressure between the entry vessels of the vascular system and the exit vessels, and R is the resistance to flow through the system, termed the **vascular resistance**. This equation (analogous to Ohm's law in electrical circuits) simply says that the rate of flow increases when the difference in pressure increases, but the rate of flow decreases when the vascular resistance increases. If we consider a simple tubular vessel, an easy relation exists between Equation 25.3 and the Poiseuille equation. Because ΔP and $(P_{\text{in}} - P_{\text{out}})$ represent the same quantity in this case, the resistance R is equal to $8\eta l/\pi r^4$. One can see that *resistance is inversely proportional to the fourth power of the vessel radius*. Halving the radius of a vessel increases the resistance to flow through the vessel by a factor of 16.

The dissipation of energy: Pressure and flow turn to heat during circulation of the blood

When blood flows through a horizontal blood vessel or system of vessels in an animal, the heart maintains a high pressure at the entry end. This pressure drives the blood through the vessel or system of vessels. However, as the blood passes through, the pressure becomes diminished. Why?

To answer this question accurately, we need to look briefly in more detail at the nature of flow through a tube or blood vessel. The **linear velocity** of a bit of liquid in a stream flowing through a tube is defined to be the length of the tube traveled per unit of time. According to ideal flow theory, when the flow of a liquid through a tube is steady and nonturbulent, the liquid moves in a series of infinitesimally thin, concentric layers (laminae) that differ in their linear velocities. This type of flow, called **laminar flow**, is illustrated in **Figure 25.9b**. The outermost of the concentric layers of liquid—the layer immediately next to the wall of the tube—does not move at all. Layers closer and closer to the center move faster and faster.

A crucial aspect of this sort of flow is that the adjacent layers of the liquid that are moving at different linear velocities do not slip effortlessly past each other. Instead, there is a sort of friction that must be overcome to make them move relative to each other. The total magnitude of this *internal friction* in a moving liquid depends in part on the dimensions of the tube. In addition, however, it depends on a property intrinsic to the particular liquid, namely the **viscosity** (specifically, *dynamic viscosity*) of the liquid. Viscosity refers to a *lack of intrinsic slipperiness between liquid layers moving at different linear velocities*; liquids that are particularly low in internal slipperiness have high viscosities and exhibit syruplike properties. The internal friction within a moving liquid is very real and, like other friction, results in the degradation of kinetic energy (energy

(a) Pressures and dimensions that affect the rate of flow

(b) The velocity profile of laminar flow

FIGURE 25.9 The physics of flow through tubes (a) Critical factors for understanding the rate of flow using the Poiseuille equation. (b) Linear velocity as a function of distance from the tube wall. A microscopically thin layer of liquid touching the tube wall does not move at all. The velocity profile seen here applies when a simple liquid such as water flows in a laminar fashion through a tube; the velocity profile for blood differs from that for a simple liquid.

of motion) into heat. Thus, as a liquid flows through a tube, some of its kinetic energy is steadily degraded.¹⁶

Understanding that energy of motion is degraded to heat, we can now see the broad outlines of the energetics of blood flow through a horizontal system of blood vessels. The pressure provided at the entry end by the heart is a form of potential energy. Some of this potential energy is converted to kinetic energy: energy of motion of the blood. Then, along each millimeter of the tubular system through which the blood flows, some of the kinetic energy is lost as heat in overcoming internal friction. *Ultimately, therefore, pressure is converted to heat.* During horizontal flow, the drop in pressure from one point in a tubular system to another point downstream is in fact a good index of the heat produced in overcoming opposing viscous forces. *Thus the drop in blood pressure from place to place can be used as a measure of the energy cost of blood flow.*

To apply these concepts, let's consider blood flow through our arteries and blood capillaries. From one end of an artery to the other, the mean blood pressure caused by pumping of the heart changes by only a small amount; for example, the pressure in an artery in our wrist—0.7 m from our heart—is only about 0.5 kPa (3 mm Hg) lower than the pressure in our systemic aorta. This small drop in pressure tells us that the cost of driving blood through the arteries is low. Shortly we will see that in blood capillaries the blood pressure drops precipitously as blood flows through. This steep pressure drop signifies that capillaries, unlike the arteries, are very costly to perfuse.

¹⁶ See Chapter 7 for a discussion of energy and energy degradation. Sometimes, people say that pumping the blood through vessels involves overcoming friction between the blood and the vessel walls. This is not correct. In fact, there is no frictional force to be overcome between a laminarily flowing liquid and the walls of a tube because no relative motion occurs between the walls and the liquid layer next to them (that layer is still). The frictional resistance to the flow of a liquid is *entirely internal* to the liquid.

SUMMARY Principles of Pressure, Resistance, and Flow in Vascular Systems

- Blood pressure is measured relative to environmental pressure; it is the extent to which the pressure in the blood exceeds that in the environment.
- During steady flow of blood through horizontal vessels or systems of vessels, the rate of blood flow is directly proportional to the difference of pressure between the inlet and outlet. It is also inversely proportional to vascular resistance. According to the Poiseuille equation, vascular resistance varies inversely with the fourth power of vessel radius.
- Blood pressure declines during the flow of blood through vessels because the potential energy represented by the pressure is converted to kinetic energy, which then is converted to heat in overcoming viscous resistance to flow. During steady flow through a horizontal system, this drop in blood pressure is a measure of the energy cost of perfusion.

Circulation in Mammals and Birds

We will talk about the circulatory systems of mammals and birds together because both groups have four-chambered hearts, and they have essentially identical circulatory plans. Mammals and birds evolved these properties independently, however. As shown by the circulatory plan in **Figure 25.10a**, O_2 -depleted blood returning from the systemic tissues enters the right heart via the great veins and is pumped by the right ventricle to the lungs, where O_2 is taken up and CO_2 is released. The blood oxygenated in the lungs then travels to the left heart and is pumped by the left ventricle to the systemic aorta, which divides to supply all the systemic tissues. A key feature of this circulatory plan is that it places the lungs in series with the systemic tissues. This series arrangement, emphasized in **Figure 25.10b**, maximizes the efficiency of O_2 delivery to the systemic tissues: All the blood pumped to the systemic tissues by the

heart is freshly oxygenated, and the tissues receive blood that is at the full level of oxygenation achieved in the lungs. These features are important ways in which the circulatory system of mammals and birds is able to meet the high O_2 demands of these animals.

The circulatory system is closed

Circulatory systems are classified as **open** or **closed**, depending on whether the entire circulatory path is enclosed in discrete vessels. In an *open* system, the blood leaves discrete vessels and bathes at least some nonvascular tissues directly. In a *closed* system, there is always at least a thin vessel wall separating the blood from the other tissues. The distinction between open and closed systems is relative because there are many intergradations. Mammals and birds, as well as other vertebrates, have essentially closed circulatory systems.

Each part of the systemic vascular system has distinctive anatomical and functional features

The blood vessels at various points in the systemic vascular system differ anatomically and functionally in important ways. In this section, we discuss the major types of vessels in the order in which blood passes through them. A significant point to mention at the start is that in vertebrates, *all* types of vessels—and the chambers of the heart—are lined on the inside with a single-layered epithelium termed (for historical reasons) the **vascular endothelium**. The cells of the endothelium are exceedingly important: They perform many functions, which are only gradually being understood. For example, some endothelial cells secrete agents into the blood—such as nitric oxide or prostacyclin (prostaglandin I_2)—that affect the contraction and relaxation of vascular smooth muscle or help control clotting. Endothelial cells also sometimes synthesize active hormones from hormone precursors in the blood or terminate hormone action (e.g., by degrading hormones). Endothelial cells also participate in immune responses.

ARTERIES The great arteries have thick walls that are heavily invested with smooth muscle and with elastic and collagenous connective tissue. Thus they are equipped to convey blood under

considerable pressure from the heart to the peripheral parts of the circulatory system. The elasticity of the great arteries enables them to perform important hydrodynamic functions. If the heart were to discharge blood into rigid, inelastic tubes, the blood pressure would oscillate violently upward and downward with each contraction and relaxation of the heart. Instead, the arteries are elastic. They stretch when they receive blood discharged from the heart. Some of

(b) The same plan, redrawn as a schematic to emphasize the arrangement of the pulmonary and systemic circuits in series with each other. Red and blue portions carry relatively oxygenated and deoxygenated blood, respectively. Ra, right atrium of the heart; La, left atrium; Rv, right ventricle; Lv, left ventricle.

the energy of each heart contraction is thereby stored as elastic potential energy in the artery walls, and consequently the increase in arterial pressure during systole is limited to some extent. The energy stored elastically at the time of systole is released as the arteries rebound to their unstretched dimensions during diastole. In this way, some of the energy of heart contraction is used to maintain the pressure in the great arteries between contractions. The end result is that arterial elasticity has two effects: Variations in arterial pressure over the cardiac cycle are reduced—termed the *pressure-damping effect*—and a substantial pressure is maintained in the arteries even when the heart is at rest between beats—termed the *pressure-reservoir effect*.

The arteries become smaller as they branch outward toward the periphery of the circulatory system. The walls of the arteries simultaneously become thinner, a fact that at first appears paradoxical when we recall that the mean blood pressure diminishes hardly at all in the arteries. The paradox is resolved in good measure by a principle identified by the great mathematician Pierre Simon, the Marquis de Laplace (1749–1827), and now known as **Laplace's law**.¹⁷ This law deals with the relation between luminal pressure and wall tension in hollow structures. As applied to tubes, it says that when the pressure in the lumen of a tube exceeds that outside the tube by any given amount, the circumferential tension (stretch) developed within the walls of the tube is directly proportional to the tube radius:

$$T = r\Delta P \quad (25.4)$$

where T is wall tension, r is the luminal radius, and ΔP here represents the pressure difference across the walls. Because of this relation, even though a small artery may be exposed to the same blood pressure as a large one, the tension developed within its walls is lower than that developed within the walls of the large artery. Accordingly, the walls of small arteries need not be as well fortified as those of large arteries to resist overexpansion. The same principle explains why blood capillaries can be exceedingly thin-walled and yet resist substantial pressures.

MICROCIRCULATORY BEDS The systemic arteries ultimately deliver blood to networks of microscopically tiny blood vessels in all the systemic organs and tissues. These **microcirculatory beds**, diagrammed in **Figure 25.11**, consist of three types of vessels: *arterioles*, *capillaries*, and *venules*.

Arterioles, although minute, have the same basic structure as arteries: Their walls consist of smooth muscle and connective tissue. The mean diameter of the lumen of the arterioles of humans is about 30 μm . Notably, the walls, which average about 20 μm in thickness, are so invested with muscle and connective tissue that they are almost as thick as the lumen is wide. The smooth muscles in the walls of the arterioles are exceedingly important because they are responsible for the *vasomotor control of blood distribution*. The adjective **vasomotor** refers to changes in the luminal radius of blood vessels. A decrease in the luminal radius is called **vasoconstriction**, whereas an increase is called **vasodilation**. In our earlier discussion of the Poiseuille equation (see Equation 25.2), we noted that the rate of flow through a tubular vessel is extremely sensitive to the radius of the tubular lumen. By contracting and relaxing, the smooth muscles in the wall of an arteriole control the luminal radius of the

vessel and thereby profoundly affect the rate of blood flow into the capillary beds that the arteriole supplies. Control of the arteriolar muscles is mediated by the sympathetic division of the autonomic nervous system, by circulating hormones, and by chemical mediators at the local tissue level, such as nitric oxide (NO), a vasodilator that is released from the vascular endothelium. In addition to the arterioles, both precapillary sphincters (see Figure 25.11) and small terminal arteries also participate in controlling blood flow to capillary beds.

An especially familiar example of the control of tissue perfusion by arterioles is provided by the responses of skin blood flow to warm and cold environments. As we discussed in Chapter 10 (see page 258), humans and other mammals often maintain relatively vigorous blood flow to their skin surface in warm environments, but reduce blood flow to the surface in cold environments. When flow is reduced, the effect occurs because arterioles supplying blood to the superficial microcirculatory beds of the skin are vasoconstricted by the action of the sympathetic nervous system and local vasoconstrictive agents. Modulation of arteriolar–venular anastomoses

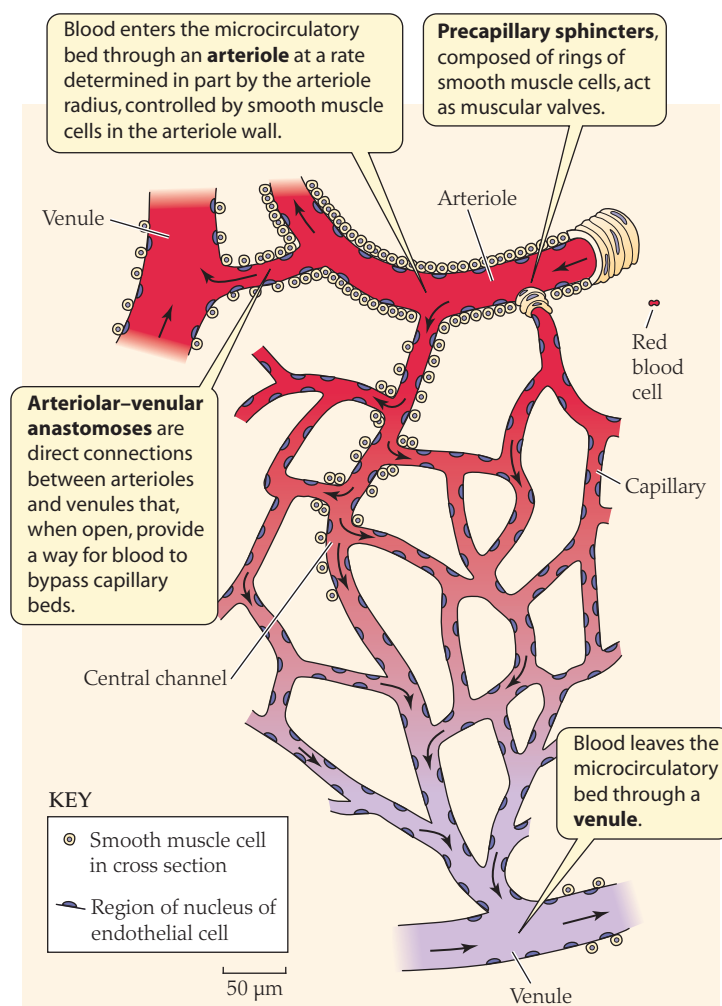

FIGURE 25.11 A microcirculatory bed In this microcirculatory bed of a mammal, capillaries form an anastomosing network between an arteriole at the top and a venule at the bottom. The endothelial cells that line the arterioles and form the walls of the capillaries are thin and flat, except where each cell is thickened in the region of its nucleus. Precapillary sphincters and arteriolar–venular anastomoses are opened and closed by smooth muscle cells. (After Copenhagen et al. 1978.)

¹⁷Laplace's law applies quantitatively only to simple elastic materials such as rubber. It is a useful principle for analyzing complex elastic structures like arterial walls, but the detailed study of arteries involves additional considerations.

(see Figure 25.11) also plays a role. Changes in the perfusion of skeletal muscles during exercise provide another important example of arteriolar control: Blood flow through a skeletal muscle can be increased by a factor of ten or more in a person during exercise. Part of the reason for the increased blood flow is arteriolar vasodilation, which appears to be mediated principally by local effects of metabolites produced in exercising muscles. A final familiar example of the control of tissue perfusion by arterioles and small arteries is the erection of the penis. During sexual arousal, parasympathetic neurons and cells in the local vascular endothelium of the penis release nitric oxide, which acts as a potent signal for dilation of the arterioles and small arteries that supply blood to the penis's spongy erectile tissues (see pages 476–477 for more detail).

Arteriolar control of microcirculatory beds is one of the premier attributes of closed circulatory systems. The heart produces pressure that is transmitted to all the microcirculatory beds in the body by way of the arteries. This driving force is always available at the entry to each microcirculatory bed, ensuring that vasodilation or vasoconstriction of arterioles will cause immediate changes in tissue perfusion. Each microcirculatory bed has its own arterioles—which determine the rate of flow into the bed—and thus is readily controlled independently of other microcirculatory beds. These features permit *highly sensitive temporal and spatial control of blood distribution*.

From the arterioles, the blood typically enters the **capillaries**. The walls of capillaries consist of *only the vascular endothelium*—a single layer of highly flattened cells resting on an outer basement membrane (see Figure 2.6c). The walls of capillaries are very thin ($<1\ \mu\text{m}$) and often fenestrated to some extent—meaning that physical openings through the walls are present, such as gaps between neighboring endothelial cells (see page 701). Moreover, in most capillaries studied (including pulmonary ones), aquaporins—water channel proteins—are abundant in the cell membranes of the endothelial cells. Because of these features, the capillaries are the *preeminent sites of exchange of O_2 , water, and other materials between the blood and the tissues*. The lumens of the capillaries are often barely wide enough to allow red blood cells to pass through in single file. A **capillary bed** (see Figure 25.11) consists of many capillaries that branch and anastomose among the cells of a tissue.

The aquaporins in the endothelial cell membranes of capillaries clearly facilitate osmosis between the blood inside and the tissue fluids outside the capillaries, although often the capillary endothelium seems to be adequately permeable to water without them, making their roles unclear. In the brain, aquaporins in astrocytes—the nonneural brain cells that, in intimate juxtaposition with capillaries, help form the blood–brain barrier—seem clearly to be involved in regulating cerebrospinal fluid volume.

The density of capillaries is a remarkable subject. Tissues differ in how many capillaries they have per unit of tissue volume; capillary density is particularly high in skeletal muscles, the myocardium, and the brain. In such tissues—rich in capillaries—the exchange surface provided by the capillary beds is nothing short of amazing. A cubic centimeter of skeletal or cardiac muscle may well contain 10–20 *meters* of capillaries! In cross sections of mammalian gastrocnemius (calf) muscles, one can see from 300 to more than 600 capillaries per *square millimeter*. Within the capillary beds of skeletal muscles, only some of the capillaries are open at rest, but all may open during exercise. It is also possible for new capillaries to

develop, or for old ones to disappear, during acclimation to changed environmental conditions, aging, or disease. Modern theories hold that a pathological loss of capillaries may be an invisible but major contributing factor to several chronic debilitating diseases. In a state of health, **angiogenesis**—the process of forming new capillaries and other microcirculatory elements—is an important process, controlled by *angiogenic activators* and *inhibitors* such as paracrine agents. New capillaries are often formed in response to wounding, athletic training, and exposure to low O_2 partial pressures (see Box 23.1). The capillary beds drain into **venules**, which are small vessels with thin walls (2–5 μm in humans) containing connective tissue and muscle cells.

VEINS The blood flows from the microcirculatory beds back to the heart through a series of veins of increasing diameter. As we will see, the blood pressure has declined precipitously by the time the blood leaves the microcirculatory beds. Thus the walls of the veins need not be capable of resisting high tensions and are thin compared with those of the arteries. To a far greater extent than the arterial system, the venous system contains passive one-way valves. These valves are sheets of tissue shaped so that they permit flow toward the heart, but pinch shut if flow reverses. The valves help ensure that blood will move consistently toward the heart in the veins even though the driving pressures are low and variable. The pressure developed by the heart is not entirely absent in the veins and aids the return of blood to the heart. However, the contraction of *skeletal muscles* is also important; when the muscles contract, they squeeze the blood in nearby veins, and because the valves in the veins permit only one-way flow, the squeezing moves blood toward the heart. Veins are sometimes important because of their *capacitive* properties: By distending, they can increase their capacity to hold blood and thus accommodate blood volume that cannot be housed elsewhere in the circulatory system.

Mammals and birds have a high-pressure systemic circuit

The blood pressures maintained in the great systemic arteries of mammals and birds are the highest blood pressures found in any animals (Table 25.1). The need for these high pressures arises from the particular flow requirements of mammals and birds and from their systemic vascular resistance: a classic application of Equation 25.3. Mammals and birds require high rates of blood flow because of their high O_2 -transport demands. The resistance to flow through their systemic circuits is high, however. To maintain high rates of flow in the face of this high resistance, mammals and birds require exceptionally high pressures in their systemic arteries. Why is the resistance to flow so high in the systemic circuit? The Poiseuille equation (see Equation 25.2) tells us that vessels of tiny radius tend to make particularly great contributions to vascular resistance. In the closed circulatory system of a vertebrate, every tissue is densely invested with microscopically minute vessels through which the blood must be forced to flow. Collectively, these minute vessels give the systemic circuit its high resistance.

As blood enters the terminal arteries (the final branches of the arterial vasculature) and then the microcirculatory beds, the total cross-sectional area of the vasculature increases markedly, and simultaneously, the average linear velocity of the blood decreases dramatically (Figure 25.12a). Although individual capillaries are

^bTo obtain blood pressures in units of kilopascals, divide the values given by 7.5.

minute in cross section, they are so incredibly numerous that their collective cross-sectional area greatly exceeds that of the systemic aorta. The blood slows where it has a greater cross-sectional area to pass through, in much the same way as a woodland stream slows where it widens. Capillaries are so short (<1 mm) that the blood must have a very low linear velocity when it passes through them for it to remain long enough to exchange with the tissues.

Even though the blood slows dramatically as it passes through the terminal arteries, arterioles, and capillaries, these are the vessels where the blood loses most of its pressure (Figure 25.12b). In humans at rest, the mean blood pressure falls from about 12 kPa to 8 kPa (90 mm Hg to 60 mm Hg) as blood flows through the terminal arteries. Then the mean pressure falls to about 4.4 kPa (33 mm Hg) as the blood flows through the arterioles, and to about 2 kPa (15 mm Hg) as it flows through the capillaries and initial venules. A pressure drop of only about 0.4 kPa (3 mm Hg) is sufficient to move blood at a high linear velocity from the systemic aorta to the wrist in the major arteries of the arm. However, a 15-fold greater pressure drop, about 6 kPa (45 mm Hg), is required to move blood at a low linear velocity over a distance of a few millimeters from the beginnings of arterioles to the initial venules in a microcirculatory bed! These quantitative measurements emphasize that a closed circulatory system is energetically costly.

(a) Vascular cross-sectional area and blood linear velocity

(b) Mean blood pressure

FIGURE 25.12 Blood flow in the human systemic vasculature

(a) Cross-sectional area and linear velocity of blood flow in the various parts of the systemic vasculature. Although the cross-sectional area of individual capillaries is minute, the capillaries are so numerous that their collective cross-sectional area greatly exceeds that of the systemic aorta. (b) Mean blood pressure in the various parts of the systemic vasculature. The jagged line does not represent the actual pulse (variation of blood pressure between systole and diastole), but symbolizes where the pulse occurs. (a from Feigl 1974.)

The venous part of the systemic circuit is a low-pressure, low-resistance system. The pressure developed by the left ventricle is essentially entirely degraded to heat by the time the blood reaches the entry of the great veins into the right atrium (see Figure 25.12b).

Fluid undergoes complex patterns of exchange across the walls of systemic capillaries

A capillary has fluid on both sides of its walls: blood plasma on the inside and extracellular tissue fluid (tissue interstitial fluid) on the outside (see Figure 27.2). The mean blood pressure in systemic capillaries typically exceeds the hydrostatic pressure in the surrounding extracellular tissue fluid. This difference in *hydrostatic* pressure favors pressure-driven oozing (bulk flow) of fluid out of the blood plasma across the capillary walls: a process termed **ultrafiltration** (see page 754). However, the blood plasma has a higher *osmotic* pressure than the extracellular tissue fluid. This difference in osmotic pressure favors the osmosis of water into the blood plasma across the capillary walls. The interplay of the processes favoring efflux of fluid from capillaries and those favoring influx has attracted considerable interest, in part because imbalances can give rise to serious disease states. Yet fluid exchanges in the capillaries are not yet thoroughly understood.

Studies by E. H. Starling (1866–1927) and E. M. Landis (1901–1987) in the early twentieth century produced a model of fluid exchange across capillary walls (Figure 25.13) that today is still believed to summarize the essentials in many tissues. The osmotic pressure of the blood plasma in most mammals exceeds that of the extracellular tissue fluid by about 3.3 kPa (25 mm Hg) along the entire length of the capillaries. This difference, called the **colloid osmotic pressure** of the blood plasma, arises because the plasma is richer than the tissue fluid in dissolved proteins (e.g., albumins)—large molecules that do not pass freely through capillary walls (see page 122). At the arterial ends of the capillaries, the hydrostatic pressure of the blood (the blood pressure) exceeds that of the tissue fluid by more than 4 kPa (30 mm Hg); because the hydrostatic-pressure difference favoring efflux of fluid from the capillaries is thus greater than the osmotic-pressure difference favoring influx, fluid is forced out of the capillaries in net fashion. However, as the blood flows through the capillaries, its hydrostatic pressure falls. At the venous ends of the capillaries, the hydrostatic pressure of the blood exceeds that of the tissue fluid by only about 2 kPa (15 mm Hg). Therefore, at the venous ends, the osmotic-pressure difference favoring influx of fluid into the capillaries exceeds the hydrostatic-pressure difference favoring efflux, and a net influx of fluid into the capillaries occurs.

The **Starling–Landis hypothesis**, stated briefly, is that the blood plasma loses volume in the initial segments of systemic blood capillaries but regains volume in the final segments. *The overall effect is often a net loss:* Fluid from the blood plasma tends to be transferred to the extracellular tissue fluid in a net fashion. The fluid added to the tissue fluid is picked up by the *lymphatic system*, which ultimately returns it to the blood. Tissues swell (a state termed *tissue edema*) if this fluid is not picked up.

The pulmonary circuit is a comparatively low-pressure system that helps keep the lungs “dry”

Discussion of the pulmonary circulation has been put off to this point because an understanding of the forces affecting fluid movement across capillary walls is essential for grasping a significant

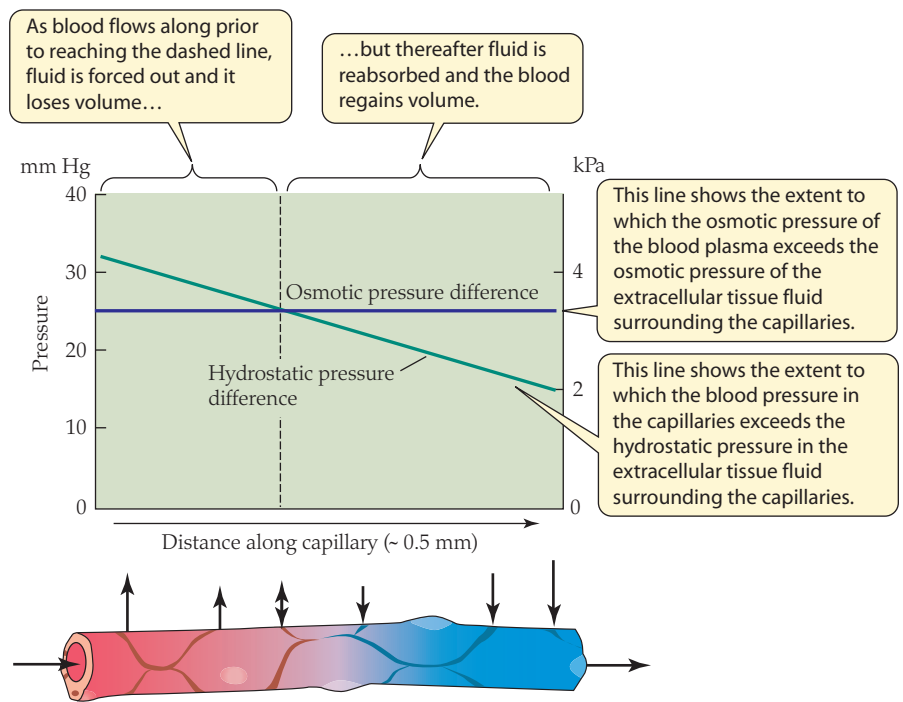

FIGURE 25.13 Fluid exchange across mammalian systemic capillary walls: The Starling–Landis hypothesis The walls of blood capillaries are *fenestrated* in most tissues, meaning that they are densely perforated by minute physical pores such as gaps between adjacent cells (see page 701). Ultrafiltration occurs readily through these fenestrations. Osmosis of water occurs readily because of the thinness of the endothelial cells, fenestrations, and presence of aquaporins in the cell membranes. The image of the capillary at the bottom shows the direction of net fluid exchange. On the graph, the osmotic-pressure difference can be represented as a horizontal line because the losses and gains of fluid volume are not great enough to change the relative osmotic pressures substantially. Values are approximate.

problem that could arise in perfusing the lungs. Rapid net loss of fluid from the blood plasma across the walls of the pulmonary capillaries could flood the terminal air spaces in the lungs—the alveoli of mammals or the air capillaries of birds—with liquid. This, in turn, would impair O_2 and CO_2 exchange.¹⁸ Indeed, when a persistent state of alveolar flooding—called *pulmonary edema*—occurs during disease states, it is a life-threatening emergency. Persistent flooding of the alveoli or air capillaries does not normally occur, however, because the pulmonary circulation is a comparatively low-resistance, low-pressure system.

The vascular resistance of the pulmonary circuit is far lower than that of the systemic circuit because the pulmonary circulatory path is much shorter than the systemic path, lacks arterioles, and exhibits other distinctive properties. The volume of blood passing through the pulmonary circuit per unit of time is the same as the volume passing through the systemic circuit because the two are connected in series (see Figure 25.10). However, because the pulmonary vascular resistance is low, the arterial pressure required to drive this flow in the pulmonary circuit is far lower than that in the systemic circuit (see Equation 25.3). In humans at rest, the mean pressure maintained in the pulmonary arteries by the right

¹⁸The rate of diffusion of O_2 and CO_2 is dramatically lower through water than through air, as emphasized in Chapter 22 (see page 574).

ventricle is about 1.9 kPa (14 mm Hg), in contrast to the much higher mean pressure, about 12.7 kPa (95 mm Hg), maintained in the systemic aorta by the left ventricle. The mean blood pressure in the pulmonary capillaries is about 1 kPa (8 mm Hg), in contrast to about 3.3 kPa (25 mm Hg) in the systemic capillaries. The low pressure in the pulmonary capillaries largely precludes any net loss of liquid from the plasma across the capillary walls by ultrafiltration. Thus the air spaces of the lungs remain air-filled, not liquid-filled.¹⁹

During exercise, blood flow is increased by orchestrated changes in cardiac output and vascular resistance

The circulatory system of mammals and birds operates at a relatively leisurely pace when individuals are at rest. Exercise heightens demands on the circulatory system and thus brings out its full capabilities. A useful equation for understanding O₂ delivery in the systemic circuit is

$$\text{Rate of O}_2 \text{ delivery} = \text{cardiac output} \times (\text{arterial O}_2 \text{ concentration} - \text{venous O}_2 \text{ concentration}) \quad (25.5)$$

During exercise, if we assume that arterial blood is always fully oxygenated, the rate of O₂ delivery can be increased by increasing the rate of blood flow (i.e., increasing cardiac output) or by extracting more O₂ from each unit volume of blood that circulates (i.e., decreasing venous O₂ concentration). *Both* of these strategies of increasing O₂ delivery are in fact simultaneously employed in mammals and birds. During vigorous exercise in humans, for example, venous blood becomes much more deoxygenated than at rest, as seen in Figure 24.5. Simultaneously, in average young adults the cardiac output can increase by at least a factor of four over the resting level through increases in both heart rate and stroke volume. Athletes who are successful in endurance events tend to have relatively high maximal cardiac outputs; some can sustain cardiac outputs that are six to seven times their resting values.

A substantial decline in the total resistance of the systemic vasculature occurs during exercise. Were it not for this drop in systemic vascular resistance, the aortic blood pressure would have to increase dramatically to drive blood through the vasculature at rates that are several times faster than at rest (see Equation 25.3). In fact, during whole-body exercise, the mean blood pressure in the human systemic aorta increases by only about 2.7 kPa (20 mm Hg), even when cardiac output far exceeds its resting level.

Vasodilation in the vascular beds of the active muscles (including the breathing muscles) is responsible for much of the decrease in systemic vascular resistance that occurs. One of the consequences of vasodilation in the terminal arteries and arterioles is that there is a great increase in the percentage of muscle capillaries that are open and carrying blood (as briefly noted before). This increase helps reduce the resistance to through-flow of blood. It also reduces the average diffusion distance between capillaries and muscle cells, and it permits the capillary beds to carry a greatly increased flow of blood without major changes in the linear velocity (or residence time) of blood in individual capillaries. Endurance training tends to

produce a chronic increase in the number of capillaries per muscle cell, an effect that clearly helps meet high muscle O₂ demand.

The response of the systemic vascular system during exercise is in fact highly coordinated and adaptive, in that it preferentially distributes the increased cardiac output to the tissues that require increased perfusion. Although the skeletal muscles in humans receive about 20% of the cardiac output at rest, they receive 70–80% or more of the much-increased cardiac output during vigorous whole-body exertion. Simultaneously, blood flow to the intestines, kidneys, liver, and inactive muscles may be substantially reduced by vasoconstriction. The brain receives about the same flow of blood regardless of exercise state.²⁰

Species have evolved differences in their circulatory physiology

When mammal species of various body sizes are compared, there is a very apparent allometric relation between resting cardiac output and body size: Cardiac output per unit of body weight tends to increase as body size decreases. Thus small mammals meet their relatively high weight-specific demands for O₂ transport in part by maintaining relatively high weight-specific rates of blood flow. In relation to body size, small mammal species typically do not have hearts larger than those of large species. Instead, as we discussed in Chapter 7 (see Table 7.4), the principal way in which small species maintain their relatively high weight-specific cardiac outputs is by having relatively high heart rates (e.g., 600 beats/min in mice!). Birds tend to have larger hearts, lower heart rates, and higher aortic blood pressures (see Table 25.1) than mammals of equivalent body size.

Many species face unique cardiovascular challenges. Among them, giraffes present one of the most thought-provoking cases. Full-grown giraffes can be more than 5 m tall. Because of their long necks, their brains can be 1.6 m above their hearts, a distance that is more than four times greater than in humans. Moreover, because of their tall columns of blood, standing giraffes have exceptionally high blood pressures in their legs and feet. A few aspects of giraffe circulatory physiology are agreed upon by all authorities who have studied them. One is that giraffes have an exceptionally well developed left ventricle and maintain unusually high systemic aortic blood pressures. Their mean aortic pressure when they are standing and at rest is about 29 kPa (220 mm Hg), in contrast to about 13 kPa (100 mm Hg) in most other mammals.

The question of how blood is circulated to the brain in a standing giraffe is a topic of contentious debate. Some physiologists argue that the arteries and veins of the head and neck function analogously to a siphon system, in which the height of the brain would pose no special challenges. The majority of physiologists who have studied the question, however, have concluded that the siphon analogy is flawed. These physiologists conclude that giraffes require their exceptionally high aortic blood pressures to be able to lift blood high enough against gravity to reach their brains and still have enough residual pressure at head height to perfuse their brains. According to this line of argument, if giraffes had mean aortic pressures like those in humans, blood would not even reach their brains! The mean human aortic pressure (12.7 kPa or 95 mm Hg) can lift blood to a height of only 1.2 m (see Figure 25.7b).

¹⁹ Current theories of gas exchange postulate that exceedingly thin and highly transient layers of liquid may accumulate under some normal physiological conditions (e.g., vigorous exercise) and affect the details of the gas-exchange process.

²⁰ Responses of the circulation to high altitude are discussed in Box 24.5.

SUMMARY Circulation in Mammals and Birds

- Mammals and birds, like virtually all other vertebrates, have closed circulatory systems, meaning that the blood always remains within blood vessels lined with vascular endothelium.
- The pulmonary and systemic circuits are connected in series. The left ventricle develops high pressures to force blood through the high-resistance systemic circuit. The right ventricle develops lower pressures to force blood through the low-resistance pulmonary circuit.
- In the systemic circuit, arteries convey blood over relatively long distances with little loss of blood pressure; arteries also perform pressure-damping and pressure-reservoir functions because of their elasticity. Arterioles in the systemic microcirculatory beds exert fine spatial and temporal control over blood flow by contraction and relaxation of the smooth muscles in their walls (vasomotor controls). The capillaries are the principal sites of exchange between the blood and systemic tissues because their walls consist of just a single layer of fenestrated endothelial cells rich in aquaporins and because they are densely distributed.
- As blood flows through systemic capillaries, blood pressure tends to force fluid to pass outward through the capillary walls by ultrafiltration. The colloid osmotic pressure of the blood plasma tends to cause fluid movement into the blood. The net effect of this interplay is a loss of fluid, which is picked up by the lymphatic system. The lower blood pressures in the pulmonary circuit help to prevent pulmonary flooding (edema).
- During exercise, cardiac output is augmented by increases in both heart rate and stroke volume. Arterial blood pressure does not rise excessively because vascular resistance is decreased, mainly by vasodilation in active muscles.

Circulation in Fish

Fish in general resemble the vast majority of other vertebrates in having closed circulatory systems. The circulatory plan of most fish is illustrated in [Figure 25.14a](#). Blood is pumped anteriorly by the heart into the **ventral aorta**, which distributes it to the afferent gill vessels.²¹ The blood then passes through the blood channels of the gills and is brought by the efferent gill vessels to the **dorsal aorta**, a large dorsal artery that distributes the blood to the systemic tissues. After perfusing the systemic capillaries, the blood returns in the veins to the heart. As in mammals and birds, the circulatory plan places the breathing organs in series with the systemic tissues, thus ensuring efficient O₂ transport.

There are two ways in which the circulatory plan of fish poses potential problems that do not exist in the mammalian and avian plan. First, in fish, there is no heart between the breathing-organ circulation and the systemic circulation to impart fresh energy to oxygenated blood as it leaves for the systemic tissues. When the heart pumps blood into the ventral aorta, the pressure it provides must be sufficient to drive the blood through the resistances of *both* the gill vasculature *and* the systemic vasculature. Second, oxygenation of the myocardium depends fully or partly on O₂ gained from the blood flowing through the lumen of the heart in fish (see Figure

25.3b,c), and this blood is *relatively deoxygenated* because it has just passed through the systemic circuit.

The fish heart ([Figure 25.14b](#)) consists of four chambers arranged in series: a **sinus venosus** into which the great veins empty, an **atrium**, a **ventricle**, and a bulbous segment that empties into the ventral aorta. The main propulsive force is developed by the ventricle. In elasmobranch fish (sharks, skates, and rays) and lungfish (dipnoans), the bulbous segment—known as the **conus arteriosus**—includes cardiac muscle and contracts in sequence with the ventricle, helping to pump the blood. In teleost fish,²² the bulbous segment—called the **bulbus arteriosus**—consists of vascular smooth muscle and elastic tissue and does not contract in sequence with the other heart chambers; it seems to act primarily as an elastic chamber that smoothes pressure oscillations and serves as a pressure reservoir between heart contractions (see pages 654–655).

Fish generally have smaller hearts and far lower cardiac outputs than mammals of similar body size (see Table 25.1). Their lower cardiac outputs correlate with their lower O₂ demands: Fish have far lower metabolic rates than mammals (see Chapter 10) and thus can satisfy their O₂ needs with lower rates of blood flow. Fish differ from mammals in that the heart empties almost completely by the end of each systole. Fish also maintain lower arterial pressures: The mean pressure in the ventral aorta is typically between 3 kPa (20 mm Hg) and 12 kPa (90 mm Hg)—usually toward the lower end of this range. The blood pressure drops significantly as the blood passes through the gills. Because of this drop, the mean pressure in the dorsal aorta—the pressure available to perfuse the systemic circuit—is generally only 60–80% as high as the pressure produced by the heart.

In many fish the ventricular myocardium is entirely spongy—consisting of a mesh of relatively narrow, long sheets of myocardial cells. The sheets are called *trabeculae* and, attached at both ends to the ventricular walls, crisscross parts of the ventricular lumen, being bathed on either side by the luminal blood (usually systemic venous blood) that is passing through (and being pumped by) the ventricle. Some fish have, in addition, a layer of compact myocardium that surrounds the spongy myocardium (see Figure 25.3b,c). The compact myocardium is vascularized by coronary blood vessels that deliver *fully oxygenated blood*. Among all fish that have been studied, the percentage of the myocardium that is compact varies from 0% (i.e., entirely spongy myocardium) to about 60%.

Different species of fish exhibit a wide and interesting range in the size and performance of the heart, correlated with how physically active the animals are. Species that are relatively inactive and sluggish tend to have relatively small hearts, little development of compact myocardium, and low cardiac outputs for their body sizes, whereas athletic species (e.g., salmon and tunas) tend to have large hearts, great development of compact myocardium, and high cardiac outputs. Tunas, the supremely active fish we featured at the start of Chapter 23, stand out among all fish in the performance of their circulatory systems. Yellowfin and skipjack tunas have weight-specific cardiac outputs at rest that are twice as high as the highest known in other fish; their ventral aortic blood pressures are also twice as high, accounting for the ability of the blood to flow through the vascular system at a high rate. The tunas are also among the fish with the highest amounts of hemoglobin per unit of blood volume. Thus tunas not only employ the most sophisticated

²¹Afferent means “going toward,” and efferent means “going away.”

²²Teleost fish are the principal group of fish with bony skeletons.

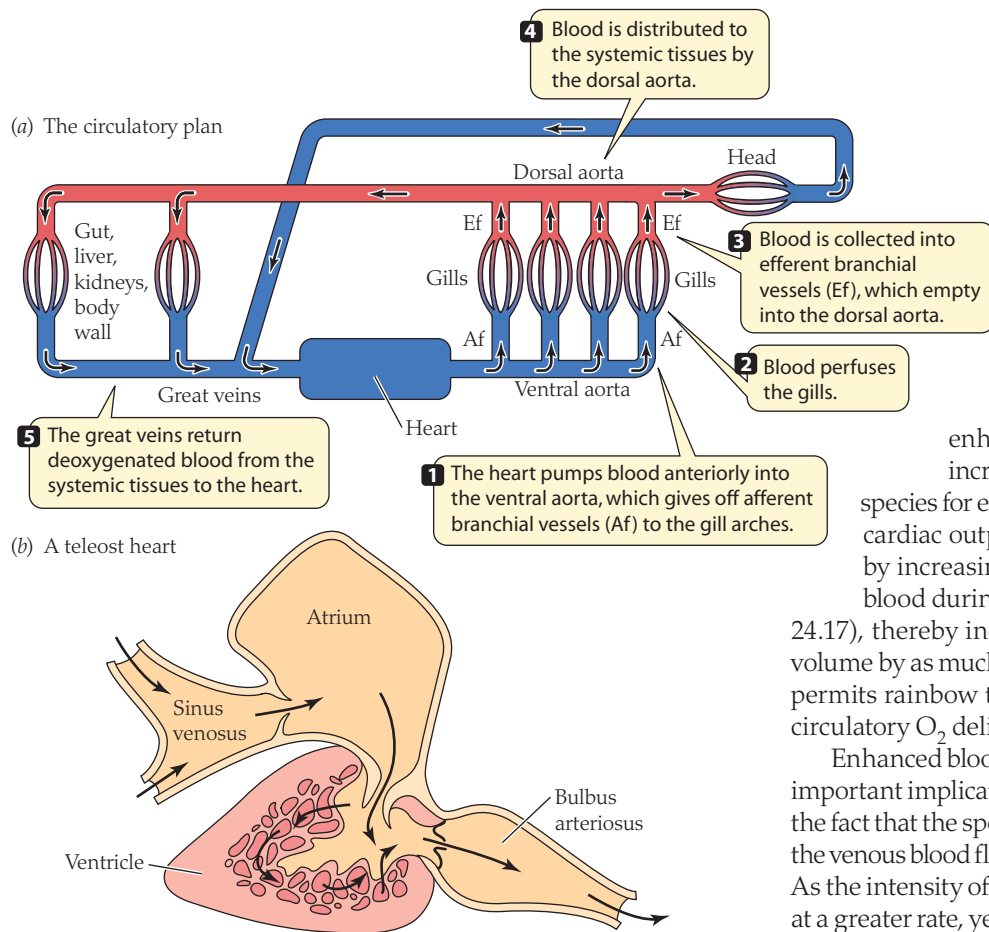

FIGURE 25.14 The circulatory plan in gill-breathing fish (a) The overall circulatory plan of fish. Red and blue portions carry relatively oxygenated and deoxygenated blood, respectively. (b) The heart of a teleost fish. As discussed earlier (see Figure 25.3), the myocardium in teleosts is usually, at least in part, spongy and oxygenated by blood flow through the ventricular lumen, as shown. In both teleost fish and elasmobranch fish (sharks, skates, and rays), the heart consists of four sequential chambers. (b after Randall 1968.)

breathing systems found among fish to obtain O_2 , but also exploit both major factors in Equation 25.5 to sustain exceptionally high rates of O_2 delivery to their tissues: They pump blood rapidly, and each unit of blood volume is able to deliver a large amount of O_2 .

The plasticity and adaptability of the fish heart are remarkable. Because of phenotypic plasticity, the size of the ventricle in an individual can vary up to threefold as a function of the individual's environment or other circumstances. Recently, various populations of sockeye salmon (*Oncorhynchus nerka*) in the Fraser River system of British Columbia have been studied. Because individuals in each population return reliably to that particular population's spawning area, the populations are distinct. When adults undertake their physically demanding upriver migration prior to spawning, those in some populations face a far more strenuous task than those in others; for example, some must swim more than 1000 km to their spawning areas, whereas others swim only about 100 km. As seen in Figure 25.15, among populations of this single species, the percentage of compact myocardium is a regular function of the effort required for migration. In populations that must exert high migration effort (because they travel especially far or face other obstacles), the heart ventricle is composed to a greater extent of compact myocardium than in populations with easy migrations. Because little gene

flow occurs between populations, these differences might represent evolutionary divergence; alternatively, they might reflect phenotypic plasticity. Compact myocardium is believed to be advantageous for fish that engage in demanding exercise because it reliably receives fully oxygenated blood owing to its coronary circulation.

Exercise in fish is only beginning to be well understood. During exercise, some species emphasize increases in stroke volume to enhance cardiac output, whereas others emphasize increases in heart rate. Rainbow trout, often a model species for exercise studies, can—on average—increase their cardiac output about threefold as they swim faster, mostly by increasing stroke volume. They also deoxygenate their blood during exercise more than they do at rest (see Figure 24.17), thereby increasing the transport of O_2 per unit of blood volume by as much as twofold. The combination of the two effects permits rainbow trout to attain a sixfold increase in their rate of circulatory O_2 delivery.

Enhanced blood deoxygenation during exercise has potentially important implications for myocardial O_2 supply in fish because of the fact that the spongy part of the myocardium obtains its O_2 from the venous blood flowing through the heart lumen (see Figure 25.3b). As the intensity of exercise increases, the myocardium requires O_2 at a greater rate, yet the partial pressure of O_2 in the luminal blood decreases because of the increased unloading of O_2 to the systemic tissues (see Figure 24.17). The diminishing O_2 supply to the spongy myocardium could place limits on exercise performance, especially in O_2 -poor environments.

FIGURE 25.15 In seven populations of sockeye salmon, the percentage of the ventricular myocardium that is compact tends to increase as required migration effort increases. The data are for females in seven populations of sockeye salmon (*Oncorhynchus nerka*) that migrate for spawning into the Fraser River system in British Columbia, Canada. Each symbol corresponds to one population and is labeled with the name of the tributary where the population spawns. The index of migration effort was calculated numerically by multiplying the river distance a population must travel by the speed of the opposing river current the fish must swim against. Whereas the Harrison and Weaver populations swim upstream only about 120 km, the Early Stuart population swims about 1080 km. Error bars represent ± 1 standard error. (After Eliason et al. 2011.)

The circulatory plans of fish with air-breathing organs (ABOs) pose unresolved questions

A few hundred species of fish are able to breathe air, as discussed in Chapter 23 (see page 593). In most cases, the air-breathing organs (ABOs) of these species are derived from structures—such as the mouth membranes, gut, or swim bladder—that are primitively served by the *systemic* circulation. Accordingly, the *oxygenated* venous blood leaving the air-breathing organs typically flows into the *systemic* venous vasculature—not the systemic arterial vasculature!

Consider, for illustration, the electric eel (*Electrophorus electricus*), an obligate air breather. Most of its O₂ uptake occurs in its mouth cavity and pharynx; the lining of the mouth cavity is thoroughly covered with highly vascularized tufts of tissue, so much so that it resembles a red cauliflower. The circulatory plan of the electric eel is shown in Figure 25.16b. The afferent blood vessels to its air-breathing organ (its mouth cavity) arise from vessels leading toward the gills. The efferent vessels from the air-breathing organ, carrying oxygenated blood, empty into the systemic venous vasculature. Thus, in contrast to the usual fish pattern (Figure 25.16a) and to the pattern in mammals and birds, the circulatory plan places the O₂ source in *parallel* with the circulation of the systemic tissues. That is, as shown by the schematic diagram of the parallel arrangement at the right of Figure 25.16b, one bloodstream splits to supply both the O₂ source and systemic tissues, and blood leaving these two sites combines.

The implications of the parallel arrangement are profound. As shown in Figure 25.16b, oxygenated blood from the air-breathing organ freely *mixes* with deoxygenated blood from the systemic tissues in the systemic veins and heart. Thus the heart pumps a mix of deoxygenated and oxygenated blood to both the air-breathing organ and the systemic arteries. The degree of O₂ saturation of hemoglobin in the blood pumped by the heart of the electric eel never exceeds 60–65%! This is true even though the blood leaving the air-breathing organ itself may be more than 90% saturated. Not just mouth breathers, but also the fish species that have a gastrointestinal air-breathing organ (Figure 25.16c)—and those that employ the swim bladder as an air-breathing organ—typically have circulatory plans that place the air-breathing organ in parallel with the systemic tissues.

In considering the implications of parallel circulatory plans, biologists have traditionally emphasized that the mixing of the oxygenated and deoxygenated bloods *reduces the efficiency of O₂ transport*. Blood that has been deoxygenated in the systemic tissues is in part recycled directly back to the systemic tissues; and blood oxygenated in the air-breathing organ is in part recycled directly back to the air-breathing organ. According to the traditional interpretation of most biologists, these consequences are, quite simply, shortcomings. When these fish evolved air breathing, according to this line of thinking, they would have benefited if the organs they adopted for air breathing had evolved a modified venous vasculature—a vasculature that emptied the oxygenated blood into systemic arteries. Instead, they retained a disadvantageous, primitive venous vasculature that empties oxygenated blood into systemic veins carrying deoxygenated blood.

An entirely new perspective has been brought to this matter in the past decade. This perspective emphasizes that the spongy myocardium gets its O₂ from the blood passing through the heart chambers. When a fish obtains its O₂ from the air, mixing the oxygenated blood from its air-breathing organ with its systemic venous

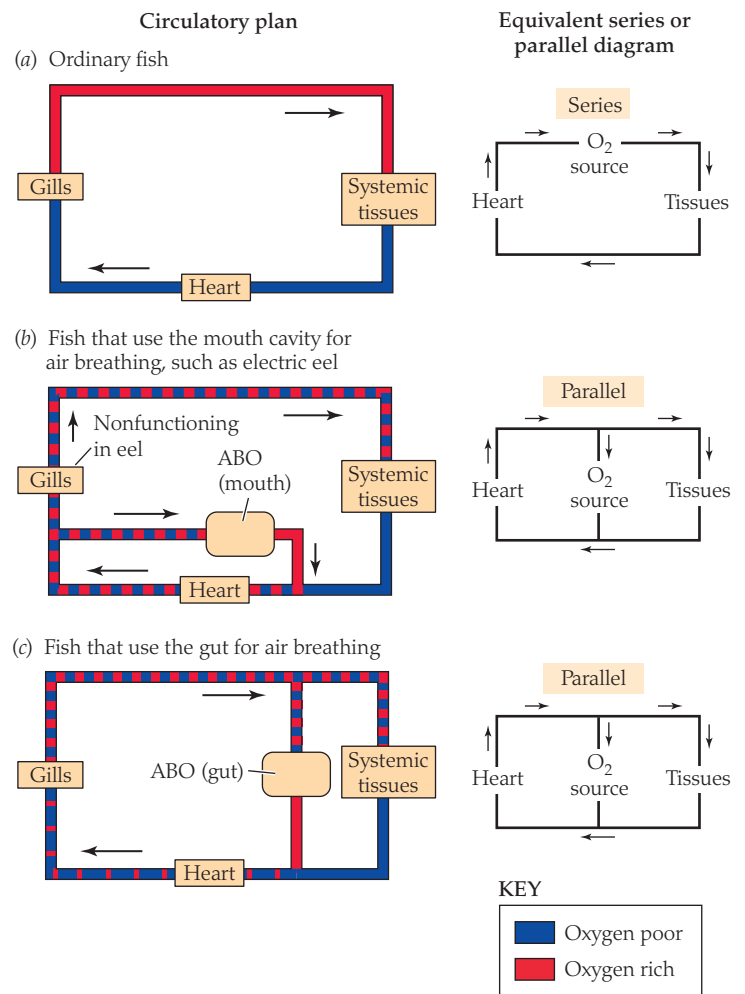

FIGURE 25.16 The circulatory plans of some air-breathing fish. The proportions of red and blue in all of the circulatory paths represent the approximate proportions of oxygenated and deoxygenated blood carried in the vessels. (a) The circulatory plan in ordinary, water-breathing fish, shown as a base of comparison. (b) The circulatory plan in the electric eel (*Electrophorus electricus*) and certain other fish that have an air-breathing organ (ABO) derived from the mouth cavity. The diagram applies specifically to the electric eel, in which the gills are not effective in taking up O₂. Afferent vessels to the ABO are derived from the afferent gill vessels; efferent vessels from the ABO connect to systemic veins. The circulatory plan in fish that use the swim bladder as an air-breathing organ is similar. In some fish species that have ABOs of these sorts, the gills remain partly functional, so in aerated water, there is at least some increase in oxygenation when blood passes through the gills. (c) The circulatory plan in certain catfish (e.g., *Hoplosternum*, *Plecostomus*) and other fish in which part of the stomach or intestine serves as an ABO. Afferent vessels to the ABO are derived from the dorsal aorta; efferent vessels enter systemic veins. (After Johansen 1970.)

blood could be an advantage because such mixing ensures that the blood flowing through the heart chambers contains increased O₂ for the heart muscle. This hypothesis is still to be evaluated.

Lungfish have specializations to promote separation of oxygenated and deoxygenated blood

The lungfish (dipnoans), which are usually considered the modern fish that most closely resemble the progenitors of terrestrial vertebrates (see page 594), display circulatory plans that differ from those of nearly all other air-breathing fish. Here we consider just the genus *Protopterus*, the African lungfish. These lungfish (one of

which is pictured in Box 25.1) have evolved a circulatory system that can maintain considerable separation between the blood oxygenated in their lungs and other, deoxygenated blood.

The lungs of *Protopterus* have a venous vasculature that is dramatically different from that of most air-breathing organs in fish: The veins from the lungs lead directly into the left side of the atrium of the heart, rather than connecting with the systemic venous vasculature. This means that blood from the lungs is kept anatomically separate from systemic venous blood until both streams of blood have entered the atrium. The sinus venosus, which receives only systemic venous blood in *Protopterus*, connects to the right side of the atrium.

The heart of *Protopterus* is very different from that of most fish in three respects. First, the atrium and ventricle are partly (but not completely) divided into right and left halves by septa. Second, the conus arteriosus, a sharply twisted tube, possesses two longitudinal ridges that project toward each other from opposite sides of its lumen, partially dividing the lumen into two channels. Third, the four pairs of afferent branchial arteries arise immediately from the anterior end of the conus arteriosus (rather than having a ventral aorta in between), as do the homologous vessels of amphibians.

As shown in Figure 25.17, two of the four pairs of afferent branchial arteries—constituting aortic arches 3 and 4—arise from the ventral channel of the conus arteriosus and travel to anterior gill arches that lack gill lamellae; these arteries do not break up into capillaries, but instead form direct through-connections to the dorsal aorta. The other two pairs of afferent branchial arteries—constituting aortic arches 5 and 6—lead from the dorsal channel of the conus arteriosus to two pairs of posterior gill arches that retain rudimentary gills; these arteries break up to supply the gills, but the gill capillaries are of large diameter and can be bypassed to at least some extent by way of vascular shunts, meaning that blood often encounters only a relatively low resistance in flowing from the afferent to the efferent vessels of these gill arches. The efferent vessels give rise to the arteries that carry blood to the lungs—arteries homologous to the pulmonary arteries of tetrapod vertebrates.

To understand blood flow through the central circulation²³ of lungfish, *functional* studies are obviously needed, because the anatomy by itself does not mandate particular patterns of flow. The functional studies that have been done vary in their results, but demonstrate that oxygenated pulmonary venous blood and deoxygenated systemic venous blood in fact follow substantially different paths through the central circulation.

One method of studying blood-flow patterns is to inject fluids that are opaque to X-rays into selected vessels and, using X-rays, monitor where these fluids are carried by the blood.²⁴ Studies of this sort show that oxygenated venous blood from the lungs tends to follow a course through the left parts of the atrium and ventricle, and is delivered preferentially to the ventral channel of the conus arteriosus. Then (Figure 25.18) the blood is pumped into vascular

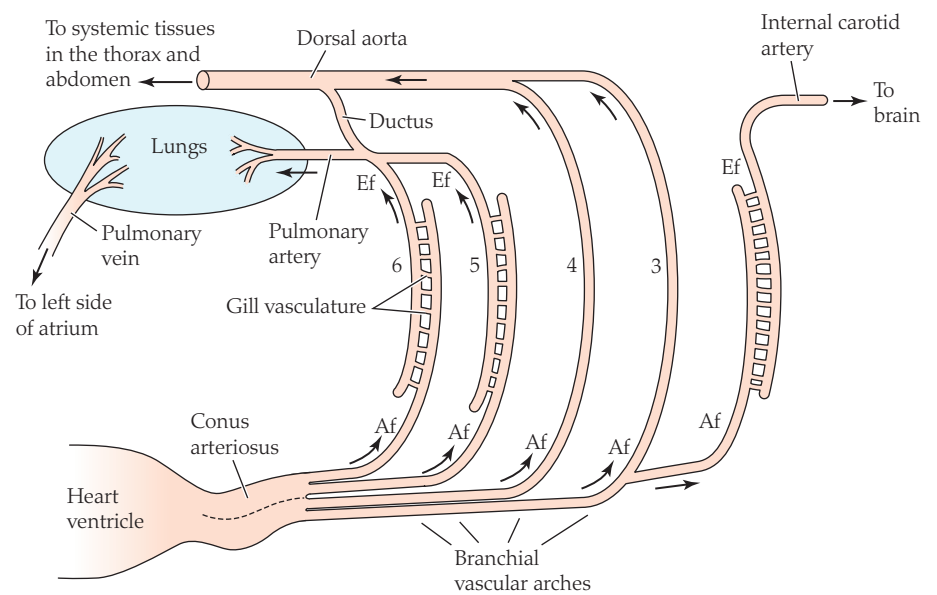

FIGURE 25.17 The branchial vascular arches of a lungfish and their relation to heart, lungs, and systemic tissues In this diagram of one side of *Protopterus aethiopicus*, the branchial vascular arches are numbered according to the aortic arches they represent (other numbering systems are sometimes used). Branchial arches 3 and 4 go to gill arches that lack gill lamellae; those branchial vascular arches do not break up into capillaries, but instead form direct through-connections to the dorsal aorta. Gills of a rudimentary sort are found on the gill arches supplied by branchial vascular arches 5 and 6. Within these gill arches, the afferent branchial arteries (Af) break up to supply the gill lamellae, and blood is collected from the lamellae by efferent branchial vessels (Ef). A similar arrangement is found in the most anterior gill arch, as shown. The efferent vessels of arches 5 and 6 form the pulmonary artery. The vessel called the ductus connects the pulmonary artery and dorsal aorta; flow through it is not well understood, although it is generally believed to help blood bypass the lungs during periods when ventilation of the lungs is suspended. Arrows show directions of blood flow. (After Laurent et al. 1978.)

arches 3 and 4, which carry the blood directly to the dorsal aorta (compare Figure 25.17). In this way, the blood oxygenated in the lungs is directed preferentially into arteries of the systemic circuit. Systemic venous blood tends to pass through the right parts of the atrium and ventricle. That blood then appears in X-ray images either to be distributed about evenly to all four pairs of vascular arches (those numbered 3–6) or to be delivered preferentially to the dorsal channel of the conus arteriosus and into vascular arches 5 and 6, which in part supply blood to the pulmonary arteries.

Another way to study blood-flow patterns is to monitor blood O_2 levels. In one study of *Protopterus*, when the O_2 partial pressure in systemic venous blood averaged 2 mm Hg and that in pulmonary venous blood was 46 mm Hg, the blood pumped into vascular arches 3 and 4 for direct passage to the dorsal aorta had an average O_2 partial pressure of 38 mm Hg, showing that it consisted mostly of oxygenated blood from the lungs. Simultaneously, the blood pumped to vascular arches 5 and 6 had a much lower O_2 partial pressure.

Physiologists have long pondered whether there might be advantages to having an incompletely divided heart. Considering lungfish, one line of thinking focuses on the fact that they are intermittent breathers. Because they alternate between periods of breathing and breath-holding, their lungs alternate between

²³The term **central circulation** refers to the heart and the veins and arteries that immediately connect to the heart.

²⁴The same sort of technique is used to visualize blood flow to organs such as the brain and myocardium in medical practice.

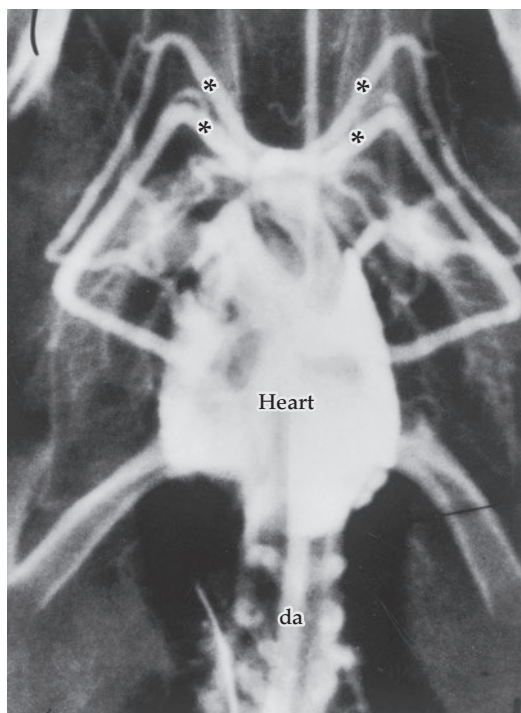

FIGURE 25.18 Oxygenated blood from the lungs of a lungfish is pumped selectively by the heart into certain branchial vascular arches. The fish under study (*Protopterus aethiopicus*) was viewed from below using X-rays. A fluid opaque to X-rays was injected into the pulmonary vein, flowed into the heart, and was being pumped by the heart when this image was made. White-colored parts of the image show the location of the fluid at the moment the image was made. Note that of the four pairs of branchial vascular arches that arise directly from the heart, only two pairs—those labeled with asterisks—received substantial amounts of the X-ray-opaque fluid. The arches receiving the fluid were numbers 3 and 4 (compare Figure 25.17). This image shows that blood from the lungs is pumped by the heart into these arches preferentially and thus flows primarily to the dorsal aorta (da). (Courtesy of Kjell Johansen; from Johansen and Hol 1968.)

periods when their O_2 concentration is high and low. Their incompletely divided heart permits them to *redistribute* the total outflow of blood from the heart in a way that birds and mammals cannot (**Box 25.1**)—they can pump a large fraction of their cardiac output to their lungs when the lung air is rich in O_2 but pump a small fraction of their cardiac output to the lungs when the lung air is O_2 -depleted. This redistribution indisputably occurs at times and may be a specific evolutionary reason that the central circulation has remained incompletely divided.

SUMMARY Circulation in Fish

- In most fish, the heart pumps blood to the gills, after which the blood passes through the systemic circuit before returning to the heart. The gill and systemic circuits are arranged in series.
- In air-breathing fish, blood leaving the air-breathing organ (ABO) usually mixes with systemic venous blood. Thus the circulation of the ABO is in parallel with the systemic circuit. This arrangement decreases the efficiency of O_2 transport but may help oxygenate the myocardium.

- Lungfish have a modified central circulation in which blood from the lungs enters the left side of the atrium and the atrium, ventricle, and conus arteriosus are partly divided. Deoxygenated and oxygenated blood can be kept relatively separate and pumped selectively to the lungs and systemic circuit. Redistribution of cardiac output is possible, and occurs in synchrony with the intermittent breathing cycle.

Circulation in Amphibians and in Reptiles Other than Birds

Three interrelated themes have dominated research on circulation in amphibians and nonavian reptiles. One is *selective distribution*: To what extent is oxygenated blood sent to the systemic tissues, and deoxygenated blood to the lungs? The second is *maintenance of different blood pressures in the systemic and pulmonary circuits*: Can high pressures be maintained in the systemic circuit to produce high flow rates in that circuit while low pressures are maintained in the pulmonary circuit to prevent flooding the airways with fluid? The third is *redistribution of cardiac output*: To what extent is flow to the lungs adjusted separately from that to the rest of the body? These phenomena interact in complicated ways, but we will discuss them as distinct processes.

In the lung-breathing amphibians and nonavian reptiles, two completely separate atrial chambers are present. Oxygenated blood from the lungs enters the left atrium, whereas systemic venous blood enters the right atrium via the sinus venosus. Separation of oxygenated and deoxygenated blood is anatomically guaranteed until the blood enters the ventricle, which in these groups consists of an outer compact myocardium with a coronary circulation and an inner spongy myocardium oxygenated by luminal blood (see Figure 25.3c). After blood leaves the anatomically separate atria and enters the ventricle, the central circulation is incompletely divided in one way or another.

In amphibians, the ventricle entirely lacks a septum. The ventricular lumen, however, is not a wide-open cavity because it is crisscrossed with ribbons and cords of the spongy myocardium. The ventricle discharges into a contractile conus arteriosus, which in turn typically discharges into paired carotid, systemic, and pulmonary arteries. The lumen of the conus in most amphibians is incompletely divided by a complexly twisted, longitudinal ridge of tissue (the *spiral fold*).

Although amphibians are diverse, it is clear that many—including certain frogs, toads, and salamanders—are capable of substantial selective distribution of oxygenated and deoxygenated blood (**Figure 25.19**). Bullfrogs (*Lithobates catesbeianus*; once called *Rana catesbeiana*) provide a dramatic example. In one study, 91% of the pulmonary venous blood arriving in the heart was channeled into the systemic arteries, whereas 84% of the systemic venous blood was directed into the pulmonary arteries. Such a high degree of selective distribution functionally places the pulmonary and systemic circuits in series, promoting efficient O_2 transport. When amphibians achieve such feats, they do so with a ventricle that entirely lacks a septum and with a conus arteriosus that is only incompletely divided! Physiologists do not know exactly how.

The skin of amphibians is an important site of O_2 uptake (see page 595). Some of the major arteries to the skin arise from the pulmonary arteries (also known as *pulmocutaneous arteries*). Thus,

BOX 25.1 AN INCOMPLETELY DIVIDED CENTRAL CIRCULATION CAN POTENTIALLY BE AN ADVANTAGE FOR INTERMITTENT BREATHERS

Intermittent breathing is common in lungfish, amphibians, lizards, snakes, and turtles—groups in which the heart is incompletely divided. It is also common in crocodilians, in which the central circulation outside the heart is incompletely divided. An intermittent breather, having ventilated its lungs with air, holds its breath for a substantial time before ventilating again (see page 590). Intermittent breathing presents both opportunities and challenges because the lungs vary from time to time in how effectively they are able to oxygenate the blood. Immediately after an animal has taken a series of breaths, the air in the lungs is rich in O_2 , and blood flowing through the lungs can become well oxygenated. However, after a long interval of apnea

(cessation of breathing), the air in the lungs may be depleted of O_2 , and little opportunity may exist for blood flowing through the lungs to gain O_2 .

A great deal of research has convincingly demonstrated that most or all air-breathing vertebrates with incompletely divided central circulations in fact modulate blood flow to their lungs independently of flow to the rest of the body—at least to some degree and under certain circumstances. They increase blood flow to the lungs immediately after each period of breathing, whereas they decrease it toward the end of each period of apnea. In doing so, they achieve **ventilation-perfusion matching** to some degree. That is, they achieve functionally efficient match-

African lungfish (*Protopterus annectens*)

ing of air flow and blood flow to the lungs. These topics are discussed further in **Box Extension 25.1**.

if deoxygenated blood is preferentially pumped to the lungs, it is also preferentially pumped to the skin. The veins draining the skin connect with the general systemic venous vasculature—a property traditionally viewed as disadvantageous because it allows blood oxygenated in the skin to mix with deoxygenated systemic venous blood rather than staying separate. However, from the

newly hypothesized viewpoint that emphasizes adequate O_2 for the myocardium, the arrangement of the cutaneous veins could be neutral or beneficial. The amphibian myocardium gets much of its O_2 from the blood flowing through the heart lumen, and cutaneous flow adds O_2 to the venous blood entering the right heart (see Figure 25.19).

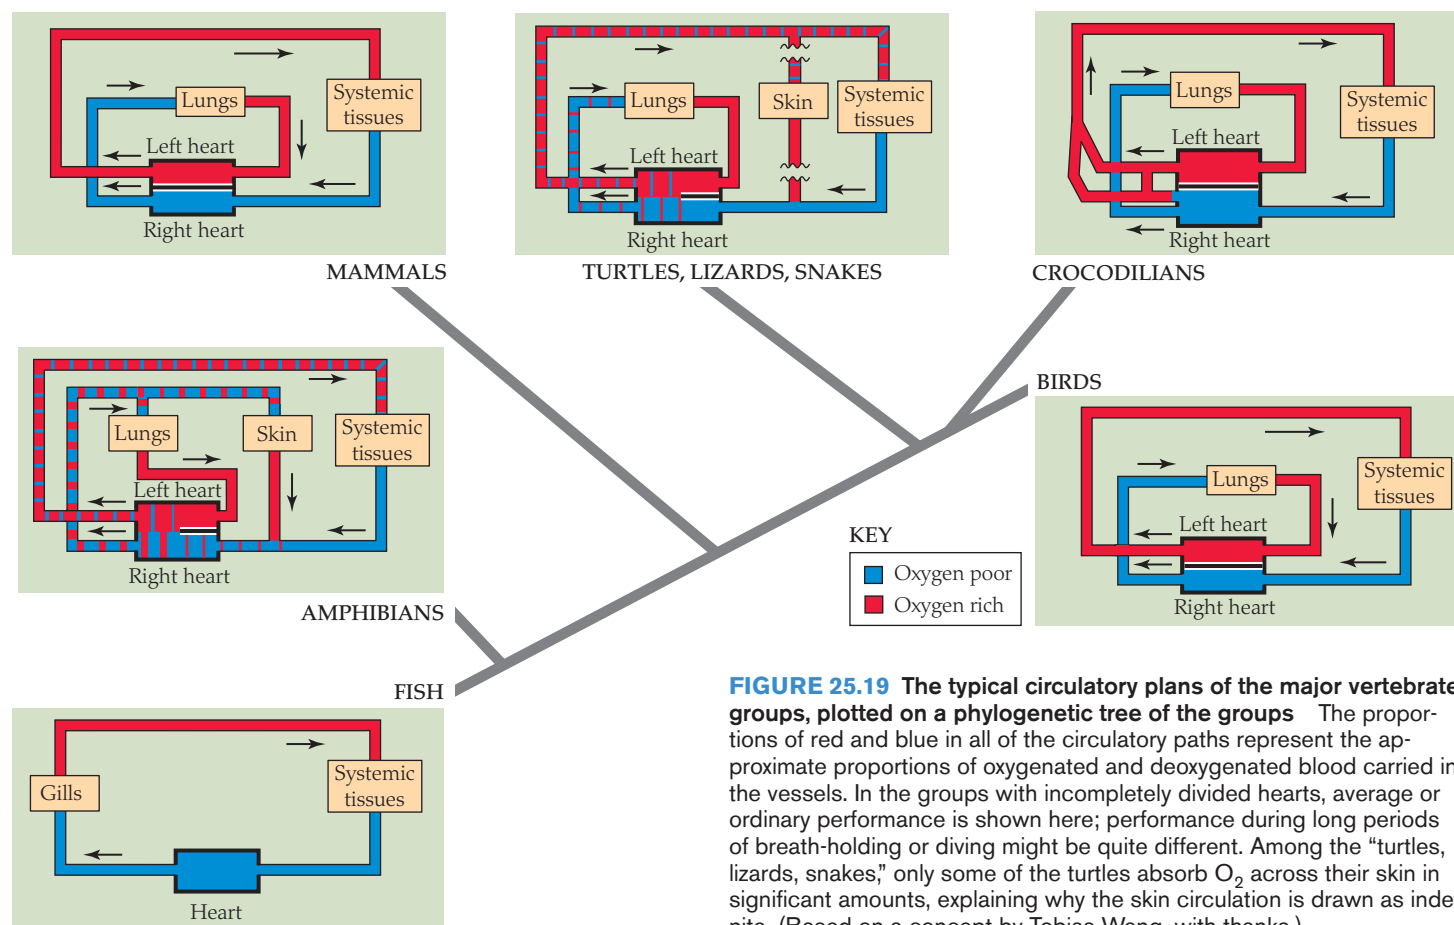

FIGURE 25.19 The typical circulatory plans of the major vertebrate groups, plotted on a phylogenetic tree of the groups. The proportions of red and blue in all of the circulatory paths represent the approximate proportions of oxygenated and deoxygenated blood carried in the vessels. In the groups with incompletely divided hearts, average or ordinary performance is shown here; performance during long periods of breath-holding or diving might be quite different. Among the “turtles, lizards, snakes,” only some of the turtles absorb O_2 across their skin in significant amounts, explaining why the skin circulation is drawn as indefinite. (Based on a concept by Tobias Wang, with thanks.)

In nonavian reptiles, just as in mammals and birds, the principal arteries arise directly from the ventricle of the heart; there is no intervening conus arteriosus. In *turtles, snakes, and lizards*, the ventricle is incompletely divided into three chambers by muscular ridges and partial septa. Although pulmonary and systemic venous bloods are potentially able to mix in the ventricle in these groups, numerous studies have demonstrated that dramatic selective blood distribution occurs (see Figure 25.19). The pulmonary arteries receive mostly deoxygenated blood under many circumstances, for example. The mechanism of selective distribution varies. Two of the best-understood cases are pythons and the strikingly active varanid lizards. In them, prominent ridges of tissue that incompletely divide the ventricular chambers are pressed so tightly against opposing structures during heart contraction as to create complete anatomical blocks to blood flow from one chamber to another. Thus, although the ventricular chambers that eject blood into the pulmonary and systemic circuits are not separated by a complete septum, they are temporarily separate during systole. Other temporary physical barriers within the heart also play roles.

Regarding blood pressures in the systemic and pulmonary circuits, the pythons and varanid lizards are unique among the reptiles we are here discussing in that they exhibit dramatically different blood pressures in different ventricular chambers during systole—a phenomenon that requires complete physical separation between the chambers. Specifically, the pressure in the chamber pumping to the systemic arteries is high (much higher than that observed in most reptiles), while simultaneously the pressure in the chamber pumping to the lungs remains low—low enough to prevent ultrafiltration of fluid into the lung air spaces. The pythons and varanids, in other words, resemble mammals and birds in being able to employ high pressures to drive a high rate of flow in their systemic circuit while not endangering lung function. In other noncrocodilian reptiles that have been studied and in amphibians, no means exist to achieve complete physical separation between parts of the ventricular lumen during systole. Thus, the systemic and pulmonary circuits receive blood at the same pressure, and that pressure has to be low enough so as not to endanger lung function.

Regarding redistribution of cardiac output, lizards, snakes, and turtles—and also amphibians—frequently display intermittent breathing, and most species that have been studied redistribute their cardiac output during periods of intermittent breathing, so that flow to the lungs is high after breaths have been taken but low after periods of apnea (see Box 25.1). Certain diving turtles and snakes provide especially dramatic examples. When their lung air becomes O₂-depleted during a dive, they continue to circulate blood round and round in their systemic circuit while sending hardly any blood to their lungs!²⁵ The control of the distribution of cardiac output is becoming better understood. In amphibians, which entirely lack a ventricular septum, blood is distributed into the pulmonary and systemic circuits as dictated by peripheral vascular resistance; the lungs get a lot of flow when their vascular resistance is low relative to the systemic circuit's vascular resistance, and vice versa. This

²⁵In the professional literature on the cardiovascular physiology of animals with incompletely divided central circulations, the variable distribution of total cardiac output to the pulmonary and systemic circuits is often called *shunting*. *Right-to-left (R-L) shunting* is diversion of systemic venous blood directly back into the systemic circuit, bypassing the lungs. This is the sort of shunting displayed by the diving turtles. *Left-to-right (L-R) shunting* is diversion of pulmonary venous blood directly back to the lungs.

same phenomenon is important in lizards, snakes, and turtles, but in addition in these groups, the regulation of temporary anatomical barriers in the heart plays an important role in determining the paths that blood follows when ejected.

In the *crocodilian reptiles*, the ventricle is completely divided into two chambers by a septum. This does not mean, however, that the crocodilians resemble mammals and birds—far from it. Crocodilians have two systemic aortas, which arise from the left and right ventricles (Figure 25.20a). The two aortas are connected shortly after their exit from the ventricles by an aperture called the **foramen of Panizza**, and the vascular beds perfused by the two aortas are also connected more distally. The pulmonary artery arises from the right ventricle. Functional studies have demonstrated that the crocodilian heart can achieve virtually perfect selective distribution of deoxygenated blood to the lungs and oxygenated blood to the systemic circuit. The way this happens is that deoxygenated systemic venous blood in the right ventricle can be pumped exclusively into the pulmonary artery because valves and pressure relationships prevent it from entering the systemic aorta that leaves the right ventricle (Figure 25.20b; see also Figure 25.19). This flow pattern is not guaranteed by anatomy, however, and flow may be redistributed during diving or breath-holding (Figure 25.20c).

Concluding Comments on Vertebrates

In studying the circulatory systems of fish, amphibians, and reptiles other than birds, there is perhaps a yearning to find a linear advance toward the condition of mammals and birds. The facts, however, do not at all reflect such a linear progression (see Figure 25.19). The groups of animals alive today are not in the business of striving to be mammals and birds (how could they be?).

Among air-breathing vertebrates, logic suggests that efficiency of O₂ transport is promoted by having the pulmonary and systemic circuits connected in series during periods of time when the lungs are being ventilated and the lung air is rich in O₂. In mammals and birds, which breathe continuously, the lung air is always rich in O₂. Thus efficiency is achieved by having an anatomically deterministic connection of the pulmonary and systemic circuits in series.

The other air-breathing vertebrates besides mammals and birds fill their lungs with air only intermittently. In these vertebrates, as explained in Box 25.1, an *incomplete* anatomical division of the central circulation can potentially be superior to an anatomically rigid separation in its ability to promote efficiency of O₂ transport. In this way, the circulatory plans of the “lower” vertebrates may have their own virtues and may have been subject to positive natural selection, rather than being evolutionary relics. There are at least a half dozen other rationales, proposed by biologists, for reaching the same conclusion. Empirical evidence for or against these evolutionary hypotheses is needed, and gathering such evidence is perhaps the central challenge at present for research in the comparative physiology of vertebrate circulation.

Invertebrates with Closed Circulatory Systems

Closed circulatory systems occur in only a few groups of invertebrates, notably some annelid worms and the cephalopod molluscs (the squids and octopuses and their relatives). The cephalopods,

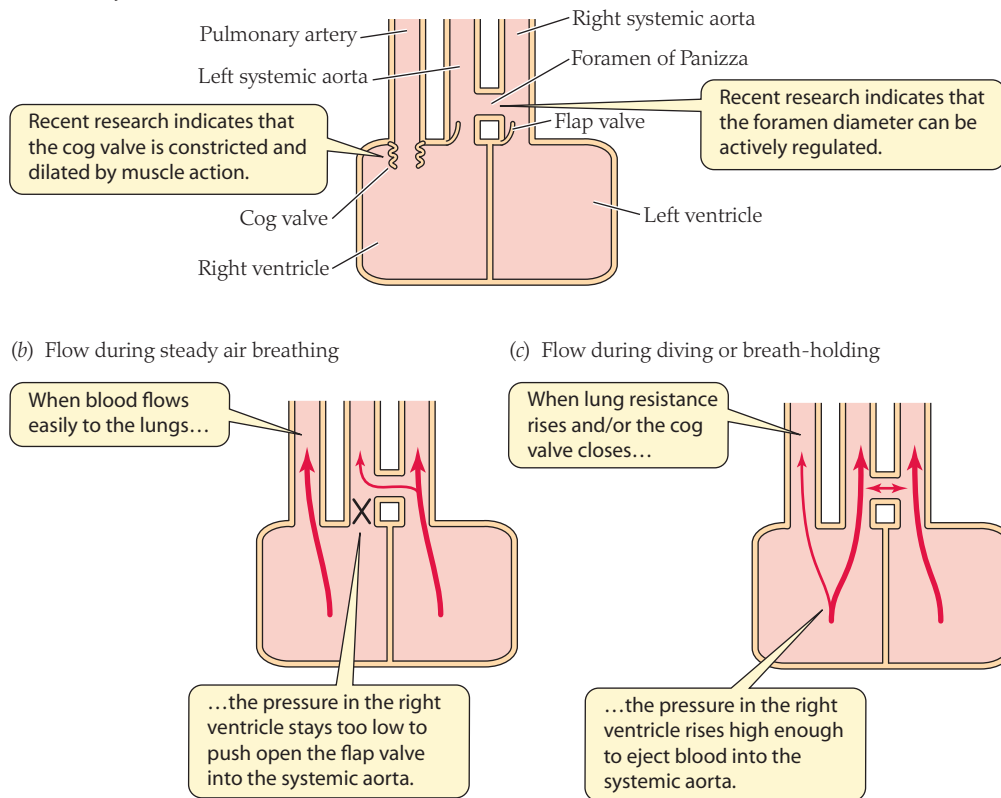

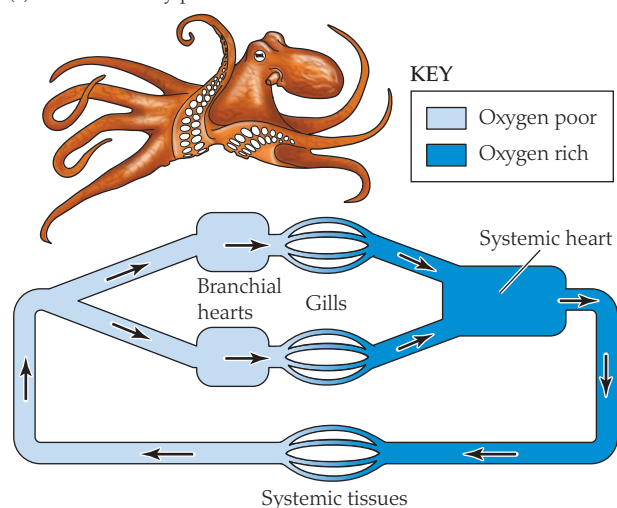

FIGURE 25.20 Blood flow in the heart ventricles and the systemic and pulmonary arteries of crocodilian reptiles (a) The basic plan of the ventricles and vessels. (b) During steady air breathing, blood flows readily from the right ventricle into the pulmonary artery. Consequently, the systolic pressure in the right ventricle does not rise particularly high, and in fact remains lower than the pressure in the left systemic aorta, so the passive flap valve between the right ventricle and left systemic aorta is not forced open. Blood from the left ventricle is pumped mostly into the right systemic aorta; some may enter the left systemic aorta through the foramen of Panizza, although this does not always occur. (c) During diving or prolonged breath-holding, resistance to flow into the pulmonary artery is raised. Blood therefore cannot flow out of the right ventricle as easily, the right ventricular pressure rises, and the flap valve into the left systemic aorta is pushed open during ventricular systole, permitting some of the systemic venous blood pumped by the right ventricle to bypass the lungs. In these ways, the incompletely divided central circulation permits pulmonary blood flow to be reduced during times when lung air is O_2 -depleted (see Box 25.1).

which we emphasize here, are of great interest because they are extraordinarily active animals compared with most members of their phylum (e.g., clams and snails). Some squids, in fact, jet around at such high speeds that they rank with fish as being among the most active of all aquatic animals. The giant squids are the largest invertebrates on Earth. The circulatory system of a squid or octopus consists of extensive networks of arteries and veins—both of which are muscular—joined in large part by capillary beds.

A squid or octopus has a principal heart, called its **systemic heart**, and two weaker, auxiliary **branchial hearts**. The systemic

heart—which is myogenic—consists of a powerful muscular chamber valved at its inflows and outflows. **Figure 25.21** shows the circulatory plan. Blood enters the systemic heart from the gills and is pumped from the systemic heart into major arteries (aortae) that take it to the systemic tissues. As blood returns to the vicinity of the systemic heart in the major veins (which, unlike vertebrate veins, often display contractions that move the blood), it is split into two symmetrical paths to be directed to the gills. Near the base of each gill is a bulbous branchial heart, which pumps blood into an afferent branchial vessel. The blood then passes through

octopuses, turns blue when well oxygenated but is clear or nearly clear when deoxygenated. (b) A more realistic drawing of the central circulatory system of an octopus. (b after Johansen and Lenfant 1966.)

BOX 25.2 BEARING THE BURDEN OF ATHLETICISM, SORT OF: A SYNTHESIS OF CEPHALOPOD O₂ TRANSPORT

Both the vertebrate and the invertebrate worlds have produced high-speed, swimming predators. The principal vertebrates in this ecological role are fish. As improbable as it may seem when gazing at a clam or snail, the molluscs have produced the invertebrate entry: the squids. The fossil record indicates that swimming cephalopods were abundant in the oceans before the appearance of marine fish and dominated in playing the role of fast-swimming predators. The arrival of fish then produced competition, which the fish won. Some species of squids alive today have been as successful as fish. However, the squids might have dominated the oceans had fish not appeared, and today it is the fish that dominate.

To generate swimming power, the cephalopods became committed to jet propulsion early in their evolution and have never turned back. Compared with propulsion of the sort employed by fish, jet propulsion is inherently inefficient. For example, a squid might well use twice the O₂ of a like-sized fish to swim at half the speed of the fish. Thus the systems that supply O₂ to the tissues of squids are asked to assume a large burden.

The gills of cephalopods are positioned in the mantle cavity, where they have always been throughout the evolution of molluscs (see Figure 23.26). Being in the mantle cavity,

the gills are exposed to extreme rates of water flow during jet propulsion and have no difficulty obtaining O₂, as we saw in Chapter 23 (see page 610).

The circulatory system is where limits develop. For one thing, molluscs are committed to hemocyanin dissolved in the blood plasma as their respiratory pigment. Dissolved hemocyanin makes the blood ever more viscous as its concentration rises. Squids and octopuses have evolved the highest concentrations of hemocyanin in any animals: They seem to have raised blood viscosity as high as it can go. Even thus maximally concentrated, hemocyanin allows the blood leaving the gills to carry only about 5 mL O₂ per 100 mL of blood, as we saw in Chapter 24. Hemoglobin in red blood cells allows many fish to have oxygen-carrying capacities more than twice as high. As also seen in Chapter 24 (see Figure 24.18), squids and octopuses, even when *approximately at rest*, are believed to have almost no venous O₂ reserve. Therefore, when they start jetting about, their sole available option to increase O₂ transport is to increase their rate of blood flow by increasing cardiac work.

If a squid and a fish were both to increase cardiac output fourfold during exercise, the squid would increase its rate of circulatory O₂ delivery about fourfold, but the fish might increase its rate tenfold by simultaneously

tapping its venous O₂ reserve to increase the amount of O₂ delivered per unit of blood volume (see Figure 24.17). This difference illustrates the implications of the resting venous O₂ reserve: If there is little resting venous reserve, O₂ delivery can be increased only by increasing the rate of blood flow.

Viewed metaphorically, the sophisticated circulatory system of the cephalopods is doomed to bearing an almost impossible burden by a series of irrevocable evolutionary commitments in other functional attributes, such as the commitment to jetting as the source of propulsive power and the commitment to hemocyanin. When a squid powers up, its O₂ cost of swimming is high compared with that of a fish, but because its blood oxygen-carrying capacity and venous O₂ reserve are comparatively low, the squid's hearts must bear almost the entire responsibility of increasing O₂ delivery. Although some squids fortunately prosper nonetheless, the "O₂ equation" is probably a key reason that the squids as a group were outcompeted by fish over the eons in the oceans.

capillaries in the gill to arrive in the efferent branchial vessel and return to the systemic heart. This circulatory plan resembles that of mammals, birds, and most fish in that it places the breathing organs and the systemic tissues strictly in series. The arrangement of hearts may seem a bit odd at first, but is actually "close to home." As seen by comparing Figures 25.10*b* and 25.21*a*, the arrangement of hearts in a squid or octopus is identical to that in a mammal, except that the respiratory pumps are anatomically separate from the systemic pump.

Physiologically, the circulatory system of squids and octopuses resembles that of vertebrates far more than it does that of the other molluscan groups (which have low-pressure, open circulatory systems). In the octopus *Enteroctopus dofleini* and the highly active squid *Loligo pealii*, the mean blood pressure produced by the systemic heart is 4–5 kPa (30–37 mm Hg), and by the time the blood has passed through the systemic tissues and reached the great systemic veins, its mean pressure has dropped nearly to zero. The systemic pressure gradient in cephalopods thus resembles that in fish (see Table 25.1). The cardiac output of resting or mildly active *E. dofleini* is typically about 10–20 mL/kg·min—also in the range seen in fish (see Table 25.1). When the vascular resistance of the systemic circuit in cephalopods is calculated (see Equation 25.3), it is relatively high, as would be expected for a closed circulatory system. Overall, therefore, the cephalopods are similar to fish in

that they maintain reasonably rapid rates of blood flow through a systemic circuit of relatively high resistance by maintaining relatively high pressures in the systemic arteries.

Exercise in cephalopods presents intriguing questions, which we have already started to discuss in earlier chapters. **Box 25.2**, in addition to summarizing points made in those other chapters, explains the special burden borne by the circulatory system during cephalopod exercise.

Invertebrates with Open Circulatory Systems

The animals with open circulatory systems—which include all arthropods and most molluscs—commonly have a well-developed central heart. The heart may discharge into a network of arteries, and the arteries may lead to capillary beds of discrete, minute vessels lined only with a single layer of endothelial cells. Ultimately, however, in an open circulatory system, the blood exits discrete vessels (**Figure 25.22**), and thereafter it flows through lacunae and sinuses. **Lacunae** are small spaces among cells of nonvascular organs and tissues. A tissue with lacunae is often thoroughly permeated by an anastomosing network of lacunar spaces—a network that brings blood close to all the cells in the tissue. Lacunar networks are like capillary networks in this respect. However, lacunar channels are characteristically

(b) 1 second later

At this moment, a major leg artery and some side branches become filled with blood containing the dye.

(c) Another moment later

A moment later, blood containing the dye spills out of discrete vessels to enter the open part of the circulation.

FIGURE 25.22 The transition of blood flow from the closed part of the circulation to the open part A fluorescent dye was injected into arteries of a spider. As the dye traveled with the flowing blood, it was imaged using fluorescent videomicroscopy. (a) A portion of a leg just before the arrival of blood containing dye. (b) The same spot 1 s later. (c) The same spot a moment later, showing blood and dye flowing out of discrete vessels. These are the first images ever obtained of this process. The specific animal studied was a spider (*Pholcus*) with book lungs, chosen for investigation because its integument (including the exoskeleton) is naturally transparent over much of the body. (Photos courtesy of R. J. Paul; from Paul et al. 1994.)

irregular in shape and are not in the form of discrete vessels lined with endothelium. **Sinuses** are larger blood spaces, commonly representing thoroughfare channels for the blood. Lacunae and sinuses in animals with open circulatory systems are sometimes bounded by a membrane of some type. However, they are believed by most physiologists to be sometimes bounded simply by cells of ordinary, nonvascular tissues. This latter point is of key importance because it means that the blood directly bathes the cells of the nonvascular

tissues, and *there is in fact no clear distinction between blood and extracellular tissue fluid (interstitial fluid)*. In recognition of this fact, some authors call the blood **hemolymph** (“blood lymph”).

As already suggested, experts debate the exact nature of the lining of lacunae and sinuses in some cases. Regardless of the ultimate outcome of these debates, it is clear that the design of the circulatory system in animals with open circulatory systems is significantly different from that in vertebrates or cephalopods. In the latter groups, not only is blood *carried to* the depths of each tissue by discrete vessels, but it remains in vessels as it *passes through* each tissue, and it is *collected from* each tissue by discrete vessels. In animals with open circulatory systems, after blood leaves the arteries (or sometimes capillaries), it is left to follow paths through lacunae and sinuses—paths that in many cases seem ill-defined—before it is again channeled into discrete vessels.

The crustacean circulatory system provides an example of an open system

Some immature, small, or sessile crustaceans lack a heart and blood vessels. Their circulation is exclusively through sinuses and lacunae, and the propulsive force is provided by ordinary body movements. In some other crustaceans, a heart is present, but empties through holes rather than arteries. In still others, arteries are present, but they end abruptly after extending only a short distance from the heart. Here we emphasize the decapod crustaceans—crabs, crayfish, lobsters, and their relatives—which have especially elaborate open circulatory systems.

In adult decapod crustaceans, the heart is a single-chambered saclike structure—positioned in the dorsal thorax—the beat of which is initiated neurogenically (see Figure 25.5).²⁶ *All the vessels connected to the heart are arteries* (as is typical of crustaceans in general). The arteries are valved at their origins and leave the heart in several directions (Figure 25.23a). Blood enters the heart not through vessels, but through slits in the heart wall, called **ostia** (singular *ostium*), of which decapods usually have three pairs. The heart is suspended by elastic **suspensory ligaments** within a bounded sinus, the **pericardial sinus** (Figure 25.23b,c). The only blood channels that enter the pericardial sinus are “veins” that bring blood from the gills or other respiratory surfaces.²⁷

When the heart contracts at systole, the ostia are closed by muscular tension, flap valves, or both; blood within the heart thus cannot spew out through the ostia into the pericardial sinus, and is driven into the arteries. Contraction of the heart stretches the suspensory ligaments attached to the heart wall. During diastole, elastic rebound of these ligaments expands the heart back to its presystolic volume. This elastic rebound is the primary force for refilling. As the heart is stretched open, the pressure within is reduced below that in the pericardial sinus, and blood is sucked inward from the pericardial sinus through the ostia.

The walls of the arteries of crustaceans, although elastic, are typically nonmuscular. Thus the arteries are neither pulsatile (as in cephalopod molluscs) nor capable of vasomotor control (as in verte-

²⁶The heart is myogenic in the embryos and juveniles of at least some decapod crustaceans and is partly or wholly myogenic in adults of some other types of crustaceans.

²⁷We term these channels “veins,” in quotation marks, because they are not typical venous vessels of the sort seen in vertebrates or cephalopods, but are usually called *veins* nonetheless.

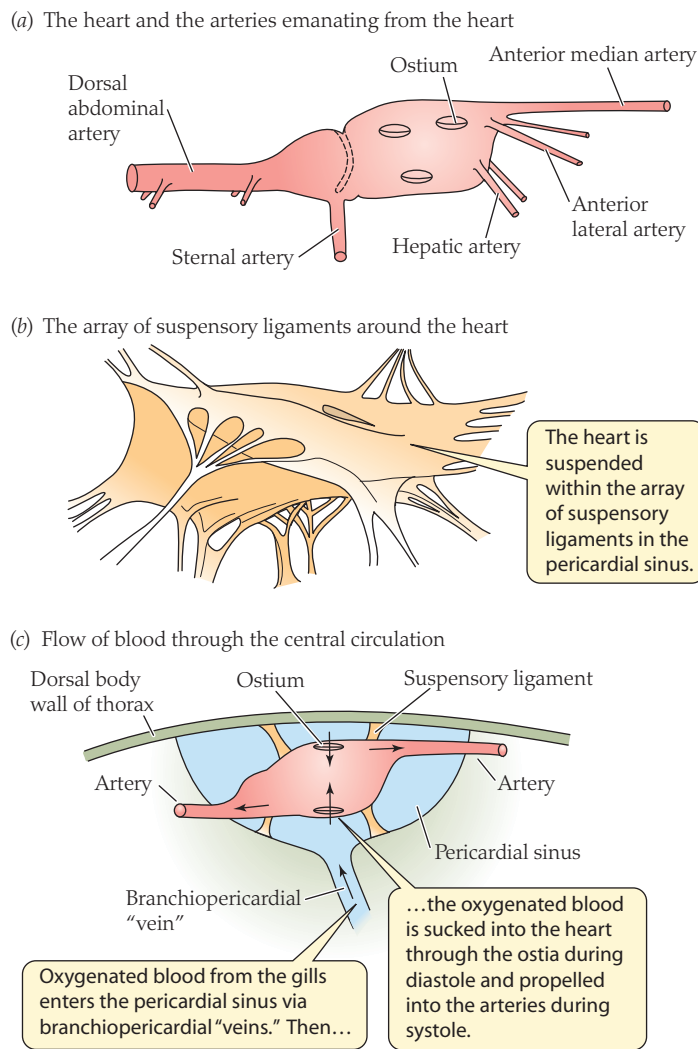

FIGURE 25.23 The heart of a decapod crustacean (a) The heart and the arteries leaving it. All the vessels connected to the heart in a crustacean are arteries. (b) The heart is surrounded by an array of elastic suspensory ligaments that run between the heart wall and the wall of the surrounding pericardial sinus, suspending the heart in the pericardial sinus. (c) The position of the heart in the pericardial sinus and the pattern of blood flow through the central circulation. (a after Wilkens 1999; b after Plateau 1880.)

brates)—raising the question of whether they can exert any control over the regional distribution of cardiac output. By now, however, it is clear that blood distribution is under control of highly localized muscular valves in the arteries. The best studied are the **cardioarterial valves**, positioned at the points where the various arteries leave the heart. Each valve contains innervated muscle. Excitatory nerve impulses, by stimulating contraction of a valve, can limit blood flow into the artery guarded by that valve; simultaneously, inhibitory impulses sent to other valves might enhance blood flow into other arteries. Hormones also help control the cardioarterial valves.

Decapod crustaceans have extensive arterial systems (Figure 25.24a). Branching arteries lead blood from the heart to most regions of the body. Sometimes the blood is discharged from the arteries directly to lacunar networks. Sometimes the arteries lead to capillary beds, which then discharge into lacunar networks. Prominent capillary beds are present, for example, in the brain and the ganglia

FIGURE 25.24 Circulation through the body of a crayfish or lobster ▶

(a) The heart and major arteries. The *cor frontale* is an accessory heart (powered by skeletal muscles) positioned upstream from the extensive vascular networks of the brain; it is believed to help ensure that adequate perfusion pressures are maintained in the brain. (b) The circulatory plan. Because the respiratory pigment of decapod crustaceans is hemocyanin, the blood turns bluish when oxygenated but is clear when fully deoxygenated. (a after McLaughlin 1980.)

of the ventral nerve cords. In all, the arterial systems of decapods are often impressively elaborate, especially in comparison with some of the other groups of arthropods such as insects (Box 25.3).

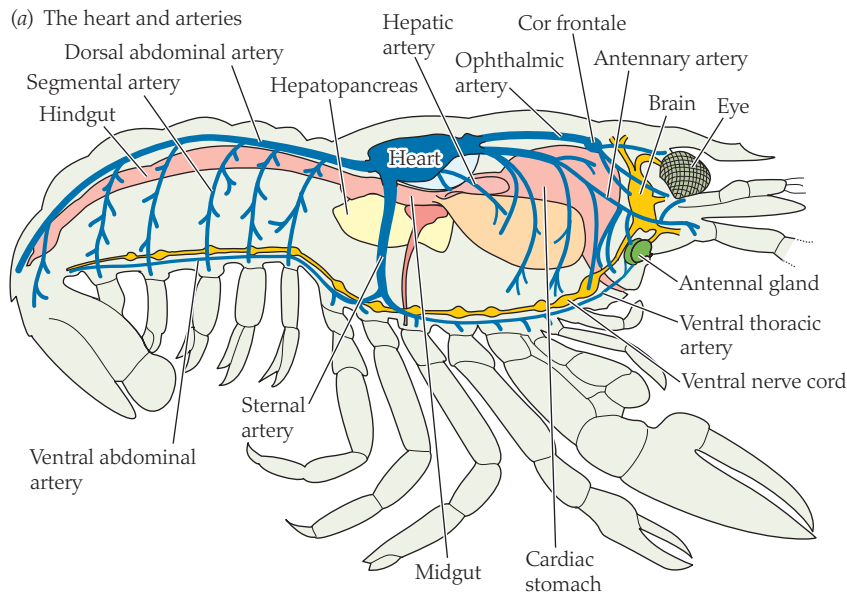

In a decapod crustacean, after blood leaves the arteries or capillaries and enters lacunar networks throughout the body, it ultimately drains into a system of sinus thoroughfare channels located ventrally along the length of the animal. In these ventral sinuses, blood from the posterior regions of the body flows anteriorly, and that from the anterior regions of the body flows posteriorly. As shown in Figure 25.24b, both flows converge on a ventral thoracic sinus termed the **infrabranchial sinus** (*infrabranchial*, “below the gills”). Afferent branchial channels that carry blood into the gills arise from this sinus. Blood flows into these channels, traverses systems of small sinuses or lacunae in the gill filaments or lamellae, and then exits the gills by way of efferent branchial channels. Importantly, these channels discharge into passageways—the branchiopercardial “veins”—that lead directly into the pericardial sinus. Therefore, after a period of seemingly poorly controlled flow following its discharge from the arterial system, the blood is channeled in a highly significant way prior to its return to the heart. The gills are placed in series with the rest of the circulation, and oxygenation of the blood pumped by the heart is ensured.²⁸

Like fish, decapod crustaceans perfuse the systemic tissues and the gills, in sequence, without repumping the blood between the two sites. In decapods, however—unlike fish—blood leaving the heart passes through the systemic circuit first and the gill circuit second. Thus blood pumped to the systemic circuit is at the pressure developed by the heart. The magnitude of the drop of blood pressure in the systemic circuit is known in only a few species, but in general ranks as being moderately large; the difference between arterial pressure and infrabranchial-sinus pressure is 1.3–2 kPa (10–15 mm Hg) in spiny lobsters (*Panulirus*) and about 1 kPa (6–7 mm Hg) in American lobsters (*Homarus*). The gill circulation typically poses a low resistance and requires only a very small pressure difference to be perfused (about 0.2 kPa [1–2 mm Hg]).

Open systems are functionally different from closed systems but may be equal in critical ways

In animals with open circulatory systems, the pressures in the blood spaces are often affected substantially by body movements—a phenomenon that must be considered for the function of these systems to be analyzed. When body movements create pressure differences from one part of an animal’s body to another, they aid blood flow; in American lobsters, for example, flexion of the abdomen—an important swimming movement (see page 161)—raises pressures in the abdomen above those in the thorax and can cause

²⁸ A small fraction of the blood returning to the heart bypasses the gills by flowing through the tissue lining the gill chambers. This circulatory path is greatly elaborated in air-breathing crabs that use the lining of the gill chambers as a breathing surface.

BOX 25.3 CIRCULATION AND O₂: LESSONS FROM THE INSECT WORLD

Like all arthropods, insects have an open circulatory system. A dorsal vessel that runs along most of the body is divisible—often indistinctly—into a posterior heart (usually restricted to the abdomen) and an anterior dorsal aorta that runs forward into the thorax and head, as shown in the figure. The heart has ostia and refills much as a crustacean heart does. It contracts in a peristaltic wave, forcing blood into the dorsal aorta, which often continues the peristaltic wave of contraction. The dorsal aorta is the only blood vessel in many species of insects. In others, segmentally arranged lateral arteries branch off from the dorsal vessel. The major blood vessels in either case end abruptly with little branching, discharging blood directly to the lacunar circulation. The blood-vessel system is far less extensive than that in decapod crustaceans, and there are no capillary beds.

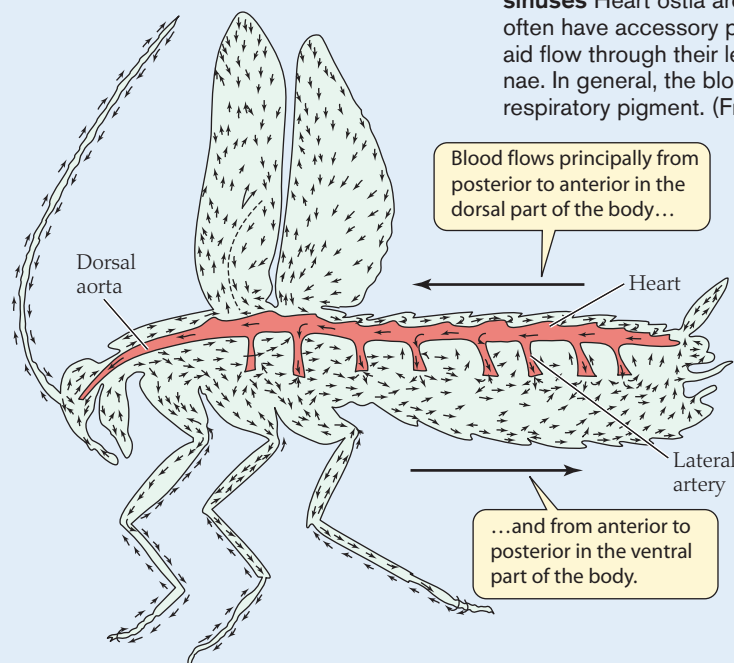

The modest development of the circulatory system in insects seems paradoxical at first. Many insects are very active animals with high O₂ demands; during sustained flight, some insects attain weight-specific rates of O₂ consumption that not only are many times higher than any reported for crustaceans, but are among the highest in the entire animal kingdom. In phyla other than the arthropods (most notably chordates and molluscs), groups with a capacity for relatively intense aerobic catabolism show unambiguous circulatory refinements in comparison with related groups with a lower capacity for aerobic catabolism: Mammals have far faster rates of blood flow than fish, for example. The circulatory system of insects, however, is not more advanced

than that of crustaceans or other arthropods, despite the extraordinary metabolic intensity of many insects.

The paradox of the modest circulatory system of insects finds its likely answer in the tracheal breathing system. Recall that O₂ is brought to all the cells of an insect by a system of gas-filled tracheal tubes that functions *independently* of the circulatory system (see Figure 23.29). The insects have a lesson to teach: *Namely, the circulatory system can remain quite simple in even highly active animals if it need not assume the burden of*

O₂ transport. The tasks the circulatory system must generally perform in insects (e.g., nutrient and hormone transport) are far less urgent than O₂ transport. Thus the insect circulatory system can be quite modest. The decapod crustaceans, in contrast, depend on their circulatory system to supply their tissues with O₂ at the rate required by their active ways of life. Thus the decapods require a relatively sophisticated version of the arthropod circulatory system.

Blood flow through the tissues of an insect is principally through lacunae and sinuses Heart ostia are not shown. Insects often have accessory pulsatile structures that aid flow through their legs, wings, and antennae. In general, the blood of insects lacks a respiratory pigment. (From Jones 1964.)

blood flow toward the thorax to speed up by a factor of ten or more. Body movements and changes in posture, however, also sometimes affect the *overall* level of pressure *throughout* the body; a change in posture, for instance, might compress all the blood spaces in the body and pressurize the blood everywhere. If pressure is changed to the same extent everywhere, blood flow is not immediately affected. Only *differences* in pressure cause flow.

When we speak of circulatory systems as being “high-pressure” or “low-pressure” systems, the *pressure gradient required to perfuse them*—not the overall pressure that exists everywhere—is the pertinent characteristic. If, for example, a pressure gradient of 0.5 kPa (4 mm Hg) is sufficient to drive blood through an animal’s circulatory system, the system is a “low-pressure” system. This remains true even if the animal is in a posture that pressurizes its whole body to a high level.²⁹

Open circulatory systems are typically low-pressure or moderate-pressure systems. In bivalve molluscs and nonpulmonate snails, arterial pressures typically exceed venous pressures by just 0.1–0.5 kPa (1–4 mm Hg) or even less. The pressure gradient in the spiny lobsters mentioned in the previous section (1.3–2 kPa, or 10–15 mm Hg) ranks with the highest known to occur with regularity in animals having open circulatory systems.

²⁹For instance, if the arterial pressure in a crustacean were 40 mm Hg and the infrabranchial-sinus pressure were 36 mm Hg, the circulatory system would rank as a “low-pressure” system, even though the two pressures are in themselves relatively high, because the pressure gradient required for perfusion would be just 4 mm Hg.

The relatively low pressure gradients in open circulatory systems have often been interpreted to mean that blood flow through open systems is sluggish. Low pressure gradients do not necessarily mean sluggish flow, however, because the rate of flow depends on resistance as well as pressure (see Equation 25.3). The first four rows of **Table 25.2** compare four critical functional attributes of the open circulatory systems in a lobster and crab with those of the closed circulatory systems of fish of similar body sizes. As the first row shows, all the species have *similar* rates of circulatory O₂ delivery under the conditions of study. The crustaceans (see the second row) circulate their blood *at least three times faster* than the fish, however. The crustaceans, that is, are the exact opposite of being sluggish! Although the crustaceans (third row) maintain *lower pressure gradients* than the fish, circulation is fast in the crustaceans because (fourth row) the *resistance to flow* through the crustacean circulatory systems is much lower than the resistance to flow in the fish.

Not all animals with open circulatory systems have high rates of blood flow. In the decapod crustaceans, however, the overall picture is that pressure gradients—although low—are adequate to circulate blood rapidly because the resistance to flow is low. Without a doubt, the resistance is low precisely because the circulatory systems of the crustaceans are open; blood flows through lacunae and sinuses during much of its travel, rather than through minutely narrow capillary vessels. Why do the crustaceans *need* their high blood-flow rates? One reason, certainly, is that their blood oxygen-carrying capacities are low (1–2 mL O₂/100 mL of blood, compared with

TABLE 25.2 Systemic circulatory function: Decapod crustaceans compared with fish

Characteristics of circulatory function	Spiny lobster	Rock crab	Starry flounder	Rainbow trout
Principal features of circulatory function				
Rate of O ₂ delivery to tissues (mL O ₂ /kg·min) ^a	0.80	0.60	0.46	0.65
Rate of blood flow through systemic circuit (mL blood/kg·min) ^b	128–148	125	39	18
Pressure change to perfuse systemic circuit (mm Hg) ^c	14	3	16	22
Systemic resistance (pressure change divided by flow rate) ^d	0.1	0.03	0.4	1.2
Secondary information				
Heart rate (beats/min)	65	101	35	63
Stroke volume (mL/kg·stroke)	2.1	1.2	1.2	0.3
Blood pressure in major systemic arteries (mm Hg) ^c	35	10	18	26
Blood pressure in major systemic veins or venous sinuses (mm Hg) ^c	21	7	2	4
Blood oxygen-carrying capacity (mL O ₂ /100 mL blood)	2.0	1.3	5.7	7.8
Temperature during studies (°C)	16	12–16	8–11	9–15
Body weight (g)	515	~370	684	~210

Source: Hill and Wyse 1989; based on a compilation of data from several sources. Species included are *Panulirus interruptus* (spiny lobster), *Cancer productus* (rock crab), *Platichthys stellatus* (starry flounder), and *Oncorhynchus mykiss* (rainbow trout). The rock crab periodically ceases heart action; after heart action resumes, the crab’s rate of O₂ consumption, cardiac output, and stroke volume gradually fall. Values given for the rock crab are averages measured 5 min or more after a cardiac pause.

^aMeasured as the animals’ rates of O₂ consumption.

^bEquals cardiac output in steady state.

^cPressure change is the difference between blood pressures in arteries and in veins (or venous sinuses); both of these pressures are listed in the “secondary information” below. The arterial pressures were measured in systemic arteries, except for the crab pressure, which was measured as systolic ventricular pressure and thus probably overestimates arterial pressure. The venous pressures were measured in the systemic veins of the fish and in the infrabranchial sinus of the crustaceans.

^dThe values of systemic resistance are in units of mm Hg·kg·min/mL blood.

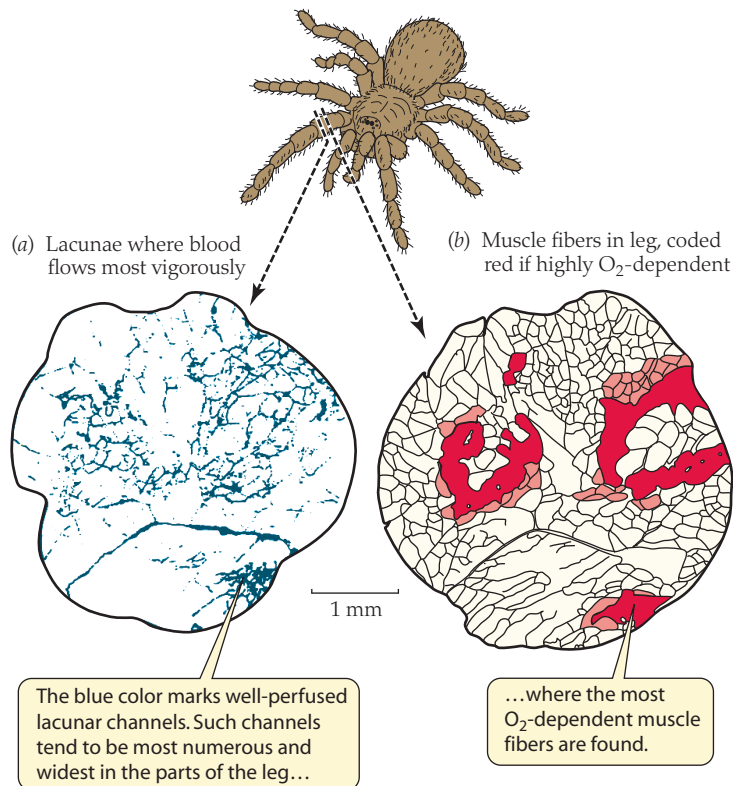

FIGURE 25.25 The microanatomy of blood flow in a lacunar system: Blood flows most vigorously where it is needed most. Adjacent cross sections of a tarantula's leg are shown. The tissue seen inside the cross sections is mostly muscle, that is, the tissue of the walking muscles. (a) Locations where blood flows particularly vigorously in the lacunar networks of the muscles. In this cross section, hemocyanin was stained immunohistochemically using monoclonal antibodies (antibodies specific to hemocyanin). The stain was then visualized. (b) Locations of muscle fibers that are particularly O_2 -dependent. In this cross section, fibers were assessed using their profiles of catabolic enzymes (similar to Figure 8.13). The fibers colored dark red are the most poised to produce ATP aerobically and are the most O_2 -dependent. Those colored light red are also aerobically poised, but less so. (From Paul et al. 1994.)

6–8 mL O_2 /100 mL in fish), meaning that each unit of volume of blood they circulate is limited in the O_2 it can deliver.

Inevitably, the question arises of whether open or closed circulatory systems are “better.” Data such as those in Table 25.2 suggest that the systems are “different but equal” in key respects—at least when sophisticated crustaceans are compared with fish. The greatest void that remains in physiological knowledge of open circulatory systems is the question of how well the flow of blood can be directed and controlled. Physiologists have tended to assume that little direction or control is possible in open systems. Increasing evidence exists, however, that open circulatory systems can direct blood flow far more exactly than physiologists have assumed—by using cardioarterial valves or other (mostly unknown) mechanisms. The novel study in Figure 25.25, for example, shows that in the leg muscles of a spider, *lacunar* blood flow tends to be most vigorous near the particular sets of muscle cells that are most O_2 -dependent. Closed circulatory systems are justly touted for their ability to exert fine spatial and temporal control over blood flow. Although open systems seem unlikely to be the equal of closed systems in this respect, the difference between the two is probably smaller than traditionally believed.

SUMMARY Invertebrates with Open Circulatory Systems

- Most invertebrates have open circulatory systems in which blood leaves discrete vessels and flows through systems of lacunae and sinuses, where it comes into contact with ordinary tissue cells (accounting for the fact the blood is sometimes called hemolymph).
- Animals with open circulatory systems typically have a heart, and they may have extensive systems of blood vessels, even including capillary beds. The blood ultimately leaves the vessels, however.
- Open circulatory systems tend to be characterized by relatively small changes of blood pressure across the systemic circuit compared with those in closed circulatory systems. Resistance is low in open systems because blood is not forced through capillary beds in most or all tissues. Thus the rate of blood flow may be high despite the small pressure changes.
- Little is known about the spatial and temporal control of blood flow in animals having open circulatory systems. Some control is known to be possible, however (as by cardioarterial valves in crustaceans), and control is probably more sophisticated than generally assumed in the past.

Study Questions

1. Imagine that the digestion of a meal has just provided a new supply of glucose and amino acids in your midgut (small intestine). Then imagine all the steps that will take place as your body uses the glucose and amino acids and disposes of the waste products that are produced. List all the individual and specific functions your circulatory system will perform during this sequence of events. Arrange your list in the correct temporal order.
2. A current working hypothesis is that diseases characterized by incurable weakness and lethargy may sometimes arise in part from loss of blood capillaries. Basing your answer on the laws of diffusion, explain how transport to and from a tissue would be affected if 20% of its capillaries were lost.
3. Thomas Kuhn, a great historian of science, said that “big ideas” in science are not discovered at fixed moments in history, but are discovered over extended periods of time by multiple scientists. We often hear it said that William Harvey “discovered the circulation of the blood.” Kuhn would say that this is not true. He would say that when we speak of today’s meaning of the “circulation of the blood,” the concept of “circulation” required centuries to be discovered. Pretend you are Kuhn, and argue for his points of view. Then, speaking for yourself, explain why you agree or disagree with Kuhn.
4. Figure 25.12b shows mean blood pressures at the entrances and exits of the large arteries, the terminal arteries, the arterioles, and the capillaries in the systemic circuit of a human at rest. Using those pressures and assuming a cardiac output of 6 L/min, calculate the collective vascular resistance of the large arteries, the terminal arteries, the arterioles, and the capillaries.
5. Looking ahead to Chapter 29, the process that initiates urine formation in most types of vertebrates is ultrafiltration of fluid from the blood plasma into kidney tubules under the force of blood pressure. What properties of the blood plasma in the urine-forming structures of the kidney are likely to affect the *rate* of ultrafiltration into the kidney tubules? Why is failure of urine production a potential side effect of heart disease?

6. During exercise—as compared with rest—what are the aspects of blood O₂ transport that can be modified to increase O₂ delivery to the exercising muscles? Based on the information discussed in this chapter, how do squids differ from vertebrates in the specific ways in which they increase O₂ delivery?
7. List the major types of blood vessels in the systemic circuit of a mammal, and outline the *functions* of each type of vessel.
8. What are the pros and cons of closed and open circulatory systems? Consider not only the types of information in Table 25.2 but also the other relevant information discussed in this chapter.
9. Mechanistically, why is pulmonary edema a threat to life? Thinking as creatively as possible, list three distinctly different potential causes of pulmonary edema.
10. Many objects designed by engineers have “circulatory systems” of one type or another. Describe at least three or four examples. Why do engineers sometimes include systems of flowing fluids in objects they design? We often hear it said that animal systems can teach us how to design engineered systems. If you were a biologist teaching a group of engineers about the lessons of animal circulatory systems, what principles would you emphasize?

Oxygen, Carbon Dioxide, and Internal Transport *at Work:* Diving by Marine Mammals

The Weddell seal (*Leptonychotes weddellii*) captures all its food under water, yet depends entirely on the atmosphere for oxygen. It seems, when first considered, to be one of the most physiologically improbable creatures one could imagine. Not only is it incapable of breathing where it hunts, it is large (400–500 kg), homeothermic, entirely predatory, and confronted by cold throughout its life. A Weddell seal lives through all seasons in the frigid Antarctic, either hauled out on ice sheets or diving in seawater at -2°C to capture fish, crustaceans, and squids. Despite the seeming improbability of such animals, they are ecologically successful. Early Antarctic explorers, such as the Scottish sea captain James Weddell, brought home news of stupendous populations of diving mammals. Weddell seals today number near 1 million.

Worldwide, there are more than 80 species of whales and dolphins, plus more than 30 species of seals and sea lions. They are descended from terrestrial ancestors, probably lured to the sea by a bounty of food. As they evolved methods of feeding on the ocean's riches, however, marine mammals did not evolve ways of gleaning O_2 from the sea, and thus they remain tied to their ancestors' mode of breathing.

Modern technology is enabling us to realize more fully than ever the enormous role of diving in the lives of these animals. **Figure 26.1**, for example, shows the dives of three seal species along a relatively short stretch of coastline in Antarctica. Each vertical yellow trace represents a dive. The seals dive often as they travel horizontally from place to place.

Diving by marine mammals first came under serious study by physiologists around 1935. From the beginning, physiological studies have focused on two basic questions: First, how do animals that are strictly dependent on the atmosphere for O_2 meet their metabolic energy demands during long periods under water? Second, how do diving mammals cope with the high pressures they encounter at depth? This chapter focuses on the first question, but considers the second briefly at the end. The individual development of diving competence, as animals mature from weaning to full adulthood, is a critical topic in the study of diving: As a youngster matures, it must acquire sufficient food at each stage of its life even though its development of full diving competence may require many months. We discussed an example of the development of diving in Chapter 4. Here our focus will be on adults.

Diving Feats and Behavior

The diving feats of seals and whales have been appreciated in a limited way for centuries. During the heroic era of whaling (chronicled most famously in Herman Melville's *Moby-Dick*), for example, the whalers were amazed by the depths to which wounded whales could dive. Sometimes a sperm whale had to be cut loose after "sounding" so deep as to draw out two lengths of harpoon line, each more than 370 m long. When physiological research on animal diving began, few techniques existed for the study of free-ranging animals in the wild, and thus the first investigations were mostly carried out in bathtubs

Weddell seals These large seals are found only in Antarctica, where they collect all their food by diving. Weddell seals (*Leptonychotes weddellii*) often cut and maintain holes through ice sheets so as to be able to access their dual habitats: water for feeding and air for breathing.

FIGURE 26.1 Natural dives of three seal species in the wild

The image is a three-dimensional representation of diving and surface movement by seals in Antarctica. Each dive (regardless of species) is represented by a vertical yellow path, the length of which represents dive depth. The lines at the water surface are the movement tracks of individual seals, color-coded to designate species: yellow, southern elephant seal (*Mirounga leonina*); green, Weddell seal (*Leptonychotes weddellii*); red, crabeater seal (*Lobodon carcinophagus*). Insight into depth is provided by recognizing that the average depth of elephant seal dives was 360 m. Because crabeater seals predominantly eat krill swarming in the upper 100 m of water, they do not dive to particularly great depths in comparison with Weddell and elephant seals, which seek fish and squid. (Courtesy of Daniel Costa.)

and swimming pools. By 1970, however, innovative scientists were starting to take advantage of the revolution in technology to monitor the diving behavior of free-living animals. They discovered that fact is indeed sometimes stranger than fiction. There are mammals that sometimes electively stay under water—holding their breath—for 2 h, and there are ones that go so deep that they leave the atmosphere—their source of O_2 —more than a mile behind.

The Weddell seal proved to be a perfect subject for early studies of diving behavior in the wild because the only devices initially available to obtain data on the durations and depths of dives were innovative but primitive instruments that—after being attached to an animal for a recording period—had to be reclaimed for the data to be acquired. Weddell seals living on ice sheets gain access to the water for feeding by cutting and maintaining holes through the ice. After a seal dives through an ice hole, it must ultimately return to that or another hole to breathe. Gerald Kooyman and his colleagues capitalized on this trait. They would attach a data recorder to a wild Weddell seal and then permit the seal to live in its ordinary way for several days, whereupon they would find the seal at one of its breathing holes to remove the device. Using this approach, they were able—for the first time with any species—to describe the durations and depths of thousands of voluntary dives.

The most fantastic revelation of the early studies was that Weddell seals sometimes stay submerged voluntarily for more than 1 h (Figure 26.2); we know today that their dives occasionally last as long as 80 min! Equally important, however, was the revelation that the vast

FIGURE 26.2 Durations of dives by wild Weddell seals These data represent more than 1000 dives by six free-living seals. Each vertical bar shows the percentage of dives falling within a particular duration category. Most dives are far shorter than the maximum duration displayed by the species. (After Kooyman et al. 1980.)

majority of dives by Weddell seals are considerably shorter than the maximum durations observed; most dives last 20–25 min or less. The pattern of diving depths resembles that of diving durations in that, during most dives, seals go to depths that are considerably shallower than the maximum the species is capable of reaching (Figure 26.3). On rare occasions, a Weddell seal descends to nearly 600 m (0.37 mile), but few dives are deeper than 400 m. While diving, a seal is sometimes subject to stupendous physical pressures. A useful rule of thumb is that water pressure increases by about 1 atmosphere (atm) (101 kPa) for every 10 m of depth. Thus a seal diving to 400 m voluntarily subjects itself to about 40 atm of hydrostatic pressure.

Today, technology has advanced to the point that data can be radioed from free-living marine mammals and picked up on a global scale by satellite receivers. One dramatic study using this

FIGURE 26.3 Depths of dives by wild Weddell seals These data represent more than 380 dives by 27 free-living individuals. Each vertical bar shows the percentage of dives falling within a particular depth category. Most dives are substantially shallower than the maximum depth displayed by the species. (After Kooyman 1966.)

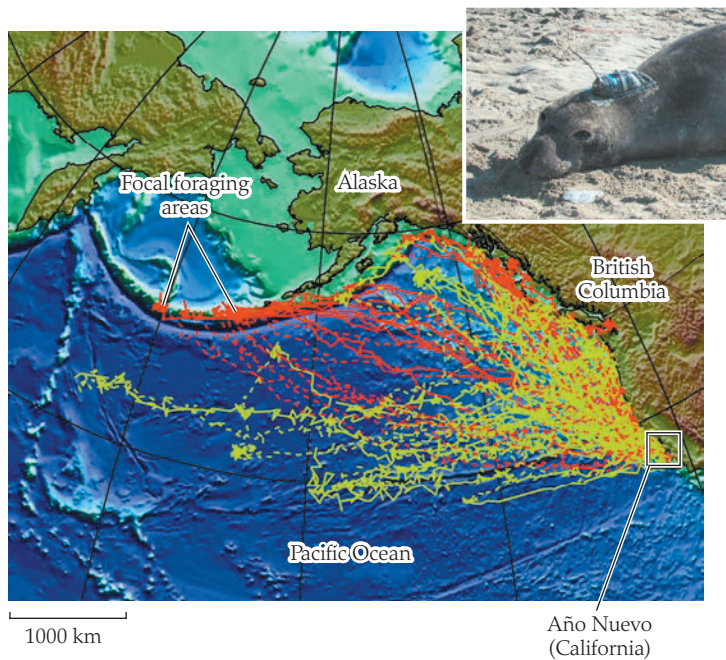

FIGURE 26.4 Migrations of northern elephant seals The elephant seals (*Mirounga angustirostris*) that breed at Año Nuevo in California get their food at distant places in the Pacific Ocean. Shown here are the migration routes of more than 30 animals from the Año Nuevo rookery. They were equipped with radio transmitters that signaled their location (see inset) and followed by satellite. The “focal foraging area” of an animal, which usually looks like a tight cluster of data in these records, is the part of the ocean where the seal lingered for many weeks of diving and feeding after its outward journey. When animals leave Año Nuevo, they tend to travel without pause to their focal foraging areas. During successive migratory trips away from Año Nuevo, individuals often return to their specific focal foraging areas using much the same outbound and inbound travel routes on each trip. Red represents males; yellow-green, females. (Courtesy of Dan Costa; after Le Boeuf et al. 2000.)

technology was carried out on the northern elephant seals (*Mirounga angustirostris*) that breed in a famous colony at Año Nuevo in California, south of San Francisco. Both sexes spend most of their lives at sea. They visit land on two occasions each year to mate, molt, and (in the case of females) rear young. Between these visits to land, the seals undertake long oceanic migrations, often across half the breadth of the Pacific Ocean, during which they feed intensively. The longitudes and latitudes of individual animals can be followed throughout their migrations using radio and satellite technology (Figure 26.4). For monitoring diving depths and durations, instruments that log the data rather than transmit them are still sometimes used. Modern digital data loggers, however, have prodigious capabilities compared with the original data loggers. Therefore, a data logger attached to a seal at the start of its migratory trip can record all the animal’s dives throughout its entire migratory trip, and the diving data can later be correlated with the seal’s satellite-recorded longitudes and latitudes. Figure 26.5 shows the depths of all the dives undertaken by a male northern elephant seal called Moo while in transit between Año Nuevo and his principal foraging area near the Aleutian Islands. Moo’s deepest dive was to about 750 m (0.47 mile). Another northern elephant seal was once observed to dive to almost 1600 m (essentially 1 mile). Most dives by northern elephant seals, however, are to depths far less than these maxima, as exemplified by Moo’s diving record (see Figure 26.5).

The marine mammals are far from uniform in their diving capabilities. The major groups—the true seals, the fur seals, and

the whales—have different phylogenetic histories, and within each group, species have diversified. Weddell seals, elephant seals, and ribbon seals—all true (phocid) seals—are among the most proficient divers. One of the longest voluntary dives ever recorded, 2 h, was observed in a southern elephant seal. Elephant seals also attain astounding depths; a male southern elephant seal was recorded recently to dive to over 2000 m (1.2 miles) on more than 160 different occasions, reaching a maximum depth of 2150 m (1.33 miles)—probably the deepest dive ever observed. Sperm whales and certain of the beaked whales also rank with the most proficient divers. Dives to 1900–2000 m have been recorded in sperm whales (*Physeter macrocephalus*) and Cuvier’s beaked whales (*Ziphius cavirostris*). Sperm whales dive routinely for 40–50 min and occasionally dive for longer than 2 h. The opposite end of the spectrum of diving proficiency is exemplified by certain of the fur seals, such as northern fur seals (*Callorhinus ursinus*).¹ Based on records of more than 3000 dives, northern fur seals do not dive longer than 8 min or deeper than 260 m. Despite wide variation in the extreme dives of which species are capable, all species of diving mammals (and birds) seem to adhere to the two important generalizations that we have already illustrated: (1) The durations of most dives are substantially shorter than the maximum duration of which each species is capable, and (2) most dives are to depths substantially more shallow than the species-specific maximum depth. Dives of record duration and

¹The fur seals and sea lions—which compose the group known as otariid seals—tend as a group to be less proficient divers than the true (phocid) seals.

FIGURE 26.5 Diving by Moo, a male northern elephant seal, during his migration The maximum depth reached by Moo during each of his dives is plotted against the time of day of the dive. Each symbol represents a single dive. This plot includes all dives that Moo undertook during several weeks while he was in transit between Año Nuevo and his focal foraging area in Alaskan waters. Even though Moo had to pay the metabolic cost of swimming 6500 km (round trip) during this migration, he increased his body weight from 1270 to 1650 kg by diving for food. Moo’s dives were recorded by a time–depth logger with prodigious memory that was attached to him before his departure from Año Nuevo and recovered after his return. (After Le Boeuf et al. 2000.)

depth, although they are awe inspiring and require physiological explanation, are uncommon.

To put the performances of marine mammals into perspective, it is instructive to look at the capabilities of a representative terrestrial mammal, *Homo sapiens*. Trained human breath-hold divers are generally limited to about 3 min of submergence when at rest and about 90 s when swimming. The *ama* of Korea and Japan earn their living by diving for shellfish and edible seaweeds. Their abilities are typical of those exhibited by other people (e.g., pearl and sponge divers) who employ breath-hold diving as a career. The *ama* who dive in deep waters receive assistance during descent and ascent so that their time at the bottom can be maximized. They carry weights to aid descent and are pulled back to the water's surface on a rope by an assistant in a boat. They routinely remain submerged for 60–80 s and reach depths of 15–25 m. They rest only about 1 min between dives and thus average about 30 dives per hour. The extremes recorded for human performance during breath-hold diving are attained by competitive divers and are difficult to summarize because several distinct types of competitive diving exist and have their own rules. When assistance can be employed in both descent and ascent, depths of about 210 m in dives lasting more than 4 min are achieved. Dives of this depth and duration can be carried out only by exceptional people and are dangerous even for them. However, such dives seem trivial and commonplace for average individuals of many species of marine mammals.

Types of Dives and the Importance of Method

An important theme throughout science—dramatized in the study of diving physiology—is that the methods employed in experiments often affect the results and, therefore, our perception of reality. During the first decades of the modern study of diving physiology (roughly 1935–1970), scientists believed that they should “bring diving into the laboratory” where they could establish experimental controls and employ sophisticated instrumentation. In the lab studies that were carried out, animals were often strapped to a movable platform and lowered under water whenever an investigator wished to elicit diving responses. By the 1960s, research of this sort had produced such a seemingly complete picture of diving physiology that most biologists believed that diving was a “solved problem.” Then some radical investigators began to study animals such as Weddell seals in the wild. The methods they had available to use were initially primitive compared with those available in the lab. Nonetheless, their early studies showed that the physiology of *voluntary* diving in the wild often differs from that of *forced* diving in the lab. Perceptions thus changed. The initial view had been that diving physiology shows little variation from one dive to another because it is controlled by highly stereotyped physiological reflexes. The newer view—now abundantly confirmed—was that marine mammals use a spectrum of physiological strategies during different sorts of dives. Today, even as advances in technology have greatly expanded the range of physiological mechanisms that can be studied in the wild, lab studies continue to play a role because certain mechanisms can be studied only in the lab even now.

Recognizing that lab and field studies of diving may produce different results, one of the first questions to ask about any set of

data is whether it was obtained by forcing animals under water or by studying free-living animals diving voluntarily. Another important question is whether the dives studied were long or short *relative to the species-specific maximum dive length*, because we know now that qualitatively different suites of responses are often marshaled in long and in short dives. Still another key question is whether the studied animals were active or quiet during diving. These, then, are some of the important organizing distinctions among dives in the study of diving physiology:

- Forced or voluntary?
- Short or long (relative to the maximum length for the species)?
- Quiet or active?

Physiology: The Big Picture

When diving mammals break contact with the atmosphere, they carry O₂ with them in three major internal stores: O₂ bound to blood hemoglobin, O₂ bound to muscle myoglobin, and O₂ contained in air in their lungs. These stores permit aerobic catabolism to continue to some extent during a dive. The internal stores of O₂ are adequate in principle to permit all the tissues of a diver's body to function aerobically throughout a relatively short dive. When we look at the physiology of actual dives, we find, in fact, that voluntary dives of relatively short duration are mostly or completely aerobic in a variety of diving species, according to available evidence.

However, internal O₂ stores are utterly inadequate to permit fully aerobic function throughout a diver's body during protracted dives. How, then, are some species able to survive for 30 min, 60 min, or even longer without breathing? Our basic concept of how energy needs are met during protracted dives was first proposed by Laurence Irving (1895–1979) in 1934. He recognized that certain tissues—notably the central nervous system and heart—are predominantly or exclusively dependent on aerobic catabolism for production of ATP; they need O₂ on a steady basis and are quickly damaged by O₂ insufficiency. However, other tissues—such as skeletal muscle—have a well-developed ability to meet their ATP demands anaerobically and thus are relatively tolerant of O₂ deprivation. Irving then reasoned that dives can be prolonged if animals “reserve” a portion of their O₂ supplies for the tissues that are O₂-dependent. During a dive, if all tissues have equal access to an animal's entire O₂ store, then the concentration of O₂ throughout the body will fall quickly to such a low level that the O₂-dependent tissues are impaired. Under such circumstances, a seal or whale will need to surface, even though many of its tissues could continue to function—anaerobically—for a longer time. However, if some O₂ is reserved for use by the O₂-dependent tissues during a dive, then those tissues can continue to have adequate O₂ even while other parts of the body exhaust their O₂ supplies and turn to anaerobic catabolism, thereby extending the time the animal can remain submerged.

The preferential delivery of some O₂ to the O₂-dependent tissues is achieved, as Irving predicted, by adjustments of circulatory function. These adjustments were first elucidated by Irving, working with Per Scholander (1905–1980), in lab experiments on seals forced under water. During forced dives, blood flow is curtailed to many body regions—such as the skeletal muscles of the appendages and

trunk, the skin, the gut, and the kidneys—by vasoconstriction of the arterial vessels that supply those regions. The tissues that are deprived of active blood flow can make use of the hemoglobin-bound O_2 in the small volume of blood that passes through their capillaries, and they can use their myoglobin-bound O_2 . However, as those limited and local O_2 stores are depleted, the circulation-deprived tissues turn to anaerobic catabolism, and lactic acid accumulates in them. *With the circulation to many parts of the body curtailed, the heart pumps blood primarily between itself and the lungs and head.* The O_2 stores of the circulating blood are thereby reserved primarily for the O_2 -dependent tissues—the brain and heart—and whatever O_2 is extracted from the air in the lungs is likewise delivered preferentially to those tissues. Consequently, adequate O_2 partial pressures can be maintained in the O_2 -dependent tissues for a long period. Lactic acid produced by the skeletal muscles and other circulation-deprived tissues tends to remain sequestered in those tissues during a dive, precisely because the tissues receive little or no blood flow. When the animal surfaces, however, circulation to such tissues is restored, and there is a sudden rise of lactic acid in the circulating blood. *The observation that circulating lactic acid increases principally after a forced dive was one of the earliest pieces of evidence that circulatory function is sometimes radically altered during diving.*

When animals are forcibly submerged, the adjustments in the pattern of blood flow just described tend to occur rapidly, consistently, and to a profound extent. Accordingly, during the era prior to 1970, when diving was studied mainly in labs, these responses were labeled a *diving reflex*. Today, however, based on studies of voluntarily diving animals, physiologists recognize that the responses of the circulatory system are not nearly as inflexible and stereotyped as once thought. Indeed, as suggested earlier, relatively little redistribution of blood flow is believed now to occur during voluntary dives that are short enough for all energy needs to be met by aerobic catabolism using an animal's O_2 stores. Seals and whales in the wild undergo a profound redistribution of blood flow when they dive voluntarily for long periods. Animals that are forced under water probably exhibit stereotypic and “reflexive” circulatory responses because they sense that they have no control over the length of time they will be submerged, and thus they consistently marshal the responses they employ for prolonged diving in the wild.

From this overview, you can see that the O_2 stores, circulatory physiology, and metabolic physiology of marine mammals all play critical roles in their diving physiology. The next three sections discuss these three elements in more detail.

The Oxygen Stores of Divers

The size of a diving mammal's total O_2 store is obviously a key determinant of how long the animal can stay submerged. Among other things, a dive can last only as long as the brain is supplied with O_2 , and the size of the O_2 store helps determine how long the supply of O_2 to the brain can be sustained.

The blood O_2 store tends to be large in diving mammals

The amount of O_2 stored in the blood depends on three features: (1) the oxygen-carrying capacity of the blood, (2) the total volume of blood, and (3) the degree to which the blood is fully loaded (saturated) with O_2 at the time of submergence.

Regarding the oxygen-carrying capacity, although some species of diving mammals have values that are well within the ordinary range for nondiving, terrestrial mammals, some other diving species have exceptionally high values. Bottlenose dolphins, northern fur seals, and Steller (northern) sea lions illustrate the first group; they have oxygen-carrying capacities of 17–22 vol %²—quite ordinary for mammals. In contrast, species of diving mammals known to have especially high oxygen-carrying capacities include the harbor seal (26–29 vol %), sperm whale (31 vol %), Weddell seal (29–36 vol %), and ribbon seal (34 vol %). Among the seals as a group, there is a trend for species that undergo long dives—such as the three true seals just mentioned—to have higher oxygen-carrying capacities than species that perform shorter dives.

Blood volumes in some representative terrestrial species—humans, dogs, horses, and rabbits—average 60–110 mL per kilogram of body weight. Although some diving species have blood volumes in the same range, some of the accomplished divers such as harbor and ribbon seals have blood volumes of 130–140 mL/kg, and the blood volumes of Weddell seals, elephant seals, and sperm whales are 200–250 mL/kg—two to three times as high as is typical of terrestrial mammals.

An animal's maximum possible blood store of O_2 is calculated by multiplying the oxygen-carrying capacity of its blood by its blood volume. This figure, while only indirectly relevant to normal physiology (because the entire volume of blood is never fully oxygenated), is useful for comparing species. The maximum possible blood O_2 store of humans and horses is about 14–15 mL O_2 per kilogram of body weight. In contrast, far higher O_2 storage capacities are found in the species of diving mammals that combine the advantages of both a high oxygen-carrying capacity and a high blood volume. The maximum blood O_2 store in Weddell seals, elephant seals, and sperm whales is 60–85 mL O_2 /kg—four to six times higher than the stores of humans and horses.

Diving mammals have high myoglobin concentrations and large myoglobin-bound O_2 stores

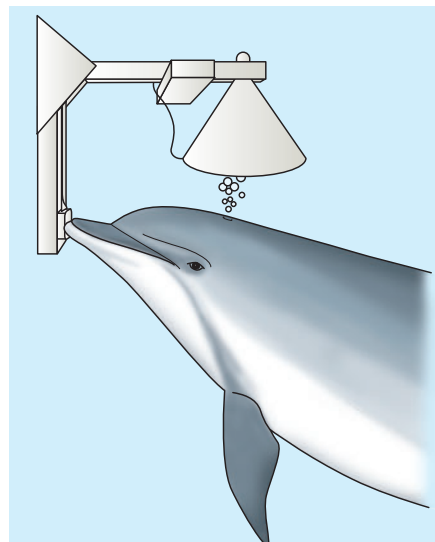

The amount of O_2 stored as oxymyoglobin at the time of submergence depends on how much myoglobin is present in each unit of muscle tissue. *One of the most consistent features of diving species of mammals is that, relative to terrestrial species, they have dramatically high myoglobin concentrations in their skeletal muscles.* The skeletal muscles of some proficient divers are so rich in myoglobin that they are almost black. In humans and horses, skeletal muscles contain about 4–9 mg of myoglobin per gram of wet weight. By contrast, sperm whales and harbor, Weddell, elephant, and ribbon seals have 55–70 mg of myoglobin per gram of wet weight!

Oxymyoglobin represents an essentially private store of O_2 for the muscles. As discussed in Chapter 24 (see page 636), myoglobin has such a high affinity for O_2 that it typically draws O_2 from blood hemoglobin rather than donating O_2 to the blood. Thus, even if muscles receive blood circulation during a dive, oxymyoglobin within the muscles does not yield much O_2 to the blood for use elsewhere in the body. Instead, the O_2 remains bound to the myoglobin until the O_2 partial pressure in the muscles falls to a low level; then it is donated to the muscle mitochondria to permit continued aerobic

²As applied to blood (see Chapter 24), O_2 vol % is the amount of O_2 —expressed as volume in mL at standard conditions of temperature and pressure—that is present per 100 mL of blood (including O_2 present both in combination with hemoglobin and in solution).

(a) A bottlenose dolphin observed at two depths

(1) Near the surface

(2) At a depth of 300 m

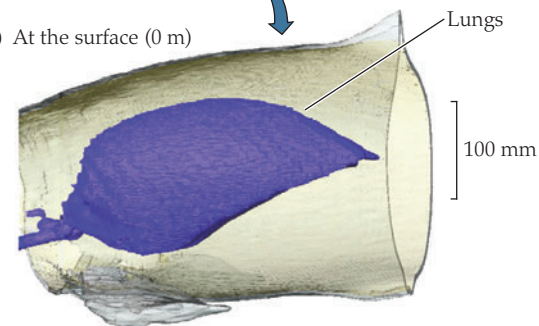

A dolphin's flexible thoracic wall is pushed inward by the high water pressure at depth, reducing the volume of the thoracic cavity and the volume of air in the lungs.

(b) Lungs of a harbor porpoise visualized by computed tomography at two depths

(1) At the surface (0 m)

(2) At depth of 100 m

FIGURE 26.6 Because the thorax is highly compressible in marine mammals, lung volume decreases dramatically as ambient pressure increases (a) Portrayed here is a bottlenose dolphin (*Tursiops truncatus*) that was trained to push a button to signal its presence as it traveled between the surface of the water and a depth of 300 m. When it exhaled near the surface of the water (1), its exhalant air was collected for analysis. When it pushed the button at 300 m (2), a camera was activated to take its photograph. The ambient pressure at 300 m was about 30 atm. The photographs of the dolphin at that depth revealed that its thoracic wall was pushed far inward by the elevated ambient pressure. (b) The lungs inside the thorax of a harbor porpoise (*Phocoena phocoena*) at two different ambient pressures. Although the porpoise had died of an accident, it was freshly dead and undamaged. As the ambient water pressure was raised to simulate depths of 0 and 100 m, the porpoise's lungs were visualized using a CT (computed tomography) scanner, with scaling identical in both images. Note that *both* the thorax and lungs decreased in volume as ambient pressure increased. (a after Ridgway et al. 1969; b from Moore et al. 2011.)

ATP production in the muscles. An interesting point is that the O_2 partial pressure in a muscle *must* be low for the muscle's myoglobin to unload. One role of the severe reduction of blood flow to the skeletal muscles during prolonged dives is probably to ensure that the muscle O_2 partial pressure falls promptly to a level that will permit myoglobin to be tapped for O_2 .

Diving mammals vary in their use of the lungs as an O_2 store

To understand lung function in diving mammals, one must first recognize the unusual structural flexibility of the thorax in these animals. In the deep-diving marine mammals that have been studied, the thorax is structured in ways that permit the thoracic walls to be shoved freely inward as the outside water pressure increases (Figure 26.6a). Thus, over extensive ranges of depth and pressure, the *thoracic cavity and lungs are freely compressible* (Figure 26.6b). If the pressure applied to the thorax is increased tenfold, for example, the volume of air in the lungs is reduced to roughly one-tenth of what it previously was.³ Humans and other terrestrial mammals are different in that their thoracic walls are structured less flexibly and resist compression.

³Too few actual measurements are available to determine if lung volume responds to changes of outside pressure identically as would be predicted from a simple application of the universal gas law (see Equation 22.1).

One might at first think that a large air store in the lungs would be of unquestionable advantage for a diving mammal. Three considerations, however, argue against this conclusion. First, a large amount of air in the lungs can strongly buoy a diving animal upward, forcing it to work hard to remain submerged. Second, the alveoli are believed to be typically the first parts of the lungs to collapse as the lung air compresses at depth. Hence, at depth, the lung air comes to be contained mostly in the *conducting* airways—the trachea, bronchi, and nonrespiratory bronchioles—where the O_2 in the air becomes unavailable because little O_2 transfer to the blood can occur in the conducting airways. Thus, whereas diving mammals can make effective use of their pulmonary O_2 stores during shallow diving, they are not necessarily able to do so at depth. A final consideration is that a large pulmonary air store means not only a large store of O_2 in the lungs, but also a large store of N_2 (air is 78% N_2). A large N_2 store can increase the likelihood of decompression sickness, as discussed later in this chapter.

The size of the air store in a marine mammal's lungs at the start of a dive depends on two factors: the *volumetric capacity* of the lungs (the amount of air they can hold when fully inflated) and the degree to which the animal inflates its lungs before diving. Regarding the first factor, marine mammals do not as a rule have exceptionally large lungs; their volumetric capacities per unit of body weight are generally similar to those of terrestrial mammals, or just modestly larger. Moreover, many of the deep-diving seals and whales have volumetric capacities that are relatively low by comparison with

those of other species of seals or whales of similar size that dive more shallowly. Regarding the second factor—the degree of lung inflation—some marine mammals dive after a vigorous inhalation and thus may carry an amount of lung air that approaches their volumetric capacity. This appears to be true, for example, of whales (including dolphins). By contrast, many deep-diving species of true (phocid) seals dive following *exhalation*; their lungs are filled to just 20–60% of their volumetric capacity when they submerge. All things considered, little premium is placed on having an exceptionally large pulmonary air (and O_2) store in marine mammals.

Total O_2 stores never permit dives of maximum duration to be fully aerobic

Three major points emerge from the study of the O_2 stores of marine mammals:

1. Some species of diving mammals have much greater total O_2 stores per unit of body weight than terrestrial mammals because they have high blood oxygen-carrying capacities and high blood volumes—giving them high blood O_2 stores—and they have high concentrations of myoglobin in their muscles—giving them high myoglobin-bound O_2 stores (Figure 26.7).
2. Among diving mammals, species such as fur seals and sea lions that dive for relatively short periods tend to have smaller O_2 stores per unit of body weight than species such as harbor and ribbon seals that are more proficient as divers and dive for longer periods (see Figure 26.7).
3. The O_2 stores of marine mammals of all kinds are utterly inadequate to sustain a rate of O_2 consumption during long dives that is equivalent to the rate of O_2 consumption of these animals while they are at rest and breathing air.

The third point is sufficiently important to deserve illustration. Paul Ponganis and his colleagues estimated the total available O_2 store of a 450-kg Weddell seal to be 38.8 L.⁴ Such a seal has a resting rate of O_2 consumption, when it is breathing air, of 1.9–2.3 L O_2 /min. Thus the seal could sustain its resting, aerial rate of O_2 consumption for 17–20 min during diving if it completely used its available O_2 store. Actually, however, Weddell seals sometimes dive for 60–80 min (see Figure 26.2). This sort of result is typical of diving species; dives of maximum length always last from two to several times longer than would be predicted if an animal were to function aerobically at the rate seen during rest in air. Another way to see that O_2 stores are inadequate to account fully for diving performance is to recognize that the diving capabilities of long-duration divers are disproportionate to their O_2 stores. For example, consider harbor seals and humans, two species of roughly the same body size. Although the weight-specific O_2 stores of harbor seals are 2–2.5 times higher than those of humans (see Figure 26.7), an average seal can remain submerged for more than 12 times as long as an average human when diving under comparable conditions. Regardless of how large the O_2 stores of diving species may be, these stores do not in themselves explain the dive durations of which the animals are capable.

⁴To calculate this amount from Figure 26.7, multiply the size of the O_2 store per kilogram, 86 mL O_2 /kg, by the seal's body weight, 450 kg.

FIGURE 26.7 A comparison of the total O_2 stores of five species of marine mammals and humans. The total O_2 available per kilogram of body weight for each species is estimated by adding the O_2 dissolved in body fluids other than blood throughout the body, the O_2 bound to myoglobin in muscles, the O_2 in blood (mostly bound to hemoglobin), and the O_2 in lung air. The lungs of humans are assumed to be fully inflated, but those of the other species are assumed to be only half inflated because many seals dive after exhalation. The data for the fur seal, sea lion, harbor seal, and ribbon seal were calculated by one research team using a standardized set of procedures and assumptions (Lenfant et al. 1970); the data for the Weddell seal (Ponganis et al. 1993) and human, although comparable, are from other sources.

Circulatory Adjustments during Dives

The circulation holds a special place in the chronicles of diving physiology because the very first physiological observations on diving were measures of heart rates. Starting in 1870, the French physiologist Paul Bert (1833–1886) studied ducks and found that their heart rates decreased from 100 to 14 beats/min when he forced them under water. A decrease in heart rate during diving is called **diving bradycardia** (*brady*, “slow”). Bert and others soon demonstrated that the phenomenon is a consistent feature of forced submergence in diving mammals and birds. The universality of diving bradycardia quickly persuaded physiologists that the slowing of the heart is important in permitting animals to stay submerged for extended periods. But how is it important?

Irving and Scholander took the next crucial step. In the 1930s, they postulated that in addition to the heart, other parts of the

cardiovascular system also respond during diving. One of their earliest tests of their idea was to study bleeding from the paw skin of seals. Small cuts that bled freely when the seals were breathing air stopped bleeding suddenly and completely when the seals were pushed under water! From simple observations like this, the modern revolution in diving physiology began, and after seven decades of knowing of the existence of diving bradycardia, scientists began to understand its true significance.

Regional vasoconstriction: Much of a diving mammal's body is cut off from blood flow during forced or protracted dives

After physiologists realized that a marine mammal's pattern of blood flow might change during dives, they employed several techniques to examine how the vascular system functions during diving. One such technique involves the use of a *contrast fluid* that is impenetrable by X-rays. When a contrast fluid is injected into an animal's bloodstream, its flow can be observed on X-ray images. In one of the watershed studies in the history of diving physiology, a group of diagnostic radiologists headed by Klaus Bron injected a contrast fluid into the aorta of a harbor seal, then took X-ray images to observe subsequent blood flow in the seal's visceral arterial system while the animal was breathing air and while it was forcibly submerged (Figure 26.8).

When the seal was breathing air, an X-ray image taken 0.5 s after the injection of the contrast fluid showed that blood flowed vigorously from the aorta into abdominal arteries that branch off from the aorta, such as the coeliac and renal arteries (see Figure 26.8a). Within 2 s after injection, the left kidney was illuminated in the X-ray image, showing that the elaborate arterial system within the kidney had filled with blood that contained the contrast fluid (see Figure 26.8b). After only 6 s, the coeliac and renal arteries had already faded from view (see Figure 26.8c), demonstrating that the contrast fluid had flowed through them and exited.

The sequence of X-ray images taken while the seal was submerged revealed a strikingly different circulatory pattern. At 1 s after injection, the X-ray image showed that the blood containing the contrast fluid had penetrated only a short distance from the aorta into the coeliac and renal arteries and stopped, leaving the branches of those arteries unfilled (see Figure 26.8d; compare with Figure 26.8a). Even after 4 s, the left kidney remained dark, indicating that most of its arterial vessels had not received blood containing contrast fluid (see Figure 26.8e). As long as 14 s after injection, the bases of the coeliac and renal arteries remained filled with contrast fluid (see Figure 26.8f), indicating that the blood in those arteries had stagnated and was unable to flow through the vessels.

Bron's pioneering radiological study confirmed that blood flow to major parts of a marine mammal's body is profoundly curtailed during a forced dive. The coeliac and renal arteries supply blood to the stomach, spleen, liver, pancreas, and kidneys. During a dive, blood is unable to flow freely (if at all) into any of those visceral organs.

FIGURE 26.8 Circulatory patterns are radically changed during forced or prolonged submergence X-ray images of the visceral cavity of a harbor seal (*Phoca vitulina*), viewed from its ventral side, after injection of contrast fluid during air breathing (a–c) and during forced submergence (d–f). The images show that although the blood labeled with contrast fluid flowed into all major branches of the aorta within seconds during air breathing, the blood was unable to flow freely out of the aorta when the seal was submerged. 1 Contrast fluid was injected into the descending portion of the systemic aorta. Within 0.5 s after the contrast fluid was injected when the seal was breathing air, the coeliac artery 2 and left renal artery 3 were filled with blood containing contrast fluid; and within 2 s after injection, the entire left kidney 4 was filled with blood containing contrast fluid. When the seal was submerged, however, the coeliac artery 5 and renal artery 6 did not readily fill with blood containing contrast fluid, and after 4 s, the kidney 7 remained dark—showing that it had not received blood with contrast fluid. L2 = second lumbar vertebra; R = right side of seal. (Photographs courtesy of Klaus Bron; from Bron et al. 1966.)

FIGURE 26.9 The forcibly submerged seal as a “heart-lung-brain machine” With blood flow to much of the body curtailed by vasoconstriction, active circulation is principally from the right heart to the lungs, the lungs to the left heart, the left heart to the brain, and the brain back to the right heart.

Vasoconstriction—under control of the sympathetic nervous system—is responsible for cutting off the blood flow. Strikingly, although arterioles are the typical sites of vasomotor control in mammals (see page 659), pronounced vasoconstriction occurs in *sizable arteries* in at least some diving species. Arteries constrict shut, and the organs they supply are denied blood flow (see Figure 26.8d–f). The parts of a diving mammal’s body that receive little or no blood flow during forced dives commonly include the animal’s limbs, the skeletal muscles of the trunk of its body, its pectoral muscles, its skin and body wall, and many visceral organs as already discussed.

Simultaneously, because vasoconstriction occurs selectively, blood flows freely—or relatively freely—to a diving animal’s brain, lungs, and myocardium. A pundit once said that a seal becomes a “heart-lung-brain machine” during forced dives (Figure 26.9). Blood is pumped by the right heart to the lungs, travels from the lungs to the left heart, then is pumped by the left heart to the head, and finally returns to the right heart to be pumped again to the lungs. The rate of blood flow to the brain during diving tends to remain similar to the rate during air breathing. Meanwhile, as the blood travels round and round between heart and head, flow to the parts of the body posterior to the heart is cut off or severely restricted.

Diving bradycardia matches cardiac output to the circulatory task

After experiments had revealed that blood flow to many regions of a diving mammal’s body is curtailed during forced or protracted dives, diving bradycardia could at last be understood for what it is: a single part of an integrated, body-wide reorganization of cardiovascular function. During a forced or protracted dive, vasoconstriction greatly reduces the dimensions of the active circulatory system. Accordingly, less output of blood from the heart is required. An analogy is provided by a faucet that sends a flow of water to six hoses; if five of the hoses are pinched off, the faucet can maintain unaltered flow to the sixth hose with only a sixth of its preexisting output. Bradycardia is a mechanism that matches the heart’s output (the cardiac output) to the dimensions of the vascular system being perfused. In marine mammals, the stroke volume of the heart changes to only a modest extent, if at all, during diving, according to studies of several species. Thus cardiac output declines during a dive roughly in proportion to the decline in heart rate (see Equation 25.1).

Studies of blood pressure demonstrate in a particularly graphic way that the drop in cardiac output during a dive is matched to the reduction in the dimensions of the active circulatory system. As

discussed in Chapter 25 (see Equation 25.3), the systemic arterial blood pressure depends on two factors: the rate of cardiac pumping and the resistance to blood flow posed by the vascular system. A change in either factor without a compensatory adjustment in the other can severely disturb blood pressure. The vasoconstriction that occurs during a dive increases the overall resistance to blood flow posed by the vascular system. However, the blood pressure in the great systemic arteries remains unaltered or changes only modestly. These two facts demonstrate that cardiac output is reduced during dives in a highly integrated way that closely matches the increase in peripheral vascular resistance.

Cardiovascular responses are graded in freely diving animals

Cardiovascular function in free-living marine mammals undergoing voluntary dives has proved particularly challenging to study but is gradually becoming understood. Today, for example, methods exist to monitor the electrocardiogram continuously in unfettered animals at sea. From use of such methods, we know that the heart rates of freely diving mammals typically decrease in a *graded* manner as the animals increase the durations of their dives (Figure 26.10). During forced dives, heart rate responses are more of an “on–off” sort; the heart rate of a forcibly submerged harbor seal, for instance, drops to less than 10% of its pre-dive level within 10 s every time the animal is submerged. An important distinction between voluntary and forced dives, therefore, is the graded versus stereotyped nature of the heart rate response during the two sorts of dives.

Ideal methods still do not exist for studying vasoconstriction in freely diving animals. For two major reasons, however, scientists believe that the vasoconstrictor response is also graded during voluntary dives. First, as we have discussed, heart rate and vasoconstriction are believed to be integrated in a way that matches

FIGURE 26.10 Diving heart rate varies with dive duration in a graded manner in freely diving seals Grey seals (*Halichoerus grypus*) living freely in the ocean near Scotland were monitored using radio and sonic transmitters. When not diving, their average heart rate was 119 beats/min. During their voluntary dives, the seals always exhibited bradycardia, but they adjusted the degree of bradycardia depending on how long they spent under water. This graded bradycardia is in contrast to the stereotyped bradycardia of forcibly submerged seals, which typically exhibit a maximum or near-maximum drop in heart rate whenever forced under water. (After Thompson and Fedak 1993.)

cardiac output to the dimensions of the vascular system requiring blood flow. If this integrated response occurs consistently, then little vasoconstriction would occur in animals that exhibit just a small reduction of heart rate, and progressively greater vasoconstriction would develop as bradycardia becomes more profound. A second line of evidence that corroborates this view is provided by studies of systemic organ function. Although studies of organ function do not tell a completely consistent story, they often indicate that vasoconstriction is graded in voluntary dives. Urine formation by the kidneys, for instance, requires blood flow. Thus one can learn about blood flow to the kidneys during dives by use of chemical markers that permit measurement of urine formation. In free-living Weddell seals, urine formation seems to continue during relatively short dives (indicating continued blood flow) but seems to stop during long dives (indicating cessation of blood flow).

The current working hypothesis of most physiologists who study diving is that the entire suite of cardiovascular responses to

voluntary diving occurs in a graded manner. During protracted voluntary dives, free-living animals probably function much like forcibly submerged ones: They undergo profound vasoconstriction accompanied by a profound drop in heart rate, and large parts of the body are cut off from active blood flow. During relatively short voluntary dives, however, vasoconstriction is probably modest, so that only a small reduction in cardiac output is warranted, and most (or all) parts of the body continue to receive blood flow. When all parts of the body receive blood flow, all can share the blood O_2 . This means that a dive cannot be of extreme length, but it also means that the animal avoids the stresses of anaerobic catabolism (discussed in Chapter 8 and later in this chapter).

One must wonder how the elaborate cardiovascular responses seen in diving mammals evolved. These responses in fact seem to be specializations of phylogenetically ancient responses to asphyxic conditions, responses that occur widely in vertebrates (Box 26.1).

BOX 26.1 THE EVOLUTION OF VERTEBRATE CARDIAC AND VASCULAR RESPONSES TO ASPHYXIA

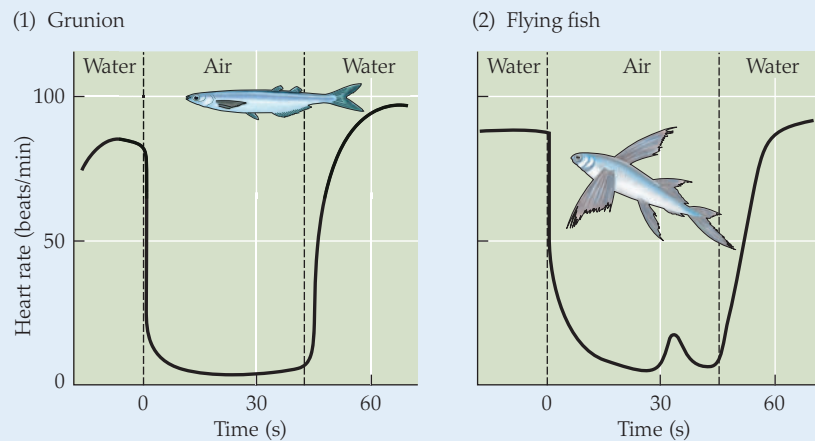

In the decades following Scholander and Irving's seminal discoveries regarding the diving physiology of marine mammals, Scholander and others sought to learn when the diving responses had originated in the evolution of vertebrates. They were intrigued to find similar responses in fish taken out of water! Two sorts of fish that they studied were flying fish and grunion, both of which breathe with gills but occasionally emerge into air voluntarily. Flying fish sometimes spend tens of seconds out of water as they skitter across the sea surface, and grunion sometimes spend minutes high on beaches where they slither out of the water to mate and lay eggs. The researchers found that both species exhibit profound bradycardia (as the figure shows), plus evidence of peripheral vasoconstriction, when they are out of water. The common denominator between diving marine mammals and these fish is that both are asphyxic (unable to breathe) when they undergo bradycardia and peripheral vasoconstriction. Scholander thus argued that bradycardia and peripheral vasoconstriction first evolved as defenses against asphyxia in the ancestors of modern fish. By now there is a large body of evidence indicating that bradycardia is a typical response of both cartilaginous and bony fish when they are exposed to O_2 -poor (hypoxic) water, reinforcing the view that bradycardia is an ancient response of vertebrates to O_2 insufficiency.

If, in fact, mammals inherited the rudiments of their cardiovascular responses to asphyxia from piscine ancestors, one would guess that those responses would be observed in many

kinds of mammals, not just diving ones. In fact, the species of mammals that habitually dive are not alone in undergoing bradycardia and peripheral vasoconstriction when they are unable to obtain O_2 by breathing. Scholander himself reported evidence for bradycardia and peripheral vasoconstriction in neonatal humans and other mammals when they pass through the birth canal, and he observed bradycardia in human pearl divers. Abundant evidence exists today that adult humans and adults of at least some other terrestrial mammals routinely display bradycardia and redistribution of blood flow (e.g., restriction of blood flow to skeletal muscles) when their whole bodies are submerged, or even if they simply immerse their faces in a bowl of water. Humans, however, are not "just like" marine

mammals: Human physiological responses to immersion are not as profound as those seen in marine mammals and are not coordinated in the same way (e.g., arterial blood pressure often soars in humans during long breath-hold dives because the output of blood from the heart and the resistance to blood flow through the vascular system are mismatched).

The marine mammals—viewed from the perspectives discussed here—seem in a sense to have "perfected" responses that all or most mammals share and that the mammals may well have inherited from fish. An important objective for future research is to understand better what exactly occurred during this "perfecting" process in the course of evolution and how exactly the control mechanisms in marine mammals differ from those in terrestrial ones.

The heart rates of fish removed from water The graphs show Scholander's original data for (1) grunion and (2) flying fish. (After Scholander 1964.)

Red blood cells are removed from the blood between dive sequences in some seals

Species of seals with large blood O_2 stores, such as Weddell seals and ribbon seals (see Figure 26.7), typically have exceptionally large concentrations of red blood cells in their blood *when they are diving*. Although an elevated red blood cell concentration enables the blood to store a large amount of O_2 , it has a downside: It increases the viscosity of the blood, forcing the heart to work harder to pump blood. In at least some of the true (phocid) seals, red blood cells are partly removed from the circulating blood and stored in the spleen when the animals are resting at the water's surface or on land. Then the cells are returned to the blood during diving.⁵ The blood of a Weddell seal, for instance, although 38% red blood cells (by volume) when the animal is resting in air, may become enriched to 52% red blood cells during diving. The removal of red blood cells from the blood when a seal is not diving means that during such rest periods the heart does not have to work exceptionally hard to pump blood. Red blood cells require at least 10–20 min to move between the spleen and blood. Thus the cells do not move in and out of the blood with each dive, but enter the blood during sequences of dives and are withdrawn during extended periods of rest.

Metabolism during Dives

The stage is now set to discuss metabolism during dives. Is it aerobic or anaerobic, or is it both? In terrestrial mammals that are resting or just modestly active, blood flows freely throughout the body—making O_2 available to all tissues—and all tissues make ATP aerobically. A similar picture seems to exist during short, voluntary dives by many marine mammals, even though they are not breathing; the circulatory system remains open to most or all body regions, and the tissues receive enough O_2 from the body's O_2 stores to function aerobically. A dramatically different picture develops during forced or prolonged dives.

The body becomes metabolically subdivided during forced or protracted dives

The intense peripheral vasoconstrictor response that occurs during forced or protracted dives effectively divides a diving animal's body into two metabolically distinct parts. This subdivision is illustrated in Figure 26.11 by the classic data that Scholander and Irving gathered on forcibly submerged harbor seals. The tissues that are denied blood flow during submergence, such as the skeletal muscles of the body trunk, initially continue to metabolize aerobically, using local O_2 stores such as O_2 bound to myoglobin. However, as shown by the muscle data in Figure 26.11, the tissues denied blood flow reduce their O_2 supplies to nearly zero long before a dive is over (see Figure 26.11a), and simultaneously they start to accumulate lactic acid (see Figure 26.11b) as they turn to anaerobic glycolysis to synthesize ATP. The O_2 concentration of the circulating arterial blood in a submerged seal falls much more slowly than the O_2 concentration of the skeletal muscles (see Figure 26.11a); therefore, long after the skeletal muscles have exhausted their O_2 , the brain, myocardium, and other perfused tissues receive substantial O_2

(a) Oxygen concentration in muscle and blood

(b) Lactic acid concentration in muscle and blood

FIGURE 26.11 Metabolic subdivision of the body in seals during forced submergence Levels of O_2 and lactic acid in the dorsal trunk muscles and circulating arterial blood are shown for forcibly submerged harbor seals (*Phoca vitulina*) as functions of their time under water. (a) Muscle O_2 concentration in each of ten seals and the average O_2 concentration in circulating arterial blood. (b) Muscle lactic acid concentration in each of ten seals and the average lactic acid concentration in circulating arterial blood. (From Scholander et al. 1942.)

supplies from the blood. The perfused tissues accordingly remain aerobic and do not produce lactic acid for most of the duration of a dive, as shown by the fact that little lactic acid accumulates in the circulating arterial blood during submergence (see Figure 26.11b). All things considered, you can see that well before a long dive is over, a seal's body becomes divided into two regions, one of which remains aerobic while the other becomes O_2 -depleted and dependent on anaerobic ATP production.

An important point to note is that lactic acid remains sequestered in the skeletal muscles and other vasoconstricted tissues while a dive is in progress, rather than entering the circulating blood (see Figure 26.11b). However, when a dive ends and the diving animal starts to breathe again, blood flow is promptly restored to the vasoconstricted tissues, and the lactic acid accumulated in them is washed out. The washout results in a relatively rapid rise in the lactic acid concentration of the circulating blood, followed

⁵Certain terrestrial mammals also vary the red blood cell concentration of their blood by sequestering cells in the spleen, as noted on page 636.

FIGURE 26.12 The aftermath of a prolonged dive: Lactic acid in muscles and blood The graph shows concentrations of lactic acid in skeletal muscles (blue line) and in circulating blood (red line) in the hour following a prolonged dive (a 43-min dive by an adult Weddell seal is assumed). Lactic acid concentrations are expressed relative to the concentration in muscle at dive's end, arbitrarily set equal to 100 units. Blood values are empirical, whereas muscle values are based on the assumption of exponential kinetics. (After Butler and Jones 1997.)

by a gradual decline. **Figure 26.12** shows the prevailing view of the processes at work after breathing is resumed. The concentration of lactic acid in the skeletal muscles falls exponentially. After blood lactic acid has risen for several minutes, it also starts to fall because the metabolic processes that clear lactic acid from the blood (see **Figure 8.6**) eventually outpace the entry of lactic acid into the blood from the muscles. The time scale is highly significant. Because the metabolism of lactic acid is slow (as emphasized in **Chapter 8**; see page 194), the concentration of lactic acid in muscles and blood may not return to baseline levels for many tens of minutes after a dive.

Metabolic limits on dive duration are determined by O_2 supplies, by rates of metabolic O_2 use and lactic acid production, and by tissue tolerances

A diving mammal usually elects to end a dive before its metabolic limits are reached. However, a highly protracted dive could be terminated by exhaustion of O_2 in the part of the body receiving active circulation, by excessive accumulation of lactic acid in anaerobic tissues, or by other metabolic limitations.

Three factors determine the limits of endurance of the O_2 -dependent tissues that receive active blood circulation during dives: (1) the magnitude of the O_2 store available to those parts of the body, (2) the rate of use of the O_2 store, and (3) the extent to which the partial pressure of O_2 can fall before impairing function. A scattering of interesting insights are available regarding each of these considerations. For example, even though the myocardium is believed to have a continuous requirement for O_2 , it may nonetheless start to employ anaerobic glycolysis to some extent after several minutes of diving. Both this partial recourse to anaerobic catabolism and the drop in cardiac work associated with diving bradycardia

reduce the heart's O_2 needs and thus help postpone the time when O_2 supplies become inadequate to sustain myocardial function.

The brain, in contrast to the heart, is believed to be entirely aerobic in diving mammals, just as it is in terrestrial mammals. However, several types of evidence indicate that the brain remains functional at lower O_2 partial pressures in at least some seals than in terrestrial mammals. Recent studies, for example, have been done on the membrane potentials of individual neurons in brain slices taken from a highly defined brain region of hooded seals (*Cystophora cristata*) and lab mice. As discussed in **Chapter 12**, a relatively normal membrane potential is required for neurons to produce action potentials (impulses), which are essential for brain function. Seal neurons are dramatically more resistant to loss of membrane potential when placed in low- O_2 conditions than are mouse neurons (**Figure 26.13**). This probably helps explain observations that indicate that seals—of at least some species—are able to remain conscious when blood O_2 has fallen to levels that would cause blackout in most mammals. Neuronal mechanisms that permit the brain cells to maintain conscious function at very low O_2 levels permit the seals to make almost complete use of their O_2 stores and thus dive especially long.

METABOLIC RATE DURING DIVING An animal's metabolic rate during diving is one of the most important factors in determining metabolic limits on dive duration. A low metabolic rate could slow both the rate of O_2 depletion and the rate of lactic acid accumulation, thereby lengthening a dive regardless of whether O_2 or lactic acid sets the limits. Physiologists have sought evidence for depressed metabolism in diving mammals from the dawn of the modern study of diving. Rigorous measurements of metabolic rates during diving are not easy, however, and knowledge of this key subject remains incomplete.

The preponderance of available evidence indicates that submergence commonly brings about a depression of metabolism. Good insight is provided, for example, by studies of free-ranging Weddell seals that were trained to breathe consistently from a monitored source

FIGURE 26.13 Loss of normal membrane potential in brain neurons of hooded seals and lab mice during exposure to tissue hypoxia The normal membrane potential in neurons of both species is about 64 mV (inside negative). The y axis shows how much of this potential is lost as a function of time after neurons are exposed, starting at time 0, to severe hypoxia. A value of 40 mV on the y axis, for example, indicates that membrane potential has fallen by 40 mV, from 64 mV to 24 mV. Error bars show ± 1 standard error. (After Folkow et al. 2008.)

of air for hours at a time as they engaged in repeated voluntary dives (most of which were short enough to be fully aerobic). Remarkably, the average rate of O_2 consumption of these *active* animals was equal to or lower than that of *resting* but nondiving seals!

Depression of metabolism during diving seems paradoxical because swimming ought to increase an animal's metabolic rate. This paradox is far from fully resolved. Hypothermia seems to be a common energy-sparing mechanism among seals: They often let their tissues cool during diving. We will return soon to specific mechanisms by which the diving metabolic rate can be kept low.

ADAPTATIONS TO THE ACCUMULATION OF METABOLIC END PRODUCTS Both the aerobic and anaerobic catabolic pathways produce end products that accumulate in a diving mammal: CO_2 and lactic acid, respectively. The ways in which a diver responds to the buildup of these compounds are important determinants of maximum dive duration.

Acidification is one concern. Both CO_2 and lactic acid tend to cause the pH of tissues and body fluids to decline. How is the pH kept from falling so low during a dive that it forces the dive to end? Part of the answer is that diving species are noted for having particularly high blood buffering capacities.

Stimulation of the urge to breathe is another concern. Anyone who has ever held his or her breath as long as possible under water knows that eventually the urge to breathe becomes impossible to resist. The underlying causes of this phenomenon are the buildup of blood CO_2 and the drop of blood pH: In terrestrial mammals, both factors are potent stimuli for pulmonary ventilation (see page 601). Diving species exhibit blunted (i.e., reduced) ventilatory sensitivity to changes in blood CO_2 and pH compared with terrestrial species. An example is provided by free-ranging harbor seals that were exposed to elevated concentrations of CO_2 in their breathing air. As the CO_2 concentration was raised, the seals increased their ventilation rates, but only about half as much as humans would. A blunted drive to breathe helps a diving mammal stay submerged for long periods.

The Aerobic Dive Limit: One of Physiology's Key Benchmarks for Understanding Diving Behavior

In protracted dives, the accumulation of lactic acid has major behavioral consequences, for three reasons. First, ridding the body of lactic acid requires a lot of time (see Figure 26.12). Second, O_2 is required for the process (see page 191), meaning that a diving mammal typically must stay at the water's surface where it can breathe, or return often to the surface, while it metabolizes lactic acid. Third, if a diving mammal has a lactic acid burden to metabolize following a protracted dive, it cannot engage immediately in a second highly protracted dive. This is so because the lactic acid of a second dive simply adds to the preexisting lactic acid, and there is a cap on the total lactic acid that can be accumulated and tolerated (see Chapter 8).

The lengths of time required to rid the body of lactic acid are impressively long, as already stressed. Table 26.1, for example, lists the lengths of time Weddell seals must stay at the water's surface to fully metabolize various accumulations of lactic acid—a requirement to regain their full range of behavioral options.

TABLE 26.1 Average surface times required for adult Weddell seals to dissipate accumulations of lactic acid

Lactic acid accumulation (mg lactic acid/100 mL blood) ^a	Time required to return to resting level ^b (min)
20	11
40	27
80	70
120	105
145	120

Source: After Kooyman et al. 1980.

^aLactic acid accumulation refers to the peak blood concentration measured during dive recovery. This concentration provides a reasonable estimate of the total-body accumulation.

^bThe times listed are for seals that remain continuously at the water's surface until the blood concentration of lactic acid is restored to resting. The resting level of lactic acid is about 5 mg/100 mL blood.

Accumulation of lactic acid can be avoided if dives are kept short. This is illustrated in Figure 26.14, which shows one of the most famous and important sets of results ever reported in the study

FIGURE 26.14 Peak concentration of lactic acid in arterial blood of freely diving, adult Weddell seals following dives of various durations Because the circulatory system is fully open after a dive, lactic acid produced anywhere in the body during a dive, even if temporarily sequestered while a seal was submerged, appears in the arterial blood after a dive. The peak blood concentration after a dive therefore provides an estimate of the total-body net production of lactic acid during the dive. The diamond on the y axis marks the average resting concentration of lactic acid in arterial blood. (After Kooyman et al. 1980.)

of diving physiology. To gather the data shown, Gerald Kooyman and his colleagues drew blood from wild Weddell seals when the seals returned to ice holes to breathe following voluntary dives. Recall that although lactic acid may be sequestered within skeletal muscles *during* a dive, it is released into the general blood circulation immediately *after* a dive (see Figure 26.12). The investigators simply waited long enough after each dive for the release process to drive the blood concentration to its peak level before they drew a seal's blood. Then they could estimate the seal's total-body accumulation of lactic acid from the blood concentration. Put another way, the total-body accumulation and the peak blood concentration are highly correlated. Figure 26.14 shows how the peak blood concentration of lactic acid varies with dive duration. Weddell seals accumulate lactic acid when they dive for 25 min or longer. In fact, they accumulate very high levels during lengthy dives. However, they do not accumulate lactic acid above the resting, baseline level if they dive for 20 min or less.

Based on the data shown in Figure 26.14, Kooyman and his colleagues defined the concept of the **aerobic dive limit (ADL)**, which is the longest dive that can be undertaken without a net accumulation of lactic acid above the resting level. In adult Weddell seals, the ADL is 20–25 min. Unfortunately, measuring lactic acid levels in freely diving animals is a challenge, and plots like the one in Figure 26.14 are available for few species. Investigators therefore sought alternative methods to estimate the ADL. The most popular alternative is to assume that a dive will not cause accumulation of lactic acid if the O_2 cost to meet all the metabolic demands of the dive is less than the total available O_2 store, and to then calculate the ADL from the O_2 store and diving metabolic rate. Estimates based on the two methods are not always similar. To distinguish them, investigators usually use the expressions *ADL* and *cADL*; in this system, *ADL* symbolizes a value based on direct measures of lactic acid, whereas *cADL* symbolizes a value calculated from O_2 stores.⁶ Here, for simplicity, we will simply use *ADL* to refer to the length of the longest dive possible without net accumulation of lactic acid, regardless of how it has been estimated.

Just as species of marine mammals vary widely in their diving competence, they also vary widely in their ADLs. Compared with the ADL of Weddell seals, the ADLs of fur seals and California sea lions (both otariids), for example, are far shorter, about 4–6 min. In contrast, ADLs in some species are far longer. Some fairly crude estimates indicate that sperm whales and male southern elephant seals have ADLs of 40–50 min!

Why does the ADL matter? *A central hypothesis of modern diving physiology is that it is adaptive for diving mammals to keep most of their dives shorter than their species-specific ADL.* By keeping their dives fully aerobic, they avoid lengthy recovery times to metabolize lactic acid. Accordingly, they can minimize their time at the surface and maximize their time under water.

How exactly do fully aerobic diving patterns translate into increased underwater time? When a dive is fully aerobic, replenishing O_2 stores is the only task an animal must carry out to recover. Vigorous breathing can replenish body O_2 stores rapidly. In fact, based on observations on several species, marine mammals require only 1–4 min to recover at the water surface—between one dive and

the next—*when their dives are shorter than the ADL.* Short surface intervals, in turn, provide lots of underwater time for foraging. Consider, for instance, an adult Weddell seal that undertakes six 15-min dives. Because these dives are shorter than its ADL and fully aerobic, the seal will need to be at the surface for only about 4 min between dives. Thus, counting dive time and recovery time, the six dives will take 114 min, of which 90 min will be spent under water. The seal will therefore be able to spend 80% of its time under water, foraging and feeding. Now let's look, in contrast, at the seal's use of time if it dives just once during 114 min for as long as it can while still being fully recovered when the total time is over. A 44-min dive will cause accumulation of lactic acid: specifically about 80 mg per 100 mL of blood (see Figure 26.14). This accumulation of lactic acid, to be metabolized, will require about 70 min of recovery at the surface (see Table 26.1). A 44-min dive and recovery will therefore take the entire 114 min. This total time is the same as required for the six 15-min dives. However, the seal diving for 44 min will spend 40%—not 80%—of its time under water! In brief, because of the long recovery times necessitated by anaerobic metabolism, a diver can typically spend a greater fraction of its time foraging and feeding if it makes many fully aerobic dives, each shorter than its ADL, than if it makes just a few lengthy dives.

Dives shorter than the ADL are also postulated to be adaptive because they permit homeostasis to be maintained throughout the body with little or no interruption. As we discussed earlier, investigators think that most or all organs receive a continuing blood flow and O_2 supply during dives that are relatively short.⁷ Short dives, therefore, permit most or all organs to continue functioning in an approximately normal way. Protracted dives, by contrast, can force many organs away from homeostasis; for instance, in a protracted dive, the kidneys may be forced to stop urine production, and enzymes throughout the body may be forced to function at highly altered pH.

If dives shorter than the ADL are, in fact, adaptive as hypothesized, then diving mammals are expected to elect short dive lengths during their natural diving behavior. With this thought, we come full circle. We stressed at the start of this chapter that dives of maximum duration, although important and amazing, tend to be uncommon; most dives are far shorter than the species-specific maximum. Now we can ask more specifically whether most dives are shorter than the species-specific ADL, as expected. Often (although not always), the answer is yes. For example, about 95% of the voluntary dives of wild, adult Weddell seals are shorter than the 20- to 25-min ADL of adult Weddell seals. Adult grey seals have a shorter ADL, about 10 min, and more than 90% of their dives are shorter than 10 min. The ADL of adult bottlenose dolphins is about 4 min, and more than 90% of their dives are shorter than 4 min.

The aerobic dive limit—a *physiological* feature of marine mammals—is therefore an important *behavioral* benchmark. Animals may dive for far longer than their ADL when faced with extraordinary behavioral challenges, such as avoiding danger or searching for new foraging areas. However, dives that are longer than the ADL

⁶There is now a push to distinguish the two methods more emphatically, by using a new expression, the *diving lactate threshold (DLT)*, to refer to estimates from lactic acid.

⁷This is not to say that blood flow is unaltered. Flow is likely to be redistributed during short dives much as it is redistributed in terrestrial animals during exercise, with some organs receiving relatively more of the total flow than they do during rest and some receiving less. Nonetheless, the current working hypothesis is that blood flow (at one rate or another) is maintained to most or all organs during short dives.

require long recovery times and force many organs away from homeostasis. Therefore, dives are usually kept shorter than the ADL. The significance of large body O_2 stores becomes clearer in this light: Large O_2 stores give a species a high ADL, thereby permitting a greater range of diving options while animals adhere to the “rule” that the ADL is the upper length limit for the majority of dives.

Marine mammals exploit multiple means of reducing their metabolic costs while under water

Intense study of ADL in recent years has led to a renewed focus on the metabolic rates of diving mammals while they are submerged. This is true because the underwater metabolic rate is one of the principal determinants of the ADL. To illustrate, consider a seal that has a usable O_2 store of 3000 mL. If its metabolism is fully aerobic and its metabolic rate during diving is 300 mL O_2 /min, its ADL is 10 min. If its metabolic rate could be halved, its ADL would be 20 min.

A lot of contemporary research on the diving metabolic rate is focused on mechanisms by which animals might reduce their metabolic rates—and therefore their rates of O_2 consumption—while they are under water. How, in other words, might they reduce their metabolic costs while diving? Three potential costs are those of keeping warm in cold water, processing food captured during diving, and swimming. Here we mention some results of recent studies on all three costs.

- **Keeping warm in cold water.** Earlier we noted that seals often let their body temperatures decline during diving. In hooded seals (*Cystophora cristata*), at least, investigators

have recently shown that tissue cooling is actually promoted during diving because shivering is inhibited. Faced with a particular cold stress, the seals shiver when on land to keep warm, but they do not shiver under water. In this way, they avoid a metabolic cost that would consume their O_2 stores while diving and shorten their ADL.

- **Processing food.** A provocative recent report indicates that grey seals, when capturing prey under water, postpone processing their prey until they are breathing air. In this way, they do not need to meet the O_2 costs of specific dynamic action (see Figure 7.5) while they are diving.
- **Swimming.** Swimming costs are currently the best understood of the topics discussed here. By employing miniature video cameras and other high-technology devices, investigators have established in the last 15 years that seals and dolphins often limit their costs of underwater travel by employing gliding (Figure 26.15a) and other high-efficiency modes of locomotion. A principle taught to all scuba divers is that as soon as a diver becomes negatively buoyant, sinking becomes self-reinforcing; a little sinking compresses air cavities in the diving gear, making a diver less buoyant and even more prone to sinking. The lungs of seals, positioned within a flexible thorax, behave as compressible air cavities, and seals seem often to employ the self-reinforcing nature of negative buoyancy to sink, holding their bodies almost motionless as they glide downward. Animals that glide to depth (see Figure 26.15a)

FIGURE 26.15 Energy-sparing behaviors of freely diving Weddell seals Behaviors that spare energy also spare O_2 . (a) A three-dimensional record of a dive by a Weddell seal, color coded to record the type of locomotion at each stage. Data were gathered by use of video cameras, accelerometers, and other remote-sensing devices attached

to each seal that was studied. (b) Simultaneous records from remote detectors of forward speed and hind-flipper activity, showing the type of evidence that is interpreted as indicating stroke-and-glide locomotion. (Both parts after data of Randall Davis, Lee Fuiman, Markus Horning, and Terrie Williams, with gratitude.)

avoid the metabolic costs (e.g., O₂ costs) of using muscle power to descend. Research has also shown that the cost of swimming is lower if seals alternately propel themselves and glide, rather than propelling themselves by muscle power continually. Telemetry data indicate that seals in fact often swim by the energy-sparing mechanism of alternately stroking with their flippers and gliding (Figure 26.15b).

Decompression Sickness

Many “diver’s diseases” have been described in the annals of human diving, and physiologists have long been concerned about whether and how these diseases are avoided by marine mammals. Although nitrogen narcosis (altered cognitive function attributed to high N₂ partial pressure) is starting to receive attention in studies of marine mammals, the disease that has been studied the most is *decompression sickness*, also called the *bends*. An informative starting point is to examine the etiology of this disease in human divers.

Human decompression sickness is usually caused by N₂ absorption from a compressed-air source

Unambiguous cases of decompression sickness occur in humans when they are diving with a source of compressed air (such as a scuba tank) that steadily resupplies the lungs with air. During a dive, the compressed-air source maintains the air pressure in the lungs at a level high enough to equal the ambient water pressure at all depths. This arrangement prevents the lungs from collapsing under the force of the ambient pressure and allows continued breathing. It also, however, means that an unusually elevated N₂ partial pressure is maintained continuously in the lung air. Assuming that a diver is breathing pressurized ordinary air, 78% of the air is N₂. Thus, if the total pressure at depth is 3 atmospheres (atm), the partial pressure of N₂ is 2.3 atm; and if the total pressure is 5 atm, the partial pressure of N₂ is almost 4 atm. Because these elevated N₂ partial pressures are maintained continuously in the lungs during dives with a compressed-air source, all the body tissues gradually come to equilibrium with them by dissolving more N₂ than ordinary. If a dive is long enough, all tissues will in fact dissolve enough N₂ to have a N₂ partial pressure equal to that in the lung air.

Decompression sickness may then occur if the person suddenly surfaces (“decompresses”). Under such circumstances, as explained in Chapter 22 (see page 573), outgassing of N₂ from solution can cause macroscopic bubbles to form within the blood and other tissues, much as bubbles form within a bottle of soda water when the cap is removed and the contents are decompressed. Bubbles formed in this way are generally believed to be the primary agents of decompression sickness. The most common symptom is throbbing pain in the joints and muscles of the arms and legs (the “bends”). In addition, an afflicted person may have neurological symptoms, such as paralysis, and severe breathing problems (the “chokes”). Exactly how the bubbles cause these symptoms remains a topic of ongoing research. Bubbles can block blood flow, press on nerve endings, and even disturb the structures of proteins because of electrical phenomena at gas–water interfaces.

The factors that determine whether *clinical* decompression sickness occurs are not completely known. One consideration is that, after a person surfaces, the N₂ partial pressure in his or

her lung air is restored to its ordinary value, and the N₂-charged blood and other tissues start to lose N₂ into the lung air. In this way, excess dissolved gas is steadily eliminated across the lungs. If the N₂ overload is not too great, this elimination may lower the N₂ partial pressure in the blood and other tissues rapidly enough that even if macroscopic bubbles start to form, their growth and proliferation are halted before clinical symptoms occur. As a very rough rule of thumb, humans can surface immediately without fear of the bends if their blood and tissue N₂ partial pressure is less than 2 atm. Otherwise they must alter their behavior and surface gradually to avoid illness (which in severe cases can be fatal).

Breath-hold dives must be repeated many times to cause decompression sickness in humans

When we consider humans undergoing *breath-hold* diving, a crucial difference from diving with compressed air is immediately apparent. A breath-hold diver descends with only the limited amount of extra N₂ contained within his or her lung air upon submergence; his or her pulmonary N₂ supply is not steadily renewed. During descent to depth, the lungs of a breath-hold diver are compressed under the force of the increasing ambient pressure, and the N₂ partial pressure in the lungs increases initially to high levels, just as in diving with compressed air. This process creates a partial-pressure gradient favoring the transfer of N₂ from the lungs to the blood and other tissues. However, the *quantity* of N₂ in the lungs is limited, and thus only a limited quantity can be transferred. In humans, the amount of N₂ that is transferred to the blood and other tissues during a single breath-hold dive is far too small to cause decompression sickness.

What happens, however, if a person undergoes *many repeated* breath-hold dives? If the time between successive dives is insufficient for the tissues to release accumulated dissolved N₂ after each dive, the tissue N₂ partial pressure can conceivably be elevated *in a series of upward steps* to a threatening level. This possibility seems to be far from theoretical. Several reports exist of people who have developed symptoms of decompression sickness after sequences of many breath-hold dives. In a classic instance described by Poul-Erik Paulev (1935–), for example, an individual complained of decompression symptoms after diving about 60 times to depths of 15–20 m over a period of 5 h.

Marine mammals have been thought—perhaps erroneously—to avoid decompression sickness during deep dives by alveolar collapse

Marine mammals are breath-hold divers. We must wonder, then, if they dive in ways such that N₂ transfer to their tissues by breath-hold dives might additively become great enough to cause decompression sickness. Calculations and experiments indicate that if N₂ is presumed to be able to move freely from the lungs into the rest of the body, N₂ partial pressures in the blood and other tissues of a diving mammal may often rise to threatening levels following many repeated dives.

Evidence indicates, however, that during deep dives, decompression sickness is in fact generally prevented in marine mammals. How? For 50 years, *alveolar collapse* has been considered the primary mechanism. Because of the compressibility of the thorax in marine mammals, the volume of the air in their lungs decreases as the animals descend during diving (see Figure 26.6). Moreover,

FIGURE 26.16 The hypothesis of preferential collapse of the alveoli and alveolar sacs at depth As the lung air is compressed to a smaller volume at depth, the alveoli and alveolar sacs collapse preferentially, and all air moves into the trachea, bronchi, and nonrespiratory bronchioles—the conducting airways (anatomical dead space)—where gas exchange with the blood is negligible.

because of distinctive patterns of structural reinforcement in their lungs, the *respiratory* parts of the lungs (see Figure 23.18) are far more prone to collapsing shut than any of the other lung parts. These factors taken together have been hypothesized to mean that as the animals descend to great depths, their lung air comes to be contained entirely in the *conducting* (nonrespiratory) airways of their lungs (Figure 26.16). In this way, below a certain depth, N_2 transfer from the lungs into the blood and other tissues cannot occur, because the N_2 in the lung air is safely sequestered in the parts of the lungs where gas exchange between the lung air and blood is not possible. Oxygen, as we have already stressed, is also sequestered within the conducting airways. The sequestration of O_2 might simply be a price an animal must pay to avoid decompression sickness, or possibly—as discussed in the next section of this chapter—it may hold advantages of its own.

Without doubt, alveolar collapse helps prevent N_2 in the lungs from dissolving in the blood and other body fluids by sequestering the N_2 in the lungs. But how complete is this sequestration? Until a decade ago, physiologists believed that alveolar collapse occurs at relatively low ambient pressures and thus occurs quickly as an animal descends into deep waters (e.g., by the time 50 m is reached).

From that viewpoint, only shallow dives could present a problem. Certain marine mammals, (e.g., some dolphins, fur seals, and sea lions) dive repeatedly to depths that, although sufficient to elevate the pulmonary N_2 pressure to levels of questionable safety, are clearly too shallow to induce full alveolar collapse. During repeated shallow dives of this sort, N_2 might invade the blood and other tissues sufficiently to pose a risk of decompression sickness. Experiments on trained bottlenose dolphins undergoing repeated dives to modest depths suggest that this worry is realistic. After an hour of shallow diving, the animals developed muscle N_2 partial pressures—1.7 to 2.1 atm—that in a human would be only marginally safe.

Deep dives are now a new concern. Under the postulated scenario in Figure 26.16, deep dives would not be a worry: The alveoli would collapse shut early in each dive, sequestering N_2 in the lungs. However, recent empirical evidence indicates that full collapse may not reliably occur at as shallow depths as previously thought during deep dives. Ultrasound scans for bubbles, for example, reveal that some deep-diving species have bubbles in their tissues when they have returned to the sea surface after deep dive sequences.

If a purely *physical* mechanism (alveolar collapse) turns out not to be fully adequate to prevent decompression sickness, *behavioral*

prevention may be required. Physiologists have started to wonder if diving marine mammals need to manage the threat of decompression sickness behaviorally just as human divers must. If a person accumulates excess dissolved N_2 , he or she slows ascent so N_2 can outgas from the tissues and body fluids without formation of clinically consequential bubbles. Perhaps that is what diving mammals do.

Decompression sickness is an unresolved phenomenon

Decompression sickness in marine mammals is clearly one of the phenomena that remain far from fully understood. It is in the spotlight now because, among other things, certain beaked whales seem to develop widespread bubble formation in their tissues after deep diving while being exposed to high-intensity sonar signals of human origin. Such bubble formation strongly suggests that the whales accumulate excess dissolved N_2 in their tissues during diving. The sonar could conceivably destabilize the dissolved state. Alternatively, it might disorient the animals so much that their normal behaviors are disrupted and they ascend too rapidly. Efforts to understand these phenomena have accentuated how little is confidently known about diving diseases in marine mammals.

A Possible Advantage for Pulmonary O_2 Sequestration in Deep Dives

A recent hypothesis regarding the relation between alveolar collapse and lung O_2 provides a thought-provoking note on which to end this chapter. From the beginning of the scientific study of marine mammals, investigators have tended to perceive the lungs as analogous to scuba tanks. Only a defective scuba tank would fail to deliver all its O_2 . Thus, when lungs fail to deliver all their O_2 , that failure is perceived as a flaw. Alveolar collapse in deep-diving marine mammals, in this view, is simultaneously advantageous and flawed. It is advantageous because even if not perfect, it helps prevent much of the lung N_2 from dissolving in the blood. It is flawed because it denies an animal the use of some of its O_2 store. Translated into evolutionary terms, this view presupposes that alveolar collapse was favored by natural selection as a means of preventing decompression sickness, and that the sequestration of O_2 is simply a negative side effect. The new hypothesis postulates that in deep divers, O_2 sequestration by alveolar collapse is itself an advantage.

As a diving mammal ascends to the water's surface at the end of a deep dive, the total pressure in its lungs declines as its lungs expand. The partial pressure of O_2 in the lung air accordingly decreases precipitously as the mammal ascends. The *amount* of O_2 in the lung air needs to be great enough that the O_2 partial pressure does not fall to a dangerously low level during this process. To illustrate, suppose that during a dive to 400 m, a seal starts with 0.1 mol of O_2 in its lungs but uses 95% of it, leaving only 5%. At 400 m, the O_2 partial pressure in its lung air will still be higher than the normal value at the sea surface because of the compression of the lung air at depth. As the seal nears the surface at the end of its dive, however, the O_2 partial pressure in the expanding lung air will fall to be only 5% of normal, a level low enough to cause blackout (unconsciousness), even in some seals. Moreover, with the lung air so dilute in O_2 , O_2 might easily diffuse *from the blood into the lung air!*

Thus, even if the blood is at a high enough O_2 partial pressure to prevent blackout when ascent begins, the blood O_2 partial pressure might fall to blackout-inducing levels before ascent is completed. These worries suggest that it is important for the lungs to retain a sizable portion of their O_2 throughout a deep dive. Thus, in addition to impeding transfer of N_2 to the seal's tissues and body fluids, alveolar collapse may in fact be a mechanism for preventing the risk of blackout during ascent by ensuring that enough O_2 remains in the lungs to keep the O_2 partial pressure acceptably high in the ever-expanding pulmonary air at the dive's end.

One reason to end on this novel note is that these thoughts emphasize the highly *interactive* nature of the challenges faced by the lungs, blood, and other tissues during all stages of diving. A second reason is to stress the importance of striving to see physiological challenges from the point of view of the animals studied. Lungs cease to look like mere scuba tanks when viewed from the perspective of a deep-diving marine mammal.

Study Questions

1. Comparative physiology is sometimes defined as being the identification and use of “ideal” species for the study of each phenomenon of interest. The Weddell seal is the best known of all diving mammals. In what ways has it been the “ideal” species for the study of voluntary diving in the wild?
2. Outline the pros and cons of carrying lots of lung air during a dive.
3. Based on the study of O_2 needs and stores, the aerobic dive limit (ADL) for young Weddell seals weighing 140 kg is calculated to be 10 min, whereas that for fully grown 400-kg Weddell seals is calculated to be about 20 min. Why might small individuals in general be expected to have shorter ADLs than large individuals? To carry out an empirical study of the changes in ADL during postnatal development in a species, what experiments and measurements would you plan?
4. There is evidence that marine mammals practice unihemispheric sleep: sleep that occurs in only one brain hemisphere at a time, so that while one hemisphere sleeps, the other is awake. Such sleep is essentially unheard of in terrestrial mammals (although common in birds). What might be the advantages of unihemispheric sleep for a marine mammal?

Previous page: Drinking is so mundane in modern human life that we can forget its challenges and life-or-death significance for many animals in a state of nature. Giraffes, although they do not live in Earth's driest places, occupy dry savannas where drinking water may at times be scarce or salty. Physiologists study the principles that determine how much drinking water is needed and how salty the water can be and still suffice. This giraffe was photographed in Etosha National Park, Namibia.

Water and Salt Physiology: Introduction and Mechanisms

Crustaceans like this blue crab must molt to grow. Between molts, the body of a crustacean is enclosed in a tough, calcified exoskeleton. The exoskeleton has the advantage that it acts like armor, protecting the soft tissues inside from predators. It has the disadvantage, however, that it must be shed for the animal to increase in size. A blue crab must molt more than 25 times in the course of its 2-year life.

The soft tissues of the blue crab in the photograph are so grossly swollen that the crab is literally breaking out of its old exoskeleton. Prior to the actual time of molting, seams in the exoskeleton are weakened under hormonal control. Then—also under hormonal control—the body of the animal takes on excess water from its surrounding environment and swells. This swelling in a nearly mature blue crab increases the weight of the animal's tissues by 50%, or sometimes even 100%. The first function of the swelling is to crack the old exoskeleton along its seams so the animal can crawl out. The swelling then serves two additional major functions. First, it gives the animal's body a degree of structural rigidity while the exoskeleton is gone. Without the swelling, the crab's muscles (which are ordinarily attached to the exoskeleton) would have no purchase, would have nothing to pull against; because of the swelling, the muscles can use the soft but taut integument as a substitute for the exoskeleton. Second, the swelling enables a crab to start *very quickly* to make a new, larger exoskeleton. Because of its swelling with water, a crab's body is bigger as soon as the animal crawls out of its old exoskeleton. Synthesis of the new, bigger exoskeleton can therefore begin immediately. Later, the crab will grow into its new exoskeleton, voiding excess water as it does so. In this way, it is protected inside its new exoskeleton while most of its growth takes place.

The swelling that blue crabs and other aquatic crustaceans routinely undergo serves as a visible, dramatic reminder that watery solutions play crucial roles in the lives of animals. It also helps emphasize the *dynamism* of water exchanges in all animals: Body water comes and goes, often turning over very rapidly. Mammals the size of mice commonly turn over 25% of their water every day in their natural habitats. People, being larger, turn over only about 7%. Even a turnover rate of 7% per day, however, means that a person's body weight could, in principle, increase or decrease by 5 kg (11 pounds) in a single day merely because of an imbalance in water gains and losses.

Despite the dynamism of water turnover, most animals, when healthy, maintain a relatively steady body-water content by means of highly responsive mechanisms that match water gains and water losses. The routine swelling of crustaceans during molting is really just a variation on this theme of water balance. The crustaceans unbalance their water gains and losses in a controlled way to swell, but between molts they regulate their body-water content.

Two principal types of body fluids are recognized in animals: the **intracellular fluids** inside cells and the **extracellular fluids** outside cells. The extracellular fluids are divided into two subparts: the **interstitial fluids** found between cells in ordinary tissues¹ and the **blood plasma**, the part of the blood other than the blood cells.² Each body fluid is an aqueous solution in which

¹For simplicity, in earlier chapters the *interstitial fluids* have been referred to by their more general name *extracellular fluids*.

²In animals with open circulatory systems, the interstitial fluids and blood plasma are identical. See Chapter 25.

Blue crabs dramatize the dynamism of animal water and salt relations when they shed their exoskeleton to grow When a blue crab (*Callinectes sapidus*) sheds its exoskeleton, it takes on extra water in a carefully orchestrated way and swells. The swelling cracks open the old exoskeleton so the crab can exit.

are dissolved a variety of inorganic ions—such as Na^+ , Cl^- , and K^+ —plus organic compounds such as the plasma proteins. The intracellular fluids, interstitial fluids, and blood plasma are often described as the **fluid compartments** of the body.

In this chapter and the three that follow, we discuss the nature and significance of the body fluids, the challenges animals face to maintain the composition and volume of their three body-fluid compartments within viable limits, and the mechanisms of body-fluid regulation. The present chapter focuses on concepts and mechanisms that pertain to animals in general or to large subsets of animals. Later chapters discuss the specifics of particular animal groups, environments, and organs involved in water–salt physiology.

The Importance of Animal Body Fluids

One sign of the importance of body fluids is simply their abundance. Collectively they account for more than half of an animal's body weight in most cases. They represent about 60% of body weight in adult humans and in many other animals (**Figure 27.1**). In some types of animals, such as certain of the gelatinous invertebrates, they account for as much as 95%.

For the most part, the cells, the subcellular structures, and the proteins and other molecules in an animal's body are bathed with body fluids or in contact with body fluids. The body fluids,

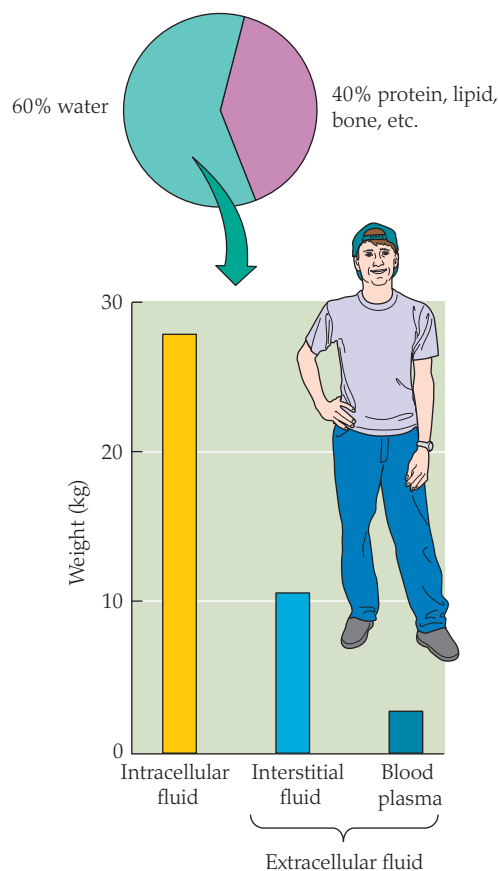

FIGURE 27.1 Body fluids account for 60% of the body weight of young adults The bar chart shows the normal weights of the intracellular fluid and the two categories of extracellular fluids—interstitial fluid and blood plasma—in a 70-kg person. (See Figure 6.2 for the composition of the 40% of the body that is not body fluids.)

therefore, constitute the immediate environment for cells and molecules in the body, a fact already recognized by Claude Bernard when he developed the concept of the *internal environment* (*milieu intérieur*) discussed in Chapter 1 (see page 12). The compositions of the body fluids constitute the context in which cells, organelles, and molecules function.

The particular *inorganic ions*—often called *salts* or *electrolytes*—in the body fluids, and the concentrations of those ions, are important aspects of body-fluid composition for several reasons. One is that the ionic composition of body fluids affects the crucial three-dimensional molecular conformations of enzymes and other proteins; the ionic composition can have immediate effects on the conformations of proteins, or it can have indirect effects, as by influencing pH. Ion concentrations in the intracellular and interstitial fluids are also important in maintaining correct electrical gradients across cell membranes, and they play key roles in nerve-impulse transmission and muscle excitation (see Chapters 12 and 20). Too little intracellular potassium (K^+), for example, can alter heart rhythm by affecting key ion gradients across the cell membranes of the pacemaker cells.

The *water* in body fluids is also important for several reasons. The conceptually simplest reason is that water is the matrix in which the ions are dissolved; the amount of water is as instrumental in determining ion concentrations as are the ions themselves. Water is also important because it affects the *volumes* of cells and tissues. In addition, osmotic movements of water affect the hydrostatic pressures that prevail in the body.

The ions, water molecules, and organic molecules within any solution in fact relate in ways that impart *structure* to the solution. Individual ions in an aqueous solution, for example, induce the water molecules immediately surrounding them to orient around the ions, forming shells of hydration. Molecules of water also associate with proteins and other macromolecules (constituting “water of hydration”). In regions of free water, the H_2O molecules structure themselves by mutual hydrogen bonding into arrays—sometimes called “flickering” arrays because individual H_2O molecules move from place to place in an array, rather than occupying fixed positions. The physiological implications of the structured nature of solutions are just starting to be explored, and there can be little doubt that new insights into the roles of body fluids will emerge as the structured nature of solutions is taken into full account.

All animals have evolved specific, *controlled* relations of their body-fluid composition to the composition of the external environment in which they live: No known species has body fluids that are simply at passive equilibrium with the external environment. In some cases, the control exerted by animals over their body-fluid composition is dramatic. Freshwater animals, for example, expend energy to maintain ionic concentrations that are far higher in their body fluids than in freshwater. By contrast, the water–salt regulatory processes in some other animals are subtle. Many invertebrates that live in the open ocean, for example, maintain just relatively small differences in salt composition between their blood plasma and seawater. Whether the differences between an animal's body fluids and its external environment are dramatic or subtle, actively maintained differences always exist. This observation suggests that for all animals, the effects of salts and water on protein function and other functional properties have led to fine-tuning of body-fluid composition during the course of evolution and to the evolution of mechanisms that can control the water–salt composition of the body fluids.

The Relationships among Body Fluids

The three major body-fluid compartments of an animal—the intracellular fluids, interstitial fluids, and blood plasma—interact and affect one another. **Figure 27.2** emphasizes that the three compartments are closely juxtaposed within an animal's tissues. The intracellular fluids are separated from the interstitial fluids just by the cell membranes of the tissue cells. The interstitial fluids are separated from the blood plasma only by the endothelium of the blood capillaries (a single cell layer).

Brisk exchange of water and ions often occurs between the intracellular fluids and the interstitial fluids across cell membranes. As discussed in Chapter 5, this is true in part because the cell membranes are permeable to water and ions; for example, the cell membranes have water channels and ion channels through which osmosis and diffusion occur. Moreover, ions are often transported between the intracellular and interstitial fluids by facilitated diffusion or active transport, mediated by transporter proteins in the cell membranes.

Brisk exchange of water and ions also often occurs between the interstitial fluids and the blood plasma. One reason is that the blood-capillary endothelium that separates the interstitial fluids and blood plasma is in most cases relatively densely perforated by minute,

physical pores. Some of these pores are formed by tiny gaps (about 4 nm in diameter) *between* cells in the endothelium; other pores are formed in some tissues by holes *through* endothelial cells.³ Water and ions freely cross the capillary endothelium through these pores by osmosis and diffusion, bringing the fluids on each side close to equilibrium with each other. In addition, as discussed in Chapter 25 (see Figure 25.13), the elevated blood pressure inside capillaries forces a bulk flow of fluid—containing both water and ions—out of the blood plasma and into the interstitial fluids by ultrafiltration.

When physiologists study the water–salt physiology of whole animals, they nearly always sample just the blood plasma to gain insight into the status of the animals, rather than trying to sample all fluid compartments. They take this approach because blood can be sampled readily without causing damage. We must wonder, though, what can we deduce about the composition of the other body fluids from measures on just the blood plasma?

Actually, the blood plasma provides a great deal of insight. The interstitial fluid is typically very similar to the blood plasma in *osmotic pressure* because of the free exchange of water and ions by osmosis and diffusion that occurs through blood-capillary pores and by other mechanisms.⁴ Moreover, the intracellular fluid inside cells ordinarily has about the same *osmotic pressure* as the interstitial fluid and blood plasma. What about *ions*? The interstitial fluid is typically very similar to the blood plasma in ionic composition for the same reasons just mentioned in discussing osmotic pressure. However, the intracellular fluid differs dramatically in ionic composition from the interstitial fluid (and the blood plasma) because of the action of ion pumps (see Figure 5.10). Summarizing, therefore, if one knows the osmotic pressure of the blood plasma, one typically also knows the osmotic pressure of the other body fluids because the blood plasma, interstitial fluid, and intracellular fluid are either isosmotic or close to isosmotic.⁵ If one knows the ionic composition of the blood plasma, one typically also knows the ionic composition of the interstitial fluid (which is similar). The intracellular fluid, however, differs dramatically from the other two fluids in its ionic composition and thus must be studied in its own right to determine its ionic composition.

Types of Regulation and Conformity

Three types of regulation of the composition of the blood plasma are possible: *osmotic regulation*, *ionic regulation*, and *volume regulation*.

³The capillaries in various tissues of an animal's body vary in their types and densities of pores. In the human body, for example, liver capillaries are very porous. Brain capillaries, however, virtually lack pores. The capillaries in most tissues are intermediate. The pores are often called **fenestrations**.

⁴Blood plasma is typically more concentrated than interstitial extracellular fluid in dissolved proteins that cannot pass through the capillary endothelium. This disparity produces a difference in osmotic pressure between the two fluids that can be of critical importance for understanding certain phenomena, such as bulk-fluid exchanges across capillary walls (see Figure 25.13 and the discussion of the Starling-Landis hypothesis in Chapter 25). The *absolute* osmotic pressures of the blood plasma and interstitial fluid are quite similar nonetheless. In human systemic tissues (see Chapter 25), the osmotic pressure of the blood plasma is about 3.3 kPa (25 mm Hg) higher than the osmotic pressure of the interstitial fluid. In the osmolarity system of units, 3.3 kPa is equivalent to about 1.5 milliosmolar (mOsm). Thus, when the blood plasma has an osmotic pressure of 300 mOsm (as is typical of human blood), the interstitial fluid has an osmotic pressure of 298.5 mOsm. For most purposes, therefore, the blood plasma and interstitial fluid can be considered to be virtually identical in osmotic pressure.

⁵*Isosmotic* means "of equal osmotic pressure," as discussed in Chapter 5.

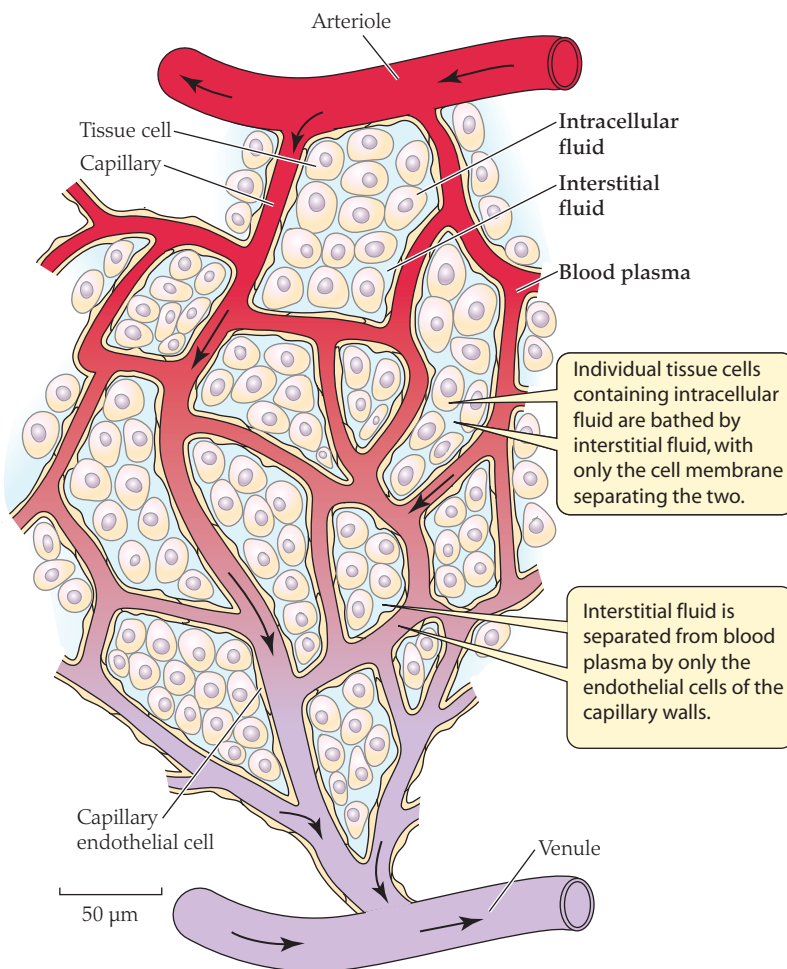

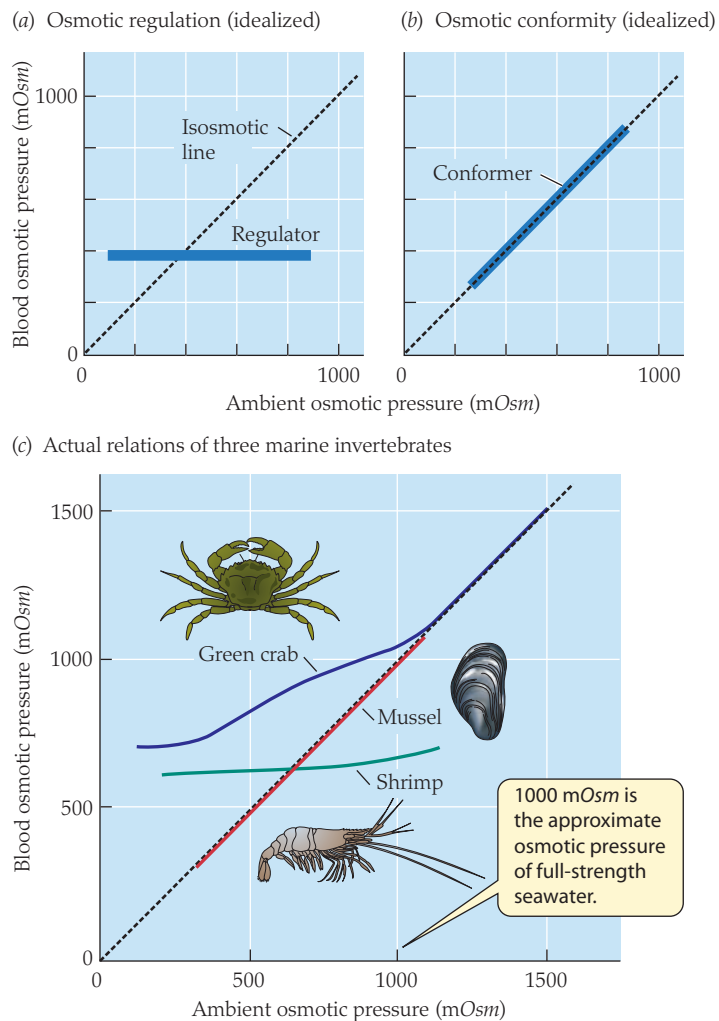

FIGURE 27.2 The three major types of body fluids are closely juxtaposed This diagram of a microcirculatory bed in a mammal shows the close juxtaposition of the three major types of body fluids. For simplicity, red blood cells and other blood cells are not shown. (See Figure 25.11 for more on the structure of microcirculatory beds.)

Some animals—such as humans and other mammals—regulate in all three ways. Other animals, however, are conformers in certain aspects of their water–salt physiology.⁶

Osmotic regulation (osmoregulation) is the maintenance of a constant or nearly constant osmotic pressure in the blood plasma. To illustrate osmotic regulation, consider an aquatic animal that is placed in environmental water of various osmotic pressures. If the animal exhibits perfect osmotic regulation, its blood osmotic pressure will remain the same regardless of the osmotic pressure of the environmental water, as seen in [Figure 27.3a](#). The dashed line in the figure is a line of equality between the blood osmotic pressure and the ambient (environmental) osmotic pressure and thus is called the **isosmotic line** (similar to the *isothermal line* discussed in Chapter 10). A perfect osmoregulator exhibits no tendency to follow the isosmotic line. The opposite of osmotic regulation is **osmotic conformity**. In an osmotic conformer, as seen in [Figure 27.3b](#), the blood osmotic pressure always equals the osmotic pressure of the environmental water and thus falls on the isosmotic line.

Actual animals often display gradations or mixes of osmotic regulation and osmotic conformity. [Figure 27.3c](#), for example, shows the relation between blood osmotic pressure and ambient osmotic pressure in three marine invertebrates. The shrimp is an almost perfect

FIGURE 27.3 Osmotic regulation and conformity In each graph, each solid line shows the osmotic pressure of blood plasma as a function of the ambient (environmental) osmotic pressure; the dashed line is a line of equality between blood osmotic pressure and ambient osmotic pressure (an isosmotic line). Osmotic pressures are expressed in units of milliosmolarity (mOsm). (a, b) The osmotic pressure of the blood plasma as a function of the osmotic pressure of the ambient water in (a) a perfect osmotic regulator and (b) a perfect osmotic conformer. (c) Actual animals often exhibit responses that are mixed or intermediate between idealized regulation and idealized conformity. The osmotic pressure of the blood plasma as a function of the ambient osmotic pressure is shown for three species of marine invertebrates: *Mytilus edulis*, the blue mussel; *Carcinus maenas*, the green crab; and *Palaemonetes varians*, a species of grass shrimp. The mussel is a strict osmotic conformer. The crab regulates in waters more dilute than seawater but is an osmotic conformer at higher ambient osmotic pressures. The shrimp regulates over a wide range of ambient osmotic pressures. (c after Hill and Wyse 1989.)

osmoregulator; its blood osmotic pressure varies just a little with the osmotic pressure of its external environment. The crab exhibits impressive but imperfect osmotic regulation in waters more dilute than 1000 milliosmolar (mOsm)—seawater concentration—but it is an osmotic conformer in waters more concentrated than 1000 mOsm. The mussel is an osmotic conformer at all the concentrations studied.

The concepts of osmotic regulation and conformity apply to terrestrial animals as well. Humans, for example, maintain a remarkably stable blood-plasma osmotic pressure of about 300 mOsm whether they drink a lot of water per day or little per day. Humans, therefore, are excellent osmotic regulators.

Ionic regulation of the blood plasma is the maintenance of a constant or nearly constant concentration of an inorganic ion in the blood plasma. There are as many potential types of ionic regulation as there are ions because each ion is subject to ion-specific physiological controls. The opposite of ionic regulation is **ionic conformity**; if an animal is an ionic conformer for a particular ion, it allows the concentration of the ion in its blood plasma to match the concentration in its external environment. Although the interstitial fluid typically resembles the blood plasma in terms of ionic regulation or conformity, one must remember that the intracellular fluid is distinctive because it is subject to its own ion regulatory processes. Ionic regulation or conformity in the intracellular fluid cannot be predicted from the physiology of the other body fluids.

Volume regulation is the regulation of the total *amount* of water in a body fluid. Volume regulation of the blood plasma, for example, is regulation of the amount of water in the plasma. Animals generally regulate their blood volume. We, for example, maintain an approximately constant amount of water in our blood plasma regardless of how much water we drink per day. Blue crabs illustrate both the presence and absence of volume regulation. At the specific times in their lives when they swell and molt, volume regulation is suspended; their blood takes on water, and their bodies swell. At other times, blue crabs are accomplished volume regulators, as already stressed.

The concept of volume regulation applies to the interstitial and intracellular fluids as well as to the blood plasma. For example, if cells maintain a constant amount of intracellular water, they exhibit cell-volume regulation.

True **volume conformity** refers to completely passive changes of body-fluid volume (e.g., driven by osmosis). It occurs only rarely in animals.

⁶See page 12 and Figure 1.6 for the distinction between *regulation* and *conformity*.

The integrated study of osmotic regulation, ionic regulation, and volume regulation can seem confusing at first because although the three types of regulation are in fact distinct, they are often intimately related. To illustrate, consider a freshwater fish that takes on a quantity of H₂O from its dilute environment by osmosis. This influx of H₂O into its body will tend to have three *simultaneous* effects:

- It will tend to lower the osmotic pressure of the fish's blood plasma (a challenge to osmotic regulation).
- It will tend to dilute ions in the fish's blood plasma (a challenge to ionic regulation).
- It will tend to increase the volume of water in the fish's blood plasma and other body fluids (a challenge to volume regulation).

Simultaneous effects such as these can create the illusion that osmotic regulation, ionic regulation, and volume regulation are the same thing. They are in fact different, however, as we will see by example later in this chapter. *An exceedingly important tool for understanding animal water–salt physiology is to maintain the conceptual distinction between the three types of regulation and analyze problems in water–salt physiology from all three perspectives.*

Both regulation and conformity have pros and cons. If an animal exhibits osmotic and ionic regulation of its blood plasma, the composition of its interstitial fluid is also regulated, and therefore its *cells*—which are bathed by interstitial fluid—experience a constant osmotic–ionic environment (in Claude Bernard's words “constancy of the internal environment”). This constancy can be of advantage to the cells, but it costs energy: Animals must invest energy to maintain constancy. If animals exhibit osmotic–ionic conformity in their blood plasma and interstitial fluid, they avoid such energy costs, but their cells must then cope with changing osmotic–ionic conditions in the interstitial fluid that bathes them.⁷

SUMMARY Types of Regulation and Conformity

- Osmotic regulation is the maintenance of a steady osmotic pressure in the blood plasma.
- Ionic regulation of any particular inorganic ion is the maintenance of a steady concentration of that ion in the blood plasma.
- The concepts of osmotic and ionic regulation can also be applied to the interstitial and intracellular fluids.
- Volume regulation is the maintenance of a steady volume (amount) of water in the body as a whole or in a particular fluid compartment. Cell-volume regulation is regulation of the amount of intracellular water.

Natural Aquatic Environments

Some aquatic animals live in environments that are approximately uniform and stable in their water–salt composition. The animals that live in the open ocean are in this category. Full-strength sea-

TABLE 27.1 Concentrations of major ions in seawater and freshwater

Ion	Concentration (mM)	
	Seawater ^a	Freshwater ^b
Sodium (Na ⁺)	470	0.35
Chloride (Cl ⁻)	548	0.23
Magnesium (Mg ²⁺)	54	0.21
Sulfate (SO ₄ ²⁻)	28	0.19
Calcium (Ca ²⁺)	10	0.75
Potassium (K ⁺)	10	0.08
Bicarbonate (HCO ₃ ⁻)	2	1.72

^aSeawater values are for a salinity of 34 g/kg.

^bFreshwater values are worldwide averages for rivers.

water is approximately the same in its concentrations of major ions (Table 27.1) everywhere in the open ocean. The **salinity** of a body of water—defined to be the number of grams of dissolved inorganic matter per kilogram of water—is a measure of the total concentration of all salts taken together. Seawater in the open ocean has a uniform salinity, 34–36 g/kg.⁸ An important and easily remembered feature of full-strength seawater is that its osmotic pressure is almost exactly 1000 mOsm, as already noted.

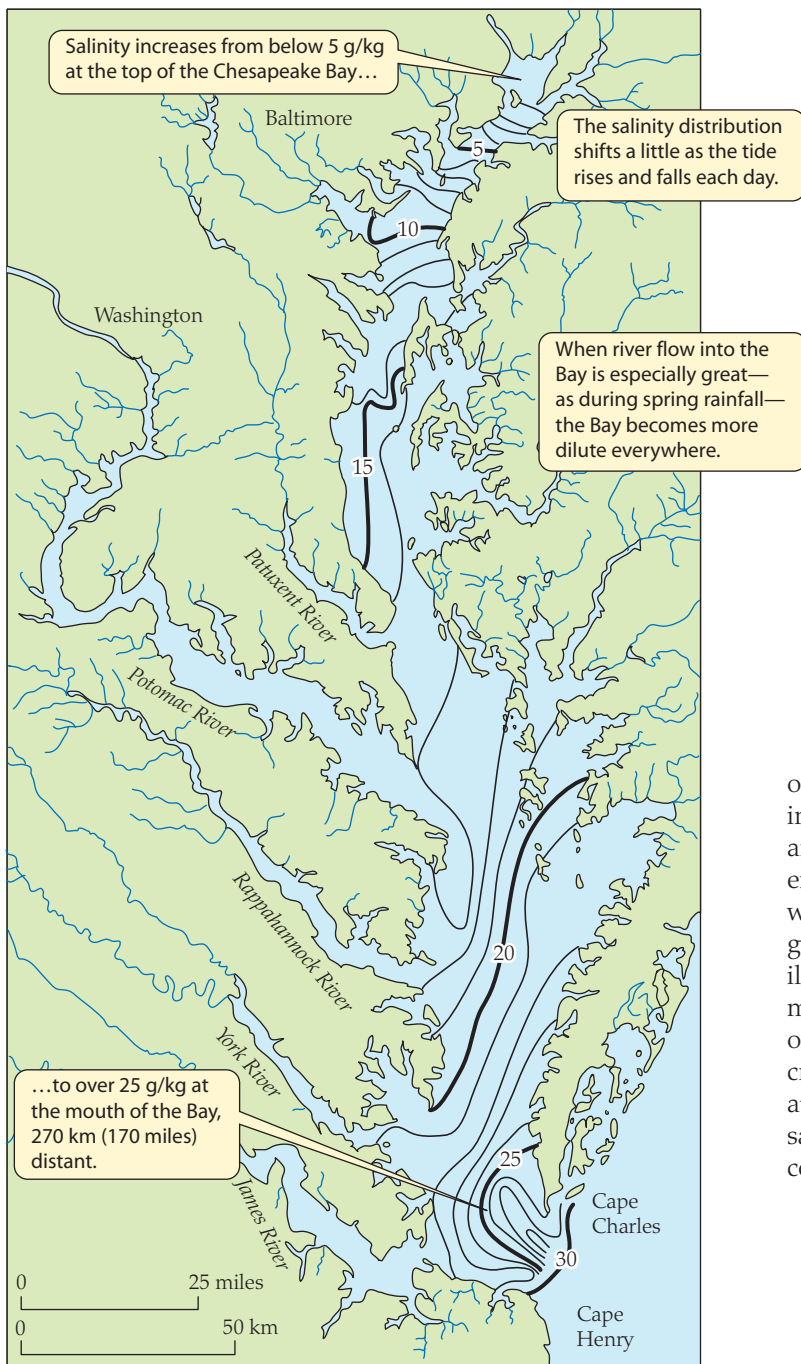

Freshwater is usually defined as water having a salinity less than 0.5 g/kg (the worldwide average for lakes and rivers is 0.1–0.2 g/kg). Freshwater is essentially a uniform environment in terms of its osmotic pressure, which is always very low (0.5–15 mOsm). Ion concentrations in freshwater present a more complex picture: Although ions are always dilute in freshwater (see Table 27.1), certain ions vary in concentration from one body of freshwater to another in ways that are biologically consequential. Calcium (Ca²⁺) is particularly noteworthy. Although always dilute, it is distinctly higher in concentration in some bodies of freshwater—termed “hard”—than in others—termed “soft.” These variations in Ca²⁺ concentration can exert substantial effects on the water–salt physiology of freshwater animals by affecting their membrane permeabilities and sometimes other functional properties.

Where ocean water mixes with freshwater along coastlines, waters of intermediate salinity, termed **brackish waters**, are formed. In these places, both osmotic pressure and ion concentrations in the water are often highly variable both spatially and temporally.

Many of the places where brackish waters occur are classified as **estuaries**. An estuary is any body of water that is partially surrounded by land and that has inflows of both freshwater and seawater. Estuaries are of great importance in human affairs. They also are among the most interesting aquatic habitats physi-

⁸Several alternative ways exist to write this unit of measure. To refer to grams per kilogram (g/kg), some scientists use the symbol ‰; others write *parts per thousand* (ppt) or *parts per mille*. Salinity can also be expressed using *practical salinity units*; values in this system are dimensionless (have no units) but are numerically very similar to values expressed in g/kg.

⁷See Chapter 1 (page 14) for a more complete discussion of the pros and cons of regulation and conformity (i.e., homeostasis and lack of homeostasis).

A typical estuarine shoreline (Chesapeake Bay)

FIGURE 27.4 Salinity trends in an estuary Salinity varies greatly along the length of the Chesapeake Bay, one of the world's most thoroughly studied estuaries. The map shows a typical pattern of salinity in the water near the surface. Numbers are salinities in g/kg. Each line connects all the surface waters of a particular salinity; therefore, for example, the line for 20 g/kg connects all the places where the salinity of the surface water is 20 g/kg. (Salinity distribution after McHugh 1967.)

ologically because of the dramatic variability they often display in their salinity from place to place and time to time—presenting animals with unusual challenges because of the great variation in environmental osmotic pressure and ion concentrations. Brackish waters are usually defined to have salinities between 0.5 and 30 g/kg—corresponding to osmotic pressures of 15 to 850 mOsm. As illustrated by the Chesapeake Bay (Figure 27.4), a single estuary may exhibit almost this entire range of salinities within a distance of 270 km (170 miles). Estuaries are the characteristic habitat of blue crabs, which—when not molting—are effective osmoregulators at brackish salinities. As a blue crab travels into waters of various salinities in an estuary, its blood osmotic pressure remains almost constant everywhere it goes (Figure 27.5).

FIGURE 27.5 The responses of a resident osmotic regulator to variations in salinity in an estuary Blue crabs (*Callinectes sapidus*) are abundant throughout the Chesapeake Bay and other similar estuaries along the Atlantic and Gulf coasts of the United States. The graph shows the average osmotic pressure of the blood plasma of blue crabs as a function of the osmotic pressure and salinity of the ambient water during nonmolting periods of their lives, when they osmoregulate. The dashed line is the isosmotic line. (After Kirschner 1991.)

Natural Terrestrial Environments

Animals on land are surrounded by a fluid—air—that contains water only in the gaseous state and, of course, is essentially free of salts. One might guess that terrestrial animals would commonly be able to gain water from the air when the humidity of the air is high. That is not the case, however: For most terrestrial animals most of the time, the atmosphere is a sink for water: Animals lose water to it by evaporation. Because living in air is inherently dehydrating, the study of the water–salt physiology of terrestrial animals is dominated by the study of water.

For scientists interested in the water relations of terrestrial animals, the world's deserts are particularly important and intriguing habitats because they present animals (including humans) with the extremes of terrestrial water stress. Deserts cover substantial areas of Earth's landmasses (Figure 27.6) and on average are expanding. Although deserts are often hot, they are not necessarily so, because they may occur at high altitudes or polar latitudes. They are defined by their dryness, not their temperature. A simple definition of a desert is that it receives less than about 25 cm (10 inches) of rain or other precipitation per year; we discuss more refined definitions in Chapter 30.

To understand the relations of animals to atmospheric water in deserts or other terrestrial habitats, one must study the principles of **evaporation**, the change of water from a liquid to a gas. Evaporation is a special case of gas diffusion, which (as discussed in Chapter 22) is analyzed using the *partial pressures* of gases.⁹

Gases always diffuse in net fashion from regions of high partial pressure to regions of low partial pressure. Thus, if a body fluid, or any other aqueous solution, is in contact with the atmosphere, net

evaporation occurs if the partial pressure of water in the solution exceeds that in the atmosphere, and the rate of evaporation increases as the difference in partial pressure increases.

What do we mean by the partial pressure of water in a solution and in the atmosphere? Let's start with the latter. Gaseous water, called **water vapor**, is simply a gas like any other gas. Thus it is a constituent of the atmosphere in the same way that other gases, such as O₂, are. The partial pressure of water—often called the **water vapor pressure**—in the atmosphere is simply the portion of the total atmospheric pressure that is exerted by the water vapor present. It can be calculated from the universal gas law (see Equation 22.1) and is independent of the partial pressures of the other gases in the atmosphere. **Humidity** is an informal term referring loosely to the water content of air. Although several measures of humidity are in common use, the *water vapor pressure* is the most useful for physiological analysis.¹⁰

Unlike other gases in the atmosphere, water vapor displays an upper limit on its partial pressure: The water vapor pressure can rise only to a certain maximum in air of a particular temperature. The limit on water vapor pressure is a direct consequence of the fact that (unlike the other atmospheric gases) water can exist as a liquid (not just a gas) under ordinary atmospheric conditions. Air that has

⁹If you are unfamiliar with the concept of *partial pressure*, you should review pages 570–572 and Figures 22.1 and 22.3.

¹⁰In addition to being expressed simply as the water vapor pressure, the humidity of air is often expressed *relative* to the air's temperature-specific *saturation water vapor pressure*, discussed in the next paragraph. One expression of this sort is the **saturation deficit**, which is the *difference* between the actual, prevailing water vapor pressure and the saturation water vapor pressure. Another such expression of humidity is the **relative humidity**, defined to be the *ratio* of the actual water vapor pressure over the saturation water vapor pressure.

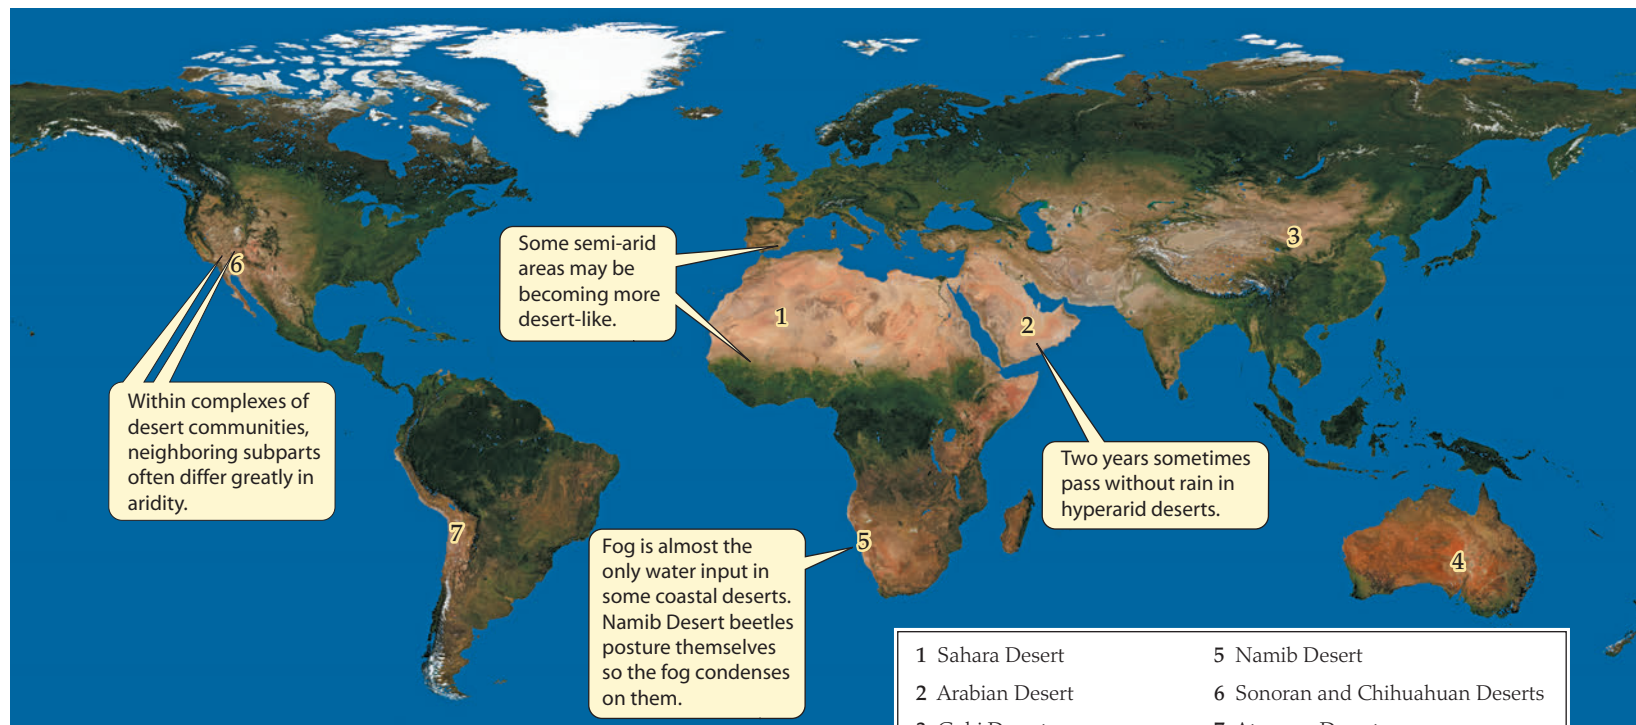

FIGURE 27.6 Deserts occur on all continents Sandy-colored areas are mostly deserts. Animals that have succeeded in living in deserts have had to evolve extreme adaptations to water stress, including extreme abilities to acquire water, conserve the water they have, and tolerate dehydration.

| 3 Gobi Desert | 7 Atacama Desert |
| 4 Great Victorian Desert | |

reached its maximum water vapor pressure is said to be **saturated**, and its water vapor pressure is termed the **saturation water vapor pressure**. If a body of air has reached saturation with water vapor, it cannot hold any more water in the gaseous state. Thus, if water vapor is added to such air from an outside source, the excess water vapor promptly condenses out in the form of liquid water droplets (e.g., fog). The saturation water vapor pressure increases dramatically with the temperature of air, as **Table 27.2** shows.

To illustrate the immediate significance of these concepts, consider that we humans exhale air at a temperature greater than 30°C, whereas a toad with a body temperature of 20°C breathes out air at 20°C. The air exhaled is essentially saturated with water vapor in both cases. Warmer air holds more water vapor when saturated, however (see Table 27.2), and therefore humans lose more water than toads lose with each liter of air they exhale.

Now we need to ask what is meant by the partial pressure of water in an aqueous solution. Any particular aqueous solution, if it is placed in contact with air in a closed system, will tend to establish a characteristic, equilibrium water vapor pressure in the air. That vapor pressure is the **water vapor pressure of the aqueous solution**. The water vapor pressure of *pure* liquid water depends on the temperature of the water. Specifically, the water vapor pressure of pure liquid water at a particular temperature is the same as the saturation water vapor pressure of air at the same temperature; Table 27.2, therefore, can be used to look up the water vapor pressure of pure liquid water. One way to think of the water vapor pressure of liquid water is that it is a measure of the tendency of the liquid water to inject water vapor into air. Liquid water at 30°C has a much greater tendency to inject water vapor into air than liquid water at 10°C.

In addition to depending on temperature, the water vapor pressure of an aqueous solution depends also on its solute concentration. The water vapor pressure is in fact a *colligative* property of a solution (see page 117). Raising the concentration of dissolved entities in a solution lowers the water vapor pressure of the solution. This effect is relatively small at the concentrations of most animal body fluids; even a 1-*Osm* solution has a water vapor pressure that is 98% as high as that of pure water. Sometimes, however, the effect of solutes is physiologically important. For instance, if salt left behind from evaporated sweat is allowed to accumulate indefinitely on a person's skin so that newly secreted sweat becomes highly concentrated by dissolving accumulated salt, the water vapor pressure of the sweat can be reduced to be only 75% of that of pure water—an effect that can significantly impair vaporization of the sweat.

Having now discussed the partial pressure of water both in air and in aqueous solutions, let's now turn to the physical laws that govern the evaporation of water from terrestrial animals. As mentioned earlier, water always diffuses from regions of relatively high water vapor pressure to regions of lower water vapor pressure. Thus water evaporates from an aqueous solution (e.g., a body fluid) if the water vapor pressure of the solution exceeds the water vapor pressure of the air next to the solution. The *rate* of evaporation depends on the difference in water vapor pressure. Specifically, if J is the net rate of evaporation per unit of solution surface area, WVP_s is the water vapor pressure of the solution, and WVP_a is the water vapor pressure in the air, then

$$J = K \frac{WVP_s - WVP_a}{X} \quad (27.1)$$

TABLE 27.2 The saturation water vapor pressure at selected temperatures

The saturation water vapor pressure is independent of other gases; for example, it does not depend on the composition of the air. This table also shows the mass of water per unit of volume when the saturation water vapor pressure prevails.

Temperature (°C)	Saturation water vapor pressure		Mass of water per unit of air volume at saturation (mg H ₂ O/L)
	(mm Hg)	(kPa)	
0	4.6	0.61	4.9
10	9.2	1.23	9.4
20	17.5	2.33	17.3
30	31.8	4.24	30.4
37 ^a	47.1	6.28	43.9
40	55.3	7.37	51.1

^aData for 37°C are included because 37°C is the usual deep-body temperature of humans and other placental mammals.

where X is the distance separating WVP_s and WVP_a , and K is a proportionality factor.

From Equation 27.1, we see that the rate at which an animal loses water by evaporation in a terrestrial environment depends partly on the environmental humidity, expressed as WVP_a . As we know from everyday experience, lowering the water vapor pressure of the air (lowering the humidity) speeds evaporation if all other factors are held constant. The rate of evaporation also depends on the water vapor pressure of the body fluid from which evaporation is occurring, WVP_s . Thus, for example, evaporation occurs faster from body fluids that are warm than from ones that are cooler. If a mammal or bird—or a lizard basking in the sun—is exposed to the open air in a hot desert, the animal may face exceptional risks of dehydration by evaporation because its body fluids are warm (meaning WVP_s is high; see Table 27.2) while simultaneously the desert air is dry (WVP_a is low).

A factor that is not immediately evident in Equation 27.1 is that the rate of evaporation also depends on the rate of air movement. If an animal is standing in still air, evaporation from the animal itself tends to humidify the air immediately next to its skin, creating a boundary layer of elevated WVP_a near the skin, very similar to the boundary layer depicted in Figure 5.3. The operative value of WVP_a in Equation 27.1 is therefore raised, slowing evaporation. A wind, however, blows water-vapor-laden air away from the skin surface, replacing it with drier air from the open atmosphere, thereby decreasing the WVP_a next to the skin and speeding evaporation. A wind in a desert can be extremely dehydrating.

A low value of K in Equation 27.1 represents the chief physiological defense that animals can marshal to protect themselves from high rates of evaporative desiccation. K is the *permeability of the integument to water* in an animal that is losing water by evaporation through its integument. A low permeability—a low value of K —slows the loss of body water by evaporation.

To complete our discussion of the diffusion of water vapor in terrestrial animals, let's return to a point made at the start: Animals tend to lose water to the atmosphere, not gain water from it. Put another way, animals rarely gain water by condensation.

When is condensation possible? For most types of animals, condensation can occur only when the body surface is cooler than the air. Under such circumstances—which are uncommon—animals can function like glasses of iced tea. We are all familiar with the fact that gaseous water from the atmosphere condenses into water droplets on the outside of a cold glass of iced tea on a humid summer day. This process depends in part on the physics of the *initiation* of water-droplet formation, an advanced topic in physical chemistry. However, after minute (invisibly tiny) water droplets have been initiated, their *growth* follows the principles of water diffusion we have been discussing. Water will diffuse from the water vapor in the atmosphere into a droplet of liquid water—causing the droplet to grow—only if the water vapor pressure in the atmosphere exceeds the water vapor pressure of the liquid water in the droplet. A *cold* water droplet has a relatively low water vapor pressure (see Table 27.2). If the water vapor pressure in the air is simultaneously high, water will move from its gaseous state in the air into the liquid state in the droplet. In this way, minute droplets will grow into big, visible droplets.

For the most part, the body surfaces of animals are not cooler than the air, explaining why animals usually lose water by evaporation rather than gaining it by condensation. Occasionally, however, animals in special circumstances have cool body surfaces. For example, when lizards that have spent the night in chilly underground burrows emerge into the open air in the morning, their skin can be cooler than the air; when the air is humid, water droplets can then form on their skin and be ingested. Such condensation is transitory, however, because the lizards warm as time passes. As soon as they are as warm as the air, they start to lose water by evaporation.¹¹

SUMMARY Natural Terrestrial Environments

- The water vapor pressure of air is the partial pressure of water vapor in the air and is the most useful expression of humidity for analysis of evaporation and condensation.
- The water vapor pressure of an aqueous solution is the equilibrium water vapor pressure the solution tends to create in juxtaposed air if the solution and air are sealed in a closed system.
- Water vapor diffuses from regions of high water vapor pressure to regions of low water vapor pressure. Thus evaporation occurs if the water vapor pressure of an aqueous solution exceeds that of the surrounding air. Evaporation takes place at a rate proportional to the difference in vapor pressure.

¹¹ Animals in *saturated air* could, in principle, gain water at a low rate while at the *same* temperature as the air, because the solutes in body fluids lower the body-fluid water vapor pressure slightly. However, in reality, when animals are in saturated air, their metabolic heat production raises their temperature to be at least slightly above air temperature, forcing the water vapor pressure gradient to favor evaporation. Thus, without a cooling mechanism, water is not gained by diffusion from the air. Of course, evaporation of body fluids can cool an animal's body surfaces. However, thermodynamics dictates that evaporative cooling cannot be sufficient to cause simultaneous condensation (one process cannot cause evaporation and condensation simultaneously). Thus, for water to be obtained by diffusion from air because of body cooling, the cooling must be caused by some process other than simultaneous evaporation. Some insects, ticks, and other terrestrial arthropods do not follow the physical rules we are discussing here and can gain water steadily from atmospheric water vapor; these cases are discussed in Chapter 28 (see page 746).

Organs of Blood Regulation

Animals living in their natural environments routinely experience conditions that tend to change their blood composition. A mammal exposed to the dryness of desert air, for example, loses water by evaporation, and its loss of water tends to raise the osmotic pressure of its blood, concentrate ions in its blood, and decrease the volume of its blood (challenges to osmotic regulation, ionic regulation, and volume regulation). Another example would be a fish that migrates from the lower part of the Chesapeake Bay (where the salinity is high) into the upper part (where the salinity is near that of freshwater) (see Figure 27.4). In the dilute water, the fish will take on water at an accelerated rate by osmosis, and the influx of water will tend to lower the osmotic pressure of its blood, lower its blood ion concentrations, and expand its blood volume, as we saw earlier. Animals such as mammals and fish are regulators of blood composition and respond to such challenges in negative feedback fashion (see Box 1.1). Certain of their organs act to reverse changes in blood composition, keeping their blood characteristics stable despite the environmental challenges they encounter.

Among the organs involved, the kidneys play particularly important roles, not only in mammals and fish but also in most other types of animals. Indeed, the most fundamental function of kidneys is to *regulate the composition of the blood plasma by removing water, salts, and other solutes from the plasma in controlled ways*. Other organs also play major roles in the regulation of blood composition. For example, the gills of aquatic animals are typically important organs of blood regulation, and salt glands (discussed in Chapter 28) are important in certain birds, lizards, turtles, and other reptiles.

In this chapter we emphasize the kidneys, and more specifically we emphasize a conceptual (rather than a mechanistic) understanding of their function.¹² Three reasons for taking this approach are paramount. First, the kidneys are of key importance. Second, some of the most important concepts of kidney function apply almost universally—providing insights that pertain regardless of the specifics of various kidney types. Third, the concepts that apply to kidney function can often be applied as well to other organs (e.g., salt glands) that regulate blood composition.

Kidneys are fluid-processing organs: They start with blood plasma and produce urine. Many of the effects of kidney function on blood composition can be analyzed by comparing the output of the kidneys with their input—that is, by comparing the urine to the blood plasma. This sort of comparison is usually carried out by use of **U/P ratios**: ratios of urine (“U”) composition over plasma (“P”) composition.

The osmotic U/P ratio is an index of the action of the kidneys in osmotic regulation

The **osmotic U/P ratio** is the osmotic pressure of the urine divided by the osmotic pressure of the blood plasma. For example, if an animal's urine osmotic pressure is 150 mOsm and its plasma osmotic pressure is 300 mOsm, its osmotic U/P ratio is 0.5. Urine may, in principle, be *isosmotic*, *hyperosmotic*, or *hyposmotic* to the blood plasma.¹³ The osmotic U/P ratio reflects this **relative osmoticity** of the urine. If U/P = 1, the urine is isosmotic to the plasma. If U/P < 1, the urine is hy-

¹² The mechanisms of operation and the anatomy of kidneys are discussed in Chapter 29.

¹³ If A and B are two solutions and A has a higher osmotic pressure than B, then A is *hyperosmotic* to B, whereas B is *hyposmotic* to A, as explained in Chapter 5.

posmotic to the plasma. If $U/P > 1$, the urine is hyperosmotic to the plasma. The kidneys of an animal typically have control over the U/P ratio and can adjust it within a species-specific range. Humans, for example, can have an osmotic U/P ratio as high as 4 or as low as 0.1.

To explore the interpretive value of the U/P ratio, let's start by considering a freshwater fish. As discussed in Chapter 5 (see Figure 5.19), the body fluids of a freshwater fish have an osmotic pressure far higher than the osmotic pressure of freshwater. That is, the blood plasma is strongly hyperosmotic to freshwater. Suppose that a fish takes a quantity of pure water— H_2O —into its body fluids by osmosis from the pond or stream in which it lives. This water will dilute the fish's blood and reduce its plasma osmotic pressure. Can the fish restore its original plasma osmotic pressure (i.e., can it osmoregulate) by producing urine? A bit of reflection will reveal that the answer is yes *only if the fish is able to produce urine that is more dilute than its plasma—that is, hyposmotic urine* ($U/P < 1$).

A urine that is hyposmotic to the blood plasma *preferentially voids water*. By this we mean that in comparison with the blood plasma, urine of this sort is richer in water and poorer in dissolved solutes. Therefore, when the urine is excreted, it disproportionately depletes the blood plasma of water. Because of this preferential removal of water from the plasma—and the converse, the preferential retention of solutes in the plasma—voiding the urine acts to elevate the osmotic pressure of the plasma toward its original level. One way to see this point is to contrast this outcome with what would happen if a fish's urine were always isosmotic to its blood plasma. A fish with a U/P ratio of 1 merely excretes water and solutes in the same ratio at which they exist in its blood plasma. Thus, if the fish's plasma were too dilute, it would remain too dilute regardless of how much isosmotic urine ($U/P = 1$) the fish might excrete.

From our analysis of the freshwater fish, we arrive at two general principles of kidney function (Figure 27.7):

- The production of urine isosmotic to blood plasma ($U/P = 1$) cannot serve directly to change the osmotic pressure of the plasma or bring about osmotic regulation of the plasma.
- The production of hyposmotic urine ($U/P < 1$) aids osmotic regulation of the blood plasma if an animal's plasma

has become too dilute and the plasma osmotic pressure therefore needs to be raised.

As one might expect, most freshwater animals have evolved kidneys that have the capacity to make urine that is hyposmotic to their plasma. We humans, as well as most other terrestrial animals, also have that capacity, which serves us well after an evening of too much iced tea or beer.

If the plasma osmotic pressure of an animal has been raised to abnormally *high* levels, urine that is more concentrated than the plasma must be produced to correct the problem. Such urine preferentially voids solutes (and preferentially retains water), thereby lowering the ratio of solutes to water in the plasma. From this analysis, we arrive at a third principle of kidney function (see Figure 27.7):

- The production of hyperosmotic urine ($U/P > 1$) aids osmotic regulation of the blood plasma if an animal's plasma has become too concentrated and the plasma osmotic pressure therefore needs to be lowered.

The ability to produce urine that is hyperosmotic to the blood plasma is not nearly as widespread as the ability to produce hyposmotic urine. The greatest capacities to concentrate the urine are found in mammals, birds, and insects—all primarily terrestrial groups that frequently face risks of dehydration.

The effects of kidney function on volume regulation depend on the amount of urine produced

The kidneys help regulate the *quantity of water* in an animal's body—that is, they aid volume regulation—by voiding greater or lesser *amounts* of water as required. We ourselves provide a familiar example: We make a lot of urine after drinking a lot of water, but we make little urine if we are short of water.

The kidneys, in fact, can play a critical role in *volume regulation* even when not playing any direct role in *osmotic regulation*. In this respect, kidney function illustrates that volume regulation and osmotic regulation are *distinct processes*, as stressed previously. To illustrate these points, let's consider freshwater crabs. These are species of true crabs that live in rivers and lakes, mostly in tropi-

U/P ratio	Implications for excretion		Effects on composition of blood plasma
	Effects on water excretion	Effects on solute excretion	
U/P = 1 (isosmotic urine)	Water is excreted in the same relation to solutes as prevails in the blood plasma.	Solutes are excreted in the same relation to water as prevails in the blood plasma.	The formation of urine leaves the ratio of solutes to water in the blood plasma unchanged, thus does not alter the plasma osmotic pressure.
U/P < 1 (hyposmotic urine)	Water is preferentially excreted. Urine contains more water relative to solutes than plasma.	Solutes are preferentially held back from excretion. Urine contains less solutes relative to water than plasma.	The ratio of solutes to water in the plasma is shifted upward. The osmotic pressure of the plasma is raised.
U/P > 1 (hyperosmotic urine)	Water is preferentially held back from excretion. Urine contains less water relative to solutes than plasma.	Solutes are preferentially excreted. Urine contains more solutes relative to water than plasma.	The ratio of solutes to water in the plasma is shifted downward. The osmotic pressure of the plasma is lowered.

FIGURE 27.7 The interpretive significance of the osmotic U/P ratio The terms *solute* and *solutes* refer to total numbers of osmotically effective dissolved entities.

cal and subtropical parts of the world. Freshwater crabs provide striking examples of animals in which the kidneys participate in volume regulation but not osmotic regulation. The crabs are dramatically hyperosmotic to the freshwater in which they live and thus experience a steady osmotic flux of water into their body fluids. To meet this challenge to volume regulation, the crabs produce a substantial flow of urine; each day, their kidneys excrete the same amount of water as they gain by osmosis. However, at least in the species that have been investigated, the kidneys of freshwater crabs are unable to produce urine that is more dilute than the blood plasma. Their urine is always isosmotic to the plasma ($U/P = 1$). Consequently, the production of urine by the crabs does not alter their plasma osmotic pressure. Although the kidneys of freshwater crabs help them dispose of their excess *volume* of water, *other* organs must maintain the high *osmotic pressure* of their blood.

The effects of kidney function on ionic regulation depend on ionic U/P ratios

The action of an animal's kidneys in ionic regulation can be analyzed in ways closely analogous to the analysis of osmotic regulation (see Figure 27.7). For each ion, an ionic U/P ratio can be computed; it is the concentration of that ion in the urine divided by the concentration of the ion in the blood plasma. The sodium U/P ratio, for example, is the urine Na^+ concentration divided by the plasma Na^+ concentration. To see the interpretive value of an ionic U/P ratio, let's continue with Na^+ . If the sodium U/P ratio is greater than 1, the urine contains more Na^+ per unit of water volume than the plasma; thus the excretion of urine preferentially voids Na^+ and lowers the plasma Na^+ concentration. Conversely, if the sodium U/P ratio is less than 1, the excretion of urine acts to retain Na^+ preferentially in the body and raise the plasma Na^+ concentration.

The kidneys can play a role in *ionic regulation* even when not playing any direct role in *osmotic regulation*. In this way, the kidneys illustrate that ionic regulation is a distinct concept from osmotic regulation. Marine teleost (bony) fish are good examples of animals in which the kidneys participate in ionic regulation but not osmotic regulation. These fish are hyposmotic to the seawater in which they live. Therefore, they lose water osmotically to their environment while simultaneously they gain ions by diffusion from the seawater. Both of these processes tend to raise the osmotic pressure and the ion concentrations of their blood plasma. The marine teleost fish produce a urine that is isosmotic to their plasma (osmotic $U/P = 1$); their urine, therefore, can play no direct role in solving their *osmotic* regulatory problem. However, their urine differs dramatically from their blood plasma in its *solute composition*. In particular, the U/P ratios for Mg^{2+} , SO_4^{2-} , and Ca^{2+} are far greater than 1. The excretion of urine by these fish therefore serves the important *ionic* regulatory role of keeping down the internal concentrations of these ions, which the fish tend to gain from the seawater.

SUMMARY Organs of Blood Regulation

- The effects of kidney function on the composition of the blood plasma are analyzed using osmotic and ionic U/P ratios. Figure 27.7 summarizes the interpretation of U/P ratios.

- Osmotic regulation, volume regulation, and ionic regulation are separable kidney functions in the sense that the kidneys can participate in volume regulation while simultaneously not aiding osmotic regulation, or they can carry out ionic regulation independently of osmotic regulation.

Food and Drinking Water

The specific composition of food and drinking water often has major implications for the water–salt physiology of animals living in their natural environments—illustrating once again that physiology and ecology are intimately related. To start our discussion of this topic, let's focus on the relative osmoticities of predators and their prey.

When one animal captures and eats another, the water–salt composition of the prey animal—not just its nutrient content—may be significant for the predator. Consider, for example, predator–prey relations in the ocean. Marine mammals and teleost fish are dramatically hyposmotic to seawater. However, most marine invertebrates are approximately isosmotic to seawater. When a mammal or fish consumes a meal of invertebrates, the body fluids of its prey are markedly more concentrated in salts than its own body fluids are. The predator must therefore eliminate excess salts to maintain its normal body-fluid composition. In contrast, consider a mammal or fish that consumes a meal of fish. In this case, the body fluids of the prey are similar in salt concentration to those of the predator. Thus the fish-eating predator incurs little or no excess salt load when it eats, in contrast to the large salt load incurred by the invertebrate-eating predator. A fish-eating predator benefits from the work that its prey performed to maintain body fluids more dilute than seawater—an intriguing lesson in ecological energetics.

Salty drinking water may not provide H_2O

When animals drink water rich in salts, the water may not serve as a useful source of H_2O . Whether an animal can gain H_2O by drinking salty water (e.g., seawater) depends on whether the animal can eliminate the salts from the salty water using less H_2O than was ingested with them. This principle, which applies to all animals, is a critical consideration when people suffering from dehydration are presented with the option of drinking salty water.

We have all heard Coleridge's famous line from *The Rime of the Ancient Mariner*, "Water, water, everywhere, nor any drop to drink." Sailors desperate for water discovered long ago that drinking ocean water was worse than drinking no water at all: Drinking the seawater paradoxically dehydrated them. We now know that a key consideration in understanding this paradox is that the maximum Cl^- concentration that the human kidney can produce in the urine is lower than the concentration of Cl^- in seawater. Therefore, if people drink seawater, the Cl^- they ingest can be excreted only by voiding more H_2O than was taken in with the Cl^- . That is, such people not only must use all the H_2O ingested with the seawater to excrete the Cl^- ; they must also draw on other bodily reserves of H_2O , thereby dehydrating their tissues. Some animals are able to excrete salts at higher concentrations than humans can and thus are able to gain H_2O by drinking salty solutions such as seawater (by excreting the salts in less H_2O than was ingested with them).

Plants and algae with salty tissue fluids pose challenges for herbivores

Some plants in terrestrial environments—particularly ones native to deserts—have very salty tissue fluids. If herbivores eat such plants, they receive a substantial salt load along with the food value of the plants.

The soils in some desert regions are very saline. One reason for this condition is that salts tend to accumulate over eons of time in the places where rain settles in deserts; the evaporation of rain water leaves the salts it contains behind in the soil, and each rainfall adds to the salts left by preceding rainfalls. Plants called **halophytes** (“salt plants”) root in these saline soils and often have high salt concentrations in their tissue fluids. Such plants form a major part of the diet of desert sand rats (*Psammomys obesus*) and are consumed in large quantities at times by dromedary camels. The total salt concentration in some halophytes exceeds that of seawater by as much as 50%. Many of the halophytes are succulent plants with juicy leaves. Animals that eat them obtain considerable water, but they obtain a large salt load as well.

Analytically, the salt levels of salty plants pose much the same problems for animals as the problem posed by salty drinking water. Suppose, for example, that the Na⁺ concentration in a halophyte’s tissues is five times that in mammalian blood plasma. A mammal would then require kidneys that can produce a sodium U/P ratio greater than 5 to be able to excrete the Na⁺ and obtain a net gain of H₂O from the plants.¹⁴ Most mammals cannot achieve such a high sodium U/P ratio. Sand rats, however, have kidneys with legendary concentrating abilities. Therefore, after scraping off and discarding the saltiest parts of the leaves, sand rats are able to eat halophytes without ill effects from the salt they ingest. Accordingly, they can eat foods that other desert rodents must avoid.

Air-dried foods contain water

Many terrestrial animals consume air-dried seeds or other dry plant matter. These air-dried foods contain moisture, even though they are ostensibly dry. The moisture they contain is significant, particularly for animals that live where drinking water is difficult to find.

Air-dried foods equilibrate with air moisture. Accordingly, they vary in their water content as the humidity varies. Whereas “dry” barley grain, for example, contains almost 4 g of water per 100 g dry weight at 10% relative humidity, its water content is five times higher at 76% relative humidity. When air-dried plant material is exposed to an altered air humidity, its moisture content changes within hours. Two humidity patterns are of importance to animals in this regard. First, the relative humidity of the air tends to rise at night, and second, it tends to be higher below ground than above ground. Animals that get water from air-dried food can often increase their water intake by feeding at night or by storing the food in burrows prior to ingesting it.

Protein-rich foods can be dehydrating for terrestrial animals

Because carbohydrates and lipids consist primarily of carbon, hydrogen, and oxygen, their oxidation during metabolism results mostly in formation of CO₂ and H₂O. The CO₂ is exhaled into the atmosphere, and the H₂O contributes to an animal’s water resources.

Proteins, by contrast, contain large amounts of nitrogen, and their catabolism results in nitrogenous wastes.

The products of protein catabolism can affect a terrestrial animal’s water balance when they must be excreted in solution in the urine. In mammals, for example, the principal nitrogenous waste is urea, a highly soluble compound voided in the urine. The amount of urinary water required to void urea depends on the urea-concentrating ability of an animal’s kidneys. When a mammal is producing urine with as high a urea concentration as it can, a high-protein meal often forces the animal to void more water (to get rid of the urea) than a low-protein meal.

Metabolic Water

When organic food molecules are aerobically catabolized, water is formed, as illustrated by the equation for glucose oxidation:

The water produced by catabolic reactions such as this is known as **metabolic water (oxidation water)**, in contrast to **preformed water**, which is water taken in as H₂O from the environment. Metabolic water is produced by all animals. **Table 27.3** lists the amount of water formed per gram of foodstuff oxidized.

The simple fact that aerobic catabolism produces water does not by itself mean that animals gain water in *net* fashion from catabolism. This is true because the catabolism of foodstuffs not only produces water, but also obligates an animal to certain water losses. The **obligatory water losses** of catabolism are the losses that must take place for catabolism to occur. To assess the *net* impact of catabolism on the water balance of an animal, the obligatory water losses must be subtracted from the gains of metabolic water. This important principle will be exemplified after we briefly discuss the *respiratory*, *urinary*, and *fecal* components of obligatory water loss. Detailed aspects of this topic can vary, depending on the type of animal and on peculiarities of diet. For simplicity, we assume here a terrestrial mammal (or similar animal) that is eating foods of ordinary salt content (i.e., not highly salty foods).

TABLE 27.3 Average gross amount of metabolic water formed in the oxidation of pure foodstuffs

The values in this table apply to the oxidation of materials that have been absorbed from a meal and to the oxidation of materials stored in the body. To emphasize this, the materials are called foodstuffs rather than foods. The gross amount of metabolic water formed is, by definition, simply the amount made by the oxidation reactions.

Foodstuff	Grams of H ₂ O formed per gram of foodstuff
Carbohydrate ^a	0.56
Lipid	1.07
Protein with urea production ^b	0.40
Protein with uric acid production ^b	0.50

Source: After Schmidt-Nielsen 1964.

^aStarch is assumed for the specific value listed.

^bWater yield in protein catabolism depends on the nitrogenous end product.

¹⁴This is just a rough calculation in the case of the plants because the organic constituents of plants must also be considered.

The **obligatory respiratory water loss** is defined to be the loss of water that is necessary to obtain O_2 for catabolism. Aerobic catabolism requires O_2 (see Equation 27.2), and when animals breathe to obtain O_2 , they lose water by evaporation. The aerobic catabolism of all types of food molecules causes obligatory respiratory water loss. The magnitude of the loss depends on a species' physiology of breathing and on the humidity of the ambient air.

The **obligatory urinary water loss** is the loss of urine water that is mandated by the ingestion or catabolism of food molecules. Protein catabolism is the usual cause of obligatory urinary water loss. As we have seen, protein catabolism produces nitrogenous wastes (urea in mammals) that demand urine excretion. The excretion of such wastes obligates water excretion. The catabolism of carbohydrates and lipids does not yield products that must be excreted in urine, and thus is not a cause of obligatory urinary water loss.

The **obligatory fecal water loss** is the loss of water that must occur in feces for food catabolism to take place. Obligatory fecal water loss occurs only when *ingested* foods are catabolized because the catabolism of organic materials stored in the body, such as lipid stores, produces no fecal waste. Ingested foods usually contain *preformed* water. If an animal must lose more water in its feces than it took in as preformed water with its ingested food, it incurs a net fecal water loss that is required for it to catabolize the food. This net loss is the obligatory fecal water loss.¹⁵

The use of these concepts is exemplified in **Box 27.1**, which focuses on kangaroo rats—animals that thrive in some of the driest places in North America's southwestern deserts. The kangaroo

¹⁵If the feces contain less water than was taken in with ingested food, the animal realizes a net gain of *preformed* water, which is not a factor in metabolic water calculations.

rats in the studies discussed were given no water to drink and fed nothing but air-dried barley grain. Remarkably, they did not suffer from dehydration, because they were able to gain metabolic water in net fashion by catabolizing the barley. Note that their net water gain is computed in two steps. The first step is to determine the immediate (gross) yield of metabolic water from the oxidation of the food molecules absorbed from a gram of ingested barley. The second step is to subtract the obligatory respiratory, urinary, and fecal water losses required to catabolize a gram of ingested barley.

Metabolic water matters most in animals that conserve water effectively

At moderate temperatures and even at low relative humidities (as low as about 20%), kangaroo rats and some other desert rodents can live indefinitely on air-dried seeds without drinking water, meeting most of their water needs with metabolic water and the remainder with the small amounts of preformed water in the seeds. Under similar conditions, most other mammals would quickly die. These striking contrasts have given rise to a myth that desert rodents produce especially large amounts of metabolic water.

In fact, *the amount of metabolic water produced per gram of food oxidized is fixed by chemistry*; it depends simply on the stoichiometry of the aerobic catabolic pathways. Thus, for a given type of food, all animals produce the same amount of metabolic water per gram of food oxidized.¹⁶

¹⁶The only exception is that when protein is catabolized, the amount of metabolic water produced depends to some extent on the particular nitrogenous end product made (see Table 27.3) because the chemistry of the reactions depends on the particular end product. The nitrogenous end products are discussed in detail in Chapter 29.

BOX 27.1 NET METABOLIC WATER GAIN IN KANGAROO RATS

Desert kangaroo rats (*Dipodomys*) were studied at an air temperature of 25°C and a relative humidity of 33%. They were fed air-dried barley grain and given no drinking water. This box shows how obligatory water losses are taken into account to calculate the kangaroo rats' *net* gain of metabolic water.

Gross Metabolic Water Production (0.54 g of H₂O per g of barley)

The food molecules absorbed by a kangaroo rat from a gram of ingested barley yield about 0.54 g of metabolic water during cellular oxidation. This value is calculated by first estimating the amounts of carbohydrate, lipid, and protein absorbed and catabolized during the processing of a gram of barley. The water yields of oxidizing the three components are then calculated from Table 27.3 and summed.

Obligatory Water Losses (total: 0.47 g of H₂O per g of barley)

1. *Respiratory* (0.33 g of H₂O per g of barley): Oxidation of the food molecules

absorbed from a gram of barley requires consumption of about 810 mL of O_2 . To acquire this amount of O_2 by breathing, a kangaroo rat loses about 0.33 g of water by pulmonary evaporation under the conditions of the experiments.

- Urinary* (0.14 g of H₂O per g of barley): The protein absorbed from a gram of ingested barley yields about 0.03 g of urea. When kangaroo rats concentrate urea maximally in their urine, this amount of urea can be excreted in about 0.14 g of water.
- Fecal* (0 g of H₂O per g of barley): About 0.1 g of preformed water is obtained with each gram of barley ingested. However, in a kangaroo rat, the feces resulting from the digestion of a gram of barley contain only about 0.03 g of water. Because the water lost in feces is less than that gained with the food, there is no net fecal water loss, and therefore the obligatory fecal water loss is 0. A kangaroo rat, in fact, *gains preformed water* by digesting barley because it loses less water in its feces than it takes in with the barley.

A kangaroo rat This species, *Dipodomys merriami*, is one of several species of kangaroo rats noted for their success in the deserts and semideserts of the American Southwest.

Net Gain of Metabolic Water (0.07 g of H₂O per g of barley)

The total of all the obligatory water losses during the catabolism of a gram of ingested barley is 0.47 g. To calculate the net gain of metabolic water, this total must be subtracted from the gross metabolic water production per gram of barley, 0.54 g. The net gain is therefore 0.07 g of water per gram of ingested barley. This gain of metabolic water can be used to offset other water losses, or if it represents an excess, it can be excreted.

TABLE 27.4 Approximate catabolic gains and losses of water in kangaroo rats (*Dipodomys*) and laboratory rats (*Rattus*) when eating air-dried barley grain and denied drinking water

Study animals were caged at 25°C and 33% relative humidity. The values given are g of H₂O per g (dry weight) of barley ingested. Values for kangaroo rats are from Box 27.1.

Category of water gain or loss	Kangaroo rats	Laboratory rats
Gross metabolic water produced	0.54 g/g	0.54 g/g
Obligatory water losses		
Respiratory	0.33	0.33
Urinary	0.14	0.24
Fecal	0.00	0.03
Total obligatory water losses	0.47	0.60
Net gain of metabolic water	+ 0.07	-0.06

Why, then, do some animals depend more on metabolic water than others? The answer lies in *water conservation*: Some animals *conserve* water more effectively than others. If two animals have the same metabolic rate and oxidize the same foods, both will produce the same amount of metabolic water. If one conserves water poorly and thus has a high overall rate of water turnover—lots of water entering and leaving its body each day—its production of metabolic water will be small relative to its total water intake and loss; thus its metabolic water will represent just a small part of its water budget. If the other animal conserves water well and thus has a low overall rate of water turnover, its production of metabolic water will be large relative to its total water intake and loss—and will represent a large part of its water budget.

To illustrate, suppose we place kangaroo rats and laboratory rats at an air temperature of 25°C and a relative humidity of 33% and we feed both species the same food: air-dried barley grain. Let's assume (as is approximately true) that individuals of the two species have similar rates of metabolism. If we provide no drinking water, the kangaroo rats will thrive—living largely on metabolic water—but the laboratory rats will deteriorate and ultimately require drinking water to save their lives. Chemical stoichiometry dictates that the two species produce similar amounts of metabolic water. How, then, can we explain why only one species survives without drinking water? The answer is seen in **Table 27.4**, which presents a *full* accounting of the effects of catabolism on water balance. The kangaroo rats conserve water more effectively than the laboratory rats; they have lower urinary water losses because they can concentrate urea to a greater degree in their urine, and they have lower fecal water losses, in part because they produce drier feces. When the obligatory water losses of the two species are subtracted from the gross amount of metabolic water produced, the kangaroo rats—because they conserve water so well—enjoy a *net gain* of metabolic water. The laboratory rats, however, suffer a *net loss*. Note that the critical difference between them is not in how abundantly they *produce* metabolic water. Exceptional *water conservation* in the kangaroo rats is what permits them to live on metabolic water.

SUMMARY Metabolic Water

- Metabolic water is produced by all animals in amounts determined by the chemical stoichiometry of the oxidation of organic molecules.
- To determine the *net* effect of catabolism on water balance, obligatory respiratory, urinary, and fecal water losses must be subtracted from gross metabolic water production.
- The role played by metabolic water in the overall water budget of an animal depends on the animal's capacity to *conserve* body water.

Cell-Volume Regulation

One of the most important attributes of cells in the body is that they have particular *volumes*. As noted earlier, cell membranes are generally sufficiently permeable to water that the intracellular fluids remain isosmotic to the extracellular fluids bathing the cells (the interstitial fluids) simply by osmosis. This condition may at first sound benign, but it in fact means that any change in the osmotic pressure of the extracellular fluids is a threat to the maintenance of a constant cell volume. If the osmotic pressure of the extracellular fluids decreases, cells tend to take on water by osmosis and swell. If the extracellular osmotic pressure increases, cells tend to lose water and shrink. How, then, can cells display **cell-volume regulation**—that is, maintain a constant cell volume—when the osmotic pressure of the extracellular fluids changes?

For cells to exhibit volume regulation, they must alter their total content of osmotically effective dissolved entities. To see this, consider the model cell in **Figure 27.8**. In **1**, the cell contains ten osmotically effective dissolved entities and is at its normal size. If the cell is transferred into a solution that has an osmotic pressure only half as great as the starting solution, its initial response **2** is to take on water by osmosis and swell to twice its normal volume, thereby reducing the concentration of dissolved entities inside by half. How can the cell restore its normal volume if it remains in the dilute solution? The answer is that the cell must reduce its content of dissolved entities. As seen in **3**, if the cell halves the number of dissolved entities in its intracellular fluid, it will return to its original volume while remaining isosmotic to the dilute solution. Suppose now that we return to the original cell **1** and we transfer it into a solution that has an osmotic pressure double that of the starting solution. The cell's initial response **4** will then be to lose water osmotically and shrink to half its normal volume, doubling the concentration of dissolved entities inside. To restore its normal volume in the concentrated ambient solution, the cell must increase its content of dissolved entities. As seen in **5**, if the cell doubles the number of dissolved entities in its intracellular fluid, it will return to its original volume while remaining isosmotic to the concentrated solution.

We see from this exercise that *if the extracellular fluids of an animal become diluted, its cells must reduce their intracellular numbers of osmotically effective dissolved entities to retain their original volumes*. Conversely, *if the animal's extracellular fluids become more concentrated, cell-volume regulation requires that cells increase their intracellular numbers of osmotically effective dissolved entities*. These insights help clarify the potential advantages of osmoregulation of the extracellular fluids: If organs such as the kidneys can keep the extracellular fluids at a constant osmotic pressure, the cells are

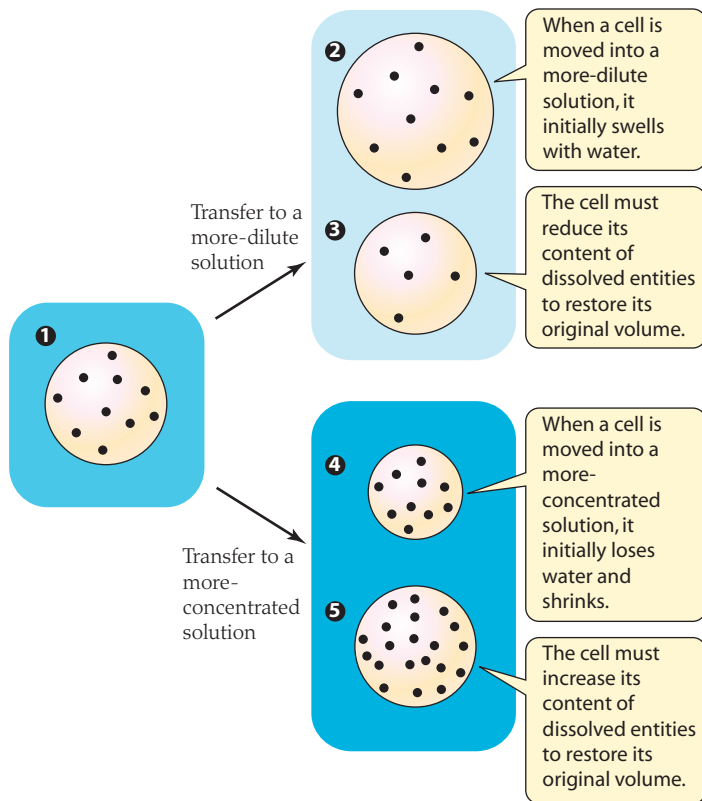

FIGURE 27.8 The fundamental principles of cell-volume regulation. Dots represent dissolved entities in the intracellular fluid of a model cell. Shading around each cell represents the osmotic pressure of the solution bathing the cell (darker blue symbolizes higher osmotic pressure). The solutions at the right have osmotic pressures that are half as great (top) and twice as great (bottom) as the osmotic pressure of the solution at the left.

freed from any requirement to adjust their content of solutes for cell-volume regulation.

When circumstances require cells to undergo cell-volume regulation, certain intracellular solutes are increased or decreased in amount more than others: Cells are selective in which solutes they modulate. The solutes that are selectively modulated vary to some extent with species and tissue. In many mammalian tissues, for example, potassium (K^+) is a principal player in cell-volume regulation. Because the osmotic pressure of mammalian extracellular fluids is generally tightly regulated, mammalian cells ordinarily need to make only small adjustments in their quantities of intracellular solutes to achieve cell-volume regulation. Often K^+ is the principal solute they adjust.

Invertebrates—meaning most animals—employ *organic solutes* as their principal agents of cell-volume regulation. Certain mammalian tissues also emphasize organic solutes. These include the brain (where stable intracellular concentrations of K^+ and other inorganic ions are particularly important for nerve impulse generation) and the renal medulla, the interior tissue of each kidney (see page 771).

Here we focus on the modulation of intracellular organic solutes in invertebrates to illustrate the selective use of particular solutes for cell-volume regulation. Consider, for example, an osmoconformer, the blue mussel (see Figure 27.3c). When a mussel is placed in a more-dilute or more-concentrated environment, its blood osmotic pressure changes to match the new environmental osmotic pressure. Cells throughout its body therefore confront volume-regulation challenges; when the blood becomes more dilute, the cells bathed by the blood face a tendency to take on water, and conversely when the

blood becomes more concentrated, the cells face a tendency to lose water. These types of challenge are not limited to osmoconformers because osmoregulating animals are rarely perfect regulators. Even blue crabs (see Figure 27.5)—which are exceptionally effective osmoregulators—exhibit changes in their blood osmotic pressure if they move into waters with a substantially altered salinity.

To carry out cell-volume regulation, the cells of mussels, blue crabs, and other invertebrates principally modulate their content of organic solutes. This use of organic solutes means—as shown in Figure 27.9—that intracellular concentrations of inorganic ions can remain relatively constant. That is, the cells achieve ionic regulation simultaneously with cell-volume regulation!

What are the mechanisms by which cells modify the numbers of dissolved organic molecules in their intracellular fluid? The mechanisms depend on the particular types of organic molecules. Here we discuss free amino acids, which are major agents of intracellular volume regulation in many sorts of animals, including mussels and blue crabs. When animals are transferred into more-saline environmental water, multiple processes are employed to raise intracellular quantities of free amino acids, including decelerated amino acid catabolism, accelerated synthesis of new amino acids, accelerated breakdown of intracellular proteins to release amino acids, and accelerated active transport of amino acids into the cells. When animals are transferred into more-dilute environmental water, the processes employed to decrease intracellular quantities of free amino acids are in many ways the opposite. For example, catabolism of amino acids is accelerated. An increase in excretion of ammonia (NH_3)—a product of amino acid catabolism (see Figure 6.3b)—is often easily detected when animals are transferred into dilute waters!

Intracellular organic solutes have been of extreme importance in the *evolution* of the composition of the intracellular fluids. Most vertebrates and freshwater invertebrates have evolved intracellular fluids that—speaking very roughly—are one-third as concentrated (in total osmotic pressure) as the intracellular fluids evolved by most invertebrates in the open ocean. Does that mean that the intracel-

FIGURE 27.9 Many animal cells achieve cell-volume regulation principally by altering their content of organic solute molecules. Here we assume for simplicity that *only* organic solutes are modulated. As the model cell is exposed to a higher and higher external osmotic pressure (from left to right), it adds organic solute molecules to its intracellular fluids. Consequently, it maintains *both* a constant cell volume *and* a constant total intracellular concentration of inorganic ions. Real cells typically adjust inorganic ions to some extent while emphasizing modulation of organic solutes. The principal intracellular inorganic ions are K^+ , Mg^{2+} , Na^+ , and Cl^- .

lular fluids are three times saltier in the ocean invertebrates? No: All these animals are similar in their intracellular inorganic ion concentrations! Much as illustrated by the cell bathed with the most concentrated external solution in Figure 27.9, the ocean invertebrates have far higher intracellular concentrations of organic solutes than the other animals do. As animals evolved different *total* intracellular concentrations, most of the difference was accounted for by evolving different concentrations of organic solutes rather than inorganic ions.

SUMMARY Cell-Volume Regulation

- For a cell to maintain a constant volume, it must reduce the amounts of osmotically effective dissolved entities in its intracellular fluid when the osmotic pressure of the surrounding extracellular fluid falls, and it must increase its content of dissolved entities when the osmotic pressure of the extracellular fluid rises.
- Organic molecules such as free amino acids are the principal intracellular solutes employed for cell-volume regulation by cells of invertebrates. They are also the principal intracellular solutes employed in certain of the tissues (e.g., brain and renal medulla) of vertebrates.
- The use of organic molecules as principal agents of cell-volume regulation permits simultaneous ionic and volume regulation of the intracellular fluid.

From Osmolytes to Compatible Solutes: Terms and Concepts

Any solute that exerts a sufficiently large effect on the osmotic pressure of a body fluid to be of consequence for understanding water–salt physiology is termed an **osmolyte** (or **osmotic agent**), regardless of what other functions it may perform. An osmolyte that an individual animal or individual cell increases or decreases in amount to achieve osmotic regulation or cell-volume regulation is called an **osmotic effector**.

Animals, as we have just seen, are selective in which solutes they employ as intracellular osmotic effectors: They generally use organic solutes, rather than inorganic ions, in this role. Why animals employ organic solutes is an important contemporary question in the study of water–salt physiology. The hypothesis favored by most physiologists is that the solutes animals preferentially employ as osmotic effectors are ones that have minimal effects on proteins and other macromolecules. Such solutes, termed *compatible solutes*, can be increased and decreased in a cell without greatly altering the cell's enzyme kinetics or other aspects of cell protein function.

The term “compatible solute” was first used more than 30 years ago to refer to a solute that, at high concentrations, does not interfere with the ability of enzymes to function effectively. Modern definitions are less specific and more rough-and-ready, but they retain the spirit of the original. Today, a **compatible solute** is a solute that, when concentrated enough to contribute significantly to the osmotic pressure of a body fluid, has little or no effect on the structure and function of macromolecules with which that body fluid is in contact. Whereas inorganic ions generally perturb enzymes or other macromolecules when their concentrations are substantially altered, some types of organic solutes are outstanding examples of compatible solutes. Particularly noteworthy compatible solutes include: (1) certain of the

FIGURE 27.10 Counteracting solutes in a stingray The enzyme pyruvate kinase was extracted from round stingrays (*Urolophus halleri*) for study. The affinity of the enzyme for one of its substrates (ADP, adenosine diphosphate) was measured. When the enzyme was independently exposed to an increasing concentration of urea (red line) or trimethylamine oxide (TMAO; green line), its affinity was strongly affected and driven out of the normal range (shaded area) in opposite directions. However, when the enzyme was exposed to a mix of urea and TMAO (black line), it exhibited approximately its normal affinity regardless of how high the concentrations of the two organic solutes were raised. Affinity decreases as the Michaelis constant increases (see Chapter 2). (After Yancey et al. 1982.)

free standard amino acids,¹⁷ (2) betaines, which are fully methylated forms of amino acids, (3) taurine, and (4) glycerol.

The concept of *counteracting solutes* is also significant for understanding the roles of solutes in water–salt physiology. Unlike compatible solutes, individual counteracting solutes may have strong effects on macromolecules. However, the effects of one counteracting solute are “opposite” to those of others, meaning that such solutes can offset each other’s effects. **Counteracting solutes** (also called *compensatory solutes* or *chemical chaperones*) are osmolytes that act *in teams* of two or more to modify the osmotic pressures of body fluids without greatly perturbing macromolecules; as teams, they are relatively innocuous because the individual solutes of a team have mutually offsetting effects on the macromolecules.

The defining example of the concept of compatible solutes is provided by the interplay of urea and methylamines in the body fluids of sharks, skates, rays, and a few other groups of marine fish. Urea tends to have strong destabilizing and inhibiting effects on enzymes and other macromolecules. Conversely, certain methylamine compounds—such as trimethylamine oxide (TMAO), glycine betaine, and sarcosine—tend to stabilize and activate enzymes, and thus can counteract the effects of urea. In animals that employ urea as an osmolyte, one or more methylamines are usually also present in quantities that more or less exactly “titrate away” the effects of the urea (Figure 27.10). This is the case in the sharks, skates, and rays, which we discuss more thoroughly in Chapter 28.

¹⁷Among the standard amino acids (those used in protein synthesis), glycine, arginine, proline, and serine—when present as free amino acids—have particularly small effects on macromolecules and thus stand out as superior compatible solutes.

Study Questions

1. In your own words, explain why an animal with excessively high blood osmotic pressure must be able to produce urine hyperosmotic to its blood plasma if its kidneys are to help correct the problem. In your answer, explain why neither urine that is isosmotic to the blood plasma nor urine that is hyposmotic to the plasma would help.
2. Based on the physical laws of evaporation, explain why the high body temperatures of mammals and birds make them prone to having higher rates of evaporative water loss than poikilothermic terrestrial vertebrates with lower body temperatures.
3. People who live and work in heated homes and office buildings in places with cold winters are well aware that the air inside becomes very dry during the winter season. Explain why the air inside a heated building is often low in humidity when the air outside is cold. Keep in mind that outside air is circulated inside by incidental or forced flow. (Hint: Consult Table 27.2.)
4. When animals oxidize stored fat, they produce metabolic water. Even though the production of metabolic water from stored fat follows principles of chemical stoichiometry, the *net* gain of water that animals realize from the oxidation of stored fat depends on the humidity of the atmosphere. Explain why. Does the net gain increase or decrease as the atmosphere becomes more humid?
5. When blue crabs living in full-strength seawater swell during molting, they take on the H₂O that bloats their bodies from the seawater in which they live. They obtain some of the H₂O by drinking. In addition, data show that the activity of Na⁺-K⁺-ATPase in their gills increases as they start to swell during molting. This rise in ATPase activity suggests that the gills increase active transport of ions from the surrounding seawater into the blood of the crabs. How could this process help account for uptake of H₂O?
6. Some species of animals gain physiological advantages by exploiting the specialized physiological capabilities of other species. Explain how marine mammals that prey on teleost fish rather than invertebrates illustrate this principle. Also explain how carnivorous mammals that prey on herbivorous mammals in deserts illustrate the same principle.
7. The kidney function of freshwater crabs illustrates that volume regulation can occur independently of osmotic regulation, and the kidney function of marine teleost fish illustrates that ionic regulation can occur independently of osmotic regulation. Explain both points.
8. People dying of dehydration because of lack of freshwater to drink inevitably ponder drinking their own urine. Analyzing the matter by use of the principles developed in this chapter, is a dehydrated person likely to gain H₂O by drinking his or her urine?
9. In many parts of the world, if one goes out at daybreak in autumn, it is a common sight to see a layer of fog formed just above the surface of the water of ponds and lakes. A fog consists of minute droplets of liquid water suspended in the atmosphere. When a layer of fog forms above a pond, the pond itself is the source of the water in the atmospheric water droplets. Inevitably, the temperature of the water in a pond is higher than the temperature of the air on mornings when fog layers form. Using the quantitative information in Table 27.2, explain why these fog layers form.
10. How are compatible intracellular solutes employed in cell-volume regulation, and why do they have advantages as intracellular osmotic effectors?
11. Consider a set of related terrestrial animals of various body sizes. Body surface area (*SA*) is an allometric function of body weight (*W*): $SA \propto W^{0.67}$. From Chapter 7, the metabolic rate (*MR*) is also an allometric function of body weight; at rest, for example, a likely relation would be $MR \propto W^{0.7}$. Predict the relation between rate of evaporative water loss (*EWL*) and body size, *taking account of both integumentary and respiratory EWL*. Explain your logic and assumptions.

Water and Salt Physiology of Animals in Their Environments

The body fluids of marine teleost (bony) fish—such as these coral reef fish—are far more dilute than the seawater in which they are swimming. Such fish have blood osmotic pressures of about 300–500 mOsm, whereas seawater has an osmotic pressure of approximately 1000 mOsm. From the viewpoint of fluid composition, marine teleost fish are packets of low-salinity fluids cruising about within a high-salinity environment!

Because the body fluids of a marine teleost fish are not at equilibrium with the seawater surrounding the fish, passive processes occur that tend to alter the composition of the body fluids, drawing them toward equilibrium with seawater. The body fluids, having a lower osmotic pressure than seawater, lose water by osmosis, a process that tends to concentrate them. Moreover, a number of inorganic ions diffuse inward from the seawater, thereby also tending to concentrate the body fluids. Marine teleost fish must steadily expend energy to maintain their body fluids out of equilibrium with the seawater in which they swim.

When we reflect on the questions that are raised by the body-fluid composition of marine teleost fish, we quickly recognize that the questions of *mechanism* and *origin* stressed in Chapter 1 are both important. *How* do the fish keep their body fluids more dilute than seawater, and *why* do they do so? These same two questions—which are the central questions of mechanistic physiology and evolutionary physiology—arise in the study of the water–salt physiology of all animals.

In terms of their water–salt physiology, animals have been versatile in adapting to an astounding range of environments on Earth—not just seawater and ordinary freshwater, but also salt lakes far more concentrated than seawater, glacial ponds almost as dilute as distilled water, estuaries with highly variable salinity, and terrestrial environments ranging from rain forests to extreme deserts. Each type of habitat poses distinct challenges, and animals of diverse types that live in a particular habitat often have converged on similar mechanisms for meeting the challenges. For these reasons, the detailed study of animal water–salt physiology is logically organized around habitats. We take that approach in this chapter. We start by focusing on freshwater habitats, in part because we have already emphasized them in Chapter 5, and in part because the study of freshwater fish will help set the stage for a better understanding of ocean fish.

Animals in Freshwater

The animals living today in freshwater are descended from ocean-living ancestors: The major animal phyla originated in the oceans and later invaded all other habitats. Seawater was probably somewhat different in its total salinity and salt composition in the early eras of animal evolution than it is today. Nonetheless, when the animal phyla invaded freshwater from the oceans, there can be no doubt that they encountered a drastic

These marine fish expend energy to keep their body fluids more dilute than seawater Major questions raised are why they do so and what mechanisms they employ.

TABLE 28.1 The composition of blood plasma in some freshwater animals

The worldwide average composition of river water is shown for comparison.

Animal	Osmotic pressure (milliosmole per kg of H ₂ O)	Ion concentrations (millimole per liter)					
		Na ⁺	K ⁺	Ca ²⁺	Mg ²⁺	Cl ⁻	HCO ₃ ⁻
Freshwater mussel (<i>Anodonta cygnaea</i>)	44	16	0.5	6	0.2	12	12
Snail (<i>Viviparus viviparus</i>)	76	34	1.2	5.7	< 0.5	31	11
Crayfish (<i>Astacus fluviatilis</i>)	436	212	4.1	16	1.5	199	15
Mosquito larva (<i>Aedes aegypti</i>)	266	100	4.2	—	—	51	—
Brown trout (<i>Salmo trutta</i>)	326	161	5.3	6.3	0.9	119	—

reduction in the concentration of their surroundings. The osmotic pressure of freshwater is typically less than 1% as high as that of seawater today, and the major ions in freshwater are very dilute compared with their concentrations in seawater (see Table 27.1).

All freshwater animals regulate their blood¹ osmotic pressures at levels hyperosmotic to freshwater and are therefore classified as **hyperosmotic regulators**. As Table 28.1 shows, the blood osmotic pressures of various types of freshwater animals span an order of magnitude, but even freshwater mussels, which are among the most dilute animals on Earth, have blood that is substantially more concentrated than freshwater; body fluids as dilute as freshwater seem to be incompatible with life. The solutes in the blood plasma of freshwater animals are mainly inorganic ions; Na⁺ and Cl⁻ dominate. As Table 28.1 shows, each of the individual inorganic ions in the blood plasma of freshwater animals is—in almost all cases—substantially more concentrated in the blood than in freshwater.

Passive water and ion exchanges: Freshwater animals tend to gain water by osmosis and lose major ions by diffusion

Being hyperosmotic to their surroundings, freshwater animals tend to gain water continuously by osmosis, and this water gain tends to dilute their body fluids. The relatively high concentrations of ions in their blood suggest that the net diffusion of ions tends to be from their blood into the ambient water. The analysis of ion diffusion is actually more complex, however, because—as discussed in Chapter 5—ion diffusion depends on electrical gradients as well as concentration gradients. When all the complexity is taken into account, nevertheless (see page 106), the direction of diffusion of the major ions—such as Na⁺ and Cl⁻—is as the concentration gradients suggest: from the blood into the environmental water. This loss of major ions by diffusion tends, like the osmotic water gain, to dilute the body fluids of a freshwater animal (Figure 28.1a).

In a broad sense, we expect a freshwater animal's energy costs for osmotic and ionic regulation to depend directly on the animal's

rates of passive water gain and passive ion loss. The more rapidly water is taken up by osmosis, and the more rapidly ions are lost by diffusion, the more rapidly an animal will need to expend energy to counteract these processes so as to maintain a normal blood composition. Three factors determine the rates of passive exchange of water and ions: (1) the magnitudes of the osmotic and ionic gradients between the blood and ambient water, (2) the permeability of an animal's outer body covering to water and ions, and (3) the surface area across which exchange is occurring. The first two of these factors deserve further discussion.

OSMOTIC AND IONIC GRADIENTS Most types of freshwater animals have *far* less concentrated body fluids than their marine relatives. The decapod crustaceans (e.g., crayfish, crabs, and lobsters) illustrate this general pattern. Although most marine decapods are essentially isosmotic to seawater (about 1000 mOsm), most freshwater decapods have blood osmotic pressures of 500 mOsm or less (e.g., ~440 mOsm in the crayfish in Table 28.1). Similarly, although marine molluscs are approximately isosmotic to seawater, freshwater molluscs have far lower blood osmotic pressures (e.g., ~40–80 mOsm in those in Table 28.1). The lower blood concentrations seen in freshwater animals result in smaller osmotic and ionic gradients between their blood and the freshwater environment than would otherwise be the case. For example, if decapod crustaceans and molluscs had retained their ancient blood concentrations when they invaded freshwater, the osmotic difference between their blood and freshwater would be almost 1000 mOsm. The actual osmotic difference between the blood and the surrounding water in freshwater decapod crustaceans and molluscs is far lower because their blood is less concentrated than that of their marine progenitors. In the crayfish in Table 28.1, for example, the osmotic difference between the blood and the surrounding water is about 440 mOsm.

The evolution of more-dilute blood when animals invaded freshwater was probably an adaptation to reduce the energy costs of living in freshwater. Less-concentrated blood means smaller osmotic and ionic gradients between the blood and freshwater, and thus lower rates of water gain and ion loss by osmosis and diffusion.

¹In this book, we always use the term *blood* to refer to the fluid that is circulated within the circulatory system, although some authors use the term *hemolymph* to refer to that fluid in invertebrates that have open circulatory systems (see page 673).

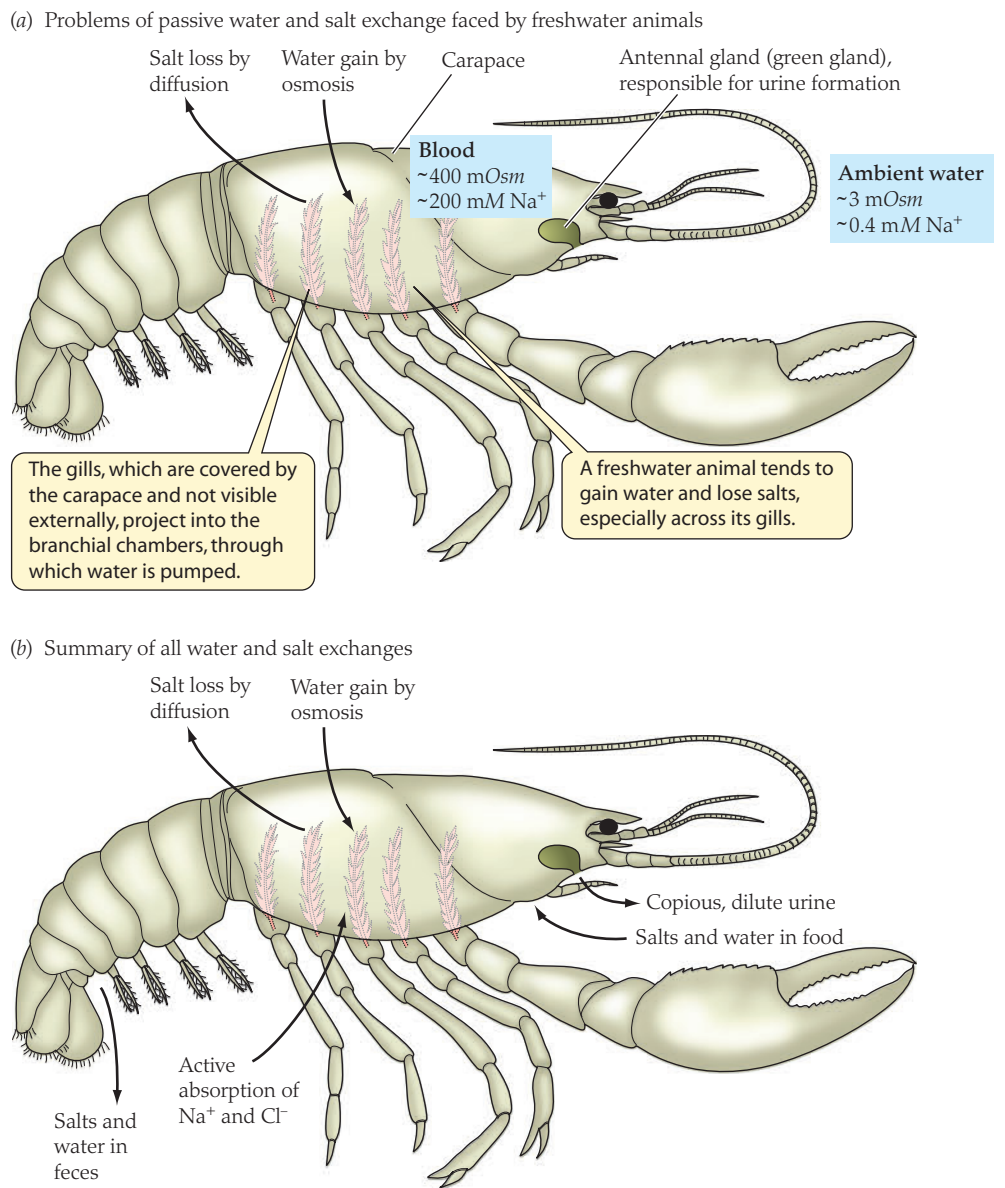

FIGURE 28.1 Water–salt relations in a freshwater animal (a) A freshwater animal, such as a crayfish, faces challenges because of passive water and salt exchange. The numbers are generalized, approximate values for the osmotic pressure and Na^+ concentration found in the blood of a crayfish and the ambient water. Values for a specific species of crayfish under specific study conditions are given in Table 28.1. (b) A summary of all the major processes of water and salt exchange, including the energy-requiring processes the animal uses to maintain water–salt balance. The antennal glands or green glands, which function as the kidneys of a crayfish, open at the bases of the second antennae.

PERMEABILITIES The permeability of the integument² of a freshwater animal to water and ions is in general relatively low. Freshwater crayfish, for example, are no more than 10% as permeable to water, Na^+ , and Cl^- as marine decapod crustaceans of similar body size. The low permeabilities evolved by freshwater animals are important in reducing their rates of passive water and ion exchange and thus in reducing their energy costs of maintaining a normal blood composition. For a freshwater animal (or any other animal that maintains a difference in composition between its blood and the ambient water), a low integumentary permeability is analogous to an insulatory pelage in an Arctic mammal; the low permeability slows the processes that tend to bring the blood and ambient water to equilibrium, just as pelage insulation slows heat losses that tend to cool an Arctic mammal to ambient temperature.

If freshwater animals did not need to breathe, they might cover themselves entirely in an integument of extremely low permeability to water and ions. However, they do need to breathe, and there seems to be no way to make gills that are both highly permeable to O_2 and poorly permeable to H_2O and inorganic ions. Thus, just as the gills of freshwater animals provide a “window” for O_2 to enter the body, they provide a window for water to enter by osmosis and for ions to leave by diffusion. In fact, the very attributes of gills that are virtues for O_2 uptake—high permeability and large surface area—are negatives for water–salt balance. A common pattern in freshwater animals is for little osmosis and diffusion to occur across the general integument—because the integument is poorly permeable to water and ions—and for most osmosis and diffusion to occur across the gills (plus possibly a few other localized body surfaces³).

²Integument is a general term for the outer body covering. For example, the integument of a vertebrate is its skin, and the integument of an arthropod is its exoskeleton (cuticle) or shell.

³The membranes of the buccal and opercular cavities in fish, for example, are relatively permeable compared with most body surfaces and are important sites of passive water–salt exchange. Little water or ion exchange occurs across a fish’s outer skin.

The importance of the gills as windows for passive water and ion exchange has an interesting and significant implication: Differences in whole-body permeability to water and salts among related freshwater animals are sometimes secondary effects of differences in their metabolic intensities and demands for O_2 . Species with high O_2 demands often have gill systems that are particularly well suited to rapid inward rates of O_2 diffusion. As a corollary, their gill systems also permit particularly rapid rates of water uptake by osmosis and ion loss by diffusion. In these cases, high rates of water–salt exchange are consequences of the evolution of high metabolic intensity.

Most types of freshwater animals share similar regulatory mechanisms

Most types of freshwater animals share a fundamentally similar suite of mechanisms for osmotic–ionic regulation. This suite of mechanisms is found in such phylogenetically diverse groups as freshwater teleost fish, lampreys, frogs, toads, soft-shelled turtles, freshwater mussels, crayfish, earthworms, leeches, and mosquito larvae.

TABLE 28.2 Rates of urine production—and osmotic and Na⁺ U/P ratios—in some freshwater animals

Animal	Rate of urine production (mL/100 g body wt·day)	Osmotic U/P ratio ^a	Na ⁺ U/P ratio ^b
Snail (<i>Viviparus viviparus</i>)	36–131	0.20	0.28
Crayfish (<i>Astacus fluviatilis</i>)	8	0.10	0.006–0.06
Mosquito larva (<i>Aedes aegypti</i>)	≤20	0.12	0.05
Frog (<i>Rana clamitans</i>)	32	—	—
Clawed toad (<i>Xenopus laevis</i>)	58	0.16	0.10
Goldfish (<i>Carassius auratus</i>)	33	0.14	0.10

Source: Hill and Wyse 1989.

^aThe osmotic U/P ratio is the osmotic pressure of the urine divided by the osmotic pressure of the blood plasma.

^bThe Na⁺ U/P ratio is the urine Na⁺ concentration divided by the plasma Na⁺ concentration.

URINE As we have seen, freshwater animals are faced with a continuous influx of excess water by osmosis. They void this excess water by making a copious (abundant) urine. A goldfish or frog, for example, might excrete urine equivalent to one-third of its body weight per day (Table 28.2). Because urine production balances osmotic water gain, the rate of urinary water excretion provides a measure of the rate of osmotic water influx. The daily osmotic water influx of a goldfish or frog is therefore equal to one-third of its body weight!⁴

The urine of freshwater animals, in addition to being produced in abundance, is typically markedly hyposmotic to their blood plasma and contains much lower concentrations of Na⁺ and Cl⁻ than the plasma. That is, the U/P ratios (urine:plasma ratios) for osmotic pressure, Na⁺, and Cl⁻ are far less than 1 in these animals (see Table 28.2). Recall from Figure 27.7 that when the osmotic U/P ratio is less than 1, urine production tends to raise the plasma osmotic pressure. Similarly, when the U/P ratio for an ion is less than 1, urine production tends to raise the plasma concentration of that ion. Typically, therefore, the kidneys of a freshwater animal not only solve the animal's volume-regulation problem by voiding the animal's excess volume of water, but also aid osmotic and ionic regulation by helping to maintain a high osmotic pressure and high ion concentrations in the blood.

Whereas the urine of freshwater animals is generally copious and dilute, an important concept to keep in mind is that kidneys are *regulatory* organs: They characteristically *adjust their function in ways that help to maintain stability of volume and composition in the body fluids*. Thus the exact volume and composition of the urine vary with the circumstances. For example, if an animal experiences an increase in the rate at which it takes in water by osmosis, its kidneys ordinarily increase their rate of urine production.

Although freshwater animals typically limit the concentrations of Na⁺ and Cl⁻ in their urine to low levels, some loss of these ions in the urine is inevitable. This urinary loss of ions can pose

⁴If a 70-kg person had a similar weight-specific rate of water uptake, he or she would gain 23 L (6 gallons) of water per day and thus would need to excrete 23 L of urine per day.

a threat to the integrity of the body fluids when Na⁺ and Cl⁻ are in short supply. The rate of loss of ions in the urine depends in part on the rate of urine production, and therefore on the rate of osmotic water flux into an animal. Any factor that increases an animal's rate of osmotic water influx tends to increase the animal's rate of ion loss. We see, therefore, that *volume regulation and ionic regulation are basically at conflict with each other in freshwater animals*.

ACTIVE ION UPTAKE IN FRESHWATER ANIMALS IN GENERAL

An important way that freshwater animals replace lost Na⁺ and Cl⁻ is that they actively transport both ions into their blood directly from the pond or river water in which they live. We have just seen that freshwater animals lose ions in their urine. Earlier we saw they also lose ions by direct outward diffusion across their permeable body surfaces. The ions lost in these two ways need to be replaced. Freshwater

animals do this by taking up Na⁺ and Cl⁻ by active transport from their ambient water. Other ions may also be transported inward in this way. Freshwater fish, for example, take up Ca²⁺ from the ambient water by active transport.

The capacities of most freshwater animals for active uptake of Na⁺ and Cl⁻ are remarkable. For example, some crayfish, fish, and frogs—which have Na⁺ and Cl⁻ concentrations of 100–200 mM in their blood plasma—can actively take up Na⁺ and Cl⁻ in net fashion from ambient waters as dilute as 0.01 mM (four orders of magnitude more dilute than their blood)! The site of active ion uptake is usually the gills or the general integument. In teleost (bony) fish and decapod crustaceans (e.g., crayfish), the site of uptake is the gill epithelium. In frogs, active ion uptake occurs across the gills when the animals are tadpoles but across the skin when they are adults.⁵ Active ion uptake also occurs across the general integument in leeches and aquatic oligochaete worms.

The cellular-molecular mechanisms of active Na⁺ and Cl⁻ uptake by freshwater animals are discussed as one of the focal examples in Chapter 5 (see especially Box 5.2). Although details may vary, the following key points are believed to apply to all or most groups of freshwater animals:

- The active uptake of ions from the ambient water requires ATP. Thus active ion uptake places demands on an animal's energy resources.
- The mechanisms that pump Na⁺ and Cl⁻ from the ambient water into the blood are typically different and independent from each other.
- The Cl⁻ pump typically exchanges bicarbonate ions (HCO₃⁻) for Cl⁻ ions, in this way remaining electroneutral (Figure 28.2).
- The Na⁺ pump typically exchanges protons (H⁺) for Na⁺ ions (or possibly exchanges ammonium ions, NH₄⁺,

⁵Recent research has revealed that an important, deadly fungal pathogen of amphibians, *Batrachochytrium dendrobatidis*, severely disrupts ion uptake across the skin, and this may be the chief way the fungus kills.

FIGURE 28.2 Ion exchanges mediated by active Na^+ and Cl^- transport in the gill epithelium of freshwater teleost fish The mechanisms of active transport exist within single epithelial cells. The view here is a whole-epithelium view and therefore, as discussed in Chapter 5 (see Figure 5.14), does not specify the cell-membrane mechanisms involved. The cell-membrane mechanisms are discussed in Box 5.2.

(a) The O_2 uptake function of a gill filament: The expanded surface area for gas exchange

20 μm

(b) The ion-transport function of a gill filament: Ion-transport proteins labeled red and green

FIGURE 28.3 A single gill filament of a teleost fish viewed in two ways that emphasize the two principal gill functions The color drawing shows the overall gill structure. The gill filament seen in (a) and (b) is from a euryhaline species that occurs over wide ranges of salinity in salt marshes, the killifish *Fundulus heteroclitus*. This specimen was captured in nearly freshwater (salinity 4‰) in coastal Virginia. The images were acquired by confocal microscopy. (a) The structure of the filament. (b) The locations of two ion-transport proteins in a particular plane (optical section) of the filament: Na^+ - K^+ -ATPase (red) and NKCC-1 (green). Cell nuclei are labeled blue. Yellow represents places where both transport proteins occurred together (red + green = yellow). See Figure 23.10 for more on gill structure. (a and b courtesy of Aaron M. Florn.)

for Na^+ in some groups of animals), thereby remaining electroneutral (see Figure 28.2).

- The HCO_3^- and H^+ pumped from the blood into the ambient water by the Cl^- and Na^+ pumps are produced by aerobic catabolism, being formed by the reaction of metabolically produced CO_2 with H_2O (see Figure 28.2). Thus the Na^+ and Cl^- pumps participate in removal of metabolic wastes.
- Because HCO_3^- and H^+ are principal players in acid–base regulation (see page 644), the Na^+ and Cl^- pumps sometimes play critical roles in the acid–base physiology of freshwater animals.

ACTIVE ION UPTAKE IN FRESHWATER FISH: THE GILLS AS ION-REGULATORY ORGANS The gills of teleost fish—although often discussed simply as breathing organs—in fact carry out two major functions that serve homeostasis: In both freshwater and seawater, the gills function both as *ion-regulatory organs* and as *gas-exchange organs*. The gills are the principle sites where Na^+ and Cl^- are taken up by active transport from freshwater, as already noted. During the development of freshwater fish, the gills—despite being thought of usually as breathing organs—assume their ion-uptake function prior to their gas-exchange function, according to recent research. Both functions are carried out by the general integument in early larvae. In rainbow trout (*Oncorhynchus mykiss*) living in freshwater, responsibility for Na^+ uptake from the ambient water shifts to the gills about 15–16 days after hatching, whereas responsibility for O_2 uptake doesn't shift to the gills until 23–28 days.

The two images of a single gill filament in Figure 28.3 help emphasize the two major functions of the gills in adult teleosts. Figure 28.3a shows the microscopic structure of the filament, which consists of a thin, principal lamellar element—shaped somewhat like the blade of a feather—bearing many folds, the secondary lamellae. Blood flows through all parts. The secondary lamellae greatly increase the surface area across which O_2 can diffuse inward from the ambient water into the blood (see Figure 23.10). Figure 28.3b shows the same filament visualized in a way

that reveals the presence and location of membrane proteins that are instrumental in ion transport between the blood and ambient water; in this specific case (although not always), cells containing the ion-transport proteins are located in parts of the filament other than the secondary lamellae.

The method used to obtain Figure 28.3*b*—immunocytochemistry applied to transport proteins—is worth brief mention before we go further because it is the principal method used at present to study gill ion-transport functions throughout the animal kingdom. Two fluor-labeled antibodies were used: one against $\text{Na}^+\text{-K}^+\text{-ATPase}$ and the other against the cotransporter protein (not an ATPase) termed NKCC-1, which transports Na^+ , K^+ , and Cl^- ions in fixed ratios during each transport cycle (see page 112). When the filament was exposed to the antibodies, they bound where $\text{Na}^+\text{-K}^+\text{-ATPase}$ and NKCC-1 occurred, respectively. Then, when the filament was scanned with lasers that excited the fluor, the antibody against $\text{Na}^+\text{-K}^+\text{-ATPase}$ glowed red, whereas that against NKCC-1 glowed green. Thus, red shows where $\text{Na}^+\text{-K}^+\text{-ATPase}$ was located, green shows where NKCC-1 was located, and yellow (the combination of red and green) shows where both membrane proteins occurred in approximately the same location.

The gill epithelium in fish consists principally of two types of cells: (1) *mitochondria-rich cells (MRCs)*, also called *chloride cells*, and (2) *pavement cells*. The MRCs are considered to be the principal (although not exclusive) sites of active ion transport in the gills.⁶ They are a central focus of research on ion transport in both freshwater and marine fish. Box 28.1 discusses their properties and diversity.

A portion of the gill epithelium of a freshwater fish, including a freshwater-type MRC surrounded by pavement cells, is visualized by scanning electron microscopy in Figure 28.4 (the magnification is far greater than in Figure 28.3). The uptake of O_2 during breathing is believed to occur principally across pavement cells, which usually occupy more than 90% of the gill epithelium and are thinner than MRCs. Until fairly recently, physiologists tended to assume that in freshwater fish, Cl^- uptake occurs across the MRCs, and Na^+ uptake occurs across both the MRCs and pavement cells, or just the pavement cells. The problem of deducing the molecular mechanisms of ion transport and localizing them to particular cells is exceedingly challenging, however, and probably the localization of pumps to cell types will require considerably more research. Current models of Na^+ and Cl^- uptake in freshwater fish are discussed in Box 5.2, and modulation of gill function when migratory fish swim between freshwater and seawater is discussed later in this chapter (see page 734).

The number of MRCs in the gill epithelium of a fish living in freshwater is variable and under adaptive (partly hormonal) control. One condition demonstrated to increase the number of MRCs is alkalosis: excess blood bicarbonate (HCO_3^-) (see page 644–645). During alkalosis, the MRCs, besides becoming more numerous, also modify their cell proteins—upregulating a key $\text{Cl}^-/\text{HCO}_3^-$ countertransport protein that exports HCO_3^- from the body fluids in exchange for Cl^- (see Figure B in Box Extension 5.2).

A second, and fascinating, condition that has been demonstrated to lead to increased numbers of MRCs in freshwater fish is life in very “soft” water: water of exceptionally low Ca^{2+} concentration

FIGURE 28.4 A mitochondria-rich cell surrounded by pavement cells in the gill epithelium of a freshwater teleost fish The image is a scanning electron micrograph of the outer surface of the gill epithelium of a brown bullhead (*Ictalurus nebulosus*) that had been living in ordinary freshwater. One pavement cell is outlined (yellow dashed line) to show its limits. (See Box 28.1 for detail on mitochondria-rich cells.) (Photograph courtesy of Greg Goss and Steve Perry; from Goss et al. 1998.)

(Figure 28.5). Freshwater fish acquire most of their Ca^{2+} from the water in which they live, rather than from their food. The MRCs (or a subset of them) are the sites of active Ca^{2+} uptake. When fish are living in Ca^{2+} -poor waters, an increase in the number of MRCs is

FIGURE 28.5 Cellular acclimation to living in two types of water in the gill epithelium of freshwater fish Tissue sections of the secondary lamellae in the gills of rainbow trout (*Oncorhynchus mykiss*), viewed using light microscopy and stained to show mitochondria-rich cells, from (a) a fish that had been living in ordinary freshwater with a Ca^{2+} concentration of 0.4 mmol/L and (b) a fish that had been living for 2 weeks in very “soft” freshwater with a Ca^{2+} concentration of 0.05 mmol/L. (Photographs courtesy of Steve Perry; from Perry 1998.)

⁶Based on the immunocytochemical evidence, the labeled cells in Figure 28.3*b* are MRCs.

BOX 28.1 FISH MITOCHONDRIA-RICH CELLS AND THEIR DIVERSITY

Mitochondria-rich cells (MRCs)—also called **mitochondrion-rich cells, chloride cells, or ionocytes**—have two distinctive morphological features, both indicative of high metabolic activity: They contain large numbers of mitochondria and an elaborate system of intracellular membranes (this system is continuous with the basolateral cell membrane) (see Figure 28.7). MRCs are typically also strikingly rich in Na^+ - K^+ -ATPase by comparison with most cells—another sign of high metabolic activity. Certain MRCs contain more than 100 million molecules of Na^+ - K^+ -ATPase per cell, one of the highest abundances known. MRCs are in general believed to be the principal sites of active ion transport in the gills of teleost fish.

A discovery of great significance—which has emerged with full clarity in just the last 15 years—is that there are *multiple types of MRCs*. Some types are distinguished by their fine structures; whereas some, for example, lack an apical crypt (a pit in the apical cell membrane), others exhibit a well-developed apical crypt (see Figure 28.7). In addition, largely owing to the revolution in immunocytochemistry, researchers now recognize that types of MRCs differ biochemically: They can differ in their *quantities* of key ion-transport proteins and in their *molecular forms* of the proteins. For example, MRCs with different molecular forms of Na^+ - K^+ -ATPase occur.

Based on the latest evidence, a fish capable of living in both freshwater and seawater typically has different types of MRCs in

its gills—dubbed *freshwater and seawater types*—in the two environments; when the fish is transferred from one environment to the other, it switches types by replacing or transforming its MRCs. Moreover, a fish may have two types of MRCs present in its gills in one environment. For example, rainbow trout (*Oncorhynchus mykiss*) living in freshwater have at least two types.

As yet researchers have not created a standardized nomenclature for the types of MRCs. Instead, different research reports commonly use project- or species-specific nomenclatures. Reading the research literature published prior to about 1995 can be confusing because, at the time, physiologists tended to think of MRCs as being relatively homogeneous and in general did not recognize types.

believed to help them acquire sufficient Ca^{2+} . However, increasing the number of MRCs can also interfere with uptake of O_2 ! Recent research on several species has shown that in fish living in very soft water, the replacement of pavement cells by MRCs in the secondary lamellae can double the average diffusion distance between blood and water in the gills, because MRCs are thicker than the pavement cells they replace (see Figure 28.5). This doubling of the diffusion distance measurably interferes with O_2 uptake. *Thus freshwater fish exhibit a trade-off between their ability to take up Ca^{2+} and their ability to take up O_2 ; increasing one ability decreases the other.*

The concept of trade-offs is a major theme in modern ecology and evolutionary biology. The situation in freshwater fish just described is one of the physiological trade-offs that, considering all of animal physiology, is best understood at a cellular level.

FOOD AND DRINKING WATER Freshwater animals of all types—fish, crayfish, and so forth—gain ions from their food, in addition to acquiring them by active uptake from the ambient water. The role of food in meeting ion needs is not well understood, although inputs of ions by active transport are generally thought to exceed those from food. In addition to eating food, freshwater animals also have the opportunity to drink water. But do they? Freshwater animals typically must produce urine at a very high rate just to deal with their passive osmotic water influxes. Thus one would not expect them to drink, and usually they do not. However, recent studies of teleost fish in freshwater have revealed that some species—especially when they are larvae—do drink sufficiently to raise their total water influx by 5–50% more than their osmotic influx alone. The reasons for and consequences of this drinking are unclear.

QUANTITATIVE EXAMPLE AND COST ESTIMATES The usual pattern of water–salt balance in freshwater animals is summarized in Figure 28.1*b* (showing a crayfish) and in Figure 28.8*a* (showing a fish). To review this pattern in words, let's look quantitatively at the gains and losses of water and Na^+ in a freshwater crayfish (*Astacus*). When fasting at 20°C, a 29-g crayfish excretes about 2.4 mL of urine per day—indicating that it gains 2.4 mL of water per day

by osmosis, principally across its gills. The crayfish's urine is very dilute in Na^+ (1 mM Na^+). Therefore, only about 2–3 μmole of Na^+ is lost per day in its urine. The animal's loss of Na^+ by direct diffusion into the surrounding water is much greater, approximately 240 $\mu\text{mole/day}$. The Na^+ lost by excretion and diffusion is replaced by active Na^+ uptake across the gills at a rate near 240 $\mu\text{mole/day}$.

According to a recent study using modern methods, the energy cost of osmotic–ionic regulation in freshwater animals is about 3–7% of the resting metabolic rate. The study—which focused on rainbow trout and mudpuppies (aquatic amphibians)—was based on measurements of ion-pumping rates in the gills, skin, and kidneys, plus information on the ATP demands of the ion pumps.

A few types of freshwater animals exhibit exceptional patterns of regulation

The typical pattern of osmotic–ionic regulation described in the previous section is not observed in all freshwater animals. As usual, a look at exceptions can be as conceptually revealing as a look at the rule. Here we will look just at those exceptional freshwater animals that fail to produce a dilute urine.

The freshwater crabs are outstanding examples. These animals are unfamiliar to most North American readers because historically they have not occurred in North American waters.⁷ Nonetheless, freshwater crabs are common on most other continents, usually at tropical or subtropical latitudes. Two species that have been studied are *Potamon niloticus*, an African crab, and *Eriocheir sinensis*, found in Asia and Europe. Freshwater crabs typically maintain high blood osmotic pressures in comparison with other freshwater animals: about 500–650 mOsm in *Potamon* and *Eriocheir*; for example (compare Table 28.1). As usual, the major blood solutes are Na^+ and Cl^- . The feature that makes freshwater crabs distinctive is that their urine is virtually isosmotic to their blood plasma. Its ionic composition is also very similar to that of blood plasma. Consequently, the loss of Na^+ and Cl^- per unit of volume of urine in the freshwater crabs is very

⁷The freshwater crab *Eriocheir* has recently been introduced into some river systems along the West Coast of the United States and is now established there as an alien species.

high by comparison with that in most freshwater animals. How do the crabs compensate? One well-known part of the answer is that the bodies of freshwater crabs exhibit extraordinarily low permeability to water. Because of this low permeability, the crabs experience relatively low rates of osmotic water influx, and therefore the rates at which they must excrete their high-concentration urine are low. *Potamon* and *Eriocheir*, for instance, excrete water equivalent to only about 0.6–3.6% of their body weight per day (compare Table 28.2). The unusually low urine output of the freshwater crabs—which results from their unusually low permeability to water—helps limit the rate at which they lose ions. The total quantities of Na^+ and Cl^- that the crabs lose—by both diffusion and urine excretion—although large by comparison with the quantities lost by freshwater crayfish, are “manageable,” in the sense that the ions can be replaced by active uptake (across the gills) from the ambient water.

A few exceptional teleost fish living in freshwater also excrete urine that is nearly isosmotic to their blood plasma. One well-studied example is the toadfish *Opsanus tau*, a primarily marine fish that enters freshwater creeks. The freshwater crabs and the toadfish seem likely to be relatively recent immigrants to freshwater. Their short evolutionary history in freshwater helps explain why their kidneys have not evolved the ability to make dilute urine.

Why do most freshwater animals make dilute urine?

The freshwater crabs and the toadfish prove that production of dilute urine is not a necessity for life in freshwater; the production of relatively concentrated urine increases ion losses per unit of volume, but if total urinary losses can be restrained enough that ions can be replaced, existence in freshwater is possible. Why, then, have the vast majority of freshwater animals evolved the capacity to make urine that is dramatically hyposmotic to their blood plasma?

The answer is probably energy savings. To produce a dilute urine, the kidneys start with a fluid that is as concentrated as blood plasma and actively extract NaCl from it, lowering its concentration and returning the ions to the blood. Every Na^+ or Cl^- ion thus removed from the urine prior to excretion is an ion that does not have to be replaced by active uptake from the ambient water. In the urine—as it is formed in the kidneys—the concentrations of Na^+ and Cl^- are initially as high as in the blood plasma; only gradually—as the ions are reabsorbed—do urine ion concentrations fall to low levels. In contrast, the concentrations of Na^+ and Cl^- in the ambient water are *always* very low. Two lines of argument—one based on thermodynamic principles and the other on the molecular details of transport mechanisms—indicate that active uptake of Na^+ or Cl^- from a relatively concentrated source costs less energy *per ion* than uptake from a dilute source. Thus removing ions from urine prior to excretion is less costly than replacing the same ions from the ambient water.

SUMMARY Animals in Freshwater

- All freshwater animals are hyperosmotic to the water in which they live. They tend to gain water by osmosis and lose ions by diffusion, especially across their permeable gill membranes. These passive fluxes of water and ions tend to dilute their body fluids.
- To void their excess of water, freshwater animals produce a copious urine.

- In nearly all freshwater animals, the urine is dilute compared with the blood plasma. The dilute condition of the urine helps to maintain not only the blood osmotic pressure but also blood concentrations of major ions at levels higher than those in the environment.
- To replace ions lost by direct diffusion into the environment and excretion in urine, freshwater animals take up Na^+ , Cl^- , and some other ions by active transport. The gill epithelium is the principal site of active ion uptake in adult teleost fish and crayfish. Foods also help to replenish ions.

Animals in the Ocean

Animal life in the oceans is far more phylogenetically diverse than that in the other major habitats on Earth, probably in good part because animals originated in the oceans. Today, all phyla and most classes of animals have marine representatives.

Many phylogenetic groups of animals moved from the oceans to freshwater and the land over the course of evolutionary time. In turn, many freshwater and terrestrial groups reinvaded the oceans. Consequently, whereas some modern marine animals have a continuously marine ancestry, others trace their history to forms that occupied other major habitats.

Such a phylogenetic history has sometimes left major imprints on the water–salt physiology of modern marine animals. For example, although the cuttlefish and the marine teleost fish seen swimming in seawater in [Figure 28.6](#) may look like they would have similar blood osmotic concentrations, their concentrations actually are very different, as we will see in the following sections. History is believed to be the explanation. Whereas cuttlefish probably trace a continuously marine ancestry, marine teleost fish are likely descended from freshwater ancestors.

FIGURE 28.6 Two ocean animals with different blood osmotic pressures, an invertebrate with blood isosmotic to seawater and a teleost fish with blood dramatically hyposmotic to seawater The cuttlefish (*Sepia officinalis*; top) belongs to the group of marine molluscs known as cephalopods, which also includes squids and octopuses. The teleost fish at the right is a queen triggerfish (*Balistes vetula*).

Most marine invertebrates are isosmotic to seawater

Most marine invertebrates are isosmotic, or nearly so, to seawater. Included are the marine molluscs—exemplified by the cuttlefish in Figure 28.6—and such other marine animals as sponges, coelenterates, annelids, echinoderms, and most arthropods. For the most part, these animals are products of lines of evolution that never left the sea. They have always lived in seawater, and this probably explains why they have the simplest possible osmotic relation to seawater. The osmotic pressure of seawater is about 1000 mOsm, and the osmotic pressure of their body fluids is about the same. Being essentially isosmotic to their environment, marine invertebrates do not tend to gain or lose water by osmosis to any great extent: They do not face problems of osmotic regulation.

The solutes in the blood plasma of marine invertebrates are mostly inorganic ions, and the ionic composition of their blood plasma tends to be grossly similar to that of seawater. Despite this similarity, as exemplified in Table 28.3, the ionic composition of the blood plasma seems universally to differ in detail from the ionic composition of seawater. A particular ion often proves to be relatively concentrated in some animal species but relatively dilute in others; for example, Mg^{2+} is relatively high in concentration in the blood plasma of the squid *Loligo* but low in that of the crab *Carcinus*. The adaptive significance of such differences in blood ionic composition is generally unknown.

Isosmotic marine invertebrates maintain the differences in ionic composition between their blood plasma and seawater by ionic regulatory processes. These animals are typically relatively permeable to ions (and water). Ions therefore tend to diffuse between their blood and seawater with ease, following their electrochemical gradients. One process these animals commonly use to maintain their blood ionic composition is active uptake of ions from seawater at the body surface or from ingested seawater in the gut. A second common process is kidney regulation of blood composition. In crustaceans, molluscs, and some other groups, although the excretory organs make a urine that is approximately isosmotic to the blood plasma, they alter the urine's ionic composition, thereby contributing to ionic regulation. For example, in most marine decapod crustaceans, the urine is richer in Mg^{2+} and SO_4^{2-} than the blood plasma (U/P =

1.1–4.2 in several species), which helps keep plasma concentrations of these ions lower than seawater concentrations (see Figure 27.7).

Hagfish are the only vertebrates with blood inorganic ion concentrations that make them isosmotic to seawater

The hagfish, an exclusively marine group of jawless primitive vertebrates, resemble the great majority of marine invertebrates in two key respects: (1) Their blood is approximately isosmotic with seawater, and (2) their blood solutes are principally Na^+ , Cl^- , and other inorganic ions (see Table 28.3). The ionic regulatory processes of hagfish are similar to those of osmoconforming marine invertebrates. Hagfish appear to be the only modern vertebrates that trace a continuously marine ancestry (see Box 28.2).

The marine teleost fish are markedly hyposmotic to seawater

As stressed at the start of this chapter, the marine teleost fish are **hyposmotic regulators**: Their blood osmotic pressures are far lower than the osmotic pressure of the seawater in which they swim. As in freshwater teleosts, Na^+ , Cl^- , and other inorganic ions constitute most of the solutes in the blood plasma. One of the most intriguing questions about marine teleosts concerns the *origin* of their hyposmotic state: *Why* is their blood plasma dramatically more dilute in ions and lower in osmotic pressure than seawater? Most biologists conclude, as discussed in Box 28.2, that the dilute body fluids of marine teleosts are an evolutionary vestige: These fish are generally believed to be descended from ancient ancestors that lived in freshwater.

The blood osmotic pressures of marine teleost fish are typically 300–500 mOsm—higher than those of freshwater teleosts (about 250–350 mOsm), but not exceptionally so. Evidently, when the teleost fish invaded the oceans from freshwater in the course of their evolution, they evolved modest increases in total blood solutes. This change served to reduce the difference between their blood plasma and the environmental water (the seawater) in their new habitat.

Despite such a change, *today's marine teleost fish—because of their profoundly dilute state relative to seawater—face a difference between*

their blood plasma and their environmental water that is far greater than that faced by freshwater teleosts. In freshwater teleosts, blood osmotic pressure averages about 300 mOsm higher than the osmotic pressure of freshwater. In marine teleosts, however, the difference between the blood and environmental osmotic pressures is about 600 mOsm: approximately twice as great!⁸ This consideration in itself would tend to saddle the marine fish with a relatively high rate of osmotic water flux. Marine teleosts, however, are typically less permeable to water than freshwater teleosts, so in fact the

TABLE 28.3 The composition of the blood plasma or other extracellular body fluids in some marine invertebrates and hagfish

All these animals are isosmotic to seawater. The ion concentrations listed are for animals living in seawater of the composition specified in the last row of the table.

Animal and body fluid	Ion concentration (mmol/kg H ₂ O)					
	Na ⁺	K ⁺	Ca ²⁺	Mg ²⁺	Cl ⁻	SO ₄ ²⁻
Mussel (<i>Mytilus</i>), blood plasma	474	12.0	11.9	52.6	553	28.9
Squid (<i>Loligo</i>), blood plasma	456	22.2	10.6	55.4	578	8.1
Crab (<i>Carcinus</i>), blood plasma	531	12.3	13.3	19.5	557	16.5
Sea urchin (<i>Echinus</i>), coelomic fluid	474	10.1	10.6	53.5	557	28.7
Jellyfish (<i>Aurelia</i>), mesogleal fluid	474	10.7	10.0	53.0	580	15.8
Hagfish (<i>Myxine</i>), blood plasma	537	9.1	5.9	18.0	542	6.3
Seawater	478	10.1	10.5	54.5	558	28.8

Source: After Potts and Parry 1964.

⁸Average blood osmotic pressure in marine teleosts is about 400 mOsm, and the osmotic pressure of seawater is about 1000 mOsm—a difference of 600 mOsm.

BOX 28.2 WHERE WERE VERTEBRATES AT THEIR START?

The traditional hypothesis held by most biologists is that vertebrates originated as jawless animals in the oceans about 500 million years ago. The lineage leading to modern hagfish (which are themselves jawless) then never left the oceans. Today's hagfish, in this view, are the one group of modern vertebrates or vertebrate-like animals (craniates) that have lived in the oceans throughout their evolutionary history. According to the traditional hypothesis, early jawless vertebrates entered freshwater, and jaws then originated in freshwater. Thus, according to the traditional hypothesis, all jawed vertebrates (plus modern lampreys) are descended from freshwater ancestors. Specifically, the jawed fish living in the oceans today arose through reinvasion of the oceans from freshwater.

The water–salt physiology of modern vertebrates provides one of the principal argu-

ments for this traditional hypothesis. The total blood-plasma salt concentrations of all jawed vertebrates alive today are monotonously similar, and the concentrations seen in vertebrates are more like those in freshwater invertebrates than in marine invertebrates. These patterns suggest that all the living jawed vertebrates had ancient ancestors that lived in freshwater and that the blood ion concentrations of vertebrates became relatively fixed at that time in evolution. According to this view, modern marine teleost fish have blood salt concentrations far lower than those in seawater because they are descended from freshwater ancestors.

You will notice the circularity of reasoning here. The features of the blood composition of modern animals are used as evidence for a freshwater origin of jawed vertebrates. The purported freshwater origin of jawed vertebrates is then used to explain the blood

composition of modern animals. This unsettling state of affairs arises in part because the fossil record is too sketchy to provide firm independent confirmation or refutation of the freshwater-origins hypothesis for jawed vertebrates.

Some evolutionary biologists believe that the available circumstantial evidence supports a scenario different from the traditional one. One alternative view, for example, is that the earliest vertebrates were closely associated with the continental margins and experienced both marine and freshwater environments. All scenarios for the early evolution of vertebrates concur in postulating that the blood composition of modern marine jawed vertebrates is a consequence of early evolutionary experience with freshwater. No other interpretation seems plausible.

osmotic fluxes experienced by the two groups are roughly similar in magnitude (for a given body size).

Of course, although the osmotic fluxes of marine and freshwater teleosts may be similar in magnitude, they are totally opposite in direction. Because a marine teleost is hyposmotic to seawater, water tends to *leave* its body osmotically, rather than entering as it does in a freshwater teleost. *For a hyposmotic animal, the ocean is a desiccating environment.*

The concentrations of Na^+ , Cl^- , Mg^{2+} , SO_4^{2-} , and some other inorganic ions are far lower in the blood plasma of marine teleosts than in seawater, suggesting that marine teleost fish also face problems of inward diffusion of multiple ions. Moreover, the concentration gradients between the blood plasma and the environment for the two major plasma ions, Na^+ and Cl^- , are large by comparison with the (oppositely directed) gradients seen in freshwater teleosts. Nonetheless, actual rates of ion diffusion depend on *electrical gradients* and gill *permeability*, not just on ion *concentration gradients*. When all these factors are taken into account, inward Na^+ diffusion turns out not to be much of a problem for marine teleosts (or may not even occur in some species), because the gill epithelium is positively charged on the inside, repelling Na^+ . In contrast, some other ions—most notably Cl^- —tend to diffuse into the blood plasma of marine teleosts from seawater at substantial rates, tending to concentrate the body fluids of the fish.

REPLACEMENT OF WATER LOSSES Marine teleost fish lose water by osmosis and, to a lesser extent, by urine production. To replace the water they lose (and thereby volume regulate), these fish *drink seawater*. Although some drink an amount of seawater that is less than 1% of their body weight per day, others drink more than 50% per day, and the average is probably 10–20% per day.

At first sight, drinking seawater seems to be a straightforward way to obtain water. Consider, however, that when seawater is first taken into the gut of a marine teleost, it is strongly *hyperosmotic* to

the fish's blood plasma. Consequently, H_2O is predicted to travel by osmosis *out of the blood plasma into the ingested seawater in the gut*, not vice versa—and that is exactly what happens. Studies of several species indicate that as ingested seawater travels through the esophagus, stomach, and (in at least some instances) anterior intestine, not only do Na^+ and Cl^- diffuse into the blood across the gut wall, but also H_2O *enters the gut fluids* by osmosis. Gradually, therefore, the ingested seawater in the gut expands in volume and is diluted. Water uptake from the gut fluids eventually occurs, nonetheless. This is true because in later parts of the intestine, Na^+ and Cl^- are *actively transported out of the gut contents into the blood*. This ATP-requiring, active uptake of Na^+ and Cl^- into the blood creates conditions that favor the *osmotic uptake of water*. In the simplest cases to understand, the active uptake of the ions from the gut fluids renders the gut fluids hyposmotic to the blood. Often, however, a process called *near-isosmotic fluid transport* occurs, in which the gut fluids and blood plasma remain approximately isosmotic as water moves briskly by osmosis into the blood; in this case, highly localized osmotic gradients within the intestinal epithelium (termed *local osmosis*) are involved in translating ion uptake into water uptake. Recent evidence, discussed more on page 734, indicates that aquaporins in the intestinal epithelia are instrumental in facilitating water uptake from the gut in fish in seawater.

By the time ingested seawater is completely processed, about 50–85% of the H_2O in the seawater is absorbed into the blood. However, a much greater proportion of the NaCl in the ingested seawater—often more than 97%—is absorbed. This is true because NaCl absorption is required to drive the absorption of H_2O . The influx of NaCl into the blood aggravates the problems of Na^+ and Cl^- regulation that the fish face. Accordingly, *in marine teleosts—as in freshwater teleosts—the process of volume regulation worsens the problems of ionic regulation.*⁹

⁹Volume regulation and ionic regulation are inextricably linked in the marine and freshwater teleosts because the major solutes of the body fluids in both of these groups of fish are inorganic ions.

Divalent ions¹⁰ in ingested seawater are handled very differently from the monovalent ions Na^+ and Cl^- . The gut epithelium is poorly permeable to the major divalent ions, Mg^{2+} and SO_4^{2-} . Consequently, although the divalent ions diffuse into the blood to a small extent as seawater passes through the gut, for the most part they remain in the gut and are expelled in the feces.

URINE We now turn to the question of how marine teleosts eliminate the excess ions that enter their body fluids from the gut, or that diffuse into their body fluids from seawater across their gills or other external body surfaces. For the most part, excess *divalent* ions in the body fluids are removed by excretion in the urine, whereas excess *monovalent* ions are excreted by the gills.

The kidneys of marine teleosts typically excrete urine that is about as concentrated as they can possibly produce, approximately isosmotic to the blood plasma.¹¹ The fact that the osmotic pressure of the urine matches that of the plasma (osmotic $U/P \cong 1$) means that the excretion of urine cannot help the fish with their osmotic regulatory problem (see Figure 27.7). However, the *ionic composition* of the urine differs dramatically from that of the plasma, and the kidneys are the principal organs that carry out ionic regulation of Mg^{2+} , SO_4^{2-} , and Ca^{2+} . Whereas U/P ratios for Na^+ , Cl^- , and K^+ are below 1, those for Mg^{2+} and SO_4^{2-} are *far* greater than 1. The kidneys thereby void the major divalent ions preferentially in relation to water and keep plasma concentrations of those ions from increasing.

For every milliliter of water that is first ingested and absorbed and then excreted as urine, a marine teleost is left with an excess of solutes because, although the water enters its body hyperosmotic to its body fluids, the water leaves its body isosmotic to its body fluids. From the viewpoint of osmoregulation, therefore, production of urine by marine teleost fish is an outright liability, and we would expect the fish to limit their volume of urine to the

minimum necessary for excretion of solutes that are not excreted by other routes. Nitrogenous wastes and the principal ions, Na^+ and Cl^- , are voided across the gills. Thus the role of the kidneys in marine teleosts is largely limited to excretion of divalent ions, and the rate of urine production can be low. The urine volumes of several species have been measured to be just 0.5–3.5% of body weight per day (compare Table 28.2).

EXTRARENAL NaCl EXCRETION BY THE GILLS The gills of an adult marine teleost assume primary responsibility for excreting excesses of the major ions, Na^+ and Cl^- , from the blood plasma into the surrounding ocean. The excretion of Cl^- is active and is carried out by seawater-type mitochondria-rich cells (MRCs) in the gill epithelium (Figure 28.7). These cells are often called *chloride cells* in the study of marine teleosts because of their well-established excretion of Cl^- . In fish soon after hatching, as discussed in Chapter 4 (see Figure 4.6), the MRCs are principally found in the general integument, but soon the cells become localized to the gills. **Box 28.3** outlines the mechanism these cells employ to pump Cl^- . Although the gill epithelium is believed always to transport Na^+ as well as Cl^- out of the blood into the seawater, the excretion of Na^+ occurs by mixed mechanisms; Na^+ excretion is probably active in about half the species that have been studied, but passive in the others (in which Na^+ *diffuses* outward, attracted by an outside-negative electrical gradient generated by active Cl^- excretion). The elimination of Cl^- and Na^+ by the gills of marine teleost fish provides our first example of **extrarenal salt excretion**: excretion of inorganic ions by structures other than the kidneys.

Present evidence indicates that excretion of NaCl by the gills in many teleosts is accomplished without concomitant excretion

¹⁰Divalent ions have two charges per ion, either two positive charges or two negative charges.

¹¹The kidneys of fish are incapable of producing urine that is hyperosmotic to blood plasma.

FIGURE 28.7 A section of a mitochondria-rich cell (chloride cell) of a marine teleost fish. In some species of marine teleosts, MRCs occur not just in the gill epithelium but also in the inner opercular epithelium, jaw epithelium, and certain other surfaces, implicating these other body parts—as well as the gills—in ion excretion. The MRC shown here is from the opercular epithelium of a seawater-acclimated killifish, *Fundulus heteroclitus*. The structure of MRCs in the gill epithelium is the same, but the cellular surroundings in the gill epithelium are different. In seawater fish—to a greater extent than in freshwater fish—a pit in the apical membrane termed the *apical crypt* is prominent and the MRCs tend to be found in multi-cell groups. (After Degnan et al. 1977.)

BOX 28.3 EPITHELIAL NaCl SECRETION IN GILLS, SALT GLANDS, AND RECTAL GLANDS

NaCl secretion by the gill epithelium of marine teleost fish is believed to occur by the mechanism shown in the figure. The same model of the secretory mechanism is believed to apply to additional NaCl-secreting structures that we will soon discuss in this chapter: the cranial salt glands of marine birds and sea turtles, and the rectal salt glands of marine sharks, skates, and rays.

To understand the model, let's focus first on active Cl⁻ secretion by the mitochondria-rich cell (MRC) in the figure. The Cl⁻-transporting protein shown in the basolateral membrane of the cell, often called *NKCC*, is *not* an ATPase. Thus Cl⁻ transport is by *secondary* rather than primary active transport (see page 112). NKCC is an electroneutral cotransporter that moves one Na⁺ ion, one K⁺ ion, and two Cl⁻ ions into the cell across the basolateral membrane on each transport cycle; in the jargon of the study of transporter proteins, it is a *Na-K-2Cl cotransporter*. The energy for Cl⁻ transport is supplied from ATP indirectly by the action of Na⁺-K⁺-ATPase (see page 112), also located in the basolateral membrane. The Na⁺-K⁺-ATPase uses ATP-bond energy to pump Na⁺ out of the cell, thereby creating a strong electrochemical gradient favoring diffusion of Na⁺ from the blood into the cell. Following its electrochemical gradient, Na⁺ diffuses into the cell bound to NKCC, and this process brings Cl⁻ from the blood into the cell. The entry of Cl⁻ into the cell creates an electrochemical gradient favoring the diffusion of Cl⁻ out of the cell, and Cl⁻ exits the cell by way of Cl⁻ channel proteins in the apical cell membrane. In the case of the gill epithelium of marine teleosts, the specific type of channel protein that is dominant is known as *CFTR* (*cystic fibrosis transmembrane conductance regulator*), and Cl⁻ leaving the cell enters the ambient water. Potassium (K⁺) ions accumu-

lated in the cell by the actions of Na⁺-K⁺-ATPase and NKCC simply diffuse back to the blood by way of K⁺ channels.

The Cl⁻ and K⁺ channels are gated channels in at least some cases. Secretion is controlled in part by regulatory mechanisms that open and close the channels. In the cells of avian salt glands, the Cl⁻ and K⁺ channels are known to be Ca²⁺-activated; thus secretion is under immediate control of a Ca²⁺-based second-messenger system (see Figure 2.30).

Let's now turn to the question of how Na⁺ is secreted across the epithelium. The transfer of Cl⁻ across the epithelium by the mechanism we have described is electrogenic, and as shown in the figure, it renders the apical side of the epithelium electrically negative relative to the blood. This difference in electrical potential across the epithelium can be large enough to create an electrochemical gradient that favors *diffusion* of Na⁺ from the blood outward across the epithelium (Na⁺ is repelled from the positively charged inner epithelial surface and attracted to the negatively charged outer surface). Current evidence indicates that when Na⁺ travels outward across the epithelium by diffusion, it follows paracellular (between-cell)

of water; the material excreted is purely ions. Thus, in addition to voiding NaCl from the blood (ionic regulation), the process produces a fluid that is essentially infinitely higher in osmotic pressure than the blood plasma. The process therefore tends to lower the osmotic pressure of the plasma (see Figure 27.7) and maintains the blood osmotic pressure at a level below the ambient osmotic pressure. *The gills are in fact the sites where osmotic regulation is principally accomplished.*

QUANTITATIVE EXAMPLE AND COST ESTIMATES In **Figure 28.8**, the pattern of water-salt regulation in marine teleost fish is summarized (see Figure 28.8*b*) and contrasted with the pattern in freshwater teleost fish (see Figure 28.8*a*). Let's review the pattern in marine teleost fish by making use of quantitative data for one

The probable mechanism of epithelial NaCl secretion

The diagram shows a mitochondria-rich cell (chloride cell) flanked by two other cells (which may or may not themselves be MRCs) in a secretory epithelium. In the gills of marine teleosts, NaCl is secreted directly into the ambient water; in the cranial salt glands of birds and sea turtles and the rectal salt glands of elasmobranch fish, NaCl is secreted into ducts, and the salty solution thus formed flows out of the animal by way of a duct system. NKCC, Na⁺-K⁺-ATPase, and the K⁺ channel are proteins in the basolateral cell membrane. The Cl⁻ channel is a protein in the apical membrane.

pathways. In some cases, diffusion is believed to be the sole mechanism of Na⁺ secretion, but in other cases there is evidence for secretion of Na⁺ by active transport.

particular species that has been thoroughly studied, the southern flounder (*Paralichthys lethostigma*). An individual flounder that weighs about 1 kg loses water equivalent to about 7.9% of its body weight per day because of osmosis from its body fluids into the surrounding seawater. To replace this water, and also to replace urinary water losses of 0.4% of body weight per day and fecal losses of 2.7% per day, the fish drinks seawater equivalent to 11% of its body weight per day. From the seawater it ingests, the fish absorbs 76% of the H₂O, but in doing so it absorbs much higher percentages of the Na⁺ (99%) and Cl⁻ (96%). The flounder produces a scanty urine having a U/P ratio for Mg²⁺ of about 100 and a U/P ratio for SO₄²⁻ of 330; the urine removes excesses of both of these divalent ions from the body fluids. The gills of the flounder excrete virtually all of the excess monovalent ions, Na⁺ and Cl⁻.

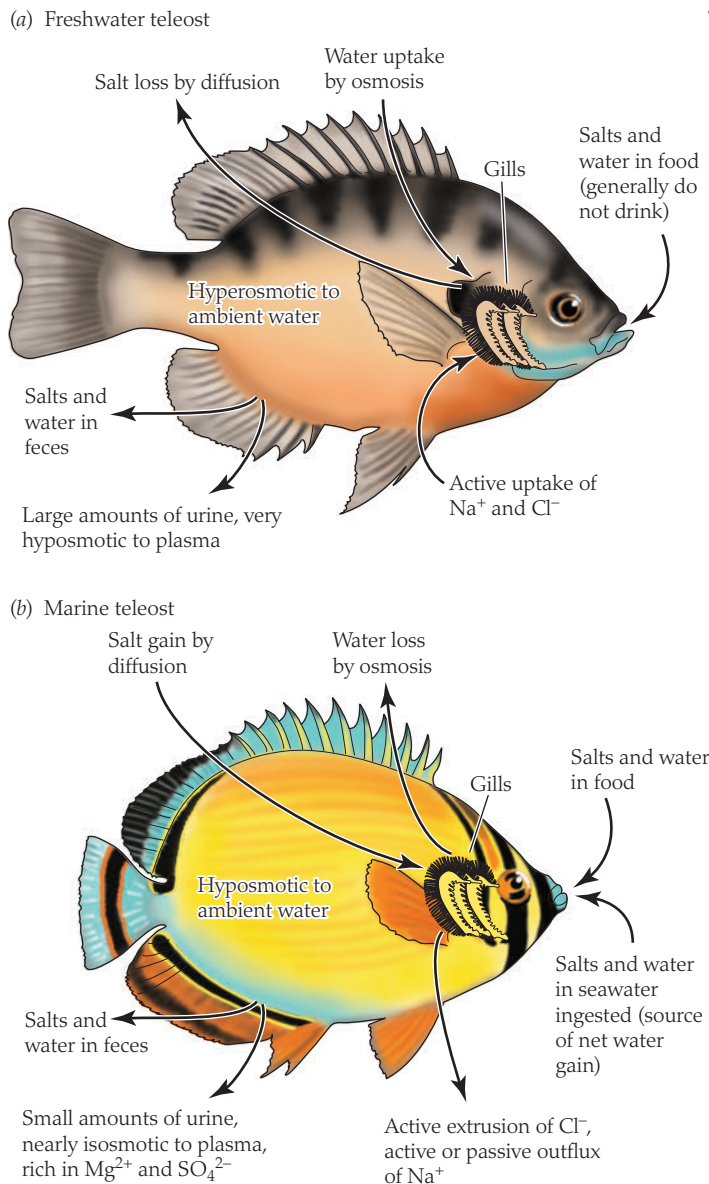

FIGURE 28.8 Contrasting water-salt relations in freshwater and marine teleost fish

The energy cost of Na^+ , Cl^- , and osmotic regulation in marine teleosts has been estimated in several species (including tunas) to be 8–17% of the resting metabolic rates of the fish, based on measured ion-pumping rates and the known ATP costs of pumping. Rainbow trout—which can live in freshwater or seawater—are estimated to devote 3% of their resting energy use to Na^+ , Cl^- , and osmotic regulation when living in freshwater, but 8% when living in seawater. The higher cost in seawater reflects the fact, earlier stressed, that for a teleost fish, the difference in concentration between the blood and the ambient water is about twice as great in seawater as in freshwater.

Some arthropods of saline waters are hyposmotic regulators

Quite a few arthropods that live in the ocean or more-saline waters, such as salt lakes, maintain their blood osmotic pressure at a level hyposmotic to the water in their environment. These animals include some marine crabs and shrimps, the small branchiopods called brine shrimp, and those insects that live (usually as larvae)

in salty waters. When in seawater (~1000 mOsm), for example, the fiddler crab *Uca pugnax* has a blood osmotic pressure of about 860 mOsm, and some prawns (e.g., *Palaemonetes varians*) are even more dilute, near 700 mOsm. Biologists generally believe that evolutionary heritage accounts for the dilute body fluids of most of these animals: Their ancestors lived in more-dilute habitats, and their body fluids bear an imprint of that earlier time. Their mechanisms of hyposmotic regulation have been well studied in a few cases and usually parallel those of marine teleost fish.

Marine reptiles (including birds) and mammals are also hyposmotic regulators

The sea turtles, sea snakes, penguins, gulls, whales, seals, and other marine reptiles and mammals—like marine teleost fish—are markedly hyposmotic to seawater. All are descended from terrestrial ancestors, and their blood compositions are clearly carryovers from their ancestors. The blood osmotic pressures of all these marine vertebrates tend to be about 400 mOsm: just modestly higher than the values seen in modern-day terrestrial and freshwater vertebrates.

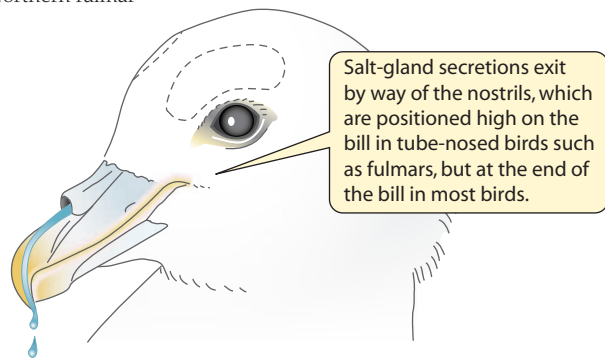

Because the marine turtles, snakes, birds, and mammals are air breathers, they do not expose permeable respiratory membranes to seawater. Another advantage of their terrestrial heritage is that they have inherited integuments that were originally adapted to limiting water losses in the dehydrating terrestrial environment, so they tend to exhibit low integumentary permeabilities. These animals nonetheless confront problems of water loss and salt loading. They lose water, for example, by pulmonary evaporation during breathing; they also lose water to some extent across their skin, not only when they are immersed in seawater, but also when they are exposed to the air. These animals often gain excess salts from the foods they eat; for example, when they prey on marine plants or invertebrates that are isosmotic to seawater, they ingest body fluids that have far higher salt concentrations than their own. In addition, they probably often take in quantities of seawater with the foods they eat, although, for the most part, they are thought not to drink seawater.

MARINE REPTILES (INCLUDING BIRDS) The marine turtles, snakes, and lizards—in common with other nonavian reptiles—are generally not able to produce urine that is more concentrated in total solutes than their blood plasma. The urine-concentrating capabilities of marine birds are incompletely understood, but for most species the maximum urine concentration appears to be isosmotic to the blood plasma or only modestly hyperosmotic ($U/P \leq 2$). Because of these facts, the kidneys of marine turtles, snakes, lizards, and birds are in general not able—by themselves—to maintain the blood of the animals hyposmotic to seawater (see Figure 27.7).

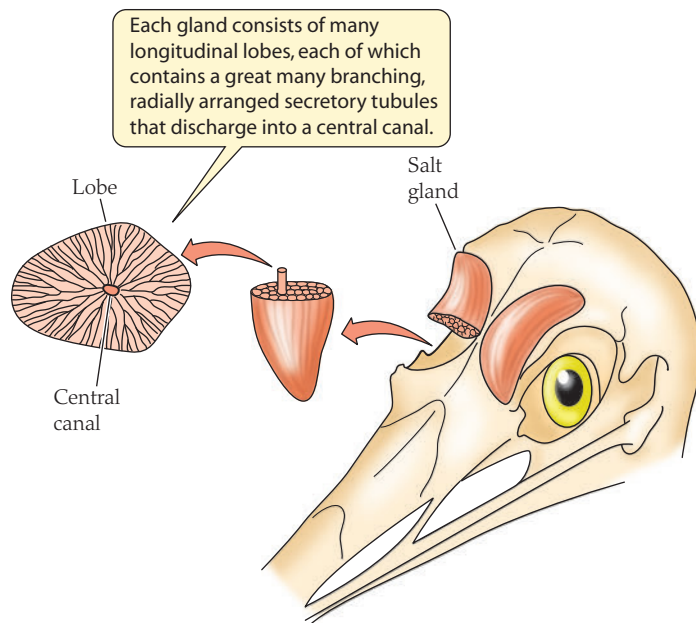

Organs of *extrarenal salt excretion* called **salt glands** are of key importance in the osmotic-ionic regulation of (1) the marine reptiles other than birds and (2) most marine birds.¹² These glands are located in the head (Figure 28.9). They produce concentrated salt solutions, which are discharged into the nasal passages in birds and lizards, and into the mouth in sea snakes. In sea turtles, their

¹²Salt glands have been reported in 14 orders of birds. However, they have not been reported in the passerine (“perching”) birds. A few species of passerines that live in association with the ocean, such as certain salt marsh sparrows, have evolved kidneys that—based on published reports (now disputed by some authorities)—have unusually great concentrating abilities compared with those of most birds.

(a) Northern fulmar

(b) Herring gull

secretions (referred to as *orbital* secretions) are emitted like tears. Not only are the secretions of the salt glands dramatically hyperosmotic to the blood (by a factor of four to five in many species), but they also, as indicated in [Table 28.4](#), contain concentrations of Na^+ and Cl^- (and K^+ as well) that exceed those in seawater. Thus birds, lizards, turtles, and snakes with salt glands are, in principle, able to extract pure H_2O from seawater; they could drink seawater and void the major monovalent ions in less H_2O than they ingested, retaining the excess H_2O in their bodies. Their kidneys alone do not provide such a capability. The cellular mechanism of salt secretion by the salt glands conforms to the model in [Box 28.3](#), at least in birds and sea turtles.

The ingestion of a salt load by an animal with salt glands is promptly followed by an increase in the rate of secretion by the glands. Control of this response, at least in birds, is mediated principally by the parasympathetic division of the autonomic nervous system. When osmoreceptors located in or near the heart and brain detect high blood osmotic pressures, the parasympathetic nervous system releases acetylcholine in the salt glands; this chemical message induces gated Cl^- and K^+ channels in the mitochondria-rich cells (chloride cells) of the salt glands (see figure in [Box 28.3](#)) to open, activating secretion. In addition to these acute responses, salt glands also undergo chronic responses (acclimatization). For

FIGURE 28.9 Avian salt glands The salt glands of birds are located above the eyes. Ducts carry the secretions of the salt glands to the nasal passages, and the secretions drip out from the external nares (nostrils). (a) A northern fulmar—a type of oceanic bird—showing the outlines of the salt glands above the eyes and the dripping of salt-gland secretions from the nostrils. (b) The structure of the salt glands of a herring gull. Each salt gland lies in a shallow depression in the skull above the eye. (a after Goldstein 2002; b after Schmidt-Nielsen 1960; for exhaustive detail on morphology, consult the article by Gerstberger and Gray in the Additional References.)

example, if an individual bird experiences a chronic increase in salt ingestion—as it would after migrating from a freshwater habitat to an ocean habitat—its salt glands typically increase in size, concentrating ability, and peak secretory rate. These changes are reversible.

The tears observed flowing down the faces of sea turtles when they emerge onto beaches to lay eggs are of some renown. We now understand that they are secretions of salt glands, not tears of emotion. If you watch a fulmar or gull standing by the ocean, you will see—emerging from its nostrils—droplets of salt-gland secretions (see [Figure 28.9a](#)), often flicked away by a shake of its head.

MARINE MAMMALS Mammals, as a group, are capable of producing the most concentrated urine of all vertebrates. This ability is important on land, and for marine mammals such as seals and whales, it is a key to hyposmotic regulation. Salt glands or other mechanisms of extrarenal salt excretion are not known in mammals.

As important as the kidneys are in marine mammals, the urine-concentrating abilities of these animals are not exceptional in comparison with other mammals, according to available data. For example, in harbor seals (*Phoca vitulina*)—as is typical for marine mammals that are relatively superior in urine-concentrating ability—the maximum osmotic U/P ratio is about 6, and the maximum

TABLE 28.4 Concentration of Na^+ in the salt-gland secretions of marine birds, turtles, and lizards

Cl^- concentrations are typically about the same as Na^+ concentrations. All data are for adults except those for the green sea turtles.

Animal	Na^+ concentration (mM)
Marine iguana (<i>Amblyrhynchus cristatus</i>)	840
Loggerhead sea turtle (<i>Caretta caretta</i>)	730–880
Newly hatched green sea turtle (<i>Chelonia mydas</i>)	460–830
Herring gull (<i>Larus argentatus</i>)	600–800
Brown pelican (<i>Pelecanus occidentalis</i>)	600–750
Humboldt penguin (<i>Spheniscus humboldti</i>)	725–850
Leach's storm-petrel (<i>Oceanodroma leucorhoa</i>)	900–1100
Standard seawater	470

urinary Na^+ and Cl^- concentrations that have been measured are slightly above 500 mM. Although these renal concentrating abilities are high in comparison with those of reptiles (including most birds), they are not particularly high in comparison with those of nonmarine mammals of similar body size.

The overall patterns of water and salt balance in seals and whales remain open to debate. Existence on a diet of teleost fish poses no great challenges. To date, however, the data available leave unclear whether or how most species could exist while chronically eating only invertebrates, which often have substantially saltier body fluids than fish. Although seals and whales are thought generally not to drink seawater, research in the last 20 years has revealed that some species of both groups do drink under certain circumstances; some otariid (e.g., fur) seals, for instance, drink seawater when hauled out on land for weeks in hot climates during their breeding season. Physiologists are debating the potential advantages of drinking for animals that in general cannot concentrate salts in their urine to levels higher than the concentrations seen in seawater (see page 709).

Marine elasmobranch fish are hyperosmotic but hypoionic to seawater

The marine sharks, skates, and rays—collectively known as the *elasmobranch fish*—have evolved a novel solution to the osmotic problems of living in the sea. Their blood concentrations of *inorganic ions* are similar to those of marine teleost fish and well below those in seawater. However, the osmotic pressure of their blood is slightly *higher* than that of seawater. As illustrated by the example of the dogfish shark in [Table 28.5](#), these fish are able to be hyperosmotic to seawater—even though their blood has far lower concentrations of inorganic ions than seawater—because their body fluids have high concentrations of two *organic solutes*: urea and, to a lesser extent,

trimethylamine oxide (TMAO).¹³ Because their blood is hyperosmotic to seawater, the marine elasmobranchs experience a small *osmotic influx* of water, in sharp contrast to the marine teleosts, which confront relentless osmotic desiccation. The hyperosmoticity of the elasmobranchs—caused by their high blood concentrations of urea and TMAO—is, in effect, a mechanism for obtaining water.

In sharp contrast to teleosts, elasmobranchs typically synthesize urea as their principal nitrogenous product of protein catabolism ([Box 28.4](#)). Of all the thousands of species of teleosts, fewer than ten are known to employ urea in this role; the others employ ammonia. In contrast, the use of urea as the principal nitrogenous product is universal in marine elasmobranchs. Among all elasmobranchs, ammonia dominates in only a few freshwater rays.

Urea accumulates in the body fluids of marine elasmobranchs because of specializations of their kidneys and gills. Elasmobranchs reabsorb urea from their urine as the urine forms in their kidneys, possibly by use of active urea transport. Moreover, the gills of marine elasmobranchs also retain urea because they have a dramatically low permeability to urea and, according to recent discoveries, they actively return outgoing urea to the blood plasma.

Urea in high concentrations can alter the structures of proteins, and the concentration of urea is kept low in most vertebrates (about 2–7 mM in human plasma). Plasma concentrations of urea in marine elasmobranchs—usually 300–400 mM—are “out of sight” by comparison. Some enzymes and other macromolecules in elasmobranchs have evolved exceptional resistance to urea’s denaturing effects. Some elasmobranch organs, such as the heart, have in fact become dependent on urea for proper function. Recent studies have revealed, however, that many elasmobranch proteins are just as sensitive to urea’s denaturing effects as homologous proteins in other vertebrates. How can this be? A key part of the

answer is that TMAO serves as a *counteracting solute*. In the amounts present, TMAO offsets the effects of urea (see [Figure 27.10](#)), evidently by opposing effects of urea on deleterious interactions of proteins with solvent water, interactions that if unopposed cause protein unfolding.

In most aquatic animals, the blood osmotic pressure is attributable primarily to inorganic ions dissolved in the blood plasma. Because of this, problems of osmotic and ionic regulation are related in particular ways: If an animal tends to gain water by osmosis, it tends to lose ions by diffusion, and vice versa.

These relations are uncoupled in the marine elasmobranch fish because about 40% of the blood osmotic pressure is attributable to urea and TMAO rather than inorganic ions. Because the elasmobranchs are slightly hyper-

TABLE 28.5 Average composition of blood plasma and excretory fluids in two sharks and the coelacanth

For the dogfish shark and coelacanth, which were living in seawater, the composition of the seawater during study is given. The bull sharks were acclimated to seawater or freshwater for only a week; thus their plasma composition may not have been entirely stabilized. TMAO = trimethylamine oxide.

	Osmotic pressure (mOsm)	Solute concentration (mM)

¹³For the chemical structures of urea and TMAO, see [Box 28.4](#) and [Figure 29.24](#), respectively.

BOX 28.4 THE EVOLUTION OF UREA SYNTHESIS IN VERTEBRATES

Because proteins are 16% nitrogen by weight, the disposition of nitrogen is a significant matter when proteins are catabolized. Simple deamination of amino acids during protein breakdown leads to formation of ammonia (NH_3) as the nitrogen-containing end product of catabolism. Urea (see the structure to the right) is one of the major alternative nitrogenous end products. The synthesis of urea costs energy: Each urea molecule requires the energy from four or five ATP molecules for its synthesis. This cost is an “extra cost” that is avoided if ammonia is made instead of urea.

The biochemical pathway by which urea is synthesized from protein nitrogen in vertebrates is known as the *ornithine–urea cycle*. In the last 25 years, a consensus has emerged that the ornithine–urea cycle

existed in the earliest vertebrates. That is, the earliest vertebrates are believed to have had genes coding for all the ornithine–urea cycle enzymes.

Despite its antiquity, urea synthesis is observed today in only a minority of modern vertebrates, which have a scattered distribution in the vertebrate phylogenetic tree. These include the elasmobranch fish, coelacanth fish, mammals, most amphibians, and some others. Two principal advantages of urea synthesis seem to account for the cases in which vertebrates invest extra energy to make urea rather than ammonia from their waste protein nitrogen. First, urea is sometimes employed as an osmolyte to raise the osmotic pressure of the blood; it is used in this way by some marine fish to render the blood hyperosmotic to seawater. Second, urea is sometimes

Urea

A phylogenetic tree of the vertebrates showing with blue dots where urea synthesis is retained in modern vertebrates The distribution of urea synthesis in modern vertebrates is distinctly scattered. The tree is presented in detail in Box Extension 28.4.

employed as a detoxification compound for waste nitrogen. Urea is far less toxic than ammonia and therefore is far better suited to being accumulated in the body than ammonia is. **Box Extension 28.4** presents the phylogenetic tree in detail and discusses the evolution of urea synthesis more thoroughly.

osmotic to seawater, they tend to gain water by osmosis, but because their blood ion concentrations are below those in seawater, they also tend to gain excess ions by diffusion from seawater. As a consequence of the fact that water enters elasmobranchs osmotically, they need not drink to obtain water, and therefore—unlike teleosts—do not incur the NaCl load caused by drinking seawater.

Excess salts are removed from the body fluids of elasmobranchs by the kidneys and, extrarenally, by **rectal salt glands**. The salt glands, consisting of thousands of secretory tubules, void into the rectum a secretion (see the data for the dogfish shark in Table 28.5) that is isosmotic to the blood, but contains only traces of urea and approximates or exceeds seawater in its concentrations of Na^+ and Cl^- . The mechanism of NaCl secretion is as described in Box 28.3. Excess divalent ions are voided largely by the kidneys, along with significant quantities of NaCl (see Table 28.5). Whether active ion excretion occurs across the gills is an unresolved question.

Ever since the “elasmobranch strategy” of water–salt regulation in the sea (**Figure 28.10**) was discovered, biologists have speculated about its possible advantages over the “teleost strategy.”¹⁴ Until recently, the usual conclusion was that the elasmobranch strategy costs less energy because marine elasmobranchs are able to obtain H_2O by “cost-free” osmosis, whereas marine teleosts must drink seawater and pump NaCl out of it to get H_2O . The error in this view, we now recognize, is that the osmosis of water into a marine elasmobranch is *not* “cost-free.” To keep its blood hyperosmotic to seawater, an elasmobranch must synthesize urea, which costs more ATP (see Box 28.4) than merely making ammonia from waste nitrogen (as most teleost fish do). The elasmobranch might also need to pay ATP costs to recover urea from its urine and intercept urea diffusing outward across its gills. In a careful analysis, Leonard Kirschner concluded that the costs of the elasmobranch and teleost strategies are essentially the same. At least in terms of energy, the strategies seem to be “different but equal.”

About 15% of the elasmobranch species alive today occur in dilute brackish waters or in freshwater. Although some are permanent residents of freshwater, most also occur in the ocean. A well-studied example of the latter is the bull shark (*Carcharhinus leucas*), famed for its rare but devastating attacks on coastal swimmers. When the elasmobranchs that live in the ocean venture into dilute waters, they lower their blood urea concentrations somewhat by decreasing urea synthesis and retention. Nonetheless, they retain elevated blood urea concentrations, as illustrated by bull sharks (see Table 28.5), even though doing so promotes osmotic uptake of excess water in dilute environments.

In addition to marine elasmobranchs, two other types of marine fish maintain high blood concentrations of urea and TMAO: the coelacanth and the holocephalans (chimaeras). The coelacanth (see Table 28.5) is a particularly interesting case because it is the only living example of the crossopterygian fish, the presumed ancestors of the terrestrial vertebrates.

FIGURE 28.10 Water–salt relations in a marine shark Protein-rich foods are required for adequate urea synthesis.

¹⁴The assumption is that marine elasmobranchs and teleosts both inherited low blood salt concentrations from freshwater ancestors, but they have diverged in how they manage the consequences.

SUMMARY Animals in the Ocean

- Most marine invertebrates are approximately isosmotic to seawater, but their blood differs from seawater in ionic composition. They exhibit ionic regulation but have little or no need for osmotic regulation. Hagfish display the same pattern.
- Marine teleost fish are hyposmotic to seawater, apparently because they are descended from freshwater or coastal ancestors.
- Because they are hyposmotic to seawater, marine teleosts tend to lose water by osmosis and gain ions by diffusion. To replace water, they drink; however, to absorb H₂O from the seawater in their gut, they must actively take up NaCl, increasing their problem of salt loading. Their kidneys make urine that is approximately isosmotic to their blood plasma but rich in divalent ions, thereby assuming chief responsibility for divalent ion regulation. Monovalent ions are excreted across their gills; although Cl⁻ is secreted actively into the ambient water by mitochondria-rich (chloride) cells, Na⁺ secretion is often secondary to Cl⁻ secretion and passive.
- Marine birds, turtles, lizards, and snakes have cranial salt glands that permit them to excrete ions at higher concentrations than possible in their urine.
- Marine mammals lack salt glands but have kidneys that can produce more-concentrated urine than reptiles (including birds). Their urinary concentrating abilities are not exceptional compared with those of other mammals, however, and their water–salt balance is not entirely understood.
- Marine elasmobranch fish, although they have blood ion concentrations far lower than those of seawater, are slightly hyperosmotic to seawater because of high concentrations of two counteracting organic solutes, urea and trimethylamine oxide (TMAO). Unlike teleosts, therefore, elasmobranchs need not drink and need not incur an extra NaCl load to gain H₂O from ingested seawater.

Animals That Face Changes in Salinity

Many aquatic animals face large changes in the salinity of the waters they occupy during their lifetimes. These include (1) animals like salmon and eels that migrate long distances between rivers and the open ocean and (2) animals that live near the margins of the continents. Along coastlines, waters of intermediate salinity—brackish waters—occur in estuaries, salt marshes, and other settings (see Chapter 27). Ocean animals that venture into brackish coastal waters encounter lower salinities than they experience when living in the open ocean. Freshwater animals face elevated salinities when they enter brackish waters. Some species live principally *within* estuaries; they face changes in salinity as they move from place to place (see Figure 27.4) or as tides or other water movements shift the waters around them.

In their relations to changing salinities, animals are often categorized as *stenohaline* or *euryhaline*. **Stenohaline** species are able to survive within only narrow ranges of ambient salinity. **Euryhaline** species, in contrast, can survive within broad ranges of salinity.

Animals are also classified as *osmoconformers* or *osmoregulators* (see Figure 27.3). **Osmoconformers**—sometimes described as **poikilosmotic**—permit their blood osmotic pressure to match the

ambient osmotic pressure. **Osmoregulators**—sometimes called **homeosmotic**—maintain a relatively stable blood osmotic pressure even as the ambient osmotic pressure rises and falls.

Most species of invertebrates that occur in the ocean are stenohaline osmoconformers; when they are placed in brackish waters, their blood osmotic pressure falls, and because they cannot tolerate blood osmotic pressures much lower than those they have in seawater, they do not prosper or may die. Certain marine osmoconformers are exceptional, however, in that they are euryhaline. Oysters and mussels provide outstanding examples; despite being osmoconformers, some species thrive over wide ranges of salinity, from seawater itself to waters less than 20% as concentrated as seawater. For osmoconformers to be so euryhaline, their cells must have remarkable abilities to function over wide ranges of blood osmotic pressure. The cells of euryhaline osmoconformers are noted for having dramatic powers of cell-volume regulation (see Figure 27.8).

An intriguing and commercially important illustration of how water–salt physiology can feature in the lives of euryhaline osmoconformers is provided by the story of MSX, a debilitating protistan parasite of the commercial oyster (*Crassostrea virginica*) of the Atlantic seaboard of the United States. These oysters live in estuaries, where the ambient salinity varies from place to place. Because their blood osmotic pressure matches the ambient osmotic pressure, their blood osmotic pressure also varies from place to place. The MSX parasite cannot survive in an oyster if its blood is more dilute than about 400 mOsm. For the oysters, therefore, ambient waters with osmotic pressures lower than 400 mOsm are safe havens from the parasite. In the Chesapeake Bay (see Figure 27.4), serious spread of MSX occurs during droughts. When there is little rain, rivers bring less freshwater into the Bay, and the salinity rises above 400 mOsm in places where it is ordinarily lower. The oysters living in such places experience a rise in blood osmotic pressure and become vulnerable to the parasite.

Among animals that are osmoregulators, regulation is often limited to certain ranges of ambient osmotic pressure. Thus different categories of regulators are recognized. In one common pattern, called **hyper-isosmotic regulation**, a species keeps its blood more concentrated than the environmental water at low environmental salinities, but allows its blood osmotic pressure to match the ambient osmotic pressure at higher salinities. Species that are predominantly freshwater animals but venture into brackish waters typically show this pattern, as do many coastal marine invertebrates (Figure 28.11a). Animals exhibit hyper-isosmotic regulation when they possess mechanisms of hyperosmotic regulation but lack mechanisms of hyposmotic regulation.

A second major category of regulators consists of those that keep their blood more concentrated than the environmental water at low environmental salinities but more dilute than the environmental water at high environmental salinities. This pattern is called **hyper-hyposmotic regulation** and requires mechanisms of both hyperosmotic and hyposmotic regulation. It is observed in salmon, eels, and other migratory fish and in a variety of crustaceans (Figure 28.11b).

Both osmoconforming and osmoregulating species occur among the crustaceans that live in the oceans and also in the marine annelids and some other related sets of marine animals. In these groups, euryhalinity and osmoregulatory ability tend to

(a) Hyper-isosmotic regulators

(b) Hyper-hyposmotic regulators

FIGURE 28.11 Types of osmotic regulation For each animal shown, blood osmotic pressure is plotted as a function of the osmotic pressure of the ambient water. Each dashed line is a line of equality between blood osmotic pressure and ambient osmotic pressure (an isosmotic line). (a) Three species of hyper-isosmotic regulators. Such regulation is typical of freshwater animals that enter brackish waters (e.g., the carp); it occurs also in many crabs of shores or estuaries (e.g., the blue crab, *Callinectes sapidus*) and in some euryhaline annelids and amphipods (e.g., *Gammarus oceanicus*, shown). (b) Four species of hyper-hyposmotic regulators. Such regulation occurs in many shore crabs (e.g., the fiddler crab, *Uca pugilator*, and the lined shore crab, *Pachygrapsus crassipes*), semiterrestrial crabs (e.g., the ghost crab, *Ocypode cursor*), coastal shrimps, and animals adapted to inland saline environments (e.g., the brine shrimp, *Artemia salina*), as well as euryhaline and migratory fish. (After Hill and Wyse 1989; D’Orazio and Holliday 1985; Greenaway 1988; Kirschner 1991.)

be correlated: The most euryhaline species are typically those that osmoregulate to a comparatively strong extent. Success in dilute waters in marine crustaceans, annelids, and other such groups, therefore, has been achieved by protecting the cells of the body from exposure to low blood osmotic pressures, in contrast to the oysters and mussels earlier discussed.

Migratory fish and other euryhaline fish are dramatic and scientifically important examples of hyper-hyposmotic regulators

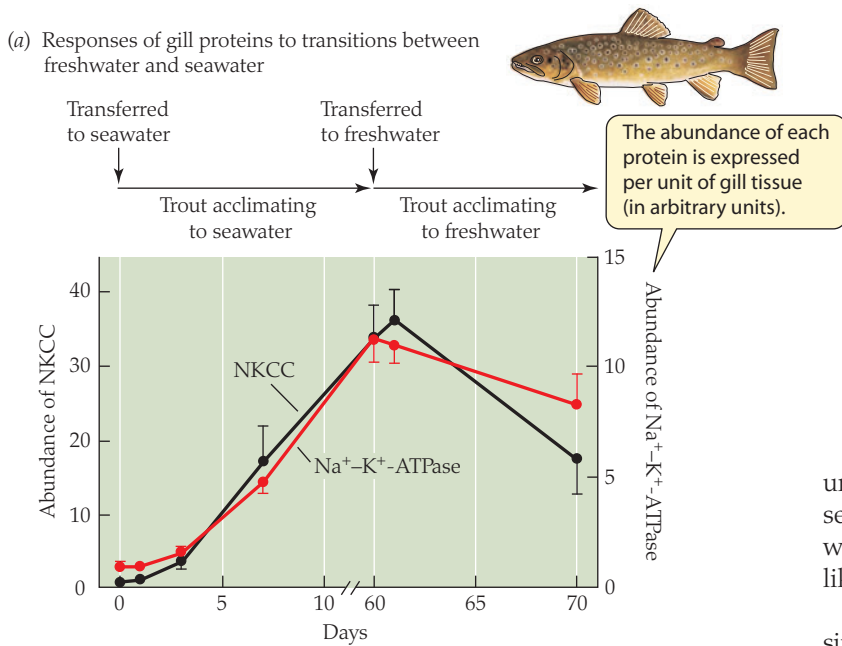

The fish that migrate between freshwater and the oceans typically breed in one habitat and undergo much of their growth and maturation in the other. Some species—termed **anadromous** (“running upward”)—ascend rivers and streams from the oceans to breed; these fish include salmon and certain smelts, shad, and lampreys. Other species—termed **catadromous** (“running downward”)—grow in freshwater and descend to the oceans for breeding; they include the freshwater eels (genus *Anguilla*) of North America, Europe, and East Asia.

The migratory fish are superb osmoregulators. They function as hyperosmotic regulators when in freshwater and as hyposmotic regulators when in seawater, and they are so effective in both habitats that their blood osmotic pressure generally changes only a little between the two. Chinook salmon (*Oncorhynchus tshawytscha*), for example, have a plasma osmotic pressure averaging about 410 mOsm when in the ocean and about 360 mOsm when at their freshwater spawning grounds.

The mechanisms of regulation employed by migratory fish—and other euryhaline teleosts—in seawater and in freshwater are the same as those we earlier discussed for marine and freshwater teleosts (see Figure 28.8). Thus, when the fish move from freshwater to seawater, they reverse the direction of active NaCl transport across their gills (inward transport in freshwater, outward in seawater); they greatly increase the rate at which they drink; they decrease their rate of urine production; and they switch from producing urine that is markedly hyposmotic to their blood plasma to producing urine that is approximately isosmotic to the plasma. In their intestinal epithelia, the activity of the NaCl-uptake mechanisms and the abundance of aquaporins also increase when they enter seawater. Some crustaceans that exhibit hyper-hyposmotic regulation, such as fiddler crabs (*Uca*; see Figure 28.11), are known to display similar and equally dramatic shifts in their regulatory mechanisms as they move between salinities.

The migratory fish—and other euryhaline teleosts—have been and continue to be the most important of all fish for studies of the physiological regulation of water–salt relations. They are studied intensely because their regulatory systems meet dramatic challenges and thus provide vivid insight into regulation in action.

One major objective of modern research on fish water–salt physiology is to understand the molecular mechanisms of successful transitions between freshwater and seawater. Studies of gill function provide a good illustration. In recent years, researchers have established that the gills of an individual fish undergo extensive molecular remodeling during such transitions—remodeling that leads to distinctive *freshwater and seawater gill phenotypes*. These phenotypic adjustments include critical changes in the cell morphology and the suites of ion-transport proteins in the mitochondria-rich cells (MRCs) that are so important for gill ion transport (see Box 28.1). Using monoclonal antibodies to assay defined cell-membrane proteins of the MRCs, for example, researchers have studied the concentrations and types of Na⁺–K⁺–ATPase and NKCC (a Na–K–2Cl cotransporter) during freshwater-to-seawater transitions. Both of these ion-transport proteins are predicted—from knowledge of molecular transport mechanisms in teleost fish (see Boxes 5.2 and

(b) Gill tissue in which NKCC is stained for identification

28.3)—to increase in individuals transferred from freshwater to seawater. Quantitative changes in the proteins follow this prediction in brown trout (*Salmo trutta*), as seen in **Figure 28.12**: The proteins increase in the gill MRCs when trout are transferred to seawater and decrease when the fish are returned to freshwater. Studies of several other species confirm these results. Moreover, research on Atlantic salmon (*Salmo salar*) and some other species reveals that the *molecular form* of Na⁺-K⁺-ATPase also changes between freshwater and seawater, implying that the detailed function of the ATPase is modulated. Aquaporins constitute another area of molecular research. Recent studies (e.g., on eels, *Anguilla japonica*) indicate that aquaporins are upregulated in intestinal epithelia following transfer to seawater—a response predicted to facilitate uptake of H₂O from ingested seawater.

A second major objective of research today is to clarify the complex endocrine controls of water–salt physiology. Years ago, investigators discovered that hypophysectomized fish died when transferred to freshwater, but they could be rescued by the specific adenohypophysial hormone prolactin. Those experiments established that hormonal controls are of vital importance in water–salt physiology; prolactin, in particular, plays a key role not only in reducing the permeability of the gills to Na⁺ but also in augmenting

FIGURE 28.12 Molecular phenotypic plasticity in gills of trout transferred between freshwater and seawater

(a) Brown trout (*Salmo trutta*) that had been living in freshwater were transferred to seawater on day 0. After living in seawater for 60 days (note the break in the *x* axis), they were returned to freshwater. Abundances of Na⁺-K⁺-ATPase (α subunit) and NKCC (Na–K–2Cl cotransporter) were quantified by immunocytochemistry. (b) Images of gill secondary lamellae, from fish acclimated more than 60 days to seawater or freshwater, in which NKCC is visualized immunocytochemically by use of a monoclonal antibody specific to the protein, resulting in a red color (nuclei are stained blue). Note that staining is more intense in the seawater-acclimated gill. (a after Tipsmark et al. 2002; b courtesy of Christian Tipsmark, from Tipsmark et al. 2002.)

urine flow by effects on the kidneys and urinary bladder. By now, several other hormones are known to be of central importance in water–salt physiology, including cortisol, growth hormone, insulin-like growth factor, and thyroid hormone.

A memorable and informative experiment was done recently by simply adding NaCl to the diets of rainbow trout kept in freshwater. One might conclude that the trout were fooled by the dietary salt because they responded by modifying their gill phenotype to that of seawater-acclimated fish! For example, they upregulated the genes coding for Na⁺-K⁺-ATPase and NKCC. The experiment indicates that salt exposure is a trigger for phenotypic remodeling.

Animals undergo change in all time frames in their relations to ambient salinity

The relations of animals to salinity can change in all the time frames we highlighted in Chapter 1 (see Table 1.2). Besides acute responses (the responses that individuals undergo soon after the salinity of their environment becomes altered), another time frame in which individuals respond is the chronic time frame (i.e., acclimation or acclimatization). The responses of trout shown in **Figure 28.12** provide one example of acclimation. Another instructive example comes from studies of groups of blue mussels (*Mytilus edulis*) collected from the North Sea—where the salinity of the ambient water was 30 g/kg—and from the brackish Baltic Sea—where the salinity was 15 g/kg. **Figure 28.13a** shows the ranges of salinities at which the two groups of mussels were able to maintain ciliary activity (rated on a scale of 0–3 on the *y* axis) at the time of collection. The groups were then switched in the salinities at which they lived. As each group acclimated to its new salinity (**Figure 28.13b–d**), the range of salinities over which it could maintain ciliary activity gradually shifted. After 30 days, the North Sea animals living at a salinity of 15 g/kg displayed normal ciliary activity over approximately the same salinity range as originally seen in the Baltic Sea animals; the Baltic Sea animals living at a salinity of 30 g/kg also acclimated, coming to resemble the original North Sea animals. These results reveal acclimation in action and suggest that the original difference between the North Sea and Baltic Sea mussels was largely a consequence of acclimation (individual phenotypic plasticity).

Evidence also suggests that populations of a species can *evolve* differences in their water–salt physiology when living in different environments over multiple generations. An intriguing illustration is provided by populations of lampreys (*Petromyzon marinus*) that have become landlocked in North American freshwater lakes. Lampreys, which are anadromous like salmon, ordinarily migrate

FIGURE 28.13 Acclimation of mussels to changed salinity Blue mussels (*Mytilus edulis*) were collected from the North Sea, where the ordinary ambient salinity is about 30 g/kg, and from the Baltic Sea, where the ordinary ambient salinity is about 15 g/kg (for reference, open-ocean seawater has a salinity of about 35 g/kg). After initial testing (a), each group was switched to living in water of the opposite salinity and periodically retested (b–d). The aspect of their physiology studied was the activity of their gill cilia—important for pumping water through the body so food and O_2 can be collected. Ciliary activity (y axis) was scored on a scale of 0 (low) to 3 (high) as a function of salinity (x axis). Blue mussels are of great importance in natural ecosystems and aquaculture. (After Theede 1965.)

to the ocean when they are young adults. The populations that are landlocked in lakes have had no experience with the sea for many generations, however. Adults from some landlocked populations exhibit osmoregulatory difficulties when they are placed in water that is only half the salinity of seawater. However, adults from migratory populations—when tested—can osmoregulate at the full salinity of seawater *even before* they have migrated and had actual experience with salty waters. These observations strongly suggest genetic divergence between the landlocked and migratory populations.

Many animals are also known to undergo *developmental changes* in their water–salt physiology. Recall, for example, the changes we have discussed in the locations of mitochondria-rich cells (chloride cells) in developing freshwater and saltwater fish (see Figure 4.6).

SUMMARY Animals That Face Changes in Salinity

- Some groups of marine invertebrates, such as molluscs, are uniformly osmoconformers. The euryhaline species in these groups are tolerant of wide ranges of blood osmotic pressure.

- Other groups of marine invertebrates, such as crustaceans, include osmoconforming and osmoregulating species. In general in these groups, there is a correlation between osmoregulation and euryhalinity: The euryhaline species are osmoregulators.
- Animals that are hyper-isosmotic regulators have mechanisms for hyperosmotic regulation but not hyposmotic regulation. Hyper-hyposmotic regulators have mechanisms for both types of regulation.
- Euryhaline fish, such as species that migrate between seawater and freshwater, are excellent hyper-hyposmotic regulators. When they transition between freshwater and seawater, they undergo many changes in gill, kidney, and intestinal function—including molecular remodeling—under control of prolactin, cortisol, and other hormones.

Responses to Drying of the Habitat in Aquatic Animals

Residents of puddles, small ponds, intermittent streams, and the like are often confronted with drying of their habitat. The lungfish (dipnoan fish), which have lungs and fleshy fins, are of particular interest in this regard because of their relatively close relation to the fish that gave rise to amphibians. All species of lungfish occur in transient bodies of freshwater. If the habitat dries out, an African lungfish (*Protopterus aethiopicus*) digs a chamber in the bed of the lake or stream where it has been living; in the chamber, the fish curls up and secretes mucus that hardens into a cocoon opening only to its mouth. The cocoon acts as a barrier to evaporative water loss. The fish then enters a state of *metabolic depression* (see page 201): Its metabolic rate ultimately drops to about 10% of the ordinary resting level. This *hypometabolism* reduces its rate of respiratory

water loss, and also its rate of use of stored energy. The lungfish's kidneys virtually stop making urine—keeping water in the body but compelling wastes to accumulate. The lungfish switches from producing ammonia as its principal nitrogenous end product to producing urea, a far less toxic compound (see Box 28.4), and urea may accumulate in its blood to levels approaching those of marine elasmobranch fish. The lungfish can survive in this dormant condition for more than a year!

Many other freshwater animals burrow into the substrate—often encasing themselves in mucus coverings—and enter a resting condition during times of drought. Included are some leeches, snails, water mites, and amphibians.

Anhydrobiosis—“remaining alive without water”—refers to survival while dried as fully as possible by desiccation in air. It represents the extreme in animal desiccation tolerance (Box 28.5). A wide diversity of small animals from freshwater, saline, and terrestrial habitats are capable of anhydrobiosis, during which they become inert and as dry as paper or any other air-dried organic matter: They are so dry that they become like dust. In anhydrobiosis these animals are often tolerant of a variety of environmental extremes, not just extreme dryness, and often they can endure the air-dried state for many years. They frequently blow about in the wind, springing magically back to an animated life when they land in water. Biologists have long recognized two advantages of anhydrobiosis: It permits survival without water and can aid dispersal. A striking experiment on anhydrobiotic bdelloid rotifers has recently revealed a new potential advantage: escape from pathogens. Populations of rotifers exposed to a potentially lethal fungus were subjected to desiccation for various lengths of time. If desiccation continued for 4–5 weeks,

FIGURE 28.14 A long period of anhydrobiosis enhances survival of bdelloid rotifer populations because, during desiccation, the rotifers outlast their fungal pathogen. Populations of the bdelloid rotifer *Habrotricha elusa* were seeded with conidia of the fungal parasite *Rotiferophthora angustispora* and desiccated. The graph shows the percentage of rotifer populations killed by fungal growth following rehydration, as a function of the time until the populations were rehydrated. (After Wilson and Sherman 2010.)

80–90% of the populations were fungus-free after rehydration and the rotifers lived—because the rotifers tolerated desiccation longer than their fungal pathogen (Figure 28.14).

Animals on Land: Fundamental Physiological Principles

As we now turn to animal life on land, we return to considering animals in their active, alert states, going about their daily lives. They will be our focus except for occasional brief discussions of dormancy.

BOX 28.5 ANHYDROBIOSIS: LIFE AS NOTHING MORE THAN A MORPHOLOGICAL STATE

Anhydrobiosis occurs particularly in a great variety of small freshwater animals. Some of these, such as many nematodes and bdelloid rotifers—and freshwater as well as terrestrial tardigrades (see photo)—are able to enter anhydrobiosis at any stage of their life cycle. In some other types of animals, anhydrobiosis is possible only during certain life stages, such as the eggs of some water fleas (cladocerans) and other crustaceans, the larvae of some chironomid flies, the embryonic cysts of coelenterates, and the gemmules of sponges. The encysted embryos (gastrulae) of brine shrimp (*Artemia*; often marketed as aquarium food under the strange name “sea monkeys”) provide some of the best-studied examples of anhydrobiosis.

Being dried in air does not mean that every molecule of water is gone. Proteins and other materials tend to hold on to adhesively and cohesively bound water, more so when the humidity of the air is high than when it is low. Nevertheless, anhydrobiotic forms are very dry, typically having less than 2% as much water

A tardigrade or “water bear” These tiny animals, frequently found in moss, can dry completely and survive. Shown is *Macrobiotus* sp., not in anhydrobiosis, imaged by scanning electron microscopy.

as they have when hydrated. Some require certain minimum air humidities to survive. Some, however, can survive drying to the ultimate possible extent: Brine shrimp embryos, for example, can survive drying in a vacuum, which reduces their water content to 0.007

gram per gram of dry weight, and recently anhydrobiotic tardigrades were shown to survive exposure to the vacuum of space!

Many anhydrobiotic forms, when dried to their maximum tolerable extent, cease to exhibit any of the usual signs of metabolism; for example, they neither consume O_2 nor accumulate wastes. Thus, as stated by one authority, they become “nothing more than a morphological state.” They are described as **ametabolic**. More specifically, they are **reversibly ametabolic** because, although their metabolism stops, it can be restarted. These ametabolic forms raise interesting questions about how animal life is to be defined, inasmuch as metabolism is often included in the list of properties that distinguish living systems from nonliving ones.

The disaccharide trehalose often accumulates in animal forms entering a state of anhydrobiosis. Trehalose prevents the structures of macromolecules, cell membranes, and intracellular membranes from being permanently destabilized by the loss of water. The way it does so remains debated.

As emphasized already, animal life originated and spent much of its early evolutionary history in water. The earliest animals that ventured to spend time on land, to consume terrestrial organisms as food, and ultimately, to develop on land were able to escape competitors and predators in their primordial aquatic habitat. For this reason, positive selective pressure for terrestriality must have been great. However, early animal life was adapted to living in an abundance of water. Evaporative losses of water on land posed a physiological threat of enormous importance for all stages of the life cycle.

We will focus on *water* in our discussion of animals on land. Although terrestrial animals sometimes face problems of salt balance, water balance usually represents their most pressing challenge in the realm of water–salt physiology.

The distinction between *humidic* and *xeric* animals provides a useful organizing principle for the study of water relations in terrestrial animals. The **humidic animals** are those that, although they live on land, are restricted to humid, water-rich microenvironments. The **xeric animals** are those that are capable of living in dry, water-poor environments.¹⁵

The humidic animals include earthworms, slugs, centipedes, most amphibians, and most terrestrial crabs. Some live underground. Others live in leaf litter or under logs or rocks. The majority of frogs and toads stay in or near bodies of water, and when they venture away from water, they remain in protected microenvironments, such as the tall grass frequented by leopard frogs. Some humidic animals, such as most amphibians and all terrestrial crabs, still resemble their aquatic progenitors in that they require standing water to breed.

The major groups of xeric animals are the mammals, birds, reptiles other than birds, insects, and arachnids (e.g., spiders and ticks). Although xeric animals often seek protected, humid microenvironments, they are not stringently tied to such environments, as humidic animals are. The xeric animals can live successfully in the open air, and many of them—as they go about their daily lives—routinely expose themselves to the full drying power of the terrestrial environment. Some thrive in deserts and other equally dry environments, such as grain stores.

In many ways, the physiological difference between humidic and xeric animals is a distinction in how *rapidly* they get into trouble by loss of water in desiccating environments. The humidic animals dehydrate rapidly in dry environments. They therefore cannot remain long in such places, as xeric animals can.

A low integumentary permeability to water is a key to reducing evaporative water loss on land

Evaporation is one of the chief modes by which terrestrial animals lose water. In this section we begin our analysis of the physiological principles of living on land by discussing evaporation across the integument of the body. In the following section we will focus on respiratory evaporation. As discussed in Chapter 27 (see Equation 27.1), the rate of evaporation through an animal's integument depends on the *difference in water vapor pressure between the animal's body fluids and the air*, and it depends on the *permeability of the integument to water* (K in Equation 27.1).

A high integumentary permeability to water ranks as one of the most important specific characteristics that restrict humidic animals to their protective microhabitats. The skin of an earthworm, the skin of most amphibians, and most of the fleshy surfaces of a snail or slug, for example, have high permeabilities and provide little barrier to water loss: These animals often lose water *through their integuments* at rates that are 50–100% as great as rates of evaporation from *open dishes of water* of equivalent surface area! With such a high integumentary permeability, a humidic animal can restrict its integumentary rate of evaporation only by limiting the difference in water vapor pressure that exists across its integument. From the viewpoint of physics, this explains why humidic animals are tied to humid habitats, where the air has a high water vapor pressure.

The xeric animals have integuments with a low permeability to water. Indeed, the evolution of a low integumentary permeability to water is one of the most important steps toward a xeric existence. In all the major xeric groups—vertebrate and invertebrate—*microscopically thin layers of lipids* are responsible for low integumentary water permeability. In mammals, birds, and nonavian reptiles, the lipid layers are structurally heterogeneous, lamellar complexes of lipids and keratin, less than 10 μm thick, located in the stratum corneum, the outermost layer of the epidermis of the skin. The principal lipids present are ceramides, cholesterol, and free fatty acids. Mammals, birds, and nonavian reptiles differ in histological details of the lipid layers, and they evidently evolved their lipid layers independently. In insects and arachnids, the lipids responsible for low integumentary permeability—such as long-chain hydrocarbons and wax esters—are contained in the outermost layer of the exoskeleton (cuticle). This layer, termed the *epicuticle*, is only 1–2 μm thick.

Because virtually all the resistance to water loss across the integument of xeric animals resides in microscopically thin lipid layers, the physical toughness of the integument is not an index of resistance to water loss. A common misconception, for example, is that the scales of lizards and snakes block water loss; the real block is the lipid layer, a microscopic property of just the stratum corneum. Many millipedes and centipedes have sturdy exoskeletons that seem just as tough as those of insects yet are far more permeable to water than the exoskeletons of insects. Such millipedes and centipedes either lack the micrometer-thin epicuticular lipid layer or possess lipids of different types than insects. They are far more humidic than insects because of these microscopic differences.

Lipids reorganize and undergo phase alterations as their temperature changes, as evidenced by observing kitchen lipids such as butter. Researchers have long known that if the temperature of an insect (or arachnid) is gradually raised, water permeability increases just slightly up to a certain temperature—called the **transition temperature**—and then increases dramatically (Figure 28.15). The marked increase in permeability at the transition temperature is a consequence of lipid melting. Although the transition temperature is often so high that it would not be experienced by individuals in nature, this is not always the case. The cockroach *Periplaneta americana* (a common household pest), for example, experiences a marked increase in permeability starting at 25–30°C and thus might naturally encounter temperatures high enough to disrupt its protection against water loss. Temperature effects within the skin of vertebrates are far more complex because of changes in blood flow and other processes, but careful studies reveal that in at least

¹⁵The term *xeric* has a standardized meaning and is widely used. However, there is no standardized term to describe the animals restricted to moist habitats; although we use *humidic*, alternative terms are used in other books and articles. The term *mesic* is sometimes applied to animals intermediate between those that are xeric and those that are humidic.

FIGURE 28.15 The rate of evaporative water loss of insects often starts to increase abruptly at a transition temperature. The graph shows how the rate of evaporative water loss of dead African migratory locusts (*Locusta migratoria*) increases as temperature increases. The rate of water loss is expressed “per mm Hg,” referring to the difference (expressed in millimeters of mercury) between the actual water vapor pressure of the air during the measurements and the saturation vapor pressure at the various temperatures. Measured and expressed in this way, changes in the rate of evaporative water loss reflect changes in the water permeability of the integument. (After Loveridge 1968.)

some cases, a rise in epidermal tissue temperature decreases the effectiveness of the cutaneous lipid layer as a water barrier.

Within sets of related xeric animals, the chemical composition of the lipid layer can vary widely. Because of these lipid composition differences and also sometimes because of structural differences or differences in amounts of lipids, the lipid layer can be far more effective as a water barrier in some species than in others. **Table 28.6** shows, for example, that the resistance of skin to water loss—

TABLE 28.6 Resistance of the skin to evaporative water loss in vertebrates

Values are for a standardized area of skin. Where a range is listed, the values are averages for different species within the group of animals.

Group of animals	Resistance (s/cm) ^a
Ranid frogs and bufonid toads	0–3
Colubrid snakes (e.g., racers)	150–890
Viperid snakes (e.g., vipers)	790–1690
Iguanid lizards	110–1360
Birds	30–200
Human	380
House mouse	160

Source: Lillywhite 2006.

^aResistance is calculated as the inverse of conductance. Conductance is the rate of water loss across the skin—expressed as grams H₂O per cm² of skin per second—divided by the driving force, which in this case is the difference in water activity across the skin—expressed in water density units of grams H₂O per cm³ of air. For a units analysis, one divides g/cm²·s by g/cm³. Thus, the units of conductance are cm/s, and the units of resistance, the inverse, are s/cm.

FIGURE 28.16 Differentiation between populations of one species in lipid-mediated protection against evaporative water loss. The graph shows the rate of evaporative water loss at 25°C as a function of body weight in live grasshoppers of a single species (*Melanoplus sanguinipes*) from two geographically separate populations in northern and southern California. According to current evidence, these populations exhibit genetically controlled differences in the lipid composition of their epicuticular layer. These differences contribute to the greater resistance of the southern animals to water loss. In each population, the rate of water loss is an allometric function of body weight, so the relation plots as a straight line on log–log coordinates (see Appendix F). (After Gibbs 1998.)

measured in a standardized way—varies widely both within and between groups of xeric vertebrates. The lipid composition of the water barrier may even differ among populations of a single species and give rise to significant differences between populations in their physiology of water balance (**Figure 28.16**). At still another level of organization, cases are known—as in certain desert larks—in which the lipid composition of individuals changes as a consequence of acclimation to different environments.

Respiratory evaporative water loss depends on the function of the breathing organs and the rate of metabolism

Some groups of humidic animals have respiratory surfaces that are directly exposed to the air. Earthworms, some isopods, and some amphibians, for instance, breathe substantially or entirely across their general integuments. This arrangement is a disadvantage from the viewpoint of evaporative water loss because movement of air across exposed respiratory surfaces can greatly exceed that necessary for exchange of O₂ and CO₂, so water loss can be much greater than the minimum required for respiratory gas exchange.

Most terrestrial animals have evolved invaginated respiratory structures (see **Figure 1.18**). In the xeric groups, breathing is carried out exclusively by such invaginated structures, and the general integument is virtually impermeable to O₂ and CO₂. The enormous advantage of this arrangement is that access of air to the thin, moist respiratory membranes can be closely controlled and thus limited to the levels required for exchange of O₂ and CO₂. The mammals, birds, and other reptiles control access of air to their lungs by regulating their breathing movements. Insects close and open the spiracles of their tracheal system (see **Figure 23.29**).

WATER CONSERVATION BY COOLING OF EXHALANT AIR A physical law of great consequence for warm-bodied air breathers is that when air is saturated with water vapor, its content of water per unit of volume approximately *doubles* with every 11°C increase in temperature (see Table 27.2). When a mammal or bird inhales air into its lungs, the temperature of the air is raised to deep-body temperature, and the air becomes saturated with water vapor at the elevated temperature. Depending on conditions, a substantial amount of water may be added to the air. For example, consider a mammal that inhales *saturated* air at 20°C. Such air (see Table 27.2) has a water vapor pressure of 2.3 kPa (17.5 mm Hg) and contains about 17 mg H₂O/L. By the time the air reaches the lungs, it is saturated at 37°C; it therefore has a water vapor pressure of 6.3 kPa (47.1 mm Hg) and contains 44 mg H₂O/L. Thus, even though the air is saturated to begin with, it contains 27 mg/L more water once it is in the lungs, all of this added water being drawn from the animal's body. If the air were then exhaled without modification, it would carry all the added water away into the environment.

Air from the lungs usually is saturated when it is exhaled. However, in many mammals and birds, when air is exhaled by way of the nasal passages, the *temperature* of the air is reduced before the air leaves the nostrils, thus lowering its water vapor pressure at saturation and reducing the amount of water it carries away.¹⁶ Suppose the mammal we have been discussing were to reduce the temperature of air from its lungs to 25°C before exhaling the air. On leaving the body, the air would then have a water vapor pressure of 3.2 kPa (23.8 mm Hg) and contain 23 mg H₂O/L (see Table 27.2). The air would still carry away some body water (it entered the body with 17 mg H₂O/L). However, the reduction in the temperature of the exhalant air would cause 78% of the water added during inhalation to be recovered before exhalation.

In those mammals and birds that reduce the temperature of air before it is exhaled, the air is cooled by a countercurrent mechanism in the nasal passages. To understand the process, let's first look in more detail at what happens during inhalation, using our example of a mammal breathing 20°C air. As inhaled ambient air travels up the nasal passages, it is progressively warmed to about 37°C, and it takes up water vapor as its temperature is elevated. The heat that warms the air and the latent heat of vaporization for the added water vapor are drawn from the walls of the nasal passages.¹⁷ Thus the walls of the nasal passages are cooled by the process of inhalation. The outer ends of the nasal passages are typically cooled most, and the inner ends least. During the ensuing exhalation, air coming up from the lungs arrives at the interior ends of the nasal passages at a temperature of 37°C and saturated. However, as the air moves down through the nasal passages toward the nostrils, it encounters the increasingly cooler surfaces created by the previous inhalation. Thus the air being exhaled is cooled as it travels toward the nostrils. This cooling lowers the saturation water vapor pressure of the air (see Table 27.2), causing water to condense out of the air onto the nasal-passage walls. The overall process is considered a *countercurrent* process because it depends on flow of air in opposite directions.

¹⁶Cooling of nasal exhalant air also takes place in some lizards when they are maintaining high, behaviorally regulated body temperatures.

¹⁷The nasal passages are not simple tubes. Their walls are often thrown into elaborate surface-enhancing structures (*turbinates*) over which air flows, as can be seen in the insets in Figure 10.37.

FIGURE 28.17 The temperature of air exhaled from the nostrils as a function of ambient air temperature in mammals and birds. The black dots are individual data points gathered on animals representing 18 species of small mammals, including shrews, bats, mice, squirrels, and rabbits. The solid lines are average results for mongrel domestic dogs (blue) and cactus wrens (*Campylorhynchus brunneicapillus*) (red). The dashed line is a line of equality between the temperature of exhaled air and the ambient air temperature (an isothermal line). (From Hill and Wyse 1989.)

If the cooling of nasal exhalant air seems unfamiliar, it may be because only a small degree of cooling occurs in humans. In contrast, the cooling of nasal exhalant air in small mammals is dramatic, as illustrated by the data plotted as black dots in Figure 28.17; a small mammal that inhales air at 20°C and warms it to 37°C in its lungs might well exhale the air at 22–23°C.

A USEFUL MODEL OF RESPIRATORY EVAPORATIVE WATER LOSS

An insight-promoting way to think about the rate of respiratory evaporative water loss is to recognize that it depends on (1) an animal's rate of O₂ consumption and (2) the amount of water lost per unit of O₂ the animal consumes:

$$\begin{aligned} \text{Rate of water loss} &= \text{rate of O}_2 \text{ consumption} \\ (\text{mg H}_2\text{O}/\text{hour}) & \quad (\text{mL O}_2/\text{hour}) \\ & \times \text{water loss per unit of O}_2 \text{ consumed} \\ & \quad (\text{mg H}_2\text{O}/\text{mL O}_2) \end{aligned} \quad (28.1)$$

The principal insight to gain from this equation is that an animal's rate of metabolism is a major determinant of its rate of evaporative water loss. Mammals and birds, as we stressed in Chapters 7 and 10 (see Figure 7.9), typically have rates of O₂ consumption that are far higher than those of lizards, snakes, or other nonavian reptiles of similar body size. Mammals and birds therefore tend to have high rates of respiratory evaporative water loss by comparison with reptiles.¹⁸

The amount of water lost per unit of O₂ consumed is affected by several factors. One is the temperature of the exhaled air we just

¹⁸A compensation is that animals with relatively high rates of O₂ consumption also have relatively high rates of metabolic water production (e.g., see Figure 28.18).

FIGURE 28.18 Within a phylogenetic group, the total rate of evaporative water loss is an allometric function of body size. This trend is illustrated here (black line and black dots) using data for birds resting at 23–25°C in relatively dry air. Evaporative water loss is expressed in weight-specific units (the expression *percentage of body weight per day* is equivalent to *mg H₂O lost per 100 mg of body weight per day*). The black line is fitted statistically to the individual data points (black dots). The red area delimits the gross rates at which birds of various body sizes are expected to produce metabolic water (expressed as percentage of body weight per day). (From Hill and Wyse 1989.)

discussed (lower exhalant temperatures mean lower water loss). Another is the efficiency of the breathing organs in removing O₂ from inhaled air.

An animal's total rate of evaporative water loss depends on its body size and phylogenetic group

If we sum an animal's rates of integumentary and respiratory water loss, we get the animal's *total rate of evaporative water loss* (EWL). Within sets of phylogenetically related species, the broad statistical trend is for the total rate of EWL measured under particular conditions to vary allometrically with body size. This important pattern is illustrated in **Figure 28.18** using birds as examples. Small-bodied species tend to have higher weight-specific rates of EWL than related large-bodied species.

There are two reasons why small-bodied species tend to have relatively high weight-specific rates of EWL. First, small animals tend to have a greater body surface area per unit of weight than related large animals (see Equation 7.6); therefore they tend to have relatively high weight-specific rates of *integumentary* water loss. Second, small animals tend to have a higher metabolic rate per unit of body weight than related large animals (see Figure 7.9); therefore they tend to have relatively high weight-specific rates of *respiratory* water loss (see Equation 28.1).

There are also consistent differences among phylogenetic groups in their total rates of EWL, as we have stressed. Animals in humidic phylogenetic groups, such as amphibians, have highly permeable integuments and other properties that give them high total rates of EWL in comparison with similar-sized animals in xeric groups. Some of these differences in total rates of EWL are brought to light in **Figure 28.19**. All the vertebrates in the figure are about the same in body size; therefore, comparing them brings out differences among the phylogenetic groups. Lizards (and other nonavian reptiles) have very low total rates of EWL compared with amphibians because the lizards have low-permeability integuments (see Table 28.6) and enclosed breathing systems. Mammals and birds share these basic properties of lizards, but they have higher total rates of EWL than

lizards (and other nonavian reptiles). Why? Because their skin tends to be less effective in restricting water loss (see Table 28.6) and, especially, because they have far higher metabolic rates than lizards.

The two species of semiterrestrial crabs in Figure 28.19 are similar in size to the vertebrates; semiterrestrial crabs, as can be seen, are similar to amphibians in their rates of EWL and are humidic. The isopods and insects in the figure are tiny compared with the other animals shown. The isopods combine the disadvantages of small size and poor defenses against EWL. Their total weight-specific rates of EWL are staggering. One can only marvel at the insects, especially the tsetse flies (weighing 0.03 g), which have such excellent defenses against water loss that they have relatively low total rates of EWL per unit of weight, despite being very small.

Within any particular phylogenetic group, researchers often find that species that have evolved in dry habitats exhibit greater defenses against evaporative water loss than related species that have evolved in moist habitats. In a classic study, for example, investigators compared two iguanid lizards of similar body size under identical conditions: the common green iguana (*Iguana iguana*)—which lives in forests and associates with water—and the chuckwalla lizard (*Sauromalus obesus*)—a desert inhabitant. They found that the total rate of EWL was more than 2.5 times greater in the iguana.

Excretory water loss depends on the concentrating ability of the excretory organs and the amount of solute that needs to be excreted

In addition to evaporative water loss, excretion in urine is a second major way that terrestrial animals lose water. Like aquatic animals, terrestrial ones modulate the concentration, composition, and volume of their urine to serve changing requirements for osmotic, ionic, and volume regulation. We humans, for example, when dehydrated, produce a limited volume of urine that is hyperosmotic to our blood (our osmotic U/P ratio can reach 4), but after we have consumed large amounts of water, we void a copious urine that is hyposmotic to our blood (our osmotic U/P ratio can be as low as 0.1–0.2). While recognizing the fundamental *regulatory* role of urine excretion, a key question in the study of water balance in terrestrial animals is how effectively the animals can *minimize* their urinary

FIGURE 28.19 The total rate of evaporative water loss varies greatly among different types of vertebrates and arthropods. All the animals shown were studied in dry or relatively dry air at 25–32°C. The vertebrates (red) are all similar in body size (16–39 g). Body weights are given for the individual arthropod species (blue). Evaporative water loss is expressed in weight-specific units (the expression *percentage of body weight per hour* is equivalent to *mg H₂O lost per*

100 mg of body weight per hour). Species, listed from top to bottom: semiterrestrial crabs, *Ocypode quadrata* and *Uca annulipes*; isopods, *Ligia oceanica* and *Armadillidium vulgare*; insects, *Locusta migratoria* and *Glossina morsitans*; amphibians, *Rana temporaria* and *Scaphiopus couchii*; lizards, *Dipsosaurus dorsalis* and *Uma notata*; mammals, *Dipodomys merriami* and *Mus domesticus*; birds, *Carpodacus mexicanus* and *Pipilo fuscus*. (After Hill and Wyse 1989.)

water losses. There are two basic ways to reduce the amount of water lost in urine. One is to concentrate the urine, thereby decreasing the amount of water required to excrete a given amount of solute. The second is to reduce the amount of solute excreted in the urine.

URINARY CONCENTRATING ABILITY Most of the humidic terrestrial animals, such as earthworms and amphibians, are unable to raise the osmotic pressure of their urine above that of their blood plasma. Lizards, snakes, and turtles, although xeric, are also generally incapable of making urine that is hyperosmotic to their blood plasma. By contrast, three of the major xeric groups—insects, mammals, and birds—have evolved the ability to make hyperosmotic urine: urine more concentrated than the blood plasma. This unusual capability evolved independently in the three groups—a fact that emphasizes the selective advantages of being able to make concentrated urine in animals confronted with desiccation stress. Let's look at the three in more detail.

In terrestrial insects, maximum osmotic U/P ratios of 2–4 have been observed in certain blowflies, desert locusts, and stick insects. Mealworms (*Tenebrio*), which live in dry grain stores, can produce urine with a U/P of 8.

In mammals, an enormous range of urinary concentrating abilities is found. The U/P ratios achieved by many species are well above those seen in any other animals. To illustrate both of these points, the maximum reported osmotic U/P ratio is about 3 for muskrats, 4 for humans, 8 for dromedary camels, 9 for laboratory rats, 14 for Merriam's kangaroo rats and Mongolian gerbils (*Meriones*), and—at the highest extreme—about 26 for certain species of Australian desert hopping mice (e.g., *Notomys alexis*)! A significant and unexpected feature of mammalian kidney function

is that the maximum concentrating ability tends to decrease with increasing body size. In **Figure 28.20**, which shows this relation, note that there is a lot of scatter at any given body size. Much of this scatter correlates with habitat; the highest values at a given body size tend to represent species that confront relatively severe threats of desiccation or high dietary salt loads.

In birds, the most evident point to stress is that, as a group, birds are far inferior to mammals in their abilities to concentrate their urine. Although osmotic U/P ratios approaching 6 have been claimed in a few species of birds, the maximum U/P ratio ranges from 1.5 to 2.5 in most species, including many that live in arid regions.

Some terrestrial lizards and birds (e.g., ostriches and roadrunners) have cranial salt glands, which assist with secreting Na⁺, K⁺, and Cl⁻. The secretions of the salt glands have higher ion concentrations than the urine in these animals. Thus the salt glands play an important role in decreasing the water expended to void excess ions.

REDUCING THE AMOUNT OF DISSOLVED MATTER EXCRETED IN THE URINE Waste nitrogen from the catabolism of proteins is usually excreted in the urine by terrestrial animals.¹⁹ One way to reduce the water demands of excretion is to incorporate the waste nitrogen into chemical compounds that are virtually insoluble—or poorly soluble—in water, thereby reducing the amount of material voided in solution. It is a testimony to the advantages of this type of nitrogen excretion that it has evolved independently many times: Insects, arachnids, some terrestrial snails, a few xeric frogs, birds, and other reptiles all produce poorly soluble nitrogenous wastes. The principal poorly soluble compounds employed are uric acid,

¹⁹See Chapter 29 (page 782) for a more thorough discussion of nitrogen excretion.

FIGURE 28.20 Urine concentrating ability in mammals: The maximum concentration is in part a function of body size. Data for 146 species of mammals are included. The species chosen for labeling were deliberately selected to represent extremes. Because the overall relation is allometric, it plots as a straight line on log–log coordinates (see Appendix F). Because all mammals have approximately the same plasma osmotic pressure, a plot of the maximum osmotic U/P ratio as a function of body size would resemble this plot. (After Beuchat 1990.)

urate salts, allantoin, and guanine. Urate salts such as sodium and potassium urate—excreted by birds, other reptiles, and some additional groups—have the advantage that they carry away not only nitrogen but also inorganic cations in precipitated form.

By no means do all terrestrial animals exclude waste nitrogen from being excreted in solution, however. Many of the humidic animals—including earthworms, isopods (e.g., pillbugs), some terrestrial molluscs, and most amphibians—excrete nitrogen principally as urea or ammonia, both of which are highly soluble. Mammals, paradoxically, also do; they produce mostly urea (see Boxes 28.4 and 29.4).

If highly soluble nitrogenous wastes are voided in the urine, they demand water for their excretion. However, some of the animal groups that produce highly soluble wastes have evolved means of reducing the water demands. Mammals, for example, possess world-record abilities to concentrate urea in their urine (see Box 29.4). Some isopods, snails, and land crabs void ammonia as a gas.

Terrestrial animals sometimes enter dormancy or tolerate wide departures from homeostasis to cope with water stress

Many terrestrial animals, both humidic and xeric, enter dormancy—often called estivation—in response to immediate or predictable water stress. Mammals and birds that enter water-related dormancy—including desert ground squirrels and poorwills—often undergo metabolic depression and become hypothermic (see page 265). Metabolism is depressed during dormancy in poikilotherms as well.²⁰ Metabolic depression has several advantages. First, an animal in metabolic depression can live on body fat or other stored

foods for a long time, and thus it can remain continuously in a protective microenvironment. Second, the animal's requirement for O_2 is reduced, thereby reducing its respiratory evaporation. Finally, nitrogenous and other wastes are produced at a low rate, which may be vital in permitting protracted existence with little or no urine output.

In addition to dormancy, another “change of status” that animals—particularly poikilotherms—commonly undergo during water stress is to permit large changes to occur in their body-fluid volume or composition while they continue to be active. Species that live in places where they are prone to dehydration are often especially tolerant to such changes. Tortoises in the Mohave Desert, for example, sometimes drop in body weight by 40%—and beetles in East African savannas sometimes lose 80% of their body water—because of dehydration during droughts or dry seasons. When Claude Bernard spoke of the *internal environment* in his groundbreaking studies that led to the concept of homeostasis, he was referring to the body fluids (see page 12). The ability to remain active and functional despite profound alteration of the body fluids has been termed **anhomeostasis** and can be a key to existence during water stress.

The total rates of water turnover of free-living terrestrial animals follow allometric patterns

A logical way to conclude our introductory discussion of animals on land is to focus on the total rates of *water turnover* (water lost and gained per day) of terrestrial animals when they are living freely in their natural habitats. The rate of water turnover is typically measured by use of isotopically labeled water (e.g., heavy water). An animal living in the wild is trapped, injected with a known amount of labeled water, and turned loose. Days later, it is recaptured, and from the amount of labeled water remaining in its body, its rate of water turnover while free can be calculated. For an animal in water balance, water lost by evaporation, urination, and other processes each day is replaced by gains of water. The rate of water turnover measures the rates of these mutually balancing processes. A high rate of water turnover means that an animal loses and replaces a lot of water per day. Life can be precarious for such an animal because if an imbalance develops, it can lead rapidly to a crisis.

Figure 28.21 shows the general water-turnover patterns of vertebrates living in the wild. Note that mammals and birds of any given body size turn over much more water per day than lizards, snakes, or other nonavian reptiles of the same size. *Within* any one phylogenetic group, as might be guessed from what we have said before in this chapter, the total rate of water turnover, T , tends to be an allometric function²¹ of body weight (W):

$$T = aW^b \quad (28.2)$$

The exponent b is typically 0.6–0.8. This means that if we consider the relation between the *weight-specific* rate of water turnover (T/W) and weight, the exponent ($b - 1$) is negative: -0.2 to -0.4 . Therefore, as seen in Figure 28.21, the rate of water turnover *per gram of body weight* decreases as animals get bigger: Big species within a particular phylogenetic group tend to turn over a *smaller fraction* (lower percentage) of their total water per day than little ones.

²⁰ Suspension of metabolism during anhydrobiosis is discussed in Box 28.5.

²¹ See Appendix F for a discussion of allometric functions.

FIGURE 28.21 Terrestrial vertebrates living freely in their natural habitats: their total daily rates of water turnover in relation to body size The water turnover is the amount of water lost and gained per day when animals are in water balance. It is plotted here in weight-specific terms (mL/g). The weight-specific version of Equation 28.2 is $T/W = aW^{(b-1)}$. Each line is a plot of this equation. Because the relation for each group is allometric, it plots as a straight line on log–log coordinates. (After Nagy and Peterson 1988.)

SUMMARY Animals on Land: Fundamental Physiological Principles

- Humid terrestrial animals are restricted to humid, water-rich microenvironments. Xeric terrestrial animals are those that are capable of a fully exposed existence in the open air.
- A low integumentary permeability to water—which reduces integumentary evaporative water loss—is required for animals to be xeric. All the major xeric groups—insects, arachnids, birds, nonavian reptiles, and mammals—have low permeabilities because of integumentary lipids.
- Respiratory evaporative water loss depends directly on (1) an animal's rate of O_2 consumption (its metabolic rate) and (2) the amount of H_2O lost per unit of O_2 consumed. One way to reduce the latter in mammals and birds is countercurrent cooling of nasal exhalant air.
- The animals with the lowest total rates of evaporative water loss (EWL) are those, like lizards, that combine the advantages of low integumentary permeability to water, tightly controlled access of air to breathing organs, and low metabolic rates.
- Water loss in urine can be reduced by producing concentrated urine (which reduces the amount of water needed to void soluble wastes) or by producing poorly soluble nitrogenous end products such as uric acid (which remove waste nitrogen from solution). Only three groups of animals can make urine hyperosmotic to their blood plasma: insects, birds, and mammals.
- Within groups of related species, water dynamism tends to vary allometrically with body size. Weight-specific EWL and weight-specific total water turnover tend to decrease as size increases.

Animals on Land: Case Studies

Now let's look at the water relations of some particular groups of animals on land. Doing so will provide an opportunity to integrate the points made in the previous section and discuss some new features of interest and importance. Chapter 30 continues this discussion of case studies with a focus on large-bodied mammals in deserts and dry savannas, such as camels and oryxes.

Amphibians occupy diverse habitats despite their meager physiological abilities to limit water losses

The terrestrial amphibians provide an instructive case study because they have invaded an impressive variety of habitats, from the shores of ponds to, quite literally, deserts. Yet despite this diversity of habitats, most species are humidic animals that, regardless of where they live, are remarkably similar to one another in their physiological water-balance characteristics. Their diversification into a wide range of habitats has depended to a substantial extent on the evolution of *protective behaviors* and *advantageous patterns of seasonality*.

Most species of amphibians, including most that live in deserts, share several attributes that significantly limit their physiological capacity to restrain water losses. First and foremost, they have an integument that poses little barrier to evaporative water loss. Second, they incorporate waste nitrogen mostly into urea, a highly soluble compound requiring considerable amounts of water for its excretion. Moreover, although amphibians are notably adept at simply shutting off urine outflow when faced with dehydration, they are unable, when they do excrete urine, to produce a urine any more concentrated in total solutes than their blood plasma.

Amphibians have the same basic sources of water as most other animals: preformed water in food, preformed water taken in as “drink,” and metabolic water. For the most part, adult amphibians are carnivores. Their food is therefore succulent, but it yields a lot of urea, which they cannot excrete in concentrated form. Significantly, if an amphibian is eating insects, the total amount of water it gets from its food (preformed and metabolic) is likely to be no more than about 15% of the amount it needs just to excrete the urea it produces from its food. This calculation emphasizes the overwhelming importance of “drink” as a water source for the majority of amphibians.

Most amphibians do not in fact drink, but instead absorb water across their skin. This absorption does not necessarily require immersion in water. Many species can gain water at substantial rates merely by pressing their ventral skin against moist soil, moss, or other substrates.²² A region of the ventral skin at the posterior of the abdomen and extending onto the thighs—called the *pelvic patch* or *seat patch*—is often specialized for rapid water uptake. Its water permeability is modulated by insertion and retrieval of aquaporins in the cell membranes;²³ when aquaporins are inserted, the water permeability of the patch cells is increased. A medium-sized and well-hydrated leopard frog (*Rana pipiens*) sitting on wet soil in its native habitat might well absorb 6–10 g of water *per hour* from the soil across its ventral surfaces, while it simultaneously loses a like amount into

²² Amphibians are far from being the only animals that take up water from moist substrates. The phenomenon has been documented in certain isopods, millipedes, insects, spiders, scorpions, land crabs, and snails.

²³ Such aquaporins are regulated acutely in a cell by trafficking between intracellular locations where they are nonfunctional and the cell membrane where they enhance the permeability of the cell to transcellular osmosis.

the air by evaporation across its dorsal surfaces—a dramatic display of dynamism!

When they are away from sources of water, most terrestrial amphibians are able to ward off dehydration for a time by using their bladder as a canteen. If an animal starts to dehydrate, the cells in the walls of its bladder are rendered permeable to water by aquaporin insertion in the cell membranes. NaCl is actively transported out of the bladder, thereby removing solute from the bladder contents and promoting osmotic outflux of water. The capacity of the bladder to hold fluid in terrestrial frogs and toads is remarkable: The water contained in the filled bladder is equal to 20–50% of an animal's bladder-empty weight. By contrast, in strictly aquatic amphibians, the bladder is usually tiny.

HORMONAL CONTROL OF RESPONSES TO DEHYDRATION In terrestrial amphibians, the neurohypophysial hormone arginine vasotocin (see Table 16.2), called *antidiuretic hormone (ADH)*, activates a suite of coordinated responses that collectively retard or reverse the process of dehydration. Release of ADH is stimulated if the volume of the body fluids (e.g., blood plasma) is decreased or if their osmotic pressure is increased. An amphibian's overall reaction to ADH has appropriately been called the amphibian *water-balance response*. In its complete form (not shown by all species), this response involves changes at three sites in the body: the kidneys, bladder, and skin. First, ADH causes the kidneys to reduce their rate of urine production and elevate the urine concentration toward isosmoticity with the blood by mechanisms discussed in Chapter 29 (see Figure 29.5). Second, ADH stimulates the bladder cells to increase their rate of NaCl reabsorption and their permeability to water by aquaporin insertion in the cell membranes, responses that augment return of water from the bladder contents to the blood. Finally, ADH causes the ventral skin through which water absorption occurs to increase its capacity for water influx—facilitating rehydration—by stimulating increased blood flow and aquaporin insertion in the cell membranes.

ADH is by no means the only hormone active in water–salt physiology. For example, *hydrins* synergize with ADH in some contexts. *Angiotensin II* (see page 441) has been shown to be a principal controller of “cutaneous drinking” in frogs, stimulating the animals to press their ventral skin against moist substrates.

HOW DO DEHYDRATION-PRONE AMPHIBIANS LIVE IN DESERTS?

As already mentioned, some species of frogs and toads, such as *Bufo cognatus* and the spadefoot *Scaphiopus couchii* in North America, have skin that provides no more protection against evaporative water loss than that of semiaquatic frogs such as leopard frogs (see Figure 28.19) yet live successfully in deserts or other arid habitats. Such desert species are in fact remarkably similar to the majority of terrestrial amphibians in all physiological respects, although some species show modest quantitative improvements over amphibians that live in moist habitats, such as by having a larger bladder, a somewhat greater tolerance of dehydration, or an accelerated pace of rehydration.

Behavior and seasonal dormancy are critical keys to the success of these desert amphibians. Dehydration can kill them *in an hour—or just a few hours*—if they are exposed in the desert. Stringent behavioral control of water loss is therefore a requirement of life. These desert amphibians spend much of their time in protective microhabitats, especially in burrows underground, and are largely

nocturnal. They also employ seasonal dormancy to simply “retire from the scene” and protect their water status during dry seasons. Spadefoot toads (*S. couchii*), for example, spend many months of each year in dormancy. Overall, these desert amphibians are reclusive animals, holed up in secluded places during much of their lives. For some, dormancy dominates their lives more than activity. Nonetheless, they are able to survive in deserts despite the high permeability of their skin and other vulnerabilities.

“RADICAL” PHYSIOLOGICAL SPECIALIZATIONS OCCUR IN SOME ARBOREAL, ARID-ZONE FROGS

For an amphibian to exist in arid places without being restricted to a secluded life, it must have evolved superior physiological mechanisms to cope with the challenges of dehydration stress. Biologists are gradually learning more about such mechanisms in several types of unusual arboreal frogs that live exposed lives in arid or semiarid habitats. Frogs of this sort in two genera—*Phyllomedusa* of South and Central America and *Chiromantis* of Africa—have been studied for several decades and are known to have physiological abilities to conserve water that are extraordinarily different from those of most amphibians. One distinctive trait of these frogs is that their integumentary permeability to water is exceptionally low; their rates of evaporative water loss are consequently little different from those of some lizards of similar size.²⁴ Cutaneous lipids are responsible for this low skin permeability in both genera. The lipids are spread on the outside of the skin rather than being incorporated within the skin tissue. *Phyllomedusa*, for example, secretes lipids (mainly waxy esters) from skin glands and spreads them on its skin surface (Figure 28.22). A second highly distinctive trait of these genera is that

²⁴ Expressed in the same units as used in Table 28.6, the resistance to evaporative water loss of the skin in species of *Phyllomedusa* and *Chiromantis* is generally 200–400 s/cm.

FIGURE 28.22 Arboreal frogs of the genus *Phyllomedusa* spread protective lipids secreted by integumentary glands over their skin surface. The lipids sharply reduce the rate of evaporative water loss across the frogs' skin. The spreading is carried out by a series of stereotyped limb movements, as shown. (After Blaylock et al. 1976.)

they excrete much of their nitrogenous waste as poorly soluble uric acid or urates (80% in *P. sauvagei*, for example).

The tiny, dramatically colorful reed frogs (*Hyperolius*) of the African savannas represent another remarkable group of arboreal frogs—a group that is only now starting to be well understood. Some species have exceptionally low skin permeabilities. They do not, however, routinely produce uric acid or other related compounds as do the frogs just discussed. During the dry season, reed frogs remain in exposed locations on the branches of bushes and trees even as they undergo profound dehydration. They stop producing urine at such times, and much of their waste nitrogen accumulates in their body fluids as urea. However, as they dehydrate, they start to synthesize guanine from the waste nitrogen retained in their bodies; in *H. viridiflavus*, 25% of waste nitrogen becomes guanine. Guanine is a low-solubility purine like uric acid (see Figure 29.24). Remarkably, the frogs deposit much of the guanine they synthesize in skin cells (iridophores), and the little animals turn bright white from its presence. The formation of guanine lengthens the time the frogs can store waste nitrogen (because it keeps the nitrogen out of solution), and it reduces solar heating by increasing the reflectance of the skin to incoming radiation!

Xeric invertebrates: Because of exquisite water conservation, some insects and arachnids have only small water needs

Certain insects are among the most successful of all animals in severe desert conditions. Being successful, they provide succulent food for other, less-adept desert dwellers.

Certainly one of the most intriguing phenomena in the living world is presented by desert ants that feed on other desert insects killed by heat. Life for diurnal insects in severe deserts is so tenuous that, every day, some individuals accidentally die of overheating despite extraordinary adaptations for desert existence. Desert ants of several species scavenge the bodies of such heat-killed insects. The deaths often occur in the heat of the day. Thus, to get moisture from their prey, the ants must venture forth from benign underground burrows in the heat of the day to gather the dead bodies before the sun quickly bakes the bodies dry. Species of such ants in deserts around the world have independently evolved unusually long legs (Figure 28.23). This is believed to be related to the fact that air temperature declines extremely steeply with altitude above the sun-heated sand. The stiltlike legs—although they elevate an ant's body just millimeters higher than it would otherwise be—can reduce the air temperature to which the body is exposed by 10°C. The ants also exploit the steep temperature gradient at times by taking breaks from desert foraging to climb up on pebbles or other high points in the desert terrain to reach even lower air temperatures than their stiltlike legs permit. These ants can tolerate tissue temperatures of 52–55°C (126–131°F). They thus rank with the most heat-tolerant of all animals. Nonetheless, they heat up promptly under intense sun and can easily suffer heat death themselves if they fail to act quickly as they exit their burrows, seek out recently heat-killed prey, and return to underground safety. Accurate *navigation* is crucial: After ants have traveled hundreds of meters to find prey in featureless deserts, they must find their burrows again. Ants of the genus *Cataglyphis* in the Sahara Desert have been shown to have evolved one of the most remarkable of animal navigation systems despite having a brain that weighs 1/10 of a milligram (see Figure 18.3).

FIGURE 28.23 Diurnal desert ants that collect heat-killed insects are noted for long, stiltlike legs that keep them above the intensely hot sand surface. Shown is *Cataglyphis diehli*. (Photograph by Rüdiger Wehner.)

Deserts are just the driest of the habitats in which insects and arachnids (e.g., spiders and scorpions) live. Some species prosper in a variety of other arid places. The suite of characteristics that permits many species to prosper in semiarid and arid habitats includes several physiological attributes that promote highly effective water conservation: high integumentary resistance to water loss (provided chiefly by epicuticular lipids); stringent limitation of respiratory water loss by control of the opening of the spiracles; excretion of waste nitrogen in poorly soluble forms; and an ability (at least in many insects) to produce concentrated urine (maximum osmotic U/P = 2–8).

Some flightless insects, ticks, and mites, in addition, have a way to obtain water that is *unique* in the animal kingdom: They are able to gain water from the gaseous water vapor in the air in a *steady* manner while they are at the same temperature as the air. For example, the desert cockroach *Arenivaga investigata* can gain water from the air steadily even when the ambient relative humidity is as low as 79–83%. The mealworms (*Tenebrio*) that people often use as food for pets can gain water down to 88% relative humidity, and firebrats (*Thermobia*) can do so down to 45%. A water gain of about 10% of body weight per day is the rule when these insects are dehydrated and living in humid air. The mechanism of water uptake in many cases remains subject to debate. The site of uptake in the desert cockroach and some ticks is the mouth. Mealworms and firebrats, by contrast, absorb water via the rectum. Some investigators believe that true, primary active transport of H₂O sometimes occurs in these arthropods, although most disagree. A mechanism that is known to operate in some species is the production—at the mouth or rectum—of *localized*, superficial pockets of body fluids with such high solute concentrations that they have water vapor pressures below ambient water vapor pressure;²⁵ water vapor diffuses from the atmosphere into such body fluids, following the vapor pressure gradient.

Few water budgets have been worked out for insects or arachnids, but it is clear that certain species are so effective in limiting water losses that they can maintain water balance at moderate temperatures and low humidities while having *no drinking water* and *eating only air-dried foods*. Common examples include grain beetles and clothes moths. Besides the small amounts of preformed water in air-dried foods, the only sources of water for such insects are metabolic water and whatever water they may gain from atmospheric water vapor.

²⁵Recall from Chapter 5 that the water vapor pressure of a solution is a colligative property and decreases as solute concentration increases.

BOX 28.6 THE STUDY OF PHYSIOLOGICAL EVOLUTION BY ARTIFICIAL SELECTION

One way to learn how the physiological features of organisms respond to evolutionary selective pressures is to expose animals to artificial (human-mediated) selection. For example, the evolutionary physiology of desiccation resistance can be studied by selecting—generation after generation—animals that are particularly resistant to desiccation and examining the traits of their descendants. In one extensive series of studies of fruit flies (*Drosophila melanogaster*), flies in successive generations of desiccation-selected populations—here termed SEL populations—were subjected to a desiccation treatment to select the parents of the next generation. Specifically, some of the flies in each generation were exposed to dry air, shortly after their emergence as adults, until 80% died; only the 20% that survived were bred to create the next generation. At each generation, flies in the SEL populations that were not subjected to desiccation treatment were used to test the populations' characteristics. The flies of control populations—CONT populations—never experienced desiccation stress.

Flies taken from the SEL and CONT populations were subjected to short-term tests of their desiccation tolerance at each

generation. In these tests, the flies in SEL populations lived longer during exposure to desiccation than those in CONT populations. **Part 1** of the figure shows the average number of hours that SEL flies lived longer as a function of the number of generations of selection. The SEL flies survived more than 30 h longer after 37 generations. Two physiological mechanisms have been identified that explain the greater capacity of SEL flies to survive desiccation. First, because of evolution driven by artificial selection, flies in SEL populations have more body water than CONT flies (**Part 2** of the figure). Second, the flies in SEL populations exhibit greater resistance to water loss.

Differences between flies in desiccation-selected (SEL) populations and control (CONT) populations in relation to the number of generations of selection

Flies used to test the population characteristics shown were chosen at random from the two types of populations. Five separate populations of each type were studied at each generation of selection. Error bars show standard errors. (After Archer et al. 2007.)

(1) Additional number of hours that flies in SEL populations survive a desiccation test, relative to CONT flies

(2) Additional water content (mg H₂O/fly) of flies in SEL populations, relative to CONT flies

Because of their short generation times, insects are among the most useful animals for studies of physiological evolution using laboratory populations. Experiments using insects demonstrate that the resistance of animals to water stress can respond dramatically to evolutionary selective pressures (**Box 28.6**).

Xeric vertebrates: Studies of lizards and small mammals help clarify the complexities of desert existence

When one treks to the driest deserts, one sees only a few sorts of animals leading active lives. Lizards and small mammals²⁶ are two groups that especially stand out, in addition to insects and arachnids. A fact that draws interest to both the lizards and small mammals is that they often have no chance of finding drinking water for months on end. Because they cannot travel far, they have drinking water only when local rains provide it, and rains come only sporadically. Desert lizards characteristically eat insects or living plant tissues, foods that supply significant amounts of preformed water. Many species of small mammals in deserts also acquire substantial quantities of preformed water in their food because they eat primarily insects or plants; in North America, these animals include pack rats, grasshopper mice, and ground squirrels. In all the major deserts of the world, however, there have evolved extraordi-

nary species of small mammals that live away from drinking water and eat principally air-dried seeds or other air-dried plant matter. The kangaroo rats (*Dipodomys*) of North America's southwestern deserts (see the opening photo of Chapter 29) provide classic examples. Others include the kangaroo mice and pocket mice of North America, some gerbils and jerboas of Old World deserts, and the hopping mice of Australian deserts.

A significant, intriguing trait of the lizards that prosper away from drinking water is that, like other lizards, they are diurnal. The key traits that permit the existence of lizards as diurnal animals in the driest places on Earth include, first, their relatively low metabolic rates (see Figure 7.9). A low metabolic rate not only can greatly reduce water losses, it also reduces food needs—an asset in habitats where populations of food organisms are themselves stressed and relatively unproductive. Second, the desert lizards excrete their nitrogenous wastes as water-sparing uric acid or urates. They also use behavior to avoid stresses that are avoidable, as by moving into underground burrows or shadows during the heat of the day. Some species employ salt glands. Finally, desert lizards tend to be remarkably tolerant of large shifts in their body-fluid composition, such as high blood solute concentrations during dehydration. They can survive perturbations of their body fluids—often for long periods—that would kill a mammal or bird.

The small mammals of deserts operate on a different, higher scale of metabolic intensity than the lizards. High metabolic intensity is in itself a liability in deserts; it raises the rate of respira-

²⁶ See Chapter 30 for a discussion of camels, oryxes, and other large mammals in deserts and dry savannas.

tory evaporative water loss, as we have seen, and it can contribute enough endogenously produced heat to add significantly to heat stress. Small mammals that live in deserts have, in general, evolved lower basal metabolic rates than nondesert mammals of the same body size. Some species, moreover, undergo daily torpor or estivation when they are short of food or dehydrated. Still, when small mammals are active, their metabolic rates are far higher than those of lizards.

The species of small desert mammals that, by far, have attracted the most curiosity are the ones that eat primarily air-dried plant matter. In classic studies 60 years ago that contributed to the genesis of modern animal physiology, researchers produced the water-balance summary for kangaroo rats (*D. merriami*) in Figure 28.24. As we discuss this information, it will be important to keep in mind that the animals were studied at 25°C (77°F). They had no drinking water and were fed only barley grain. Each of the five lines in the figure shows how a key attribute of their water physiology varied with the humidity of the air. The red lines show the animals' *minimum* water losses by evaporation and elimination of urine and feces. Kangaroo rats have several specializations for conserving water. They exhibit exceptionally low cutaneous permeability to water; they cool their exhalant air by nasal countercurrent exchange; they can produce very concentrated urine (osmotic U/P = 14); and they can restrict their fecal water losses exceptionally. Their minimum evaporative, urinary, and fecal water losses are *stacked on top of each other* in the figure so that the heavy red line at the top represents their *total* water losses. Evaporative losses decrease with increasing humidity, but minimum urinary and fecal losses are independent of humidity, so the animals' total water losses decrease as humidity increases. The blue lines show the water inputs of the kangaroo rats. Their production of metabolic water is the same at all humidities because it depends on metabolic rate, which is the same regardless of humidity. In contrast, the rats' input of preformed water increases as humidity increases because air-dried plant matter, such as barley grain, comes to equilibrium with the water vapor in the air and contains more water when the humidity is high. The animals' inputs of metabolic and preformed water are stacked so that the heavy blue line represents their total water intake.

Kangaroo rats can be in water balance if their total water inputs equal or exceed their total, minimum water losses. Based on Figure 28.24, therefore, the animals can be in water balance while eating air-dried grain and drinking nothing if the relative humidity is above about 10%. Most of their water input is metabolic water. As stressed in Chapter 27 (see page 711), this is not because they produce exceptional amounts of metabolic water. It is because they conserve water so well that metabolic water can meet most of their needs.

Now we need to recall that the studies in Figure 28.24 were done at 25°C. The researchers who carried out the studies also obtained data on soil temperatures and nocturnal air temperatures in the parts of the southwestern deserts of the United States where they worked.²⁷ They concluded that temperatures at the depths of kangaroo rat burrows, and at night on the desert surface, were generally about 25°C or less. The kangaroo rats, being nocturnal, lived in their cool burrows during the heat of the day, and they emerged onto the desert surface only in the cool of the night. Thus, not only were free-living kangaroo rats never heat-stressed, but also—based on Figure 28.24—they were

FIGURE 28.24 A kangaroo rat water budget For this study, carried out at 25°C, kangaroo rats (*Dipodomys merriami*) were fed husked barley grain at equilibrium with atmospheric moisture and provided no drinking water (they usually do not drink even if water is available). The water losses shown (red lines) are the minimum possible water losses; in actuality, if water intake exceeds minimum losses, the animals increase their losses (as by excreting more-dilute urine) so that losses match inputs (blue lines). The amounts of water graphed on the y axis are those gained or lost each time 100 g (dry weight) of barley is consumed. Under the conditions of study, the animals normally consume 100 g of barley in about a month. (After Schmidt-Nielsen and Schmidt-Nielsen 1951.)

able to stay in water balance while eating air-dried seeds or other air-dried plant material and drinking nothing.

How is the water physiology of kangaroo rats affected if the ambient temperature is different from 25°C? The *dominant* modes of water gain and loss are metabolic water production (MWP) and evaporative water loss (EWL) (see Figure 28.24). A straightforward (although not complete) way to gain insight into the effect of temperature on water balance is to examine how MWP and EWL relate to each other as temperature varies. The two are often expressed as a ratio of gain over loss—**MWP/EWL**—for this purpose. The numerator, MWP, tends to *increase* as ambient temperature decreases because MWP varies with metabolic rate, which increases as temperature decreases below the thermoneutral zone (see Figure 10.28). The denominator, EWL, by contrast, typically tends to *decrease* as ambient temperature decreases in small mammals and birds. The MWP/EWL ratio (water gain over water loss) therefore becomes dramatically more favorable as the ambient temperature falls (Figure 28.25). Based on this analysis, we would expect kangaroo rats to be under far less water stress during the cool seasons of the year than during the warm seasons. In fact, studies of kangaroo rats (*D. merriami*) in the wild match this expectation. In one population, the urinary osmotic pressure of the rats averaged about 1000 mOsm (U/P = 3) in midwinter but rose to about 4000 mOsm (U/P = 11) in midsummer. Low winter temperatures apparently placed the rats in such a favorable situation

²⁷For soil temperatures they used the information in Figure 1.15.

FIGURE 28.25 An index of water balance: metabolic water production (MWP) as a ratio of total evaporative water loss (EWL) This ratio provides a useful (although incomplete) index of ability to stay in water balance for species in which metabolic water production and evaporation are the principal processes of water gain and loss. Shown are data for two populations of kangaroo rats, *Dipodomys merriami*, and two species of desert birds, the dune lark (*Mirafra erythrochlamys*) and zebra finch (*Poephilia guttata*). The populations of kangaroo rats, which differed to a statistically significant extent, lived in two regions of desert that differed in the severity of water stress. (Data from Tracy and Walsberg 2001; Williams 2001.)

that they had a water surplus and didn't need to concentrate their urine maximally.

Figure 28.25 suggests, however, that if kangaroo rats were to live at ambient temperatures of 30°C or higher, where their rates of evaporative water loss would be greatly heightened, they might potentially fall into severe negative water balance if eating only air-dried foods. In fact, although most populations live in places where they experience the conditions we have discussed up to now, certain unusual populations do live in hotter places. In particularly hot parts of the Sonoran Desert where kangaroo rats are found, the soil at the depths of their burrows remains steadily at a temperature of about 35°C (95°F) during the summer! Moreover, the summer air temperature near the desert surface during the times of night when the animals are particularly active is 35–37°C. In these particularly hot habitats, the kangaroo rats' water gains from metabolism and from preformed water in air-dried foods are *less than half of their water needs*. The rats can't make up the difference by drinking because no drinking water is present. Fortunately, insects are able to exist and accumulate body fluids in this severe environment. The kangaroo rats probably achieve water balance by adding insects and green-plant parts to their usual diet of air-dried seeds: a striking example of one species taking advantage of adaptations of other species.

Xeric vertebrates: Desert birds are again a new frontier for research

The fundamental conflict between heat balance and water balance in hot deserts is emphasized by the study of birds because most desert birds are diurnal and therefore do not evade the heat of the day. Despite the fact that birds often confront the stresses of deserts head-on, the species of desert birds first studied seemed to exhibit remarkably few specializations for desert existence. Birds as a group

have higher body temperatures than mammals, are especially tolerant of hyperthermia, synthesize uric acid, and can fly to distant watering places. Such traits, shared by birds as a group, seemed initially to be sufficient for successful desert existence. Two recent developments have precipitated a recognition that the presence of birds in deserts is not simply a consequence of a happy marriage between the standard features of all birds and the requirements of desert life. First, now that birds have been studied long enough for a large background of data to exist, statistical studies reveal patterns: Desert birds tend to be systematically different from other birds; for example, they exhibit, on average, higher resistance to evaporative water loss.

The second major development is an influential, ongoing comparative study of a group of closely related birds, the Old World larks, that occupy an extreme diversity of habitats. Whereas certain species of Old World larks occur in moist habitats, others occur in semiarid places, and some live in hot, hyperarid deserts. The hoopoe lark (*Alaemon alaudipes*), seen in the inset in Figure 28.26, exempli-

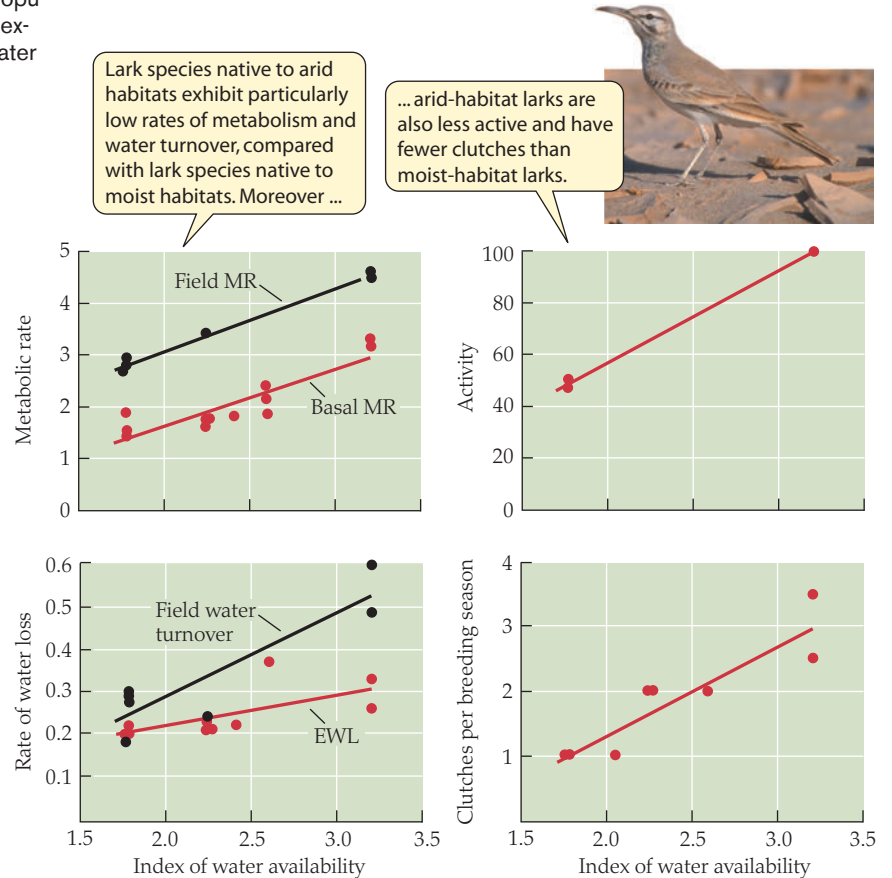

FIGURE 28.26 Lark species along a gradient of water availability Water availability in a species' habitat is quantified by an index that can vary from 1.5 (very arid) to 3.5 (moist). In each graph, each symbol represents a different species of lark. Metabolic rates and rates of water loss are expressed using indices designed to be independent of body weight. Metabolic rates shown are basal metabolic rates (red) and average free-living metabolic rates (black). Rates of water loss shown are rates of total evaporative water loss (red) and free-living water turnover rates (black). Activity is percentage of daylight hours spent active. Shown in the photograph is a desert-dwelling hoopoe lark (*Alaemon alaudipes*), one of the species found in the most arid habitats. (After Tieleman 2005.)

fies the latter. When hoopoe larks are living in hyperarid deserts such as those of the Arabian Peninsula, they eat insects and other arthropods and thereby get preformed water from their food, but they never drink—water is nearly never within flight distance. As Figure 28.26 illustrates, when diverse species of larks are arrayed along an axis of water availability—with a water-availability index of 1.5 representing a very arid habitat and an index of 3.5 representing a moist habitat—the species native to dry habitats display distinctive features. Included are physiological specializations: They exhibit low metabolic heat production and low water turnover. The low water turnover of the dry-habitat species is accounted for, in part, by integumentary lipids that, in comparison with those of other larks, are unusually protective.

These new revelations in the study of birds help emphasize that although molecular biology is one of today's most important cutting edges, the comparative study of related species (the products of evolution) in divergent habitats remains a powerful source of insight for understanding life on Earth.

SUMMARY Animals on Land: Case Studies

- Most terrestrial amphibians have meager physiological abilities to limit water loss because their skin is highly permeable to water and they cannot make urine that is hyperosmotic to their body fluids. Stringent behavioral control of water balance and seasonal dormancy are essential for their success in arid places. A few types of arboreal amphibians that live in arid areas have unusual adaptations such as cutaneous lipids that protect against rapid evaporative water loss.
- Insects and lizards are among the animals that are most physiologically capable of living in the driest places on Earth. Their key traits for existence in extreme places include very low integumentary permeability to water, relatively low metabolic rates, excretion of poorly soluble nitrogenous wastes, and tolerance of profound changes in body-fluid composition. Insects can produce hyperosmotic urine and sometimes gain water from water vapor, but the fact that they are small is in itself a physiological (although not behavioral) disadvantage.
- Some small mammals that eat predominantly air-dried foods (e.g., seeds) live in deserts without needing to drink. In addition to having highly evolved physiological mechanisms of water conservation, they depend on behavioral selection of relatively benign microhabitats to maintain water balance. In the hottest places they live, they probably must supplement their diet with water-rich foods such as insects.
- Although some desert birds seem to succeed because of general avian properties that are of advantage under desert conditions, others exhibit dramatic specializations for desert existence.

Control of Water and Salt Balance in Terrestrial Animals

The kidneys and other organs responsible for water and salt regulation in terrestrial animals are generally under hormonal control in both vertebrates and invertebrates, although the nervous system is sometimes a principal player, as in the control of avian salt glands. Some of the most important hormones involved are the *antidiuretic*

and *diuretic* hormones. **Diuresis** is the production of an abundant (and usually dilute) urine. A **diuretic** hormone promotes diuresis. An **antidiuretic** hormone opposes diuresis or, in other words, modulates the excretory organs so that a relatively low volume of (usually concentrated) urine is produced.

Vertebrates are considered to produce only antidiuretic hormones. In insects, however, diuretic as well as antidiuretic hormones occur. Certain blood-sucking insects, for example, have a diuretic hormone that is secreted after a blood meal, promoting rapid excretion of much of the water in the blood and thereby concentrating the nutritious part of the meal (e.g., proteins) in the gut.

In vertebrates, which will be our focus in this brief discussion, three hormones or types of hormones play particularly important roles in the regulation of water–salt physiology:

1. **Antidiuretic hormone (ADH)**, produced by the neurohypophysis (see page 439–440 and Table 16.2)
2. **Mineralocorticoids**, most notably **aldosterone**, produced by the adrenal cortex or homologous interrenal tissue (see page 430)
3. **Natriuretic** hormones (see page 442)

Focusing on ADH first, its principal effect in mammals—and its principal effect on the kidneys in other terrestrial vertebrates—is to control the excretion of *pure water* (*osmotically free water*) relatively independently of solute excretion. To see this point, let's use a mammal as an example. Consider that a mammal has a certain *quantity* of urea, salts, and other solutes that it must excrete per day. If the solutes collectively are excreted at the maximum concentration the individual can achieve, the accompanying water loss can be considered to be strictly obligated by solute excretion. However, if the solutes are excreted at less than maximum concentration, then the urine contains additional water that is not obligated by solute excretion; in essence, the urine is diluted by the addition of pure water above and beyond the amount needed to void solutes, and the additional water represents a specific excretion of water itself. The urine can therefore be considered to consist of two components: (1) the solutes and their associated water and (2) a quantity of additional pure water. The magnitude of the latter component is controlled by ADH. If a person, for instance, has a constant daily solute output, but consumes little water on one day and a lot of water the next day, secretion of ADH on the first day—because of its antidiuretic effect—will restrict the amount of water excreted with the solutes; however, inhibition of ADH secretion on the second day will permit diuresis and thus the excretion of a great deal of water with the solutes.²⁸

The principal effect of aldosterone is to cause the kidneys to hold back Na^+ from excretion while promoting the excretion of K^+ in the urine. These actions of aldosterone most obviously affect the quantities of Na^+ and K^+ in the body. Less obviously, the action of aldosterone is one of the most important elements in the routine regulation of the volume of the extracellular body fluids (including blood plasma volume). To understand this latter role of aldosterone, consider that Na^+ is largely excluded from intracellular fluids by being actively transported out of cells (see Figure 5.10). Increases or decreases in the amount of Na^+ in the body therefore lead to

²⁸The action of ADH is discussed in more detail in Chapters 16 and 29.

quantitatively similar increases and decreases in the amount of Na^+ (and accompanying anions, notably Cl^-) in the extracellular fluids. When Na^+ is retained in the body by being held back from the urine—and thus accumulates in the extracellular fluids—the systems controlling the osmotic pressure of the extracellular fluids cause water to be retained as well, so that the osmotic pressure of the extracellular fluids remains normal. In that way, the extracellular-fluid volume is expanded. Actually, although aldosterone has its major effects on the kidneys, it often functions as an all-purpose Na^+ -retention hormone. In mammals, for example, it stimulates the salivary glands, sweat glands, and intestines to increase reabsorption of Na^+ . Moreover, aldosterone stimulates salt appetite.

The natriuretic hormones—often termed *natriuretic peptides* because they are types of peptides—promote addition of Na^+ to the urine, as their name indicates (*natri*, “sodium”; *uretic*, “having to do with excretion in the urine”). Certain of these hormones are called *atrial natriuretic peptides* because they are produced principally by the atria of the heart (see page 442). Despite an explosion of knowledge since 1990, many uncertainties remain about the functioning of the natriuretic hormones because there are multiple chemical forms—each of which potentially has multiple effects—which can differ from one set of vertebrates to another. The heart and certain brain regions (e.g., hypothalamus) are the chief sites of secretion in mammals. The atrial natriuretic peptide (ANP) of mammals, the best understood of these hormones, has actions that in many ways are opposite to those of aldosterone. The mammalian ANP inhibits aldosterone secretion and directly affects the kidneys to promote Na^+ excretion by increasing both urine volume and urine Na^+ concentration.

The mechanisms of control of the secretion of ADH, aldosterone, and ANP are complex and incompletely understood. All of these hormones participate in negative feedback systems that act to stabilize the volume and osmotic pressure of the extracellular body fluids.

For the volume of the extracellular body fluids to be regulated, either the volume itself or reliable correlates of volume must be *sensed*, so that the regulatory systems will “know” whether to promote an increase or a decrease in volume at any particular moment. Probably volume itself is not sensed. However, good evidence exists that certain correlates of volume *are* sensed; for example, both the blood pressure and the extent to which blood-vessel walls are stretched are functions of blood volume, and pressure and stretch receptors that participate in volume regulation are known (e.g., in and around the heart). Similarly, if the osmotic pressure of the extracellular body fluids is to be regulated, either it or close correlates must be sensed. No doubt exists that receptors for osmoregulation are present (e.g., in the hypothalamus), but whether they respond to osmotic pressure itself, Na^+ concentration, or other correlated properties remains debated.

Secretion of ADH is partly responsive to changes in blood volume; pressure sensors and other sensors of volume affect ADH secretion by way of nervous inputs to the hypothalamus and also via the renin–angiotensin–aldosterone system (see next paragraph). Decreases in pressure activate ADH secretion, a response favoring fluid retention. Secretion of ADH is also under the control of osmoreceptors or other detectors of the concentration of the body fluids. Increases in the osmotic pressure of the body fluids induce increased ADH secretion; the ADH then favors the specific retention

of water by the renal tubules, thereby tending to lower the osmotic pressure of the body fluids.

Aldosterone secretion is controlled to a major extent by another hormonal system, the *renin–angiotensin system* (see Figure 16.17), which itself is partly under the control of blood-pressure receptors and other detectors of blood volume. A decrease in blood pressure, signifying a reduction in blood volume, activates secretion by the kidneys of the hormone *renin* (pronounced “ree-nin”), which in turn causes formation in the blood of *angiotensin II*. The angiotensin stimulates the adrenal glands to secrete aldosterone, which induces increased Na^+ reabsorption from the urine, tending to expand extracellular-fluid volume and raise blood pressure.

Secretion of ANP is stimulated by expansion of extracellular-fluid volume, which is detected by stretching of the walls of the atria in the heart. ANP then promotes loss of extracellular fluid. One of ANP’s principal overall effects is a decrease in blood pressure.

SUMMARY Control of Water and Salt Balance in Terrestrial Animals

- The control of body-fluid volume, composition, and osmotic pressure is mediated mostly by hormones that are themselves secreted under control of negative feedback systems. Stretch or pressure receptors provide information on blood volume, and osmoreceptors provide information on blood osmotic pressure.
- In vertebrates, antidiuretic hormone (ADH) regulates the amount of pure, osmotically free water that is excreted by the kidneys; it does so by controlling whether a more-than-minimum amount of water is excreted with solutes.
- Aldosterone and natriuretic hormones in vertebrates act to favor Na^+ retention or Na^+ excretion, respectively. The control of body Na^+ content by these hormones helps to control extracellular-fluid volume because body Na^+ is present mostly in the extracellular fluids.

Study Questions

1. It has been said that in terms of water balance, behavior can compensate for physiology, or physiology can compensate for behavior. Do you agree? Give examples to support your answer.
2. When a salmon or other teleost fish migrates from seawater into freshwater, what are all the changes that take place or are likely to take place in its patterns of water–salt physiology?
3. Theory predicts that when both terrestrial and freshwater animals evolve higher metabolic rates, they can be expected to evolve greater challenges to maintaining water balance. Explain why this is so for both terrestrial and freshwater animals.
4. We noted in Chapter 10 that dogs are believed to benefit when they pant by breathing at a fixed resonant frequency. Although dogs inhale and exhale exclusively through the nose when not under heat stress, they exhale orally to some (variable) extent when panting. Air exhaled by way of the mouth remains nearly at deep-body temperature. Explain how a panting dog could *vary its rate of evaporative cooling—even while breathing at a fixed frequency—*by modulating how much it exhales by way of its nose or mouth.
5. Animals often face trade-offs, and one of the goals of modern physiology is to understand mechanistically why improvement of performance in one way may degrade performance in other

ways. In freshwater fish, explain why O_2 uptake and Ca^{2+} uptake probably cannot be simultaneously maximized. In other words, why is there a trade-off between the ability to take up O_2 and the ability to take up Ca^{2+} ?

6. Being as specific as possible, discuss how global warming can be expected to alter the water physiology of animals and what the ecological consequences might be. Figure 28.25 might provide a useful starting point, but do not limit yourself to it. Parks set aside to protect animals have defined geographical boundaries. How might the relation between global warming and water physiology affect the effectiveness of the park program?
7. Walter Cannon, who coined the term *homeostasis*, argued that lizards and amphibians are less highly evolved than mammals and birds because they are not as fully homeostatic as are mammals and birds. Considering water–salt relations and any other aspects of physiology you find to be pertinent, explain in detail why you agree or disagree.
8. Green crabs (*Carcinus maenas*) are hyperosmotic regulators in brackish waters. When water salinity is lowered, a green crab responds by increasing its rate of urine production; its urine output, on average, rises from 4% to 30% of its body weight per day when the ambient salinity is reduced from 35 g/kg to 14 g/kg. Explain the value of this response. If one arranges to keep a green crab in full-strength seawater and bathe just its antennules with an alternative water source, urine production increases as the salinity of the water bathing the antennules is lowered. What can one conclude from this result?
9. Related species of terrestrial animals typically display allometric relations between body–water dynamism and body size. For example, the weight-specific rate of evaporative water loss tends to decrease allometrically as body size increases. What are the mechanistic reasons for these relationships?
10. We discussed the fact in Chapter 23 (see Figure 23.10) that the efficiency of O_2 exchange across the gills of teleost fish is enhanced by countercurrent exchange between the water pumped over the gills and the blood flowing through the secondary lamellae of the gills. A recent review article makes the point that the countercurrent arrangement of blood flow and water flow—which has positive consequences for O_2 exchange—has disadvantageous side effects because it enhances osmotic water uptake by freshwater fish, osmotic water loss by marine teleosts, loss of NaCl by diffusion in freshwater fish, and NaCl gain by diffusion in seawater teleosts. Do you agree or disagree? Explain.
11. Probably the most complete account of water and salt balance in a marine mammal is not for a seal or whale but for a remarkable bat, *Pizonyx vivesi*, that lives on desert islands in the Gulf of California, where it subsists on fish and crustaceans. It gets much of its water as preformed and metabolic water from its food. However, it needs more water than its food provides, and the amount of additional water it needs increases as it flies more, because flight greatly increases its rate of evaporative water loss. The bat can concentrate NaCl to about 620 mM in its urine. Based on this information and the composition of seawater (see Table 27.1), could it maintain water balance by drinking increasing amounts of seawater as it flies more? What additional information would you need to be certain?

Kidneys and Excretion (with Notes on Nitrogen Excretion)

An animal's body fluids are dynamic—continuously gaining and losing water, inorganic ions, and organic solutes. When a kangaroo rat in the desert is successfully maintaining water balance in moderate summer weather, about 15% of the water in its body fluids is lost and replaced each day. This rate of turnover is low for a mammal of its body size; species of mice and rats living in moist temperate habitats often turn over 35% or more of their water per day. Humans, being larger, have lower percentage turnover rates, but even in people going about their ordinary daily lives, about 7% of the water in the body fluids is lost and replaced every day. Organic solutes and inorganic ions in the body fluids also undergo incessant turnover. Ions such as Na^+ and Cl^- , for example, are added from foods and excreted in urine.

The great dynamism of the body fluids means that their composition is continuously in danger of being shifted away from normal. As water, for example, leaves the body fluids and is replaced each day, any mismatch between the rates of loss and replacement may render the body fluids excessively dilute or concentrated.

For the blood and other body fluids to be maintained at a normal composition, an animal requires organs that are capable of correcting any departures from normal that develop during the complex fluxes of materials in and out. In aquatic animals such as fish and crayfish, the kidneys and gills are the organs primarily responsible for this task. In terrestrial animals such as kangaroo rats, the kidneys bear the primary responsibility alone.

Kangaroo rats and other desert rodents that have been studied have a status in the physiology of kidney function not unlike the status of cheetahs in the physiology of running. The kidneys of these desert rodents represent the ultimate product of evolution in their ability to concentrate urine. Most types of animals cannot concentrate their urine at all, in the sense that they cannot produce urine with an osmotic pressure higher than the osmotic pressure of their blood plasma. Some insects can make urine that is 6–8 times higher in osmotic pressure than their blood plasma. Birds also can concentrate their urine, typically to an osmotic pressure that is 3 times the blood osmotic pressure, or lower. Certain species of kangaroo rats, however, can make urine that is 14 times higher in osmotic pressure than their blood plasma, and some of the desert hopping mice of Australia can make urine more than 20 times higher.

The advantage of the high concentrating ability of the kidneys of desert rodents is that the kidneys have an extraordinary capacity to correct a type of error in blood composition that desert rodents are particularly likely to face. When a kidney can produce urine with a higher osmotic pressure than the blood plasma, it can dilute the blood (see Figure 27.7). During the dynamic daily flux of water and solutes in and out of the body, the blood plasma of desert

Species of small mammals that have evolved in deserts are, among all animals, the extreme performers in their ability to concentrate their urine Excretion of dissolved wastes in as little water as possible is a key to maintaining water balance in water-poor environments. Around the world, each desert has its own assemblage of small mammals. Some of these unique animals—such as the kangaroo rats (bottom) of the American southwest—have been carefully studied. Others—such as the jerboas (top) of Asian deserts—have been little studied by physiologists and, because of habitat destruction, may be driven to extinction before we know them. Shown here are the desert kangaroo rat (*Dipodomys deserti*) from the American southwest and the long-eared jerboa (*Euchoreutes naso*) from the Gobi Desert in China. (Jerboa courtesy of Zoological Society of London.)

rodents tends often to be shifted toward concentrations higher than normal. The kidneys of these rodents, with their unique abilities to produce urine hyperosmotic to the blood plasma, are exceptionally suited to correcting this sort of problem.

Considering animals in general, what are **kidneys**? We will see in this chapter that the kidneys of various types of animals are very diverse in morphology as well as in details of their physiology. All kidneys, however, have three features in common. First, they all consist of tubular elements that discharge directly or indirectly to the outside world. Second, they all produce and eliminate aqueous solutions derived from the blood plasma or other extracellular body fluids. Third, *their function is the regulation of the composition and volume of the blood plasma and other extracellular body fluids by means of controlled excretion of solutes and water.*

Urine, the product of the kidneys, is typically a complex solution containing multiple inorganic and organic solutes. All the constituents of the urine—including the water—are drawn from the blood plasma, and the urine concentration of each affects the blood concentration according to the principles we discussed in Chapter 27 (see page 709 and Figure 27.7). The urine often contains nitrogenous wastes, but the role of the urine is much more far-reaching than merely excreting waste nitrogen. The urine of a mammal, for example—although it contains urea (the nitrogenous end product)—also contains Na^+ , Cl^- , K^+ , PO_4^{3-} , SO_4^{2-} , creatinine, and numerous other components. The kidneys excrete each of these in greater or lesser amounts day by day, closely regulating the concentration of each in the blood plasma. The kidneys also excrete greater or lesser amounts of H^+ in the urine, thereby helping to maintain a steady blood pH. Moreover, the kidneys regulate the osmotic pressure of the blood by means of the controlled excretion of water relative to total solutes. It seems almost impossible—but is true—that the kidneys perform all these functions *simultaneously* by structuring the composition of a *single* fluid output: the urine.

Basic Mechanisms of Kidney Function

Urine formation can usually be conceptualized as occurring in two steps, although these “steps” may sometimes be partly contemporaneous. First, an aqueous solution, called **primary urine**, is introduced into the kidney tubules. Second, this solution is modified as it moves through the kidney tubules and other excretory passages, ultimately becoming the **definitive urine** that is eliminated.

Primary urine is introduced into kidney tubules by ultrafiltration or secretion

One widespread mechanism by which fluid is introduced into kidney tubules is *ultrafiltration*. This is the mechanism used in most vertebrates and in many invertebrates, such as molluscs and decapod crustaceans (e.g., crayfish and crabs). Ultrafiltration into a kidney tubule occurs when the hydrostatic pressure is higher outside the tubule than inside the tubule lumen¹ at a place where the tubule wall is structured in a specialized, minutely porous way that permits fluid to pass through the wall. Under these circumstances, the difference in hydrostatic pressure—provided it is high enough²—forces fluid to enter the tubule through the wall by

means of pressure-driven *bulk flow*, or *streaming*. This flow is termed **ultrafiltration**. The process is literally a form of *filtration* because solutes of large molecular size typically are unable to pass through the wall of the tubule. Thus the fluid introduced into the tubule lumen—which is termed a **filtrate** or **ultrafiltrate**—consists only of water and the subset of solutes that are able to stream through with the water. The blood plasma is the source of the water and solutes that stream through. Although there are exceptions in some groups of invertebrates, the *blood pressure produced by the heart* is typically the pressure that drives ultrafiltration, explaining why heart weakening can interfere with urine formation.

To understand the formation of primary urine by ultrafiltration more fully, let’s examine the process in the vertebrate kidney. Each kidney consists of many tubules, called **nephrons**, the walls of which consist of a single layer of epithelial cells (see Figure 2.6b). As diagrammed in **Figure 29.1a**, each nephron *begins blindly* with its walls thrown into a hemispherical, invaginated structure termed a **Bowman’s capsule**, named after William Bowman (1816–1892), who first described it. Tucked inside each Bowman’s capsule is an anastomosing cluster of blood capillaries, termed a **glomerulus** (**Figure 29.1b**), which is supplied with blood at relatively high pressure by branches of the renal artery. A Bowman’s capsule and its glomerulus together constitute a **renal corpuscle**.³ The glomerular capillaries are intimately juxtaposed to the inner wall of the Bowman’s capsule. Moreover, the wall of each capillary consists of a single layer of epithelial cells (the capillary endothelium), just as the wall of the Bowman’s capsule consists of a single layer of cells. The lumen of the capillaries, therefore, is separated from the lumen of the Bowman’s capsule by only two layers of cells and a nonliving, porous basement membrane between the cell layers (see inset in Figure 29.1b). These intervening structures have a specialized morphology and act as a filter. Fluid is driven through this filter from the blood plasma into the lumen of the Bowman’s capsule by the hydrostatic pressure of the blood. The fluid that accumulates in the lumen of the Bowman’s capsule is known as the **capsular fluid** and is the *primary urine*. Although a critical determinant of whether a solute will pass through is its molecular size, molecular charge and shape can also be significant; thus the filter has complex features, which include, but are not limited to, simple physical pores or slits.

Current theories regarding the function of the filter place particular importance on the cellular wall of the Bowman’s capsule, which is composed of specialized cells called **podocytes** (drawn highly diagrammatically in Figure 29.1b). The podocyte cells have processes, and the processes of neighboring podocytes interdigitate in geometrically intricate ways, creating countless narrow slits between the processes. The assembly of processes and slits is called the *slit diaphragm*, believed to be the most critical part of the filter.

Inorganic ions and small organic molecules such as glucose, urea, and amino acids move freely with filtered fluid as it passes from the blood plasma into the lumen of a Bowman’s capsule. Thus the concentrations of these solutes are virtually the same in the capsular fluid—the primary urine—as in the blood plasma. In contrast, solutes with molecular weights of about 10,000 daltons or more—such as albumins and other plasma proteins—are essentially unable to pass through the structures that separate the blood plasma and the

¹The *lumen* of a hollow structure such as a kidney tubule is the open central cavity.

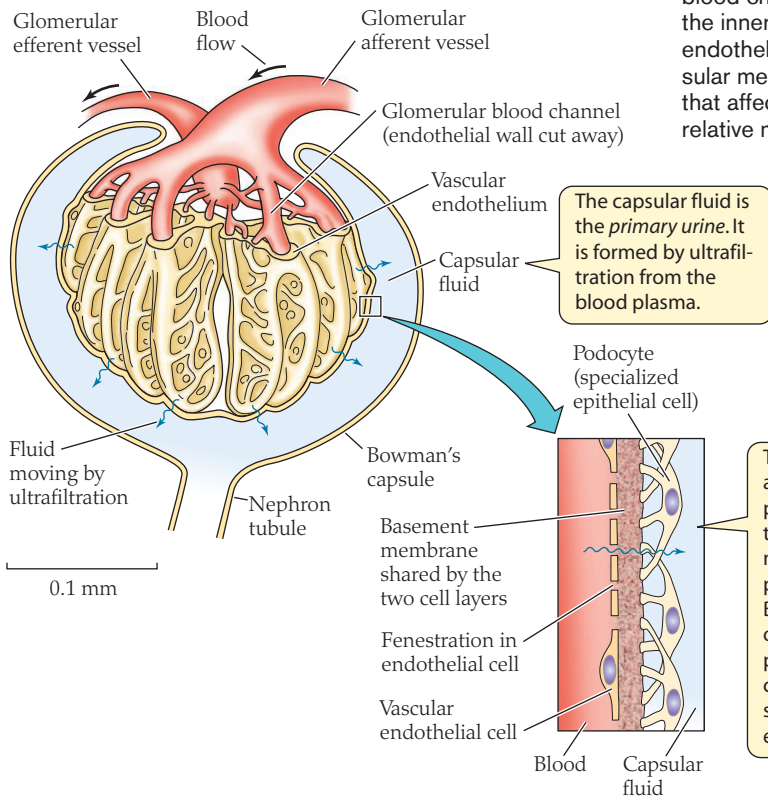

²We discuss this important topic shortly.

³Another name for *renal corpuscle* is *Malpighian corpuscle*. Sometimes the entire renal corpuscle is called a *glomerulus*.

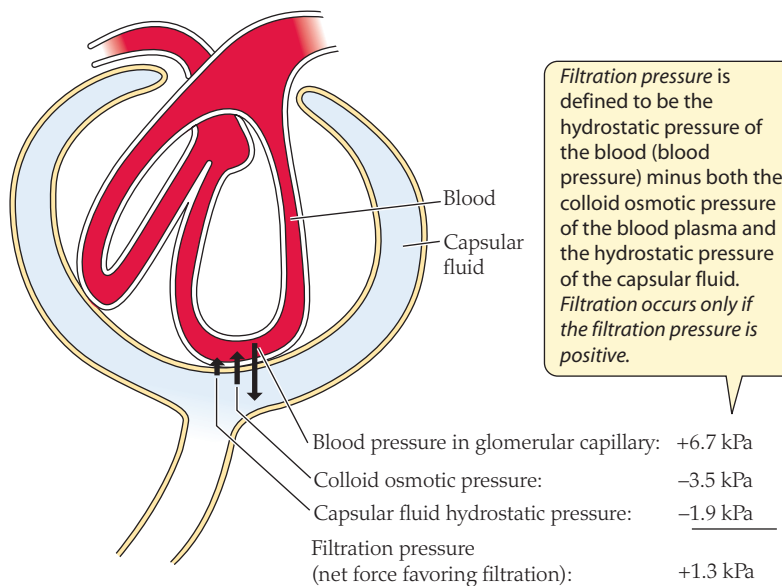

FIGURE 29.1 The structural and functional basis for formation of primary urine by ultrafiltration in the vertebrate kidney (a) The blind end of a vertebrate nephron, where ultrafiltration occurs. (b) A human renal corpuscle, consisting of glomerulus and Bowman's capsule. The vascular endothelium that forms the walls of the glomerular capillaries has been cut away at the top of the drawing, so that only the blood channels are shown there. The Bowman's capsule is drawn diagrammatically; the inner membrane of the capsule actually interdigitates with the sheets of vascular endothelium so that there is intimate juxtaposition of all blood capillaries and the capsular membrane. (c) The forces of hydrostatic pressure and colloid osmotic pressure that affect the rate of filtration: The relative lengths of the black arrows symbolize the relative magnitudes of these forces. (b after Elias et al. 1960.)

fluid (see page 122). This difference in osmotic pressure is called the *colloid osmotic pressure* of the blood. Taking the colloid osmotic pressure into account, there are two processes that tend to cause water (H_2O) to move between the blood plasma and capsular fluid. The first is the *difference in osmotic pressure*, which tends to cause osmosis of water from the capsular fluid into the blood plasma.

The second is the *difference in hydrostatic pressure*, which tends to cause bulk flow of water from the blood plasma into the capsular fluid. *Net filtration* of fluid into the capsular lumen will occur only if the difference in hydrostatic pressure is greater than the difference in osmotic pressure. In the renal corpuscles of the species of mammals that have been used as model systems for research, the blood pressure (hydrostatic pressure of the blood) is about 6.7 kPa, and the opposing hydrostatic pressure in the capsular fluid is about 1.9 kPa,

meaning that the difference in hydrostatic pressure is about 4.8 kPa. The colloid osmotic pressure averages about 3.5 kPa. Thus the net force favoring filtration—termed the *filtration pressure*—is about 1.3 kPa, as shown in **Figure 29.1c**. The blood pressure in the glomerular capillaries is significantly higher than the blood pressure in most capillaries in mammals, helping to promote filtration and formation of primary urine. Part of the reason for the high capillary blood pressure is that the arterioles leading to the glomeruli are relatively large in diameter and thus offer a relatively low resistance as blood flows to the glomeruli.

The rate of primary-urine formation by all of an animal's kidney tubules taken together is called the **filtration rate**. In vertebrates, it is termed specifically the **glomerular filtration rate**, or **GFR**. Adult humans, for example, have a GFR of about 120 mL/min. At this rate, *the equivalent of all the plasma water in a person's body is filtered about every 30 minutes!* This example points to an important property of vertebrates, namely that the GFR *greatly* exceeds the rate of excretion of definitive urine. Most of the filtered water is ultimately reabsorbed back into the blood, rather than being excreted. The sheer magnitude of the rate of filtration means, however, that the nephrons have very intimate access to the blood plasma to carry out their function of regulating plasma composition.

The rate of production of definitive urine by an individual vertebrate animal can, in principle, be controlled in part by regulating the GFR. This mode of controlling urine flow is employed to some degree by mammals. It is employed to a greater extent by other types of vertebrates. There are two principal ways to adjust the GFR. One is to vary the rate of filtration into all the nephrons of

capsular fluid. The primary urine, therefore, closely resembles the blood plasma in its composition of inorganic ions and low-molecular-weight organic solutes, but differs from the plasma in being almost devoid of high-molecular-weight organic solutes such as proteins.

Because proteins remain more concentrated in the blood plasma than in the capsular fluid, the osmotic pressure of the blood plasma is higher than the osmotic pressure of the capsular

the kidneys collectively. The second is to increase or decrease the numbers of nephrons that are actually functioning as filtration units at any given time. The latter strategy is the norm in nonmammalian vertebrates. The rate of filtration into an individual nephron depends on the nephron's glomerular blood pressure, which is modulated by vasomotor changes in the diameter (and hence flow resistance) of the glomerular afferent vessel. Vasomotor changes of this sort are under the control of the autonomic nervous system and circulating hormones. Variation in the GFR is not the only way in which the rate of production of definitive urine can be controlled. Animals can also modulate the rate at which the nephrons reabsorb filtered fluid prior to excretion; this, in fact, is the preeminent process of urine volume control in mammals, as discussed later.

In addition to ultrafiltration, **active solute secretion** is the second mechanism by which water and solutes can be moved into kidney tubules to form the primary urine. This is the mechanism employed, for example, by insects and some marine fish.

To see how urine formation can be initiated by secretion, consider **Figure 29.2**, which presents the essentials of a secretory system in a conceptual, stepwise fashion. For simplicity, only two uncharged solutes are assumed to be present. Moreover, the fluid outside the tubule is assumed to be abundant, so that over short periods of time, movements of solutes and water into the tubule do not greatly modify its composition. At the start, which is labeled step ❶, the osmotic pressure and the concentrations of both solutes are equal on the inside and outside of the kidney tubule. In step ❷, an active-transport pump uses energy from ATP to secrete a quantity of solute X into the lumen of the kidney tubule, increasing the inside concentration of X and also increasing the inside osmotic pressure. In step ❸, water moves inward by osmosis—following the osmotic gradient that was set up by secretion of solute X—and the volume of fluid in the tubule increases. Because of this increase in volume, the inside concentration of solute Y, initially the same as the outside concentration, is reduced so that it is now lower than the outside concentration. In step ❹, solute Y diffuses inward following its concentration gradient. Although simplified and artificial, this model system demonstrates that *active secretion of even just a single solute into a kidney tubule can*

lead to passive influx of water and other solutes. Thus a complex solution of many solutes can be introduced into the lumen of a kidney tubule from the body fluids bathing the tubule by a secretory mechanism. During the operation of a secretory system, the epithelium of the kidney tubule acts as something of a filter. The permeability of the epithelium to the various solutes that *might* passively diffuse into the tubular lumen determines which solutes *do*, in fact, enter.

Whether the process of primary-urine formation is ultrafiltration or secretion, energy is required. In ultrafiltration systems, energy is expended in maintaining a suitably high blood pressure to cause net filtration. In secretory systems, energy is expended by the active-transport pump responsible for solute secretion.

The predominant regulatory processes in kidney function: After primary urine forms, solutes and water are recovered from it for return to the blood, and some solutes are added from the blood

As the fluid introduced into a kidney tubule moves down the tubule and through other parts of an animal's excretory system, it is typically altered extensively in volume and composition before it is eliminated as definitive urine. Most of the water in the primary urine is usually reabsorbed and returned to the blood plasma. Solute Y may be reabsorbed and returned to the blood—lowering the amounts excreted—or they can be added from the blood.

These processes that occur *after* primary-urine formation are the *predominant regulatory processes* in kidney function. That is, they are the predominant processes by which the formation of urine ultimately regulates the composition and volume of the blood plasma and other body fluids. This last statement is of central importance. *Regulating the composition and volume of the blood plasma and other body fluids is the function of the kidneys.* Their function is not to regulate the urine composition and volume. Instead, the formation of urine is a means to an end. It is a means to the specific end of regulating the body fluids.

As urine flows through a kidney tubule, it is separated from blood capillaries or blood spaces by the epithelial wall of the tubule, a single layer of cells. This epithelium is typically differentiated into distinct regions along the length of the tubule. Within each of these regions, the epithelial cells express distinctive membrane proteins, such as ion channels, transporters, and aquaporins; and the cells may have a distinctive structure. These properties give each region of the tubule distinctive abilities to reabsorb water and solutes from the tubular fluid—returning them to the blood—and to secrete solutes from the blood into the tubular fluid. The processes carried out by each region of a kidney tubule, and the permeability properties of each region, are commonly under endocrine control and hormonally modulated in regulatory ways.

FIGURE 29.2 Formation of primary urine by active solute secretion

In this model system, there are two uncharged solutes. Although the renal tubule is completely surrounded by the outside solution, only a small sample of the outside solution is shown at the upper right of the tubule in each step. For simplicity, the outside solution is assumed to stay constant in volume and composition. Movement of water into the tubule is represented by an increase in the length of the tubule filled with solution.

In mammals, the regulatory exchange of solutes and water between urine and blood is complete (and the composition of the definitive urine is fixed) when the urine leaves the kidneys. This is not always the case, however. In many types of animals, solutes and/or water are further exchanged between the urine and blood in the urinary bladder, cloaca, or other postrenal (“after kidney”) structures, before the urine is finally excreted from the body.

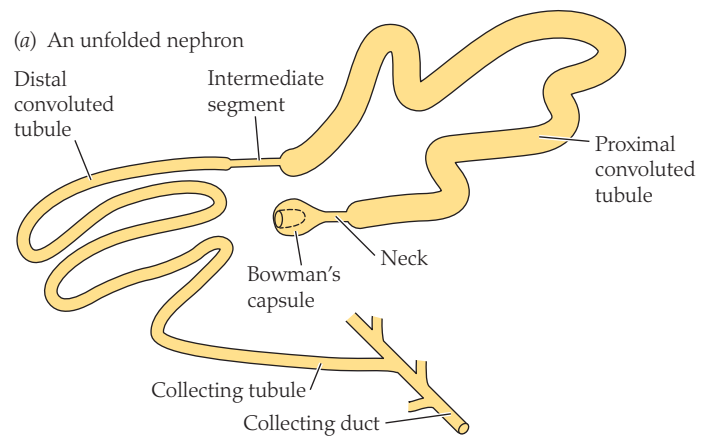

SUMMARY Basic Mechanisms of Kidney Function

- Primary urine is formed by ultrafiltration or by active solute secretion.
- During ultrafiltration, fluid is driven by elevated hydrostatic pressure from the blood plasma into the kidney tubules through intervening epithelia and basement membranes that act as a filter. The filtrate, which is the primary urine, is almost identical to blood plasma in its composition, except that it lacks high-molecular-weight solutes such as plasma proteins.
- In cases in which primary urine is formed by active solute secretion, the process that initiates and drives primary-urine formation is the active transport of one or more solutes into the kidney tubules. Water then follows by osmosis, and other solutes enter by diffusion, following electrochemical gradients set up by the active solute transport and osmosis.
- As primary urine flows through the kidney tubules, it undergoes exchange with the blood plasma by active or passive transport of solutes and by osmosis of water across the epithelial walls of the tubules. These processes are the *predominant regulatory processes in the kidney tubules*: They determine the ways in which the production of urine ultimately alters the composition and volume of the blood plasma. The urine produced by the kidneys is sometimes (as in mammals) the definitive urine, but in many animals, further regulatory exchange between urine and blood occurs by postrenal processing.

Urine Formation in Amphibians

The amphibians provide an excellent starting point for the study of vertebrate nephron function. Much is known about the amphibian nephron because of practical considerations that make the nephrons of amphibians relatively easy to study. Furthermore, the amphibian nephron can reasonably be considered a “generalized” vertebrate nephron. Our purpose in this section is not only to describe how amphibians form urine, but also to bring out many additional general principles of vertebrate kidney function by example.

Each nephron of an amphibian (Figure 29.3a,b) consists of (1) a Bowman’s capsule; (2) a convoluted segment known as the **proximal convoluted tubule**; (3) a short, relatively straight segment of small diameter, the **intermediate segment**; (4) a second convoluted segment known as the **distal convoluted tubule**; and (5) a relatively straight

Symbols help to trace the nephron along the course of its intricate geometry. Two of the segments—part of the proximal convoluted tubule and part of the late distal convoluted tubule—are shown in cross section at greater magnification than the main drawing. (c) A single collecting duct, showing the connections of the collecting tubules of many nephrons. (b after Møbjerg et al. 1998; c after Huber 1932.)

segment, the **collecting tubule**.⁴ The nephrons are microscopic in diameter but macroscopic in length; in an average-sized toad, for example, each might be 1 cm long. Hundreds or thousands of nephrons are found in each kidney, and the nephrons constitute much of the bulk of the kidney tissue. In each nephron, the structure and function of the nephron epithelium change along the length of the nephron, from one segment to the next of the major nephron segments we have described. Structure and function also often change *within* each major nephron segment (e.g., along the length of the distal convoluted tubule). In each kidney, the collecting tubules of all the nephrons feed into **collecting ducts** (Figure 29.3c), and all the collecting ducts connect to a single **ureter**, which carries fluid from the kidney to the bladder.

The proximal convoluted tubule reabsorbs much of the filtrate—returning it to the blood plasma—without changing the osmotic pressure of the tubular fluid

The amount of water filtered each day by the kidneys typically far exceeds the amount that needs to be excreted. The same can be said of Na^+ and Cl^- , which are the principal solutes in the blood plasma and therefore also in the filtrate: Na^+ and Cl^- enter the Bowman's capsules as briskly as water does, yet amphibians often need ultimately to conserve Na^+ and Cl^- to the maximum possible extent (see page 720). A high rate of filtration ensures that the nephrons have intimate access to the blood plasma to perform regulatory functions, as noted earlier. However, a high filtration rate also necessitates reabsorption of much of the water and NaCl filtered.

The reabsorption begins in the proximal convoluted tubule. Na^+ is actively reabsorbed across the walls of the proximal tubule. Cl^- may also be reabsorbed actively in some species, but in general its reabsorption is passive, induced by the electrical gradient set up by active Na^+ reabsorption. Although the quantities of Na^+ and Cl^- reabsorbed in the proximal tubule are substantial, the osmotic pressure of the tubular fluid does not fall in the proximal tubule. Instead, the tubular fluid—which is isosmotic to the blood plasma when introduced into the Bowman's capsule by ultrafiltration⁵—remains isosmotic to the plasma as it flows through the proximal tubule. Its osmotic pressure remains unchanged because as NaCl is reabsorbed, a proportional reabsorption of water from the tubular fluid occurs simultaneously. The epithelial walls of the proximal tubule are freely

permeable to water.⁶ Water therefore moves out of the tubular fluid by osmosis rapidly enough that the active reabsorption of NaCl does not produce a lower osmotic pressure in the tubular fluid than in the blood; the water is said to undergo near-isosmolar transport driven by the NaCl reabsorption. In those species of amphibians that have been studied, 20–40% of the filtered NaCl and water are reabsorbed in the proximal tubule. Even as these large *amounts* of NaCl and water are reabsorbed, the *concentrations* of ions and water in the tubular fluid—as shown in Figure 29.4—remain unaltered because ions and water are removed in proportion to each other (Box 29.1).

Another important process that takes place in the proximal tubule is the reabsorption of glucose. Glucose in the blood plasma is a valuable metabolite that—because of its small molecular size—cannot be withheld from the primary urine during ultrafiltration. However, in amphibians and other vertebrates, glucose is promptly reclaimed and returned to the blood. Glucose is reabsorbed into the cells of the proximal tubule (and then passed to the blood) by *secondary* active transport driven by the *primary* active transport of Na^+ —a mechanism similar to that diagrammed in Figure 5.12. Amino acids are also valuable organic molecules that are freely carried into the Bowman's capsules by ultrafiltration because of their small size. Their reabsorption begins in the proximal tubule. Box 29.2 discusses some

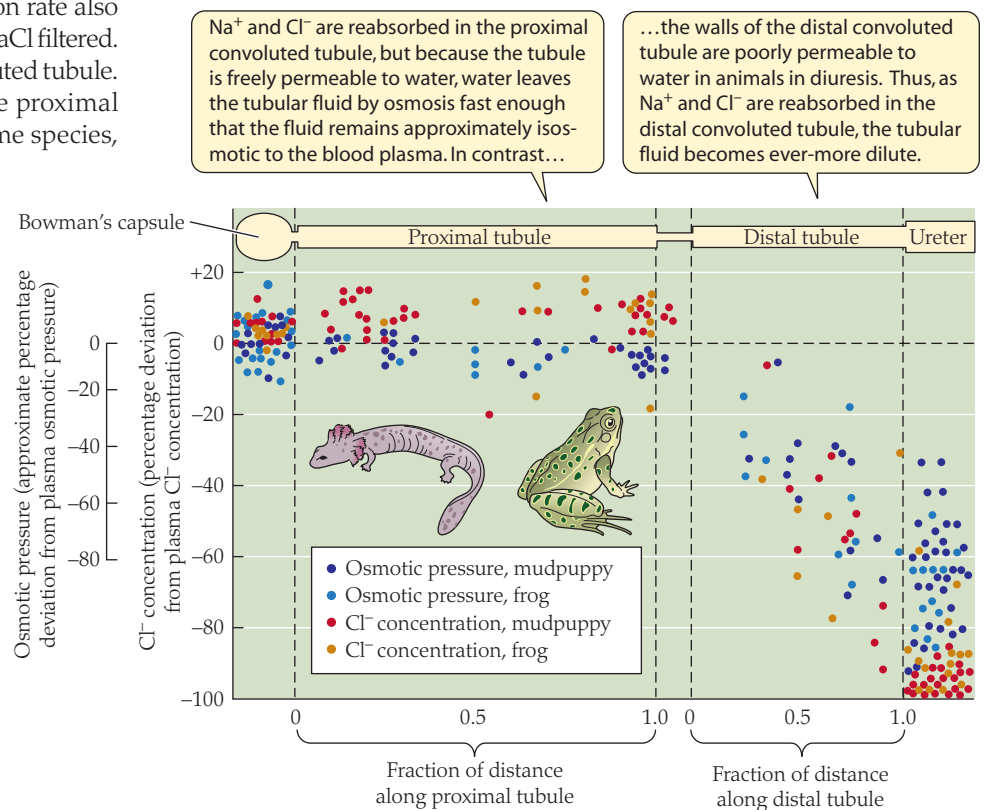

FIGURE 29.4 Urine formation in amphibians during diuresis The osmotic pressure and Cl^- concentration of urine as it flows through the nephrons of two species of amphibians—the semiterrestrial leopard frog (*Rana pipiens*) and the aquatic mudpuppy (*Necturus maculosus*)—when the animals are in diuresis. Fluid was sampled for analysis by use of minute pipettes inserted into the nephrons (see Box 29.2). Concentrations are expressed as percentage deviations from plasma concentrations; for example, a value of -40 indicates that the concentration in the tubular fluid was below the plasma concentration by an amount equal to 40% of the plasma concentration. (After Walker et al. 1937)

⁴The names of the nephron segments are not standardized. For example, the *collecting tubule* is sometimes called the *initial collecting duct*.

⁵The difference in osmotic pressure that actually exists between the filtrate and the blood plasma—the colloid osmotic pressure—is large enough to affect filtration, as discussed earlier (see Figure 29.1c). However, not only in amphibians but also in other vertebrates, the difference in osmotic pressure is less than 1% of the *absolute* osmotic pressure of either the filtrate or plasma. Thus for most purposes, the filtrate and the plasma can be considered isosmotic.

⁶This high permeability is presumably a consequence of abundant constitutive (i.e., chronically present) aquaporins in the cell membranes of the epithelial cells.

of the methods used to study kidney function: methods that have played important roles in creating the knowledge discussed here and throughout the chapter.

The distal convoluted tubule can differentially reabsorb water and solutes, thereby regulating the ratio of water to solutes in the body fluids

Active reabsorption of NaCl from the tubular fluid continues in the distal convoluted tubule. In this way, the quantity of NaCl destined for excretion from the body—that is, removal from the body fluids—is gradually lowered toward the level that is appropriate for maintenance of internal NaCl balance.

A major function of the distal convoluted tubule in many amphibians—a function that may be shared by the collecting ducts and urinary bladder—is control of the excretion of *pure* water, often termed **osmotically free water**. By controlling the excretion of free water, the distal tubule controls the amount of water in the body fluids. Recall from Chapter 28 (see page 750) that the water in urine may be considered to consist of two parts: (1) water that is *required* to accompany excreted solutes and (2) additional water that may be excreted but is not required for solute excretion. The second component may be considered to represent an excretion of pure, or “free,” water—a regulated removal of water from the body fluids—precisely because it is not required for solute excretion.

In amphibians, the amount of water that is *required* to be excreted with solutes is determined by the fact that the maximum possible osmotic U/P ratio is 1.0: The urine osmotic pressure cannot exceed

BOX 29.1 QUANTITY VERSUS CONCENTRATION

When analyzing kidney function, it is important to maintain a clear distinction between measures of *quantity* (or *mass*) and measures of *concentration*. The importance of this distinction is illustrated nicely by the events in the proximal tubule of amphibians. As shown in Figure 29.4, the *concentrations* of Na⁺, Cl⁻, and water in the tubular fluid remain, on average, unchanged. Yet, the *quantities* of these substances exiting the proximal tubule are much lower than those entering.

Measures of quantity and concentration are each informative, although in different ways. Quantity is an absolute measure, whereas concentration is a relative measure (quantity of solute relative to quantity of water). As a general principle, measures of *quantity* provide the most direct insight into questions of salt and water *balance*. For instance, to determine whether an animal is in Na⁺ balance, you would measure the quantity of Na⁺ gained per day and the quantity lost per day (including the quantity lost in urine) and compare them. Although urine *concentrations* are not directly useful for balance calculations, *concentrations* provide the most direct insight into the effects of urine production on blood composition. For instance—as explained in Figure 27.7—if you wanted to know whether the kidneys are lowering the Na⁺ concentration of the blood plasma, you would examine the urine Na⁺ concentration relative to the plasma Na⁺ concentration. Urine production is lowering the plasma Na⁺ concentration if the urine Na⁺ concentration is greater than the plasma Na⁺ concentration (meaning that Na⁺ U/P > 1.0).

BOX 29.2 METHODS OF STUDY OF KIDNEY FUNCTION: MICROPUNCTURE AND CLEARANCE

Some of the methods used to study kidney function, although technically difficult, are intuitively easy to understand. A technique of this sort that has revolutionized renal physiology is **micropuncture**. Fine micropipettes are inserted into individual nephrons at identified points, permitting samples of tubular fluid to be withdrawn for analysis of composition. Such samples from amphibian nephrons reveal, for example, that the glucose concentration falls virtually to zero by the end of the proximal convoluted tubule. This is how we know that the proximal tubule is the site of glucose reabsorption.

A method that is not so intuitively simple to understand—but important in both physiological research and medical practice—is the study of **renal clearance**. Clearance studies are used to measure the glomerular filtration rate and can be used to quantify the reabsorption or secretion of solutes in the renal tubules. **Box Extension 29.2** explains the principles and uses of renal clearance studies.

the plasma osmotic pressure.⁷ This means that *at least* enough water must be excreted with solutes in the urine to create a solution that is isosmotic to the blood plasma. If the urine osmotic pressure of an amphibian in fact equals the animal’s plasma osmotic pressure, the urine contains *only* water that is *required* for solute excretion. That is, the urine contains no water of the second kind: no pure, osmotically free water. However, if the urine osmotic pressure of an amphibian is less than the animal’s plasma osmotic pressure (osmotic U/P < 1), the urine carries an “extra” quantity of water, an amount not strictly required by solute excretion. This extra quantity represents an excretion of pure water—removal of water from the body fluids. This excretion of pure water can be varied: The more dilute the urine, the more free water it contains. Thus *an animal can control its excretion of water independently of its excretion of solutes by varying the osmotic pressure of its urine*.

The extent of pure-water excretion is controlled in the distal convoluted tubule by varying the degree to which osmotic water reabsorption keeps pace with solute reabsorption there. The extent of water reabsorption is controlled by modulating the permeability of the walls of the tubule to water. This control of permeability is exercised at least partly by **antidiuretic hormone (ADH)** secreted by the neurohypophysis (posterior pituitary gland).⁸ As we now explain these points, refer to **Figure 29.5** for a visual summary.

When ADH levels are low (see Figure 29.5a), the permeability of the wall of the distal convoluted tubule to water is low. Consequently, NaCl and water reabsorption from the tubular fluid are significantly uncoupled. The active reabsorption of NaCl tends to dilute the tubular fluid and thus create an osmotic gradient that favors water reabsorption by outward osmosis. However, the low permeability of the tubule wall to water impedes osmosis. This

⁷Recall from Chapter 27 that the osmotic U/P ratio is the ratio of urine osmotic pressure to plasma osmotic pressure.

⁸The antidiuretic hormone of amphibians, birds, and nonavian reptiles is *arginine vasotocin*; see Table 16.2 on page 429.

(a) Diuresis (low ADH)

(b) Antidiuresis (high ADH)

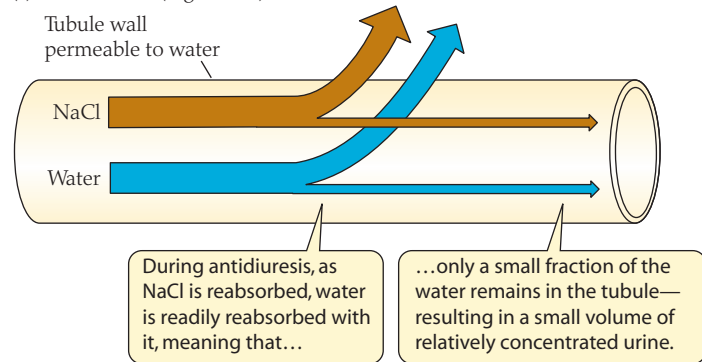

FIGURE 29.5 Major solute and water fluxes in the late distal convoluted tubule during diuresis and antidiuresis The pathways followed by NaCl and water are symbolized by the relative sizes of the arrows. (a) In diuresis, low permeability of the tubule walls to water impedes osmotic water reabsorption; thus a relatively large fraction of the water remains in the tubule, and the ratio of solute to water (the osmotic pressure) in the tubular fluid is dramatically reduced. (b) In antidiuresis, the tubule walls are more permeable to water; thus a larger fraction of the water is reabsorbed, and the ratio of solute to water in the tubular fluid is affected relatively little. This conceptual diagram is simplified in two ways: First, it assumes that NaCl and water reabsorption occur in the same parts of the tubule, and second, it ignores solutes other than NaCl (e.g., urea).

limitation of water reabsorption has three important and complementary consequences. First, relatively little water is returned to the body fluids. Second, NaCl reabsorption makes the tubular fluid more dilute than the blood plasma, both in osmotic pressure and in ion concentrations. This dilution is progressive: As fluid flows through the distal tubule, the fluid becomes ever-more dilute as ever-more ions are reabsorbed from it (see Figure 29.4). The active reabsorption of solutes from the urine across tubule walls that are poorly permeable to water is, in its fundamentals, the *universal mechanism by which animals make urine hyposmotic to the blood plasma*, and we see that mechanism in action here. The third principal consequence of low permeability to water in the amphibian distal convoluted tubule is that a high proportion of the water that enters the distal tubule passes through to be excreted in the urine. Considering the second and third consequences together, one can see that in the presence of low levels of ADH, the urine is *dilute* and *voluminous*. It carries away far more water than is necessary just to excrete solutes; thus it extracts relatively

large amounts of water from the body fluids and has a high content of pure, osmotically free water.

When ADH levels are high (see Figure 29.5b), the presence of ADH induces the wall of the late distal convoluted tubule (the half or so of the distal tubule closest to the collecting tubule) to become relatively permeable to water, and the distal tubule then functions more like the proximal tubule. Osmotic water reabsorption is promoted. Thus, as NaCl is reabsorbed, more water is reabsorbed than when ADH levels are low. Again, there are three complementary consequences. First, a relatively large amount of water is returned to the body fluids. Second, the tubular fluid stays more nearly isosmotic to the blood plasma than when ADH levels are low. Third, a smaller proportion of the water that enters the distal tubule passes through to be excreted. In the presence of high levels of ADH, therefore, the urine is relatively *concentrated* and *scanty*. It contains relatively small amounts of water extracted from the body fluids and carries away little or no pure, osmotically free water.

You can see now why ADH has the name it does. Recall from Chapter 28 that **diuresis** is production of abundant urine. High levels of ADH promote the opposite: **antidiuresis**.

ADH is believed to control the water permeability of the amphibian distal convoluted tubule by controlling the insertion and retrieval of aquaporin proteins (see page 774) in cell membranes in parts of the tubular epithelium. When the level of ADH is high, aquaporins are inserted into the cell membranes, and—with the water channels therefore in place in the cell membranes—water can pass through the epithelium relatively readily by osmosis. When the level of ADH is low, aquaporins are retrieved from the cell membranes (i.e., returned to intracellular locations where they are nonfunctional), and osmosis through the epithelium is impeded. More will be said of aquaporin function later in this chapter, when we discuss mammals.

Active H^+ secretion into the tubular fluid is an additional function that is known to occur in the distal convoluted tubule. The amount of H^+ added is adjusted to maintain a normal pH in the body fluids.

ADH exerts an elaborate pattern of control over nephron function

In amphibians—and also in birds, lizards, and other reptiles—ADH not only increases the permeability of parts of the distal convoluted tubule to water, but also decreases the glomerular filtration rate. Specifically, ADH reduces the GFR in these vertebrate groups by reducing the numbers of actively filtering nephrons, an effect mediated by inducing vasoconstriction in glomerular afferent blood vessels. The decrease in GFR tends to reduce urine flow and promote water retention in the body, thereby complementing the increase in water reabsorption induced by ADH in the distal tubules.

ADH has also been shown in some frogs and toads to increase the rate of active NaCl reabsorption from the renal tubules. This effect, like the others mentioned, also tends to reduce urine volume and promote water retention because it enhances solute-driven water reabsorption and decreases the solute load of the urine.

Clearly, ADH mediates a multifaceted *pattern* of control over nephron function. If an amphibian experiences excess water influx—as can occur during immersion in freshwater—secretion of ADH is reduced. Then the GFR is relatively high, distal-tubule reabsorption of water is relatively low, and a voluminous, dilute urine results. If dehydration sets in, ADH is secreted from the

neurohypophysis, apparently under the control of osmoreceptors (which detect an increase in body-fluid osmolarity) and of pressure or stretch receptors (which signal a decrease in blood volume). The ADH induces a reduction in GFR, an increase in distal-tubule water reabsorption, and an increase in NaCl reabsorption, thereby promoting water retention and production of a scanty, concentrated urine. The renal responses to ADH are not as well developed in some amphibian species from consistently moist or wet habitats as they are in species that are more terrestrial and thus more likely to experience dehydration (see pages 744–745).

The bladder functions in urine formation in amphibians

In many species of amphibians, the bladder not only stores urine but also plays a substantial role in adjusting the volume and composition of the urine. In these species, the function of the bladder can be described very much in the way we have described that of the distal convoluted tubules. The bladder wall is poorly permeable to water when ADH levels are low but becomes quite permeable to water when ADH levels are high; the participation of aquaporins in these changes of permeability in the amphibian bladder has been directly demonstrated. NaCl is actively reabsorbed across the bladder wall, and this reabsorption is stimulated by ADH.

The amphibian excretory system has mechanisms to promote excretion of urea

Urea is the principal compound used to excrete waste nitrogen in most adult amphibians. The nephrons, bladder, and other excretory passages of adults seem generally to be poorly permeable to urea; thus urea introduced into the tubular fluid tends to be retained in it and removed from the body by excretion. Filtration is one process by which urea enters the nephrons, and in many amphibians it is probably the sole process. However, in at least some ranid frogs (e.g., bullfrogs), urea is also actively secreted into the tubular fluid across the nephron walls. As water is reabsorbed from the tubular fluid, urea in the fluid tends to be concentrated.

SUMMARY Urine Formation in Amphibians

- A primary function of the proximal convoluted tubule of the amphibian nephron is the return of both water and solutes to the body fluids by the isosmotic reduction of urine volume. NaCl is actively reabsorbed from the tubular fluid. Because the epithelial wall of the proximal tubule is permeable to water, water exits the tubular fluid by osmosis, keeping the tubular fluid isosmotic to the blood plasma.
- Glucose and amino acids are actively reabsorbed from the tubular fluid in the proximal tubule, returning them to the body fluids.
- The distal convoluted tubule *differentially* returns water and solutes to the body fluids; in the process it determines the volume and osmotic concentration of the definitive urine produced by the kidney. An important mechanism by which control of distal tubule function is exercised is that the epithelial wall of the distal convoluted tubule can have high or low permeability to water, depending on blood levels of antidiuretic hormone (ADH) secreted by the neurohypophysis (posterior pituitary).

- When ADH levels are low, the distal tubule epithelium is poorly permeable to water. Active reabsorption of NaCl returns NaCl to the body fluids and dilutes the tubular fluid. However, relatively little water is returned to the body fluids because water cannot readily move out of the tubular fluid by osmosis. The volume of the tubular fluid remains high, and both the osmotic pressure and the NaCl concentration of the fluid become progressively lower as the tubular fluid flows through the tubule.
- When ADH levels are high, aquaporins are believed to be inserted into cell membranes in the distal tubule epithelium, causing the water permeability of the epithelium to become high. As active reabsorption of NaCl takes place, osmosis carries water out of the tubular fluid. Thus relatively high amounts of water are returned to the body fluids. The volume of the tubular fluid is reduced, and the fluid remains similar to the blood plasma in its osmotic pressure and NaCl concentration.

Urine Formation in Mammals

The nephrons of amphibians, as noted earlier, may reasonably be considered to represent the generalized vertebrate condition. The nephrons of lizards, snakes, turtles, and crocodilians resemble them. Mammalian nephrons differ, however. Compared with an amphibian nephron, each nephron of a mammal has an added, long segment of tubule, positioned between the proximal and distal convoluted tubules. This added segment is arranged in the shape of a hairpin loop and—having first been described by Jacob Henle in the 1860s—is called the **loop of Henle** (pronounced Hen-lee). An additional “innovative” feature of the mammalian kidney is that the loops of Henle of the various nephrons in a kidney, along with the collecting ducts, are arranged in parallel arrays, giving the kidney a pronounced macroscopic structure not seen in the kidneys of amphibians or reptiles. The loops of Henle and their parallel arrangement provide the anatomical basis for the production of urine that is more osmotically concentrated than blood plasma: *hyperosmotic urine*. Amphibians, lizards, snakes, turtles, and crocodilians—lacking these anatomical attributes—cannot produce hyperosmotic urine.

We saw in Chapter 28 that the ability of mammals to concentrate their urine is one of their most dramatic and important adaptations for life on land. Now, as we study the mammalian kidney, we will examine the mechanism by which their urine is concentrated. Mechanisms for producing urine that is hyperosmotic to the blood plasma might seem simple to evolve. The history of life offers a very different verdict, however. In the entire animal kingdom, only three major groups have mastered the task: mammals, birds, and insects. In each case, the ability to concentrate the urine has opened up new habitats and ways of life—such as by aiding certain small mammals, like the kangaroo rats described at the start of this chapter, to survive as seed eaters in deserts. Thus, as we examine the mammalian mechanism of concentrating urine, we focus on a physiological attribute of enormous ecological and evolutionary significance.

The nephrons, singly and collectively, give the mammalian kidney a distinctive structure

The loop of Henle in a mammalian nephron consists of two long and parallel tubes, termed *limbs*, connected by a hairpin bend: The **descending limb** leads from the proximal convoluted tubule to the

(a) Kidney in sagittal section

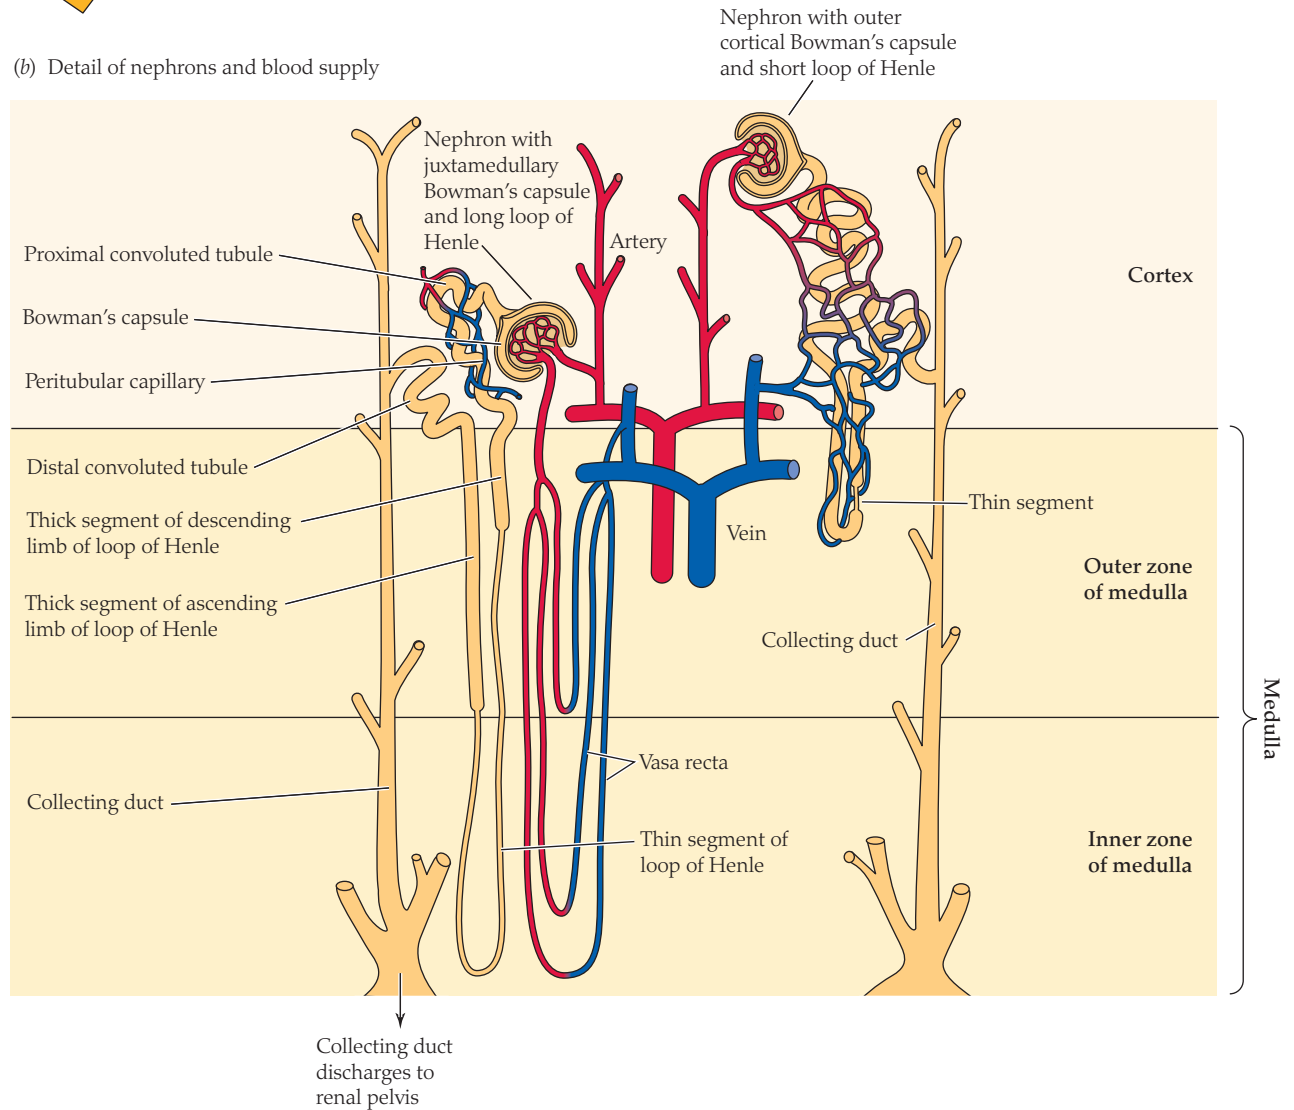

FIGURE 29.6 The human kidney, emphasizing the nephrons and their blood supply (a) A sketch of a kidney in sagittal section, showing the basic features of kidney structure. (b) A more detailed look at nephrons and their blood supply. The structures of the nephrons and vasculature seen in (b)—and the subdivision of the kidney into cortex and medulla—are similar in all mammals, although the gross shape of the kidney varies. (b after Smith 1951.)

(b) Detail of nephrons and blood supply

bend, and the **ascending limb** runs from the bend to the distal convoluted tubule (Figure 29.6b). The descending limb begins with a segment of relatively large diameter termed a **thick segment**, and the ascending limb terminates with a thick segment. Interposed between these thick segments, at various positions and for various lengths, is a segment of very small diameter, the **thin segment**. The epithelium of the thin segment differs cytologically from that of the intermediate segment discussed earlier and occurs only in mammals and birds. The loop of Henle varies considerably in length among species of mammals and among the nephrons within the kidneys of any one species.

As can be seen in Figure 29.6b, the Bowman's capsules and convoluted tubules of the nephrons in each kidney of a mammal are aggregated toward the outer surface of the kidney, whereas the loops of Henle and collecting ducts project inward, toward the

renal pelvis, a tubular structure that represents the expanded inner end of the ureter that drains the kidney (Figure 29.6a). Because of this highly ordered arrangement of the renal tubules, histologically distinct layers are evident in the gross structure of the kidney tissue. In sagittal section, the tissue of each kidney consists of an outer layer, the **cortex**, which surrounds an inner body of tissue, the **medulla** (see Figure 29.6a). The cortex (see Figure 29.6b) consists of Bowman's capsules, convoluted tubules, the beginnings of collecting ducts, and associated vasculature. The medulla consists of loops of Henle and collecting ducts, as well as their associated vasculature. Within the medulla, the loops of Henle and collecting ducts run in parallel to one another.

To get oriented to fluid-flow patterns in the mammalian kidney, let's now trace the path of fluid through a nephron, focusing on the nephron to the left in Figure 29.6b. After filtration into the Bow-

man's capsule, fluid moves first through the proximal convoluted tubule and then descends into the medulla in the loop of Henle. After rounding the bend of the loop, the fluid returns to the cortex, passes through the distal convoluted tubule, and leaves the nephron to enter a collecting duct. The fluid then again passes through the medulla, this time in the collecting duct. After the fluid is discharged from the collecting duct into the renal pelvis, it flows into the ureter and to the bladder to be excreted. A convention worthy of note is that when fluid flows from the cortex toward the medulla, it is said to move *deeper* into the kidney.

We have already mentioned that the various nephrons in the kidney of a species may have loops of Henle of different lengths. Nephrons differing in this regard are positioned differently within the kidney, a fact that contributes to gross kidney structure. As can be seen at the left side of Figure 29.6b, there is a region deep in the medulla—termed the **inner zone** of the medulla—that is defined by the fact that the only *loop* elements present are *thin* descending and ascending segments of *relatively long* loops of Henle. The surrounding, more superficial layer of the medulla is the **outer zone**. Loops of Henle that project into the inner zone are termed **long loops**. Loops that turn back within the outer zone of the medulla or within the cortex are called **short loops**. The thin segments of long and short loops of Henle differ cytologically. Bowman's capsules may be positioned near the outer cortical surface, at mid-depth in the cortex, or within the cortical tissue next to the medulla; the last location is termed the *juxtamedullary* ("near the medulla") position. As depicted in Figure 29.6b, nephrons with short loops tend to have their Bowman's capsules positioned toward the outer cortex, whereas those having long loops tend to have midcortical or juxtamedullary capsules. Laboratory rats have about 30,000 nephrons of all types combined in each kidney. Domestic dogs have about 400,000, and humans have 0.4–1.2 million.

A final morphological feature of importance is that the thick ascending segment of each nephron, near its outer (upper) end, passes immediately next to the Bowman's capsule of the very same nephron.⁹ At this point, the wall of the thick ascending segment is modified, forming a set of specialized cells, the **macula densa**. The macula densa and other associated cells form a structure called the **juxtaglomerular apparatus**.¹⁰ Specialized vascular endothelial cells in this apparatus are responsible for secreting the key hormone renin, which controls secretion of another hormone, aldosterone, which is a major controller of renal ion excretion (see page 441 and Figure 16.17).

Comparative anatomy points to a role for the loops of Henle in concentrating the urine

Even before the physiology of the loops of Henle began to be understood, morphological evidence strongly suggested that the loops are intimately involved in the production of urine that is hyperosmotic to the blood plasma. This evidence helped to center attention on the physiology of the loops.

One type of comparative morphological evidence comes from studies of certain species of mammals—characteristic of freshwater environments—that lack long loops of Henle and have only short

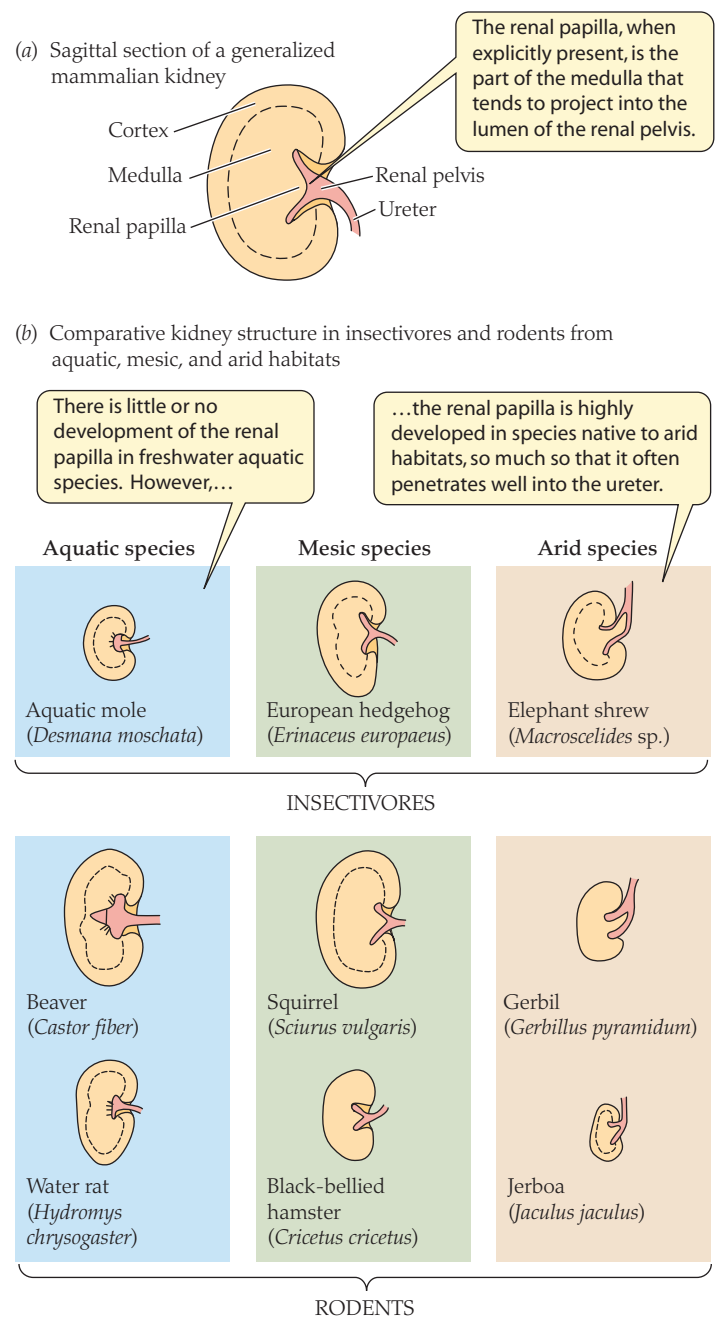

FIGURE 29.7 Evolutionary development of the renal papilla in mammals native to different habitats (a) Sagittal section of a generalized mammalian kidney, showing the location of the renal papilla. (b) Kidney structures of insectivores (e.g., shrews and moles) and rodents (e.g., rats and squirrels) from aquatic, mesic, and arid habitats. (After Sperber 1944.)

loops, so that they have no inner medulla. Hippos, mountain beavers (*Aplodontia*), and muskrats are examples. Such species are noted for having only meager abilities to concentrate their urine. Long loops are essential for achieving high urinary concentrations; in mammals that achieve high concentrations, at least 15–20% of the nephrons have long loops of Henle.

Another type of comparative morphological evidence comes from studies of the **renal papilla** (Figure 29.7a). Not all mammals have a grossly apparent renal papilla. Commonly, however, the

⁹Figure 29.6b is drawn to emphasize other features and does not show this.

¹⁰Be certain not to confuse the juxtamedullary capsules and the juxtaglomerular apparatus.

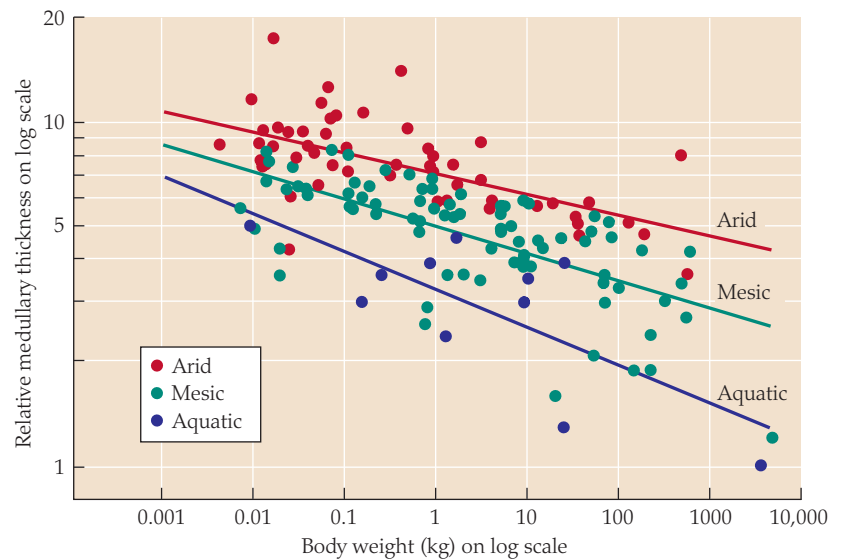

FIGURE 29.8 Maximum urine concentration correlates with the relative thickness of the medulla The relation is plotted for 68 species of mammals, each point representing a different species. The relative medullary thickness is a dimensionless number. To calculate it, an index of kidney size is first calculated by taking the cube root of the product of the three principal linear dimensions (length, width, and thickness) of the kidney. Medullary thickness is then expressed as a ratio of the index of kidney size to obtain relative medullary thickness. (After Beuchat 1990.)

renal medulla has a roughly pyramidal shape and forms a projection into the lumen of the renal pelvis. This projection, the renal papilla, is composed in major part of long loops of Henle. Thus the prominence of the renal papilla provides an indication of the number and length of long loops in a mammal's kidney. In 1944, Ivar Sperber (1914–2006) reported seminal observations on the papilla in about 140 species of mammals from diverse habitats. He found that the papilla was uniformly poorly developed in species inhabiting freshwater habitats. The papilla was more evident in species from mesic (moderately moist) habitats and was most developed in species from arid habitats (Figure 29.7b). Insofar as habitat may be taken as an indicator of demand for urinary concentration, Sperber's results indicated that there is a greater evolutionary development of the long loops of Henle in species that produce relatively concentrated urine.

Inspired by Sperber's work, comparative studies have since been conducted on **medullary thickness**. The thickness of the medulla provides a measure of the lengths of the longest loops of Henle. A problem that needs to be addressed in such comparative studies is that medullary thickness depends on the body size of mammals; humans, for example, have a

FIGURE 29.9 The relation between relative medullary thickness and body size depends on whether mammals are native to arid, mesic, or aquatic habitats Each point represents a different mammal species. The three lines are fitted statistically through the points for the arid, mesic, and freshwater aquatic species. The straight lines on this log–log plot indicate that the relations are allometric (see Appendix F). To interpret this plot, keep in mind that logarithmic scales tend to cause visual compression of data. The differences in relative medullary thickness among the arid, mesic, and aquatic mammals of a particular body size are substantial; for example, the medullary thickness of a representative 1-kg arid species is more than twice that of a 1-kg aquatic species. See the legend of Figure 29.8 for a description of how relative medullary thickness is calculated. (After Beuchat 1996.)

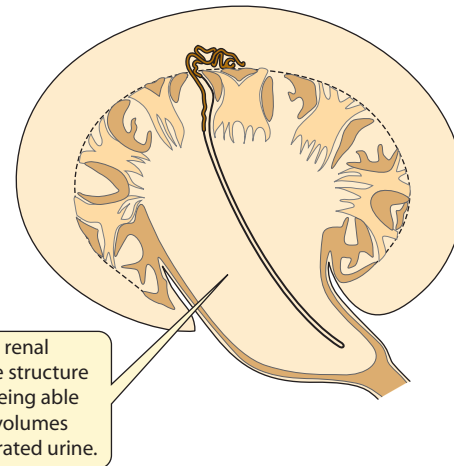

very thick medulla compared with all species of mice merely because humans are more than 1000 times larger than mice. To remove the effects of absolute kidney size, medullary thickness is expressed as a ratio of kidney size. This ratio is called **relative medullary thickness**. A high relative medullary thickness means that the longest loops of Henle are long relative to the overall dimensions of the kidney. By now, data are available on many species, and as Figure 29.8 shows, urinary concentrating ability is strongly correlated with relative medullary thickness: Species with high relative medullary thickness tend to be able to produce especially concentrated urine.

The latest incarnation of Sperber's work is shown in Figure 29.9, where relative medullary thickness is plotted as a function of body weight (size) for mammals from several types of habitats. This modern analysis reveals that the relative thickness of the medulla tends to decrease allometrically with body size (just as concentrating ability tends to decrease with body size, as seen in Figure 28.20). Habitat, however, is a significant factor. At any given body size, mammals from arid habitats tend to have the thickest medullas and longest loops of Henle, whereas those from freshwater aquatic habitats have the thinnest and shortest, and those from intermediate mesic habitats are in between.

A dramatic morphological comparison of the kidneys of three species of rodents of roughly similar body size is seen in Figure 29.10. Two of the species, the Mongolian gerbil and sand rat, evolved in deserts. Both have far more-prominent renal papillae (singular *papilla*) and thicker medullas than the laboratory rat (see Figure 29.10a–c). Moreover, the sand rat has a thicker, longer papilla than the gerbil. Detailed studies of the sand rat reveal that its renal medulla is particularly elaborately organized; in comparison with most mammals, an especially high proportion of the long loops of Henle in the sand rat extend far into the papilla (see Figure 29.10d), rather than turning back only a fraction of the way toward the tip. The sand rat, when living in its natural habitat, experiences far higher dietary salt loads than the gerbil because it subsists largely on succulent plants of very high salt content (see page 710), whereas the gerbil is a seed eater. The sand rat can produce a slightly more-concentrated urine than the gerbil (6300 mOsm versus 5000 mOsm, respectively). What is more striking, however, is that the sand rat produces far greater volumes of highly concentrated urine than the gerbil. The longer, thicker papilla

in the sand rat kidney correlates with the species' ability to produce an abundance of concentrated urine.

Countercurrent multiplication is the key to producing concentrated urine

When renal physiologists finally figured out how mammals make urine hyperosmotic to their blood plasma, they were guided to the loops of Henle by Sperber's studies of comparative kidney morphology. We will soon return to the loops, but first we need to distinguish *urea* and *nonurea solutes* and discuss the immediate concentrating process for the latter. The nonurea solutes are simply the solutes other than urea. They consist mostly of inorganic ions such as Na^+ , K^+ , Cl^- , and SO_4^{2-} . An important operational parameter is the osmotically effective concentration of all the nonurea solutes taken together, termed the **total concentration of nonurea solutes**.

THE IMMEDIATE CONCENTRATING PROCESS FOR NONUREA SOLUTES

The immediate concentrating process for the nonurea

solute is the removal of water from the urine as it flows through the collecting ducts to leave the kidney. Recall that on its way out of the kidney, urine is discharged from the nephrons into the collecting ducts, and then flows down the collecting ducts—passing first through the renal cortex and then the medulla—prior to being discharged into the renal pelvis and ureter (see Figure 29.6b). At the point where urine enters the collecting ducts, the total concentration of nonurea solutes in the urine is *lower* than that in the blood plasma. However, when a mammal is in a state of antidiuresis, as the urine passes in the collecting ducts through deeper and deeper layers of the medulla, its total concentration of nonurea solutes is progressively elevated: The urine ultimately reaches a concentration of nonurea solutes far above the plasma concentration. The immediate mechanism that concentrates the nonurea solutes during this process is movement of water out of the urinary fluid by osmosis. Nonurea solutes are largely trapped within the collecting ducts because the collecting-duct walls are poorly permeable to such solutes. Thus, as water passes by osmosis out of the urine, the nonurea solutes in the urine become more concentrated. Why does water undergo osmosis out of the urine? The fluids that *surround* the collecting ducts in the medulla, known as the **medullary interstitial fluids**, have a high NaCl concentration. In fact, their NaCl concentration rises steadily with increasing depth in the medulla,

so that in the deepest parts of the medulla the osmotic pressure attributable to NaCl is *far* above plasma osmotic pressure. During antidiuresis, the cells of the collecting-duct walls are freely permeable to water. As urine inside the collecting ducts flows deeper into the medulla and encounters ever-more-concentrated medullary interstitial fluids just on the other side of the collecting-duct epithelium, water progressively moves by osmosis out of the urine into the medullary interstitial fluids.

An important attribute of these processes is that a *high NaCl concentration on the outside of the collecting ducts serves to concentrate not only NaCl, but also many other nonurea solutes, on the inside*. This happens because the solutes involved cannot readily cross the walls of the collecting ducts, yet the cells in the duct walls (the duct epithelium) are freely permeable to water. Because of this difference between permeability to solutes and to water, when high interstitial NaCl concentrations are encountered deep in the medulla, the primary process of equilibration between the urine and the medullary interstitial fluid is osmosis. As this osmosis occurs, nonurea solutes in the urine are concentrated *indiscriminately* until their total osmotically effective concentration matches the total osmotically effective concentration of NaCl in the medullary interstitial fluids.

A SINGLE EFFECT BASED ON ACTIVE NaCl TRANSPORT Now we must consider how the gradient of NaCl concentration in the medullary interstitial fluids is created. The loops of Henle are responsible. The first step in understanding how the loops of Henle produce the NaCl gradient is to study a phenomenon, termed the *single effect*, that is well documented in the outer zone of the medulla, where the thick segments of the ascending limbs of the loops of Henle occur.

The cells in the walls of the ascending thick segment of a loop of Henle actively transport NaCl from the tubular fluid inside the loop into the adjacent medullary interstitial fluid. The *consequences* of this NaCl transport, illustrated in **Figure 29.11**, depend on the permeability characteristics of the ascending limb and the adjacent descending limb of the loop of Henle. The walls of the ascending limb are essentially impermeable to water. Thus the active transport of NaCl out of the tubular fluid inside the ascending limb creates a difference in osmotic pressure between that fluid and the adjacent interstitial fluid, in addition to decreasing the NaCl concentration of the fluid inside the ascending limb and increasing the NaCl concentration of the interstitial fluid. The permeability characteristics of the descending limb appear to vary from species to species. Nonetheless, by passive processes of one sort or another, the fluid inside the descending limb readily approaches equilibrium with the interstitial fluid in terms of osmotic pressure and ion concentrations.

In a few words, the active transport of NaCl out of the ascending limb lowers the NaCl concentration and osmotic pressure of the ascending-limb fluid and raises the NaCl concentration and osmotic pressure of both the adjacent interstitial fluid and adjacent descending-limb fluid. These differences between the ascending-limb fluid and the *adjacent* interstitial and descending-limb fluid represent the **single effect** of the active-transport mechanism.

COUNTERCURRENT MULTIPLICATION The major hurdle in understanding how mammals produce concentrated urine was crossed in the 1940s and 1950s when Werner Kuhn (1899–1968), Heinrich

FIGURE 29.11 Generation of the single effect in the loop of Henle
