

ANIMAL THIRD EDITION PHYSIOLOGY

HILL • WYSE • ANDERSON

Themes in the Study of Animal Physiology

Listed are 15 overarching themes that reappear throughout the study of animal physiology. Some of the listed themes overlap with, or even encompass, others; they are not intended to be mutually exclusive or, in all cases, equivalent

in importance. To help explain each theme, an illustrative example is presented in the second column of the table. Further examples are on the pages listed in the third column (italic listing elaborates the featured example).

Theme	An Example of the Theme in Action	See Pages
<p>The Study of Function: Animal physiology is the study of how animals function. That is, it is the study of how their cells and organs operate.</p>	When physiologists study muscle, one of their goals is to understand how the proteins in muscle cells are able to develop mechanical forces, which are employed in locomotion, heart contraction, or other activities.	114 (Fig. 5.12) 527 (Fig. 20.5) 606 (Fig. 23.22) 687 (Fig. 26.9)
<p>Integration of the Sciences: Physiologists often find that they must integrate knowledge of mathematics, chemistry, or physics with knowledge of biology to answer important questions. Physiology is one of the most integrative branches of biology.</p>	To understand how animals employ odors to orient their movements, physiologists study the <i>chemical</i> structural differences between molecules that attract or repel, and they <i>mathematically</i> describe the <i>physics</i> of how winds or water currents transport odor molecules from odor sources to the olfactory organs of animals.	6 (Fig. 1.2) 60 (Fig. 2.28) 165 (Fig. 7.3) 377 650 (Fig. 25.2)
<p>Emphasis on Quantitative Methods: Physiologists <i>quantify</i> the properties of animals as carefully as possible as they seek to test hypotheses or make predictions.</p>	Starting in ancient Roman times, people thought that the dromedary camel could carry enough water in its rumen to explain its unusual ability to live without drinking. When physiologists <i>quantified</i> the amount of water in the camel rumen rather than just speaking qualitatively about it, however, they found that there was not nearly enough water in the rumen for the old idea to make sense. Negating the old idea helped lead to understanding that camels do not store water to a greater degree than other mammals. Instead, they have excellent abilities to conserve water and endure dehydration.	209 (Box 9.1) 212 (Fig. 9.7) 234–235 (Fig. 10.8) 799–800
<p>The Tandem Goal of Understanding Mechanism and Adaptation: When physiologists study a process, they typically emphasize a two-part goal: They try to understand both the <i>mechanism involved</i> (i.e., how the process is executed) and the <i>potential adaptive significance</i> of the process (i.e., how, if at all, it enhances evolutionary fitness).</p>	A number of animals, including fireflies and certain fish, produce light. When physiologists study light production in such animals, they try to learn both <i>how</i> the animals make light and <i>why</i> they make it.	5–9 248–249 (Fig. 10.26) 455–456 735 (Fig. 28.12) 760 (Fig. 29.5)
<p>The Comparative Method: To understand the adaptive significance of animal features, physiologists make extensive use of the <i>comparative method</i>, which is the examination of how particular functions are carried out by related and unrelated species living in similar and dissimilar environments.</p>	When physiologists compare animals as distantly related as mammals and insects, they find that desert species tend consistently to have great abilities to concentrate their urine. Desert species of mammals are typically able to make urine of higher concentration than nondesert mammals, and desert insects are similarly superior to nondesert insects. These comparative observations provide evidence that the ability to make concentrated urine is an advantage—favored by natural selection—in deserts.	26 (Fig. 1.18) 114 (Fig. 5.13) 675 (Box 25.3) 688 (Box 26.1) 743 (Fig. 28.20)
<p>Phylogenetic Reconstruction: To understand the evolution of physiological properties—and thus gain perspective on the evolutionary significance of modern-day properties—physiologists employ <i>phylogenetic reconstructions</i>, in which genetic or other information on multiple species is used to reconstruct the paths of evolution.</p>	Although body temperature is the same as water temperature in most species of fish, regardless of how big they are, certain species of fish maintain elevated temperatures in some of their tissues. From phylogenetic reconstructions, physiologists have found that the warm-tissue condition evolved on at least four independent occasions. We know, therefore, that today's fish with warm tissues do not all simply inherit the condition from a single common ancestor.	27 53 (Fig. 2.21) 71 (Fig. 3.5) 270 (Fig. 10.47) 732 (Box 28.4)
<p>The Centrality of the Environment: The specific environments in which animals have evolved and live must be considered for the functional properties of the animals to make sense.</p>	Many specialists in high-altitude physiology argue that when lowland people travel to high altitudes, some of their typical responses are more harmful than helpful. These specialists emphasize that the human species did not evolve in high-altitude environments. Accordingly, there is no reason to <i>presume</i> that all the human responses to such environments would be beneficial.	53 (Fig. 2.22) 67 264 (Fig. 10.41) 639 (Box 24.5)
<p>Body Size: The physiological properties of related animal species typically scale in mathematically consistent ways with their body sizes. These relations are often nonproportional and thus termed <i>allometric</i>.</p>	The metabolic rate per gram of body weight is usually higher in small-bodied species than in related large-bodied ones. Because of this relation, whenever two species of mammals of different body sizes—like mice and horses—are compared, the smaller species typically needs more food per gram of body weight than the larger one.	17 (Fig. 1.9) 173 (Fig. 7.6) 285 (Fig. 11.9) 741 (Fig. 28.18)

Theme	An Example of the Theme in Action	See Pages
<p>The Dynamic State of Body Constituents: Great quantities of many of the key constituents of the body are added and subtracted every day in many animals under many conditions. Thus the constituents of the body—far from being static—are continuously in a dynamic state of flux. This is true even though additions and subtractions are often relatively balanced, resulting in relatively constant concentrations (a phenomenon termed <i>homeostasis</i>).</p>	<p>Averaged over the course of an ordinary 24-h day, an adult person is likely to process more than 2 kg of adenosine triphosphate (ATP) each hour, synthesizing that amount of ATP from adenosine diphosphate (ADP) and, with only a short delay, breaking it back down to ADP. To synthesize the ATP, the person—during each hour—will use about 20 liters of oxygen (O₂) that he or she takes up from the atmosphere. During a 24-h day, the oxygen used will combine with almost 100 g (a fifth of a pound) of hydrogen atoms that have been removed from food molecules, forming about 800 milliliters of water. This water is added to the body fluids.</p>	<p>11–12 183–184 378 699 743–744 (Fig. 28.21)</p>
<p>Multiple Forms of Key Molecules: Animals have often evolved multiple molecular forms (sometimes called <i>isoforms</i>) of particular proteins or other sorts of molecules. Physiologists hypothesize that when two species or two tissues exhibit different molecular forms of a molecule, the forms are often specialized to function in the specific settings in which the animals live or the tissues function.</p>	<p>The cell membranes of all animals are composed principally of lipid molecules. Physiologists have found, however, that the membranes of all animals are not composed of chemically identical lipid molecules. Instead, multiple molecular forms of lipids are employed by different animals living under different circumstances. Cold-water fish species, for instance, construct their cell membranes using molecular forms of lipids that are less likely to harden at low temperatures than the molecular forms synthesized by warm-water species.</p>	<p>34 (Fig. 2.3) 242–243 (Fig. 10.19) 537 620 (Fig. 24.2) 640 (Fig. 24.20)</p>
<p>Phenotypic Plasticity: An individual animal is often able to change its phenotype in response to changes in the particular circumstances under which it is living (e.g., its particular environment). This ability of an individual animal to adopt two or more phenotypes despite having a fixed genotype is termed <i>phenotypic plasticity</i>.</p>	<p>Animals that eat only occasionally, such as pythons, often alternate between two intestinal phenotypes. When they have not had a meal for weeks, their intestinal tract is physically small, and it has poorly developed molecular mechanisms for absorbing food. After a meal, the tissues of the intestinal tract enlarge greatly, and the intestinal tract expresses well-developed absorption mechanisms.</p>	<p>15 (Fig. 1.5) 79 (Table 3.1) 90–92 157 (Box 6.2) 264 (Fig. 10.40) 555 (Fig. 21.7)</p>
<p>Interdependency of Function and Form: The <i>function</i> of a biological system typically cannot be understood without knowledge of its <i>structure</i>, and vice versa.</p>	<p>The kidney tubules of mammals not only produce the most concentrated urine observed in vertebrates but also differ from other vertebrate kidney tubules in that they all have distinctive hairpin shapes. Physiologists have shown that the <i>functional</i> ability to produce highly concentrated urine depends on the hairpin <i>structure</i>, which guides the urine (as it is being formed) to flow first in one direction and then in the opposite direction.</p>	<p>140 (Fig. 6.13) 259 (Fig. 10.35) 370 (Fig. 14.10) 649 (Fig. 25.1) 768 (Fig. 29.12)</p>
<p>Applicability of the Laws of Chemistry and Physics: Animals must adhere to the laws of chemistry and physics. Sometimes chemistry and physics act as constraints, but sometimes animals gain advantages by evolving systems that capitalize on particular chemical or physical principles.</p>	<p>Heat transfer through air follows different physical laws when the air is still rather than moving; heat tends to move much more slowly through still air than moving air. Animals cannot change such laws of physics. They sometimes can affect which law applies to them, however, as when the ancestors of mammals evolved fur. The hairs of a furred mammal keep the layer of air next to the body relatively motionless. Heat transfer through that air is therefore slow, helping mammals retain internal heat when living in cold environments.</p>	<p>230 493 (Fig. 18.8) 576 (Box 22.2) 694–695</p>
<p>The Interdependency of Levels of Organization: An animal's <i>overall</i> functional properties depend on how its <i>tissues</i> and <i>organs</i> function, and the function of its tissues and organs depends on how its <i>cells</i> and <i>molecular systems</i> function. All these levels of organization are interdependent. An important corollary is that properties at one level of organization often cannot be fully understood without exploring other levels of organization.</p>	<p>When your physician strikes a tendon near your knee with a mallet, your leg straightens. For this response, electrical signals must travel along nerve cells to the spinal cord and back. The rate of travel depends in part on the <i>molecular</i> properties of ion-transporting proteins in the cell membranes of the nerve cells. It also depends in part on key <i>cellular</i> properties, such as the spacing between the sections of each nerve cell membrane that are fully exposed to the fluids bathing the cell. Molecular and cellular properties of these sorts determine the <i>overall</i> properties of the process. For instance, they determine the length of time that passes between the moment the mallet strikes and the moment your leg muscles contract.</p>	<p>6 (Fig. 1.2) 116 (Box 5.2) 199 (Fig. 8.12) 306–307 508 (Fig. 19.4)</p>
<p>The Crucial Importance of Control Mechanisms: In addition to mechanisms for reproducing, breathing, moving, and carrying out other overt functions, animals require <i>control</i> mechanisms that orchestrate the other mechanisms. The control mechanisms—so diverse that they include controls of gene expression as well as those exerted by the nervous and endocrine systems—determine the relations between inputs and outputs in physiological systems. They thereby crucially affect the functional properties of animals.</p>	<p>Although sheep and reindeer are born at cold times of year, newborns receive no heat from their parents and must keep warm on their own or die. They possess a process for rapid heat production. Proper control of this process requires that it be activated at birth, but not before birth when it would tend needlessly to exhaust fetal energy supplies. The control mechanism has two key properties: It activates heat production when neural thermal sensors detect cold, but its capacity to activate heat production is turned off by chemical factors secreted by the placenta. The control mechanism remains in a turned-off state until a newborn is separated from the placenta at birth. The cold environment is then able to stimulate rapid heat production.</p>	<p>50 (Fig. 2.19) 252 (Box 10.2) 283 (Fig. 11.8) 480 (Fig. 17.15)</p>

ANIMAL PHYSIOLOGY

THIRD EDITION

Richard W. Hill

Smith College

Sinauer Associates, Inc. Publishers • Sunderland, Massachusetts

About the Cover

One of the central themes of this book is the intimate relationship between animals and their environments. The gemsbok oryx (*Oryx gazella*) provides an iconic example. Gemsboks succeed in one of Earth's most demanding settings—the hot, dry deserts of Africa—because of their evolution of a variety of specialized behavioral, morphological, and physiological attributes. Among the truly wild large mammals, the three species of oryxes that are scientifically well known probably represent the pinnacle of evolution in their ability to survive in such deserts. Oryxes are discussed in depth in Chapter 30.

Preface

Thomas Kuhn wrote that a textbook is principally a means of communicating to students the paradigms of their time. We have had three principal goals in preparing the content of this book. One, in accord with Kuhn's dictum, has been to articulate the central paradigms of contemporary animal physiology. A second content goal has been to provide our readers with a source of both lucid explanations of physiological concepts and accurate information about physiological systems. Our third content goal has been to draw attention to the cutting edges of physiological science, the places where the onward progress of research is challenging old paradigms and potentially creating footholds for new ones.

We have also had goals for presentation. Most visibly, we have combined our words with an ambitious, informative art program. More fundamentally, we have strived to take advantage of all the assets of traditional bookmaking to achieve a book that—through constant integration of the full suite of pedagogically relevant elements—is a first-rate learning tool. Many sorts of professionals have important contributions to make for a book to be excellent. Thus many sorts of professionals have traditionally found personal fulfillment by engaging in the cooperative, synergistic production of books. The authors listed on the cover are just the tip of the iceberg. A book's art program depends on scientific illustrators. Coordination between the art and the text—a key to the success of any textbook—depends on the editorial expertise of the book's editor. An attractive science text needs to be designed and physically executed by talented people who combine scientific acumen with artistic sensibility. To the degree that the presentation of the material in this book achieves success, the reason is that it is the creative product of a team of at least a dozen people playing diverse, mutually reinforcing roles. One of our goals has been to take advantage of this time-proven model to provide students with a superior text.

In these pages, we consistently and deliberately address animal physiology as a discipline integrated with other disciplines in biology—especially genetics, molecular biology, evolutionary biology, and ecology. We also consistently emphasize the roles of physiology throughout the life cycle of an animal by discussing physiological development and by examining animal function during such important life-cycle processes as exercise, long-distance migration, seasonal rhythms, and accommodation to severe conditions (we generally omit pathology and parasitism, however). Although we give particular attention to mammals, we make a point of recognizing the other vertebrate groups and at least the arthropods and molluscs among invertebrates. We address all levels of organization that are germane, from the genome to the ecological context.

We want to mention four specific strategies we have adopted to add interest and breadth to the book. First, we start every chapter with a vivid example of the application of the chapter's material to

the lives of animals in their natural habitats. Second, we devote five entire chapters (our "At Work" chapters) to in-depth explorations of how physiologists do their work; in these chapters we break out of the usual textbook mold to discuss exciting topics—such as the diving physiology of marine mammals—with emphasis on experiments, theory maturation, integration of physiological systems, and prospects for future research. Third, we include many photographs and drawings of animals throughout the book to remind readers of the animals we discuss. Fourth, entirely new to this edition, we have started a program of inviting specialists to contribute expert Guest Boxes on emerging topics that expand the book's subject content.

With our aspirations being as numerous as we have described, we have put a great deal of effort into balancing competing demands for space. The product is a complete physiology textbook that in one volume will meet the requirements of a diversity of one- or two-semester courses in animal function. Our intended audience is sophomores through beginning graduate students. To make the book accessible to as wide an audience as possible, we have included both a glossary of nearly 1200 terms and 11 appendices on important background concepts.

Our approach to the writing has been to work from the original scientific literature and obtain extensive peer review. Another aspect of our approach is that we have opted for the pedagogical consistency of a book written by just three principal authors. Margaret Anderson wrote Chapters 16, 20, and 21, and Gordon Wyse wrote Chapters 12–15, 18, and 19. Richard Hill wrote Chapters 1–11, 17, and 22–30. David S. Garbe, Scott A. Huettel, Matthew S. Kayser, Kenneth J. Lohmann, and Margaret McFall-Ngai wrote Guest Boxes. Matthew S. Kayser and Gordon Fain assisted with topic development in certain parts of the principal text.

NEW TO THIS EDITION: As in other editions, our two central goals for this edition were to update content and enhance pedagogical effectiveness. To these ends, we have reconsidered every sentence and every element of the art program. Of the 690 figures and tables in this edition, over 60 are either new or greatly enhanced. Chapter 14, on sensory processes, has been entirely rewritten. We have also added a new chapter (Chapter 4) on physiological development and epigenetics. Other chapters that have received exceptional attention are: Chapter 5 (transport of solutes and water), Chapter 8 (aerobic and anaerobic metabolism), Chapter 9 (activity energetics), and Chapter 29 (kidney physiology, edited throughout to emphasize plasma regulation). The book now includes Guest Boxes on functional magnetic resonance imaging, magnetoreception, optogenetics, sleep, symbiosis in the bobtail squid-*Vibrio* system, and synaptic development. Treatment of topics in global warming has been tripled. Treatment of altitude physiology in Chapters 23 and 24 is entirely revised. The index is new and upgraded. A limited list of

the many topics that have been added or substantially upgraded includes: aquaporins, basal ganglia function, bioluminescence, breathing in crocodilians, chemiosmosis, calcium metabolism, color change, daily rhythms in transcription, efficiency of ATP synthesis in oxidative phosphorylation, endothermy in plants, evolution of nervous systems, function of P-type ATPases, the gut microbiome, hibernation, hippocampal specialization in place learning, ion-transport proteins in fish, kisspeptin neurons, metabolic scaling, neurotransmitter release mechanisms, photoperiodic control, reactive oxygen species, smooth muscle, thermal performance curves, and voltage-gated channels.

The book is organized in modular fashion with the express purpose of providing instructors and students with flexibility in choosing the order in which they move through the book. The first of the six parts (modules) consists of Chapters 1 to 5, which are background chapters for the book as a whole. Most instructors will want to assign those chapters at the beginning of the course of study (or, when students have exceptional preparation, skip the chapters in part or in whole). Each of the subsequent five parts of the book is written to be free-standing and self-contained, so that students who have mastered the material in Part I will be well prepared to work through any of the other five parts. Two of the final five parts begin with explicitly introductory chapters that present fundamentals. All five of these parts end with “At Work” chapters. Within a part, although chapters will probably be best read in order, most chapters are themselves written to be relatively self-contained, meaning that the order of reading chapters within a part is flexible. Three additional features promote flexibility in the order of reading: the glossary, the new index, and page cross-references. Text is cross-referenced both forward and backward, so that instructors and students can link material across chapters.

We have tried to keep animals front and center. At the end of our production, as the orchestra goes silent and the klieg lights dim, we hope that animals leading their lives in their natural habitats will be the enduring image and memory left by this work—animals now better understood, but still with much to attract the curiosity of upcoming generations of biologists.

Our peer reviewers are particularly important to the quality of the book, even though at times—accepting full responsibility for the product—we have followed our own inclinations rather than theirs. We are thus happy to acknowledge our current peer reviewers as well as individuals who acted as reviewers for earlier editions and whose influence remains clearly evident: Doris Audet, Brian Bagatto, Jason Blank, Charles E. Booth, Eldon Braun, Warren Burggren, Heather Caldwell, Jeffrey C. Carrier, Sheldon Cooper, Daniel Costa, Emma Creaser, David Crews, Stephanie Gardner, Stephen Gehnrich, Joseph Goy, Bernd Heinrich, Raymond Henry, James Hicks, Carl S. Hoegler, Richard Hoffman, Mark A. Holbrook, Jason

Irwin, Steven H. Jury, William Karasov, Fred J. Karsch, Leonard Kirschner, Sharon Lynn, Megan M. Mahoney, Robert Malchow, Duane McPherson, Ulrike Muller, Barbara Musolf, Randy Nelson, Gilbert Pitts, Fernando Quintana, Matthew Rand, Susan Safford, Malcolm Shick, Bruce Sidell, Mark Slivkoff, Paul Small, George Somero, Frank van Breukelen, Itzick Vatnick, Curtis Walker, Zachary Weil, Alexander Werth, and Eric Widmaier.

Another group to whom we offer special thanks are the many scientists who have provided us with photographs, drawings, or unpublished data for direct inclusion in this book: Jonathan Ashmore, William J. Baker, Lise Bankir, Jody M. Beers, Rudolf Billeter-Clark, Walter Bollenbacher, Richard T. Briggs, Klaus Bron, Marco Brugnoli, Jay Burnett, Christina Cheng, Daniel Costa, Matthew Dalva, Hans-Ranier Duncker, Aaron M. Florn, Jamie Foster, Peter Gillespie, Greg Goss, Bernd Heinrich, Dave Hinds, Michael Hlastala, Hans Hoppeler, José Jalife, Kjell Johansen, Toyoji Kaneko, Matthew S. Kayser, Mary B. Kennedy, Andor Kiss, Daniel Luchtel, David Mayntz, Margaret McFall-Ngai, Nathan Miller, Eric Montie, Michael Moore, Mikko Nikinmaa, Sami Noujaim, Dan Otte, Thomas Pannabecker, R. J. Paul, Steve Perry, Bob Robbins, Ralph Russell, Jr., Josh Sanes, Klaus Schulten, Stylianos Scordilis, Bruce Sidell, Helén Nilsson Sköld, Jake Socha, Kenneth Storey, Karel Svoboda, Emad Tajkhorshid, Irene Tieleman, Christian Tipsmark, Shinichi Tokishita, Walter S. Tyler, Tom Valente, Tobias Wang, Rüdiger Wehner, Ewald Weibel, Judith Wopereis, Eva Ziegelhoffer, and the Zoological Society of London.

Thanks are due too for encouragement, feedback, and other help with writing that we have gratefully received from Richard T. Briggs, Michael Cook, John Dacey, Giles Duffield, Aaron M. Florn, Fritz Geiser, Loren Hayes, Gerhard Heldmaier, Richard L. Marsh, Steve Perry, George Somero, Mark Vermeij, Tobias Wang, and Joseph Williams.

Of course, no book of this scope emerges fully formed in a single edition. Thus, we also thank the following who played important roles in earlier versions of this work: Simon Alford, Kellar Autumn, Robert Barlow, Al Bennett, Eric Bittman, Jeff Blaustein, Batrice Boily, Beth Brainerd, Richard C. Brusca, Gary Burness, Bruce Byers, John Cameron, Donald Christian, Barbara Christie-Pope, Corey Cleland, Randal Cohen, Joseph Crivello, Peter Daniel, Bill Dawson, Gregory Demas, Linda Farmer, Jane Feng, Milton Fingerman, Dale Forsyth, Christopher Gillen, Kathleen Gilmour, Judy Goodenough, Edward Griff, Jacob Gunn, James Harding, Jean Hardwick, John Harley, Ian Henderson, David Hillis, Kay Holekamp, Charles Holliday, Henry John-Alder, Kelly Johnson, Alexander Kaiser, Reuben Kaufman, M. A. Q. Khan, William Kier, Peter King, Rosemary Knapp, Heather Koopman, Richard Lee, John Lepri, Robert Linsenmeier, Stephen Loomis, William Lutterschmidt, Steffen Madsen, Don Maynard, Grant McClelland, Kip McGilliard, Stephen McMann,

Allen Mensinger, Tim Moerland, Thomas Moon, Thomas Moylan, Richard Nyhof, David O'Drobinak, Linda Ogren, Sanford Ostroy, Christine Oswald, Linda Peck, Sandra Petersen, Chuck Peterson, Richard Petriello, Nathan Pfost, Robert Rawding, Heinrich Reichert, Larry Renfro, David Richard, R. M. Robertson, Robert Roer, William Seddon, Brent Sinclair, Laura Smale, Amanda Southwood, Tony Stea, Philip Stephens, Georg Striedter, Rebekah Thomas, Heather Thompson, Irene Tieleman, Lars Tomanek, Terry Trier, Kay Ueno, Joshua Urio, Mark Wales, Winsor Watson, Leonard E. White, Susan Whittemore, Steve Wickler, Robert Winn, and Tom Zoeller.

Of the many colleagues who have made contributions, Richard Hill would like in particular to thank Kjell Johansen, one of the greats, who way back at the beginning said without a moment's hesitation, "This is good." Energy still emanates from those words three decades later.

Thanks to our students, who have challenged us, encouraged us, taught us, and—if nothing else—listened to us over our many years of classroom teaching. Our classes with our students have been our proving ground for teaching physiology and our most fundamental source of reinforcement to take on a project of this magnitude. We are grateful to work and teach at institutions—Michigan State University, the University of Massachusetts, and Smith College—at which efforts of this sort are possible.

Special thanks to Andy Sinauer, who has helped us to think big and provided the resources to realize ambitious goals for three editions. We have all worked with many editors and publishers in our careers, and Andy is tops: an entrepreneur dedicated to putting the life of ideas on the printed page. We also extend special thanks to our editor, Laura Green, who has brought expertise and sound judgment to our work on every aspect of the book, including text, art, and pedagogy. Warm thanks, too, to Chris Small, head of production, David McIntyre, photo editor, Joan Gemme, production specialist, and the others at Sinauer Associates whose talents and dedication have been indispensable. We feel privileged to have had Elizabeth Morales execute the art, which makes such a contribution to our pages.

We each have particular thanks to offer to the people in our personal lives whose support and patience have been indispensable. Richard Hill thanks Sue, Dave, and Chrissie, who have always been there even though the hours of writing have often meant long waits between sightings of their husband and father. Sue in particular has been a major contributor by repeatedly offering the benefits of her knowledge and judgment as a biologist. Gordon Wyse thanks Mary for her editorial talents, support, and willingness to keep planning around this long project, and Jeff, Karen, and Nancy for inspiration. Likewise, Margaret Anderson expresses gratitude to her family, especially Andy and Anita, and to her friends and students, whose boundless enthusiasm and idealism provide great inspiration.

While acknowledging the many ways others have helped, we of course accept full responsibility for the finished product and invite readers' opinions on how we could do better. Please contact us with your observations.

One of the gratifications of writing a book like this is the opportunity to participate in the raw enthusiasm of scientists for science. On countless occasions, many colleagues have performed great favors on short notice without the slightest hint of wanting pay for their professional expertise. Pure science must be one of the last redoubts of this ethic in today's professional world. We are honored to play the role of synthesizing and communicating the insights and questions that arise from the exciting search for knowledge.

To Our Readers

If you've ever been to a show and one of the producers stepped out on stage before the curtain went up to offer remarks about the upcoming event, you will understand the nature of these two pages. We, your authors, want to say a few words about the way we approached writing this book. We would also like to mention how we have handled several challenging issues.

One of our primary goals has been to create a book in which you will find the fascination of physiology as well as its content. Thus we have started each of the 30 chapters with an intriguing example that illustrates the application of the chapter to understanding the lives of animals. Collectively, these examples highlight the many ways in which the study of physiology relates to biology at large.

Besides our desire to emphasize the fascination of physiology, we have also wanted to stress the importance of integrating knowledge across physiological disciplines—and the importance of integrating physiology with ecology, behavior, molecular biology, genetics, and other fields. We have wanted, in addition, to discuss how concepts are tested and revised during research in physiology and to focus on the cutting edges in physiological research today. To help meet these goals, we have included five “At Work” chapters, which appear at the ends of five of the book's six parts. You will find that the “At Work” chapters are written in a somewhat different style than the other chapters because they give extra emphasis to the *process* of discovery. For the topics of the “At Work” chapters, we chose subjects that are especially intriguing and important: diving by seals and whales, animal navigation, muscle in states of use (e.g., athletic training) and disuse, mammals in the Arctic, and desert animals. Each “At Work” chapter uses concepts introduced in the chapters preceding it. We hope you will find these chapters to be something to look forward to: enjoyable to read and informative.

One of the thrills of science today, besides the extraordinary pace at which new knowledge is being generated worldwide, is the revolution in how readily each of us can access information. The first step in learning more about a field of knowledge is to gather references. Even as recently as 15 years ago, the reference-gathering stage could easily require days or weeks. Today, however, the search engines available to find references in the scientific literature enable rapid review and assembly of information sources. Specialized search engines such as the Web of Science®—which are similar to internet search engines but far more effective for exploring the scientific literature—will permit you to glean references rapidly from the thousands of scientific journals in which research is reported. Such search engines will then enable you to read the abstracts of dozens of papers in a few hours of time, so you can identify the research reports and other papers you want to read in full. Today *is* the information era. And indeed, knowledge *is* power. We encourage you to place a priority on mastering the tools available for information-gathering from the scientific literature.

You might wonder, if information is so easy to find, why should I take the course in which I am enrolled and why should I read this book? The answer in a few words is that extraordinary quantities of information create extraordinary challenges for synthesis. The more information each of us can locate, the more we need frameworks for organizing knowledge. Scientists, philosophers, and historians who comment on the practice of science are of one mind that the mere accumulation of facts leads quite literally nowhere. The successful pursuit of scientific knowledge requires testable concepts that organize facts. Scientists create concepts that organize raw information. Then, in science, it is these concepts that we test for their accuracy and utility.

A good course taught with a good textbook provides a conceptual framework into which raw information can be fitted so that it becomes part of the life of ideas and concepts. We hope we have provided you not simply with a conceptual framework, but one that is “good for the future.” By this we mean we have not tried merely to organize the knowledge already available. We have tried in equal measure to articulate a conceptual framework that is poised to grow and mature as new knowledge becomes available.

Just briefly we want to comment on four particular topics. First, our Box design. Boxes that start on the pages of this book often continue on the web. To find the web content, go to the book's website that is mentioned prominently at the end of each chapter. The part of a Box that you will read online is called a Box Extension. All the Box Extensions are fully integrated with the rest of the book in terms of concepts, terminology, and artistic conventions. Moreover, many of the Box Extensions are extensive and include informative figures. Thus, we urge that you keep reading when a Box directs you to a Box Extension.

Second, units of measure. For 30 years there has been a revolution underway focused on bringing all human endeavor into line with a single system of units called the *Système International* (SI). Different countries have responded differently, as have different fields of activity. Thus, if you purchase a box of cereal in much of the world, the cereal's energy value will be quoted on the box in kilojoules, but elsewhere it will be reported in kilocalories. If you go to a physician in the United States and have your blood pressure measured, you will have it reported in millimeters of mercury, but if you read a recent scientific paper on blood pressures, the pressures will be in kilopascals. The current state of transition in units of measure presents challenges for authors just as it does for you. We have tried, in our treatment of each physiological discipline, to familiarize you with the pertinent units of measure you are *most likely to encounter* (SI or not). Moreover, you will find in Appendix A an extensive discussion of the *Système International* and its relations to other systems of units.

A third specific matter we want to mention is the classification of birds. Systematists now agree that birds and crocodylians (alligators and crocodiles) are more closely related to each other than crocodylians are related to lizards, snakes, and turtles. This means that, logically, when we speak of reptiles, the birds belong with them. Probably your textbook in general biology has already presented this new classification of the vertebrates. In this book, we treat birds as being reptiles, but we also make a point of speaking of the groups in ways that keep the traditional distinctions clear.

The fourth and final specific matter on our minds is to mention our referencing system. For each chapter, there are three reference lists: (1) a brief list of particularly important or thought-provoking references at the end of the chapter, (2) a longer list of references in the section titled Additional References at the back of the book, and (3) a list of all the references cited as sources of information for figures or tables in the chapter. The final list appears in the Figure and Table Citations at the back of the book; highly detailed or specific references that we used to prepare figures or tables often appear only in the Figure and Table Citations. In terms of the formats used in citations to research reports in the scientific journals, our most common citation format is to provide the journal volume number

and inclusive page numbers where a report is found. However, online journals often do not employ inclusive page numbers; in those cases, our citation provides the volume number and an index to the location of the report in that volume. In unusual cases, our citation format is to employ a *doi* (digital object identifier) number. You can enter the *doi* number into a search engine to find the pertinent research report; the most reliable search engine for use of *doi* numbers is found at www.doi.org.

All three of us who wrote this book have been dedicated teachers throughout our careers. In addition, we have been fortunate to develop professional relationships and friendships with many of our students. This book is a product of that two-way interaction. In the big universities today, there are many forces at work that encourage passivity and anonymity. We urge the opposite. We encourage you to talk science as much as possible with each other and with your instructors, whether in classroom discussions, study groups, office hours, or other contexts. Active learning of this sort will contribute in a unique way to your enjoyment and mastery of the subjects you study. We have tried, deliberately, to write a book that will give you a lot to talk about.

RICHARD W. HILL GORDON A. WYSE MARGARET ANDERSON

Media and Supplements *to accompany*

Animal Physiology, Third Edition

eBook

(ISBN 978-0-87893-879-7)

www.coursesmart.com

Animal Physiology, Third Edition is available as an eBook via CourseSmart, at a substantial discount off the price of the printed textbook. The CourseSmart eBook reproduces the look of the printed book exactly, and includes convenient tools for searching the text, highlighting, and note-taking. The eBook is viewable in any Web browser, and via free apps for iPhone/iPad, Android, and Kindle Fire.

Companion Website

sites.sinauer.com/animalphys3e

New for the Third Edition, the *Animal Physiology* Companion Website includes content that expands on the coverage in the textbook as well as study and review tools. The site includes Chapter Outlines & Summaries to provide quick overviews of each chapter; Box Extensions, which expand on topics introduced in the textbook and cover important additional conceptual material; Online Quizzes, which cover all the key material in each chapter; Flashcards and Key Terms which allow the student to master the many new terms introduced in the textbook; and a complete Glossary.

Instructor's Resource Library

(ISBN 978-0-87893-880-3)

Available to qualified adopters, the *Animal Physiology* Instructor's Resource Library includes all of the figures (including photos) and tables from the textbook in a variety of formats, making it easy to incorporate images from the book into your lecture presentations and other course materials. The Resource Library includes both labeled and unlabeled versions of all figures in JPEG format (both high- and low-resolution versions) and in PowerPoint® format.

New to this edition are a Test Bank, answers to the Online Quiz questions, and answers to the end-of-chapter Study Questions. The Test Bank consists of a broad range of questions covering key facts and concepts in each chapter. Both multiple-choice and short-answer questions are provided. The Test Bank also includes the Companion Website Online Quiz questions. All questions are ranked according to Bloom's Taxonomy and referenced to specific textbook sections and page numbers. The entire Test Bank is provided in Wimba's Diploma software, making it easy to assemble quizzes and exams from any combination of publisher-provided questions and instructor-created questions. Answers to the end-of-chapter Study Questions are provided as Word documents.

Brief Contents

PART I

Fundamentals of Physiology 1

- 1 Animals and Environments: Function on the Ecological Stage 3
- 2 Molecules and Cells in Animal Physiology 31
- 3 Genomics, Proteomics, and Related Approaches to Physiology 67
- 4 Physiological Development and Epigenetics 85
- 5 Transport of Solutes and Water 99

PART II

Food, Energy, and Temperature 125

- 6 Nutrition, Feeding, and Digestion 127
- 7 Energy Metabolism 161
- 8 Aerobic and Anaerobic Forms of Metabolism 183
- 9 The Energetics of Aerobic Activity 207
- 10 Thermal Relations 225
- 11 Food, Energy, and Temperature *at Work*: The Lives of Mammals in Frigid Places 277

PART III

Integrating Systems 293

- 12 Neurons 295
- 13 Synapses 327
- 14 Sensory Processes 359
- 15 Nervous System Organization and Biological Clocks 397
- 16 Endocrine and Neuroendocrine Physiology 419
- 17 Reproduction 455
- 18 Integrating Systems *at Work*: Animal Navigation 485

PART IV

Movement and Muscle 501

- 19 Control of Movement: The Motor Bases of Animal Behavior 503
- 20 Muscle 523
- 21 Movement and Muscle *at Work*: Plasticity in Response to Use and Disuse 549

PART V

Oxygen, Carbon Dioxide, and Internal Transport 567

- 22 Introduction to Oxygen and Carbon Dioxide Physiology 569
- 23 External Respiration: The Physiology of Breathing 583
- 24 Transport of Oxygen and Carbon Dioxide in Body Fluids (with an Introduction to Acid-Base Physiology) 617
- 25 Circulation 647
- 26 Oxygen, Carbon Dioxide, and Internal Transport *at Work*: Diving by Marine Mammals 679

PART VI

Water, Salts, and Excretion 697

- 27 Water and Salt Physiology: Introduction and Mechanisms 699
- 28 Water and Salt Physiology of Animals in Their Environments 717
- 29 Kidneys and Excretion (with Notes on Nitrogen Excretion) 753
- 30 Water, Salts, and Excretion *at Work*: Mammals of Deserts and Dry Savannas 787

Contents

PART I • Fundamentals of Physiology

CHAPTER 1

Animals and Environments: Function on the Ecological Stage 3

The Importance of Physiology 4

Mechanism and Origin: Physiology's Two Central Questions 5

The study of mechanism: How do modern-day animals carry out their functions? 5

The study of origin: Why do modern-day animals possess the mechanisms they do? 7

Natural selection is a key process of evolutionary origin 8

Mechanism and adaptive significance are distinct concepts that do not imply each other 8

This Book's Approach to Physiology 10

Animals 11

The structural property of an animal that persists through time is its organization 11

Most cells of an animal are exposed to the internal environment, not the external environment 11

The internal environment may be permitted to vary when the external environment changes, or it may be kept constant 12

Homeostasis in the lives of animals: Internal constancy is often critical for proper function 12

BOX 1.1 Negative Feedback 13

Time in the lives of animals: Physiology changes in five time frames 14

BOX 1.2 The Evolution of Phenotypic Plasticity 16

Size in the lives of animals: Body size is one of an animal's most important traits 16

Environments 18

Earth's major physical and chemical environments 18

The environment an animal occupies is often a microenvironment or microclimate 22

Animals often modify their own environments 23

Evolutionary Processes 24

Some processes of evolution are adaptive, others are not 24

A trait is not an adaptation merely because it exists 25

Adaptation is studied as an empirical science 25

Evolutionary potential can be high or low, depending on available genetic variation 27

CHAPTER 2

Molecules and Cells in Animal Physiology 31

Cell Membranes and Intracellular Membranes 32

The lipids of membranes are structured, diverse, fluid, and responsive to some environmental factors 33

Proteins endow membranes with numerous functional capacities 35

BOX 2.1 Protein Structure and the Bonds That Maintain It 35

Carbohydrates play important roles in membranes 36

Epithelia 37

Elements of Metabolism 40

Enzyme Fundamentals 40

Enzyme-catalyzed reactions exhibit hyperbolic or sigmoid kinetics 42

Maximum reaction velocity is determined by the amount and catalytic effectiveness of an enzyme 43

Enzyme–substrate affinity affects reaction velocity at the substrate concentrations that are usual in cells 43

Enzymes undergo changes in molecular conformation and have specific binding sites that interact 44

Enzymes catalyze reversible reactions in both directions 45

Multiple molecular forms of enzymes occur at all levels of animal organization 46

Regulation of Cell Function by Enzymes 47

The types and amounts of enzymes present depend on gene expression and enzyme degradation 48

Modulation of existing enzyme molecules permits fast regulation of cell function 48

Evolution of Enzymes 52

Enzymes Are Instruments of Change in All Time Frames 54

The Life and Death of Proteins 54

Light and Color 55

BOX 2.2 Squid and Bioluminescent Bacteria, a Study in Cross-Phylum Coordination: The *Euprymna scolopes*–*Vibrio fischeri* Symbiosis
Margaret McFall-Ngai 57

Reception and Use of Signals by Cells 58

Extracellular signals initiate their effects by binding to receptor proteins 58

Cell signal transduction often entails sequences of amplifying effects 61

Several second-messenger systems participate in cell signal transduction 63

CHAPTER 3

Genomics, Proteomics, and Related Approaches to Physiology 67

Genomics 72

Genomics is inextricably linked with advanced methods of information processing 72

One overarching goal of genomics is to elucidate the evolution of genes and genomes 73

A second overarching goal of genomics is to elucidate the current functioning of genes and genomes 73

Genomes must ultimately be related empirically to phenotypes 74

Top-down versus Bottom-up Approaches to the Study of Physiology 75

Screening or Profiling as a Research Strategy 76

The Study of Gene Transcription: Transcriptomics 76

Transcription profiling often identifies large numbers of genes that exhibit altered transcription in response to environmental or other conditions 78

Transcription profiling reveals that many genes routinely undergo daily cycles of transcription 78

Manipulations of protein synthesis can be used to clarify gene function 79

Proteomics 80

Metabolomics 82

CHAPTER 4

Physiological Development and Epigenetics 85

The Physiology of Immature Animals Always Differs from That of Adults 86

Phenotypic Plasticity during Development 90

Environmental effects during development may arise from programmed responses to the environment or may be forced by chemical or physical necessity 91

Insect polyphenic development underlies some of the most dramatic cases of phenotypic plasticity 91

Epigenetics 93

Two major mechanisms of epigenetic marking are DNA methylation and covalent modification of histones 93

Epigenetic marking during an animal's early development affects the animal's lifelong phenotype 94

Epigenetic marks on paternal and maternal copies of genes set the stage in mammals and insects for the two copies to exert nonequivalent effects 95

CHAPTER 5

Transport of Solutes and Water 99

Passive Solute Transport by Simple Diffusion 101

Concentration gradients give rise to the most elementary form of simple solute diffusion 102

Electrical gradients often influence the diffusion of charged solutes at membranes 103

Biological aspects of diffusion across membranes: Some solutes dissolve in the membrane; others require channels 104

Diffusion of ions across cell membranes is determined by simultaneous concentration and electrical effects 105

Diffusion often creates challenges for cells and animals 105

Concentration gradients can create electrical gradients that alter concentration gradients 107

Passive Solute Transport by Facilitated Diffusion 108

Active Transport 108

Active transport and facilitated diffusion are types of carrier-mediated transport 109

Basic properties of active-transport mechanisms 109

Recognition of active transport completes our overview of a single animal cell 109

Primary and secondary active transport differ in their cellular-molecular mechanisms 110

BOX 5.1 Energy Coupling via the Potential Energy of Electrochemical Gradients 113

Active transport across an epithelium does not imply a specific transport mechanism 114

Two epithelial ion-pumping mechanisms help freshwater fish maintain their blood composition 114

BOX 5.2 Cellular Mechanisms of Ion Pumping in Fresh-water Fish Gills 116

Diversity and Modulation of Channels and Transporters 116

Osmotic Pressure and Other Colligative Properties of Aqueous Solutions 117

Physiologists usually express osmotic pressure in osmolar units 118

Osmotic pressures can be measured in several ways 118

Osmosis 120

Quantification and terminology 120

Hydrostatic pressures develop from osmotic pressures only when two or more solutions interact 121

Water may dissolve in membranes or pass through aquaporin water channels during osmosis 121

Aquaporins 121

Osmosis and solute physiology often interact 122

PART II • Food, Energy, and Temperature

CHAPTER 6

Nutrition, Feeding, and Digestion 127

Nutrition 129

Proteins are “foremost” 129

Lipids are required for all membranes and are the principal storage compounds of animals 132

Carbohydrates are low in abundance in many animals but highly abundant when they play structural roles 133

Vitamins are essential organic compounds required in small amounts 134

Elemental nutrition: Many minerals are essential nutrients 134

Feeding 136

Many animals feed on organisms that are individually attacked and ingested 137

Suspension feeding is common in aquatic animals 139

Symbioses with microbes often play key roles in animal feeding and nutrition 141

BOX 6.1 Types of Meal Processing Systems 146
Digestion and Absorption 148

Vertebrates, arthropods, and molluscs represent three important digestive–absorptive plans 148

Digestion is carried out by specific enzymes operating in three spatial contexts 151

Absorption occurs by different mechanisms for hydrophilic and hydrophobic molecules 153

Responses to Eating 155

Nutritional Physiology in Additional Time Frames 157

Nutritional physiology is responsive to the environment 157

BOX 6.2 Long-term Natural Fasting, Emphasizing Pythons 157

The nutritional physiology of individuals is often endogenously programmed to change over time 158

CHAPTER 7

Energy Metabolism 161

Why Animals Need Energy: The Second Law of Thermodynamics 161

Fundamentals of Animal Energetics 163

The forms of energy vary in their capacity for physiological work 163

Transformations of high-grade energy are always inefficient 163

Animals use energy to perform three major functions 164

BOX 7.1 Views on Animal Heat Production 165

Metabolic Rate: Meaning and Measurement 166

BOX 7.2 Units of Measure for Energy and Metabolic Rates 166

Direct calorimetry: The metabolic rate of an animal can be measured directly 167

Indirect calorimetry: Animal metabolic rates are usually measured indirectly 167

BOX 7.3 Direct Measurement versus Indirect Measurement 168

BOX 7.4 Respirometry 170**Factors That Affect Metabolic Rates** 170

Ingestion of food causes metabolic rate to rise 170

Basal Metabolic Rate and Standard Metabolic Rate 172**Metabolic Scaling: The Relation between Metabolic Rate and Body Size** 172

Resting metabolic rate is an allometric function of body weight in related species 173

The metabolic rate of active animals is often also an allometric function of body weight 175

The metabolism–size relation has important physiological and ecological implications 176

BOX 7.5 Scaling of Heart Function 177

The explanation for allometric metabolism–size relations remains unknown 178

Energetics of Food and Growth 180**Conclusion: Energy as the Common Currency of Life** 181**POSTSCRIPT: The Energy Cost of Mental Effort** 181**CHAPTER 8****Aerobic and Anaerobic Forms of Metabolism** 183**Mechanisms of ATP Production and Their Implications** 184

Aerobic catabolism consists of four major sets of reactions 184

BOX 8.1 Reactive Oxygen Species (ROS) 189

O₂ deficiency poses two biochemical challenges: Impaired ATP synthesis and potential redox imbalance 189

Certain tissues possess anaerobic catabolic pathways that synthesize ATP 190

Anaerobic glycolysis is the principal anaerobic catabolic pathway of vertebrates 190

What happens to catabolic end products? 190

The functional roles of ATP-producing mechanisms depend on whether they operate in steady state or nonsteady state 191

Phosphagens provide an additional mechanism of ATP production without O₂ 192

Internal O₂ stores may be used to make ATP 192

Comparative Properties of Mechanisms of ATP Production 193

Question 1: What is each mechanism's total possible ATP yield per episode of use? 193

Question 2: How rapidly can ATP production be accelerated? 193

BOX 8.2 Genetic Engineering as a Tool to Test Hypotheses of Muscle Function and Fatigue 194

Question 3: What is each mechanism's peak rate of ATP production (peak power)? 194

Question 4: How rapidly can each mechanism be reinitialized? 194

Conclusion: All mechanisms have pros and cons 194

Two Themes in Exercise Physiology: Fatigue and Muscle Fiber Types 194

Fatigue has many, context-dependent causes 194

The muscle fibers in the muscles used for locomotion are heterogeneous in functional properties 195

The Interplay of Aerobic and Anaerobic Catabolism during Exercise 196

Metabolic transitions occur at the start and end of vertebrate exercise 196

The ATP source for all-out exercise varies in a regular manner with exercise duration 198

Related species and individuals within one species are often poised very differently for use of aerobic and anaerobic catabolism 200

Responses to Impaired O₂ Influx from the Environment 201

Air-breathing vertebrates during diving: Preserving the brain presents special challenges 201

Animals faced with reduced O₂ availability in their usual environments may show conformity or regulation of aerobic ATP synthesis 202

Water-breathing anaerobes: Some aquatic animals are capable of protracted life in water devoid of O₂ 202

BOX 8.3 Human Peak O₂ Consumption and Physical Performance at High Altitudes 204**CHAPTER 9****The Energetics of Aerobic Activity** 207**How Active Animals Are Studied** 208**BOX 9.1** The Cost of Carrying Massive Loads 209**The Energy Costs of Defined Exercise** 210

The most advantageous speed depends on the function of exercise 211

The minimal cost of transport depends in regular ways on mode of locomotion and body size 213

The Maximal Rate of Oxygen Consumption 215**BOX 9.2** Finding Power for Human-Powered Aircraft 215

$\dot{V}_{O_2\max}$ differs among phyletic groups and often from species to species within a phyletic group 216

$\dot{V}_{O_2\max}$ varies among individuals within a species 217

$\dot{V}_{O_2\max}$ responds to training and selection 217

The Energetics of Routine and Extreme Daily Life 218**Long-Distance Migration** 219**Ecological Energetics** 220**BOX 9.3** Eel Migration and Energetics: A 2300-Year Detective Story 221

CHAPTER 10

Thermal Relations 225

Temperature and Heat 227

Heat Transfer between Animals and Their Environments 227

BOX 10.1 Global Warming 228

Conduction and convection: Convection is intrinsically faster 230

Evaporation: The change of water from liquid to gas carries much heat away 230

Thermal radiation permits widely spaced objects to exchange heat at the speed of light 231

Poikilothermy (Ectothermy) 233

Poikilotherms often exert behavioral control over their body temperatures 234

Poikilotherms must be able to function over a range of body temperatures 234

Poikilotherms respond physiologically to their environments in all three major time frames 234

Acute responses: Metabolic rate is an approximately exponential function of body temperature 235

Chronic responses: Acclimation often blunts metabolic responses to temperature 236

The rate–temperature relations and thermal limits of individuals: Ecological decline occurs at milder temperatures than acute stress 239

Evolutionary changes: Species are often specialized to live at their respective body temperatures 241

Temperature and heat matter to animals because they affect the rates of processes and the functional states of molecules 242

Poikilotherms threatened with freezing: They may survive by preventing freezing or by tolerating it 246

Homeothermy in Mammals and Birds 250

Metabolic rate rises in cold and hot environments because of the costs of homeothermy 251

BOX 10.2 Thermoregulatory Control, Fever, and Behavioral Fever 252

The shape of the metabolism–temperature curve depends on fundamental heat-exchange principles 252

Homeothermy is metabolically expensive 255

Insulation is modulated by adjustments of the pelage or plumage, blood flow, and posture 256

Heat production is increased below thermoneutrality by shivering and nonshivering thermogenesis 256

Regional heterothermy: In cold environments, allowing some tissues to cool can have advantages 257

Countercurrent heat exchange permits selective restriction of heat flow to appendages 258

Mammals and birds in hot environments: Their first lines of defense are often not evaporative 260

Active evaporative cooling is the ultimate line of defense against overheating 261

Mammals and birds acclimatize to winter and summer 263

Evolutionary changes: Species are often specialized to live in their respective climates 264

Mammals and birds sometimes escape the demands of homeothermy by hibernation, torpor, or related processes 265

Warm-Bodied Fish 268

Endothermy and Homeothermy in Insects 270

The insects that thermoregulate during flight require certain flight-muscle temperatures to fly 271

Solitary insects employ diverse mechanisms of thermoregulation 272

Colonies of social bees and wasps often display sophisticated thermoregulation 273

Coda 273

BOX 10.3 Warm Flowers 273

CHAPTER 11

Food, Energy, and Temperature *at*

Work: The Lives of Mammals in Frigid Places 277

Food, Nutrition, Energy Metabolism, and Thermoregulation in the Lives of Adult Reindeer 277

Newborn Reindeer 280

BOX 11.1 Knockout Mice Clarify the Function of Brown Fat 281

BOX 11.2 Genomics Confirms That Piglets Lack Brown Fat 282

The Future of Reindeer: Timing and Ice 283

Thermoregulatory Development: Small Mammals Compared with Large 283

The Effect of Body Size on Mammals' Lives in Cold Environments: An Overview 284

Hibernation as a Winter Strategy: New Directions and Discoveries 285

Arctic ground squirrels supercool during hibernation and arouse periodically throughout their hibernation season 286

The composition of the lipids consumed before hibernation affects the dynamics of hibernation 286

Although periodic arousals detract from the energy savings of hibernation, their function is unknown 288

The intersection of sociobiology and hibernation physiology 289

PART III • Integrating Systems

CHAPTER 12 Neurons 295

The Physiology of Control: Neurons and Endocrine Cells Compared 295

Neurons transmit electrical signals to target cells 296

Endocrine cells broadcast hormones 297

Nervous systems and endocrine systems tend to control different processes 298

Neurons Are Organized into Functional Circuits in Nervous Systems 298

The Cellular Organization of Neural Tissue 299

Neurons are structurally adapted to transmit action potentials 299

Glial cells support neurons physically and metabolically 300

The Ionic Basis of Membrane Potentials 301

Cell membranes have passive electrical properties: Resistance and capacitance 302

Resting membrane potentials depend on selective permeability to ions: The Nernst equation 305

Ion concentration differences result from active ion transport and from passive diffusion 306

Membrane potentials depend on the permeabilities to and concentration gradients of several ion species: The Goldman equation 308

Electrogenic pumps also have a small direct effect on V_m 308

The Action Potential 309

Action potentials are voltage-dependent, all-or-none electrical signals 309

Action potentials result from changes in membrane permeabilities to ions 310

The molecular structure of the voltage-dependent ion channels reveals their functional properties 315

There are variations in the ionic mechanisms of excitable cells 316

BOX 12.1 Evolution and Molecular Function of Voltage-Gated Channels 317

BOX 12.2 Optogenetics: Controlling Cells with Light Matthew S. Kayser 318

The Propagation of Action Potentials 320

Local circuits of current propagate an action potential 320

Membrane refractory periods prevent bidirectional propagation 320

The conduction velocity of an action potential depends on axon diameter, myelination, and temperature 322

BOX 12.3 Giant Axons 322

CHAPTER 13 Synapses 327

Synaptic Transmission Is Usually Chemical but Can Be Electrical 328

Electrical synapses transmit signals instantaneously 329

Chemical synapses can modify and amplify signals 329

Synaptic Potentials Control Neuronal Excitability 332

Synapses onto a spinal motor neuron exemplify functions of fast synaptic potentials 332

Synapses excite or inhibit a neuron by depolarization or hyperpolarization at the site of impulse initiation 332

Fast Chemical Synaptic Actions Are Exemplified by the Vertebrate Neuromuscular Junction 333

Chemical synapses work by releasing and responding to neurotransmitters 335

Postsynaptic potentials result from permeability changes that are neurotransmitter-dependent and voltage-independent 335

EPSPs between neurons resemble neuromuscular EPSPs but are smaller 336

Fast IPSPs can result from an increase in permeability to chloride 337

Presynaptic Neurons Release Neurotransmitter Molecules in Quantal Packets 337

Acetylcholine is synthesized and stored in the presynaptic terminal 338

Neurotransmitter release requires voltage-dependent Ca^{2+} influx 338

Neurotransmitter release is quantal and vesicular 338

Synaptic vesicles are cycled at nerve terminals in distinct steps 339

Several proteins play roles in vesicular release and recycling 340

Neurotransmitters Are of Two General Kinds 341

Neurons have one or more characteristic neurotransmitters 342

An agent is identified as a neurotransmitter if it meets several criteria 342

Vertebrate neurotransmitters have several general modes of action 343

Neurotransmitter systems have been conserved in evolution 344

Postsynaptic Receptors for Fast Ionotropic Actions: Ligand-Gated Channels 345

ACh receptors are ligand-gated channels that function as ionotropic receptors 345

Many, but not all, ligand-gated channel receptors have evolved from a common ancestor 347

Postsynaptic Receptors for Slow, Metabotropic Actions: G Protein-Coupled Receptors 347

G protein-coupled receptors initiate signal transduction cascades 347

Metabotropic receptors act via second messengers 347

Other mechanisms of G protein-mediated activity 349

G protein-coupled receptors mediate permeability-decrease synaptic potentials and presynaptic inhibition 350

Synaptic Plasticity: Synapses Change Properties with Time and Activity 350

Neurotransmitter metabolism is regulated homeostatically 351

Learning and memory may be based on synaptic plasticity 351

Habituation and sensitization in *Aplysia* 351

Long-term potentiation in the hippocampus 353

BOX 13.1 Synapse Formation: Competing Philosophies Matthew S. Kayser 356

Long-term potentiation is a necessary component of learning 356

CHAPTER 14

Sensory Processes 359

Organization of Sensory Systems 360

Sensory receptor cells can be classified in four different ways 360

Sensory receptor cells transduce and encode sensory information 361

Mechanoreception and Touch 362

Insect bristle sensilla exemplify mechanoreceptor responses 362

Touch receptors in the skin of mammals have specialized endings 364

Proprioceptors monitor internal mechanical stimuli 365

Vestibular Organs and Hearing 366

Insects hear with tympanal organs 366

Vertebrate hair cells are used in hearing and vestibular sense 366

Vertebrate vestibular organs sense acceleration and gravity 368

Sound stimuli create movements in the vertebrate cochlea that excite auditory hair cells 369

The localization of sound is determined by analysis of auditory signals in the CNS 372

BOX 14.1 Echolocation 373

Chemoreception and Taste 373

Insect taste is localized at chemoreceptive sensilla 373

Taste in mammals is mediated by receptor cells in taste buds 374

Olfaction 377

The mammalian olfactory epithelium contains odor generalist receptor cells 378

The vomeronasal organ of mammals detects pheromones 380

Photoreception 381

Photoreceptor cells and eyes of different groups have evolved similarities and differences 382

Rhodopsin consists of retinal conjugated to opsin, a G protein-coupled receptor 382

Phototransduction in *Drosophila* leads to a depolarizing receptor potential 382

The vertebrate eye focuses light onto retinal rods and cones 385

Rods and cones of the retina transduce light into a hyperpolarizing receptor potential 386

Enzymatic regeneration of rhodopsin is slow 388

Visual Sensory Processing 389

Retinal neurons respond to contrast 389

The vertebrate brain integrates visual information through parallel pathways 392

BOX 14.2 What roles do individual neurons play in higher visual integration? 394

Color vision is accomplished by populations of photoreceptors that contain different photopigments 394

CHAPTER 15**Nervous System Organization and Biological Clocks 397****The Organization and Evolution of Nervous Systems 398**

Nervous systems consist of neurons organized into functional circuits 398

Many types of animals have evolved complex nervous systems 398

BOX 15.1 Evolution of Nervous Systems 399**The Vertebrate Nervous System: A Guide to the General Organizational Features of Nervous Systems 401**

Nervous systems have central and peripheral divisions 401

The central nervous system controls physiology and behavior 401

Five principles of functional organization apply to all mammalian and most vertebrate brains 402

BOX 15.2 Functional Magnetic Resonance Imaging Scott A. Huettel 405

The peripheral nervous system has somatic and autonomic divisions that control different parts of the body 405

The autonomic nervous system has three divisions 406

Biological Clocks 410

Organisms have endogenous rhythms 410

BOX 15.3 Sleep David S. Garbe 411

Biological clocks generate endogenous rhythms 412

Control by biological clocks has adaptive advantages 412

Endogenous clocks correlate with natural history and compensate for temperature 413

Clock mechanisms are based on rhythms of gene expression 414

The loci of biological clock functions vary among animals 415

Circannual and circatidal clocks: Some endogenous clocks time annual or tidal rhythms 416

Interval, or “hourglass,” timers can time shorter intervals 416

CHAPTER 16**Endocrine and Neuroendocrine Physiology 419****Introduction to Endocrine Principles 420**

Hormones bind to receptor molecules expressed by target cells 421

Concentrations of hormones in the blood vary 421

Most hormones fall into three chemical classes 421

Hormone molecules exert their effects by producing biochemical changes in target cells 423

Synthesis, Storage, and Release of Hormones 425

Peptide hormones are synthesized at ribosomes, stored in vesicles, and secreted on demand 425

Steroid hormones are synthesized on demand prior to secretion, and are released into the blood by diffusion 426

Types of Endocrine Glands and Cells 426**Control of Endocrine Secretion: The Vertebrate Pituitary Gland 427**

The posterior pituitary illustrates neural control of neurosecretory cells 427

The anterior pituitary illustrates neurosecretory control of endocrine cells 428

Hormones and neural input modulate endocrine control pathways 430

The Mammalian Stress Response 432

The autonomic nervous system and HPA axis coordinate the stress response to an acute threat 433

The HPA axis modulates the immune system 434

Chronic stress causes deleterious effects 435

Plasma glucocorticoid concentrations show seasonal variations 436

Endocrine Control of Nutrient Metabolism in Mammals 436

Insulin regulates short-term changes in nutrient availability 436

Glucagon works together with insulin to ensure stable levels of glucose in the blood 437

Other hormones contribute to the regulation of nutrient metabolism 439

Endocrine Control of Salt and Water Balance in Vertebrates 439

Antidiuretic hormones conserve water 439

The renin–angiotensin–aldosterone system conserves sodium 440

Atrial natriuretic peptide promotes excretion of sodium and water 442

Endocrine Control of Calcium Metabolism in Mammals 442

Parathyroid hormone increases Ca^{2+} in the blood 442

Active vitamin D increases Ca^{2+} and phosphate in the blood 442

Calcitonin opposes bone resorption and decreases Ca^{2+} and phosphate in the blood 443

Endocrine Principles in Review 444**Chemical Signals along a Distance Continuum 444****BOX 16.1 Can Mating Cause True Commitment? 445**

Paracrines and autocrines are local chemical signals distributed by diffusion 446

BOX 16.2 Hormones and Neuromodulators Influence Behavior 447

Pheromones and kairomones are used as chemical signals between animals 447

Insect Metamorphosis 448

Insect metamorphosis may be gradual or dramatic 448

BOX 16.3 Insects in Forensics and Medicine 449

Hormones and neurohormones control insect metamorphosis 450

CHAPTER 17

Reproduction 455

What Aspects of Reproduction Do Physiologists Study? 457

Reproduce Once or More Than Once?—Semelparity versus Iteroparity 459

BOX 17.1 Semelparity in a Mammal 460

Eggs, Provisioning, and Parental Care 460

External or Internal Fertilization? 461

The Environment as a Player in Reproduction 462

The Timing of Reproductive Cycles 463

Sperm storage permits flexible timing between copulation and fertilization 463

Embryonic diapause permits flexible timing between fertilization and the completion of embryonic development 463

The timing of reproductive events is often rigorously controlled in seasonal environments 464

Sex Change 467

Reproductive Endocrinology of Placental Mammals 468

Females ovulate periodically and exhibit menstrual or estrous cycles 468

Males produce sperm continually during the reproductive season 473

BOX 17.2 Sex Determination and Differentiation, Emphasizing Mammals 476

Pregnancy and birth are orchestrated by specialized endocrine controls 477

Lactation is governed by neuroendocrine reflexes 480

CHAPTER 18

Integrating Systems at Work: Animal Navigation 485

The Adaptive Significance of Animal Navigation 486

Navigational abilities promote reproductive success 486

Navigational abilities facilitate food acquisition 487

Migrating animals need navigation 487

Navigational Strategies 487

Trail following is the most rudimentary form of animal navigation 488

Piloting animals follow a discontinuous series of learned cues 488

Path integration is a form of dead reckoning 489

Animals can derive compass information from environmental cues 489

Some animals appear to possess a map sense 494

BOX 18.1 Magnetoreceptors and Magnetoreception Kenneth J. Lohmann 495

Sea turtles exemplify the degree of our understanding of navigation 496

Innate and Learned Components of Navigation 497

Some forms of navigation have strong innate aspects 497

The hippocampus is a critical brain area for vertebrate spatial learning and memory 497

PART IV • Movement and Muscle

CHAPTER 19

Control of Movement: The Motor Bases of Animal Behavior 503

Neural Control of Skeletal Muscle Is the Basis of Animal Behavior 503

Invertebrate neural circuits involve fewer neurons than vertebrate circuits 504

Vertebrate spinal reflexes compensate for circumstances, as well as initiate movements 504

BOX 19.1 Muscle Spindles 505

Motor neurons are activated primarily by central input rather than by spinal reflexes 507

Neural Generation of Rhythmic Behavior 509

- Locust flight results from an interplay of central and peripheral control 509
- There are different mechanisms of central pattern generation 510
- Central pattern generators can underlie relatively complex behavior 513

Control and Coordination of Vertebrate Movement 514

- Locomotion in cats involves a spinal central pattern generator 515
- Central pattern generators are distributed and interacting 515
- The generation of movement involves several areas in the vertebrate brain 516

BOX 19.2 Basal Ganglia and Neurodegenerative Diseases 521**CHAPTER 20
Muscle 523****Vertebrate Skeletal Muscle Cells 524**

- Thick and thin filaments are polarized polymers of individual protein molecules 526
- Muscles require ATP to contract 527
- Calcium and the regulatory proteins tropomyosin and troponin control contractions 528

Excitation–Contraction Coupling 529**Whole Skeletal Muscles 531**

- Muscle contraction is the force generated by a muscle during cross-bridge activity 531
- A twitch is the mechanical response of a muscle to a single action potential 532
- The velocity of shortening decreases as the load increases 532
- The frequency of action potentials determines the tension developed by a muscle 532
- A sustained high calcium concentration in the cytoplasm permits summation and tetanus 533
- The amount of tension developed by a muscle depends on the length of the muscle at the time it is stimulated 534
- In general, the amount of work a muscle can do depends on its volume 535

BOX 20.1 Electric Fish Exploit Modified Skeletal Muscles to Generate Electric Shocks 536**Muscle Energetics 536**

- ATP is the immediate source of energy for powering muscle contraction 536
- Vertebrate muscle fibers are classified into different types 537

BOX 20.2 Insect Flight 539**Neural Control of Skeletal Muscle 540**

- The vertebrate plan is based on muscles organized into motor units 540

The innervation of vertebrate tonic muscle is intermediate between the general vertebrate and arthropod plans 540

The arthropod plan is based on multiterminal innervation of each muscle fiber by more than one neuron 540

Vertebrate Smooth (Unstriated) Muscle 542

- Smooth muscle cells are broadly classified 542
- Ca²⁺ availability controls smooth muscle contraction by myosin-linked regulation 543
- Most smooth muscles are innervated by the autonomic nervous system 545

Vertebrate Cardiac Muscle 545**CHAPTER 21
Movement and Muscle *at Work*: Plasticity in Response to Use and Disuse 549****Muscle Phenotypes 550**

- Power output determines a muscle's contractile performance, and changes in response to use and disuse 551
- Endurance training elicits changes in fiber type, increased capillary density, and increased mitochondrial density 551
- Resistance training causes hypertrophy and changes in fiber type 555
- Hypertrophy also occurs in cardiac muscles 557

Atrophy 559

- Humans experience atrophy in microgravity 559
- Disuse influences the fiber-type composition of muscles 560
- Muscles atrophy with age 560
- Some animals experience little or no disuse atrophy 561

BOX 21.1 No Time to Lose 562**Regulating Muscle Mass 563**

- Myostatin 563
- The PI3-K–Akt1 pathway 564

Summary 565

PART V • Oxygen, Carbon Dioxide, and Internal Transport

CHAPTER 22

Introduction to Oxygen and Carbon Dioxide Physiology 569

The Properties of Gases in Gas Mixtures and Aqueous Solutions 570

Gases in the gas phase 570

Gases in aqueous solution 571

Diffusion of Gases 572

Gases diffuse far more readily through gas phases than through aqueous solutions 574

Gas molecules that combine chemically with other molecules cease to contribute to the gas partial pressure 574

BOX 22.1 Diffusion through Tissues Can Meet O₂ Requirements over Distances of Only 1 Millimeter or Less 575

Convective Transport of Gases: Bulk Flow 575

BOX 22.2 Induction of Internal Flow by Ambient Currents 576

Gas transport in animals often occurs by alternating convection and diffusion 576

The Oxygen Cascade 577

Expressing the Amounts and Partial Pressures of Gases in Other Units 578

The Contrasting Physical Properties of Air and Water 579

Respiratory Environments 580

CHAPTER 23

External Respiration: The Physiology of Breathing 583

Fundamental Concepts of External Respiration 584

Principles of Gas Exchange by Active Ventilation 585

The O₂ partial pressure in blood leaving a breathing organ depends on the spatial relation between the flow of the blood and the flow of the air or water 585

The relative changes in the partial pressures of O₂ and CO₂ depend dramatically on whether air or water is breathed 587

Introduction to Vertebrate Breathing 588

Breathing by Fish 590

Gill ventilation is usually driven by buccal–opercular pumping 592

Many fish use ram ventilation on occasion, and some use it all the time 593

Decreased O₂ and exercise are the major stimuli for increased ventilation in fish 593

Several hundred species of bony fish are able to breathe air 593

Breathing by Amphibians 594

Gills, lungs, and skin are used in various combinations to achieve gas exchange 595

Breathing by Reptiles Other than Birds 596

Breathing by Mammals 597

The total lung volume is employed in different ways in different sorts of breathing 598

The gas in the final airways differs from atmospheric air in composition and is motionless 599

The power for ventilation is developed by the diaphragm and the intercostal and abdominal muscles 599

The control of ventilation 600

BOX 23.1 Low O₂: Detection and Response 601

BOX 23.2 Mammals at High Altitude (with Notes on High-Flying Birds) 602

In species of different sizes, lung volume tends to be a constant proportion of body size, but breathing frequency varies allometrically 604

Pulmonary surfactant keeps the alveoli from collapsing 604

Breathing by Birds 605

Ventilation is by bellows action 606

Air flows unidirectionally through the parabronchi 606

The gas-exchange system is cross-current 608

BOX 23.3 Bird Development: Filling the Lungs with Air Before Hatching 608

Breathing by Aquatic Invertebrates and Allied Groups 608

Molluscs exemplify an exceptional diversity of breathing organs built on a common plan 608

Decapod crustaceans include many important water breathers and some air breathers 610

Breathing by Insects and Other Tracheate Arthropods 611**BOX 23.4 The Book Lungs of Arachnids 612**

Diffusion is a key mechanism of gas transport through the tracheal system 612

Some insects employ conspicuous ventilation 613

Microscopic ventilation is far more common than believed even a decade ago 614

Control of breathing 614

Aquatic insects breathe sometimes from the water, sometimes from the atmosphere, and sometimes from both 615

CHAPTER 24**Transport of Oxygen and Carbon Dioxide in Body Fluids (with an Introduction to Acid-Base Physiology) 617****The Chemical Properties and Distributions of the Respiratory Pigments 618****BOX 24.1 Absorption Spectra of Respiratory Pigments 619**

Hemoglobins contain heme and are the most widespread respiratory pigments 619

BOX 24.2 Blood Cells and Their Production 622

Copper-based hemocyanins occur in many arthropods and molluscs 622

Chlorocruorins resemble hemoglobins and occur in certain annelids 623

Iron-based hemerythrins do not contain heme and occur in three or four phyla 623

The O₂-Binding Characteristics of Respiratory Pigments 623

Human O₂ transport provides an instructive case study 624

A set of general principles helps elucidate O₂ transport by respiratory pigments 627

The shape of the oxygen equilibrium curve depends on O₂-binding site cooperativity 627

Respiratory pigments exhibit a wide range of affinities for O₂ 628

The Bohr effect: Oxygen affinity depends on the partial pressure of CO₂ and the pH 629

The Root effect: In unusual cases, CO₂ and pH dramatically affect the oxygen-carrying capacity of the respiratory pigment 631

Thermal effects: Oxygen affinity depends on tissue temperature 631

Organic modulators often exert chronic effects on oxygen affinity 631

BOX 24.3 The Challenges of Regional Hypothermia and the Resurrection of Mammoth Hemoglobin 632

Inorganic ions may also act as modulators of respiratory pigments 633

The Functions of Respiratory Pigments in Animals 633**BOX 24.4 Heme-Containing Globins in Intracellular Function: Myoglobin Regulatory and Protective Roles, Neuroglobins, and Cytoglobins 634**

Patterns of circulatory O₂ transport: The mammalian model is common but not universal 635

Respiratory pigments within a single individual often display differences in O₂ affinity that aid successful O₂ transport 636

Evolutionary adaptation: Respiratory pigments are molecules positioned directly at the interface between animal and environment 636

The respiratory-pigment physiology of individuals undergoes acclimation and acclimatization 637

Icefish live without hemoglobin 638

Carbon Dioxide Transport 638**BOX 24.5 Blood and Circulation in Mammals at High Altitude 639**

The extent of bicarbonate formation depends on blood buffers 640

Carbon dioxide transport is interpreted by use of carbon dioxide equilibrium curves 640

The Haldane effect: The carbon dioxide equilibrium curve depends on blood oxygenation 641

Critical details of vertebrate CO₂ transport depend on carbonic anhydrase and anion transporters 642

Acid-Base Physiology 643

Acid-base regulation involves excretion or retention of chemical forms affecting H⁺ concentration 644

Disturbances of acid-base regulation fall into respiratory and metabolic categories 644

CHAPTER 25**Circulation 647****Hearts 648**

The heart as a pump: The action of a heart can be analyzed in terms of the physics of pumping 649

The circulation must deliver O₂ to the myocardium 649

The electrical impulses for heart contraction may originate in muscle cells or neurons 650

A heart produces an electrical signature, the electrocardiogram 653

Heart action is modulated by hormonal, nervous, and intrinsic controls 653

Principles of Pressure, Resistance, and Flow in Vascular Systems 655

The rate of blood flow depends on differences in blood pressure and on vascular resistance 656

The dissipation of energy: Pressure and flow turn to heat during circulation of the blood 657

Circulation in Mammals and Birds 658

The circulatory system is closed 658

Each part of the systemic vascular system has distinctive anatomical and functional features 658

Mammals and birds have a high-pressure systemic circuit 660

Fluid undergoes complex patterns of exchange across the walls of systemic capillaries 662

The pulmonary circuit is a comparatively low-pressure system that helps keep the lungs “dry” 662

During exercise, blood flow is increased by orchestrated changes in cardiac output and vascular resistance 663

Species have evolved differences in their circulatory physiology 663

Circulation in Fish 664

The circulatory plans of fish with air-breathing organs (ABOs) pose unresolved questions 666

Lungfish have specializations to promote separation of oxygenated and deoxygenated blood 666

Circulation in Amphibians and in Reptiles Other than Birds 668

BOX 25.1 An Incompletely Divided Central Circulation Can Potentially Be an Advantage for Intermittent Breathers 669

Concluding Comments on Vertebrates 670

Invertebrates with Closed Circulatory Systems 670

BOX 25.2 Bearing the Burden of Athleticism, Sort of: A Synthesis of Cephalopod O₂ Transport 672

Invertebrates with Open Circulatory Systems 672

The crustacean circulatory system provides an example of an open system 673

Open systems are functionally different from closed systems but may be equal in critical ways 674

BOX 25.3 Circulation and O₂: Lessons from the Insect World 675

CHAPTER 26

Oxygen, Carbon Dioxide, and Internal Transport *at Work*: Diving by Marine Mammals 679

Diving Feats and Behavior 679

Types of Dives and the Importance of Method 682

Physiology: The Big Picture 682

The Oxygen Stores of Divers 683

The blood O₂ store tends to be large in diving mammals 683

Diving mammals have high myoglobin concentrations and large myoglobin-bound O₂ stores 683

Diving mammals vary in their use of the lungs as an O₂ store 684

Total O₂ stores never permit dives of maximum duration to be fully aerobic 685

Circulatory Adjustments during Dives 685

Regional vasoconstriction: Much of a diving mammal's body is cut off from blood flow during forced or protracted dives 686

Diving bradycardia matches cardiac output to the circulatory task 687

Cardiovascular responses are graded in freely diving animals 687

BOX 26.1 The Evolution of Vertebrate Cardiac and Vascular Responses to Asphyxia 688

Red blood cells are removed from the blood between dive sequences in some seals 689

Metabolism during Dives 689

The body becomes metabolically subdivided during forced or protracted dives 689

Metabolic limits on dive duration are determined by O₂ supplies, by rates of metabolic O₂ use and lactic acid production, and by tissue tolerances 690

The Aerobic Dive Limit: One of Physiology's Key Benchmarks for Understanding Diving Behavior 691

Marine mammals exploit multiple means of reducing their metabolic costs while under water 693

Decompression Sickness 694

Human decompression sickness is usually caused by N₂ absorption from a compressed-air source 694

Breath-hold dives must be repeated many times to cause decompression sickness in humans 694

Marine mammals have been thought—perhaps erroneously—to avoid decompression sickness during deep dives by alveolar collapse 694

Decompression sickness is an unresolved phenomenon 695

A Possible Advantage for Pulmonary O₂ Sequestration in Deep Dives 695

PART VI • Water, Salts, and Excretion

CHAPTER 27 Water and Salt Physiology: Introduction and Mechanisms 699

The Importance of Animal Body Fluids 700

The Relationships among Body Fluids 701

Types of Regulation and Conformity 701

Natural Aquatic Environments 703

Natural Terrestrial Environments 705

Organs of Blood Regulation 707

The osmotic U/P ratio is an index of the action of the kidneys in osmotic regulation 707

The effects of kidney function on volume regulation depend on the amount of urine produced 708

The effects of kidney function on ionic regulation depend on ionic U/P ratios 709

Food and Drinking Water 709

Salty drinking water may not provide H₂O 709

Plants and algae with salty tissue fluids pose challenges for herbivores 710

Air-dried foods contain water 710

Protein-rich foods can be dehydrating for terrestrial animals 710

Metabolic Water 710

Metabolic water matters most in animals that conserve water effectively 711

Cell-Volume Regulation 712

From Osmolytes to Compatible Solutes: Terms and Concepts 714

CHAPTER 28 Water and Salt Physiology of Animals in Their Environments 717

Animals in Freshwater 717

Passive water and ion exchanges: Freshwater animals tend to gain water by osmosis and lose major ions by diffusion 718

Most types of freshwater animals share similar regulatory mechanisms 719

BOX 28.1 Fish Mitochondria-Rich Cells and Their Diversity 723

A few types of freshwater animals exhibit exceptional patterns of regulation 723

Why do most freshwater animals make dilute urine? 724

Animals in the Ocean 724

Most marine invertebrates are isosmotic to seawater 725

Hagfish are the only vertebrates with blood inorganic ion concentrations that make them isosmotic to seawater 725

The marine teleost fish are markedly hyposmotic to seawater 725

BOX 28.2 Where Were Vertebrates at Their Start? 726

BOX 28.3 Epithelial NaCl Secretion in Gills, Salt Glands, and Rectal Glands 728

Some arthropods of saline waters are hyposmotic regulators 729

Marine reptiles (including birds) and mammals are also hyposmotic regulators 729

Marine elasmobranch fish are hyperosmotic but hypoionic to seawater 731

BOX 28.4 The Evolution of Urea Synthesis in Vertebrates 732

Animals That Face Changes in Salinity 733

Migratory fish and other euryhaline fish are dramatic and scientifically important examples of hyper-hyposmotic regulators 734

Animals undergo change in all time frames in their relations to ambient salinity 735

Responses to Drying of the Habitat in Aquatic Animals 736

Animals on Land: Fundamental Physiological Principles 737

BOX 28.5 Anhydrobiosis: Life as Nothing More than a Morphological State 737

A low integumentary permeability to water is a key to reducing evaporative water loss on land 738

Respiratory evaporative water loss depends on the function of the breathing organs and the rate of metabolism 739

xxviii Contents

An animal's total rate of evaporative water loss depends on its body size and phylogenetic group 741

Excretory water loss depends on the concentrating ability of the excretory organs and the amount of solute that needs to be excreted 741

Terrestrial animals sometimes enter dormancy or tolerate wide departures from homeostasis to cope with water stress 743

The total rates of water turnover of free-living terrestrial animals follow allometric patterns 743

Animals on Land: Case Studies 744

Amphibians occupy diverse habitats despite their meager physiological abilities to limit water losses 744

Xeric invertebrates: Because of exquisite water conservation, some insects and arachnids have only small water needs 746

BOX 28.6 The Study of Physiological Evolution by Artificial Selection 747

Xeric vertebrates: Studies of lizards and small mammals help clarify the complexities of desert existence 747

Xeric vertebrates: Desert birds are again a new frontier for research 749

Control of Water and Salt Balance in Terrestrial Animals 750

CHAPTER 29

Kidneys and Excretion (with Notes on Nitrogen Excretion) 753

Basic Mechanisms of Kidney Function 754

Primary urine is introduced into kidney tubules by ultrafiltration or secretion 754

The predominant regulatory processes in kidney function: After primary urine forms, solutes and water are recovered from it for return to the blood, and some solutes are added from the blood 756

Urine Formation in Amphibians 757

The proximal convoluted tubule reabsorbs much of the filtrate—returning it to the blood plasma—without changing the osmotic pressure of the tubular fluid 758

The distal convoluted tubule can differentially reabsorb water and solutes, thereby regulating the ratio of water to solutes in the body fluids 759

BOX 29.1 Quantity versus Concentration 759

BOX 29.2 Methods of Study of Kidney Function: Micropuncture and Clearance 759

ADH exerts an elaborate pattern of control over nephron function 760

The bladder functions in urine formation in amphibians 761

The amphibian excretory system has mechanisms to promote excretion of urea 761

Urine Formation in Mammals 761

The nephrons, singly and collectively, give the mammalian kidney a distinctive structure 761

Comparative anatomy points to a role for the loops of Henle in concentrating the urine 763

Countercurrent multiplication is the key to producing concentrated urine 765

BOX 29.3 Countercurrent Multipliers versus Countercurrent Exchangers 767

The regulatory roles of the kidney tubules in overview: the concentrating and diluting kidney and the control of transitions 771

Modern molecular methods create new frontiers in the study of kidney function 774

Urine Formation in Other Vertebrates 775

Freshwater and marine teleost fish differ in nephron structure and function 775

The reptiles other than birds have nephrons like those of amphibians, but birds have some mammalian-type nephrons 776

Urine Formation in Decapod Crustaceans 777

Urine Formation in Molluscs 778

Urine Formation in Insects 778

The Malpighian tubules form and sometimes modify the primary urine 779

The hindgut modulates urine volume and composition in regulatory ways 779

Nitrogen Disposition and Excretion 782

Ammonotelism is the primitive state 782

Urea is more costly to synthesize but less toxic than ammonia 783

Uric acid and related compounds remove nitrogen from solution 784

CHAPTER 5 ■ Transport of Solutes and Water

Previous page: Bioluminescent fireflies, when contemplated, are among the animals that most vividly exemplify how the extreme endpoints of the hierarchy of life—molecules and ecology—interact and are interdependent. Having evolved unusual molecular mechanisms that permit light production, fireflies are able to communicate ecologically in unique ways. Shown is a long exposure of fireflies in early summer in Japan.

Animals and Environments: Function on the Ecological Stage

Animal physiology is the study of animal function—the study of “how animals work.” Physiologists—the scientists who carry out this study—bring a special perspective to scenes such as birds migrating. They wonder how much energy the birds must expend to fly, where and when the birds obtain the energy, and how the birds stay oriented toward their destination so as to arrive efficiently. More broadly stated, physiologists seek to identify the functional challenges that migrating birds face and learn how those challenges are met.

Billions of animals migrate over the face of the planet every year, making the functional properties of migrating animals a subject of paramount importance. By definition, however, migrating animals are on the move; they do not stay in one place where they might be investigated with ease. Consequently, researchers have had to be inventive to study these animals.

Physiologists now have high-quality methods for measuring the cost of flight. Sandpipers such as those shown in the opening figure are trained to fly in a wind tunnel, where their speed of flight can be controlled. While the birds fly, their rates of energy use are measured by techniques designed not to disturb them. One such technique makes use of unusual, benign isotopes of oxygen and hydrogen. These isotopes are injected into the sandpipers before they start flying, and then the rates of loss of the isotopes from the birds are measured as they fly unencumbered in the wind tunnel. From the isotope data, their rates of energy use can be calculated as they fly at speeds typical of migratory flight. These rates turn out to be very high: about seven or eight times the birds’ resting rates of energy use.¹ Physiologists have then combined this information with field observations on food ingestion and processing to learn how the birds obtain sufficient energy and how they manage their energy supplies to meet their flight needs during migration. One population of the sandpipers is famous for migrating every spring from southern South America to the Arctic—a distance of 15,000 km (9300 mi). In common with other populations of the same species, when these birds migrate, they alternate between extended *stopover periods*, during which they “refuel” by feeding, and *flight periods*, during which they fly nonstop for long distances—sometimes more than 5000 km (3100 mi). Based on the information available, the sandpipers fuel each long, uninterrupted flight by eating lots of clams, snails, and other food during the stopover period—often lasting 3–4 weeks—that immediately precedes the flight. By the time they take off, the birds must have enough stored energy to fuel the entire next leg of their journey because they do not eat as they fly.

During a stopover period, as the birds eat day after day, they store a great amount of energy as fat, and their body weight can increase by 50%. Physiologists have discovered, however, that the birds’ adjustments during a stopover period are far

¹The method of measuring rate of energy consumption discussed here, known as the *doubly-labeled water method*, is explained in greater detail on page 208.

Long-distance migrants Some populations of these sandpipers, which are known as red knots (*Calidris canutus*), breed in the high Arctic every summer but overwinter in southern Argentina. They thus migrate almost halfway around the globe twice a year. They use energy at relatively high rates not only while migrating but also during several other phases of their annual life cycle, such as their period of nesting on the cold, exposed Arctic tundra.

more complex than simply storing fat. For part of the time, the birds' stomach and intestines are large, aiding them in processing food at a high rate. During the week before they take flight, however, several organs that they will not use during flight, including their stomach and intestines, decrease significantly in size. Other organs, such as their heart, grow larger. Overall, during that week, the body of each bird is re-proportioned in ways that poise the bird to fly strongly, while reducing the amount of unnecessary weight to be carried. By investigating these phenomena, physiologists have revealed that the fascinating migrations of these birds are, in truth, far more fascinating than anyone could have imagined prior to the detailed study of function.

As you start your study of physiology, we—your authors—believe you are at the beginning of a great adventure. We feel privileged to have spent our professional lives learning how animals work, and we are eager to be your guides. If we could hop with you into a fantastic machine and tour Earth in the realms we are about to travel in this book, we would point out sperm whales diving an hour or more to depths of a mile or more, electric fish using modified muscles to generate 500-V shocks, newborn reindeer calves standing wet with amniotic fluid in the frigid Arctic wind, reef corals growing prolifically because algae within their tissues permit internal photosynthesis, and moths flying through cool nights with bodies as warm as those of mammals. Each of these scenes draws the interest of physiologists and continues to spark new physiological research.

The Importance of Physiology

Why is the study of animal physiology important to you and to people in general? Not the least of the reasons is the one we have already emphasized—namely, that a full understanding and appreciation of all the marvels and other phenomena of the animal world depends on an analysis of how animals work. The study of physiology draws us beyond surface impressions into the inner workings of animals, and nearly always this venture is not only a voyage of discovery, but also one of revelation.

The study of physiology also has enormous practical applications because physiology is a principal discipline in the understanding of health and disease. The analysis of many human diseases—ranging from aching joints to heart failure—depends on understanding how the “human machine” works. A physician who studies heart disease, for instance, needs to know the forces that make blood flow into the heart chambers between one heartbeat and the next. The physician also needs to know how pressures are developed to eject blood into the arteries, how the cells of the heart muscle coordinate their contractions, and how the nutrient and O₂ needs of all parts of the heart muscle are met. We discuss these and other aspects of mammalian physiology extensively in this book. Even when we turn our attention to other types of animals, our study will often have application to human questions. One reason is that nonhuman animals are often used as “models” for research that advances understanding of human physiology. Research on squids, for instance, has been indispensable for advancing knowledge of human neurophysiology because some of the nerve cells of squids are particularly large and therefore easily studied.

Physiology is as important for understanding the health and disease of nonhuman animals as it is for understanding health and disease in humans. An example is provided by studies of another

FIGURE 1.1 Pacific salmon migrating upriver to their spawning grounds Having spent several years feeding and growing in the Pacific Ocean, these fish have once again found the river in which they were conceived. Now they must power their way back to their birthplace to spawn, even though they ate their last meal at sea and will starve throughout their upriver journey. Shown are sockeye salmon (*Oncorhynchus nerka*).

group of migrating animals, the Pacific salmon—which swim up rivers to reach their spawning grounds (Figure 1.1). Physiologists have measured the costs these fish incur to swim upstream and leap waterfalls. This research has enabled better understanding of threats to their health. For instance, although each individual dam along a river might be designed to let salmon pass, a series of dams might so increase the overall cost of migration that the fish—which don't eat and live just on their stores of energy when migrating—could run out of energy before reaching spawning grounds. With knowledge of the energetics of swimming and leaping, managers can make rational predictions of the cumulative effects of dams, rather than simply altering rivers and waiting to see what happens. The effects of water pollutants, such as heavy metals and pesticides, are other important topics in salmon physiology. Examples in other animals include studies of stress and nutrition. Conservation biologists gauge the stress experienced by wild vertebrate animals by measuring levels of stress-response hormones in their blood (see page 433). Careful studies of nutrition have solved mysterious cases of population decline by revealing that the animals were unable to find adequate amounts of acceptable foods.

In brief, physiology is one of the key disciplines for understanding

- The fundamental biology of all animals
- Human health and disease
- The health and disease of nonhuman animals of importance in human affairs

Physiology is also important because *it is one of biology's most integrative disciplines*. Physiologists study all the levels of organization of the animal body. In this respect, they are much like detectives

who follow leads wherever the leads take them. To understand how an organ works, for instance, information about the nervous and hormonal controls of the organ might be required, plus information about enzyme function in the organ, which might lead to studies of the activation of genes that code for enzyme synthesis. Physiology not only pursues all these levels of biological organization within individual animals but also relates this knowledge to the ecology and evolutionary biology of the animals. Students often especially enjoy their study of physiology because the discipline is so integrative, bringing together and synthesizing many concepts that otherwise can seem independent.

Consider again, for example, the Pacific salmon. As juveniles, these fish migrate from rivers to the open ocean. Years later, they return to the very rivers of their conception to procreate the next generation. Before a returning salmon enters freshwater, it maintains its blood more dilute than the seawater in which it swims. After it enters freshwater, however, it must maintain its blood more concentrated than the dilute freshwater now surrounding it. Another challenge the salmon faces is meeting the energy costs of its migration. Once in its natal river, a salmon no longer eats. Yet it may swim for many weeks before it reaches its spawning grounds—sometimes traveling against the river current as far as 1100 km (680 mi) and, in mountainous regions, climbing 1.2 km (0.75 mi) in altitude. During this trip, because the fish is starving, it gradually breaks down the substance of its body to supply its energy needs; 50–70% of all tissues that can supply energy are typically used by the time the fish reaches its destination.

As physiologists study salmon, they take a highly integrative approach, illustrated in **Figure 1.2**. As part of their background of knowledge, they recognize that the populations and species of salmon alive today not only are products of evolution but also are still evolving (see **Figure 1.2a**). Physiologists also recognize that the laws of chemistry and physics need to be considered (see **Figure 1.2b**), because animals must obey those laws—and sometimes they *exploit* them. For understanding swimming, multiple levels of organization must be considered (see **Figure 1.2c**). The nervous system generates coordinated nerve impulses that travel to the swimming muscles, which contract using energy drawn from adenosine triphosphate (ATP) that is synthesized from organic food molecules. The contraction of the swimming muscles then exerts biomechanical forces on the water that propel the fish forward. The investigation of swimming illustrates, too, the important general point that the study of *function* typically goes hand in hand with the study of *form*; knowledge of anatomy often sets the stage for understanding physiology, and as function is clarified, it typically helps account for anatomy. Often, the ultimate goal of a physiological study is to understand how an animal functions in its natural environment. Thus, an ecological perspective is vital as well. As seen in **Figure 1.2d**, when an individual salmon's fluid environment changes from saltwater to freshwater, the fish alters the set of ion-transporting proteins expressed in its gills, permitting inward ion pumping in freshwater whereas ions were pumped outward in saltwater. The distance a fish swims is another important ecological consideration. Different populations of salmon travel vastly different distances. Going far upriver can provide advantages of certain kinds, such as providing pristine spawning grounds. However, this ecological factor has other consequences as well. Females that exert great effort to reach their spawning grounds, such as by swimming great

distances, spawn fewer eggs because swimming diverts energy away from use in reproduction (see **Figure 1.2d**).

Mechanism and Origin: Physiology's Two Central Questions

Physiology seeks to answer two central questions about how animals work: (1) What is the mechanism by which a function is accomplished, and (2) how did that mechanism come to be? To understand why there are *two* questions, consider the analogous problem of how a car works. In particular, how is an engine-driven wheel made to turn?

To understand this function, you could disassemble a car and experiment on its parts. You could study how the pistons inside the cylinders of the engine are made to oscillate by forces released from exploding gasoline, how the pistons and connecting rods turn the drive shaft, and so forth. From studies like these, you would learn how the car works.

At the conclusion of such studies, however, you would have only half the answer to the question of how the car works. Presuming that you have investigated a routine design of modern car, your experiments will have revealed how a routine internal combustion engine turns a wheel by way of a routine transmission. Let your mind run free, however, and you may quickly realize that there are alternative designs for a car. The engine could have been a steam engine or a fuel cell–based engine, for example. Accordingly, when you ponder how a wheel turns, you see that you really face two questions: the *immediate* question of how a particular design of car makes a wheel turn, and the *ultimate* question of how that particular design came into being. Physiologists also face these two questions of *mechanism* and *origin*.

The study of mechanism: How do modern-day animals carry out their functions?

If you examine a particular car and its interacting parts to understand how it works, you are learning about the *mechanisms* of function of the car. Likewise, if you study the interacting parts of a particular animal—from organs to enzymes—to learn how it works, you are studying the animal's *mechanisms*. In physiology, **mechanism** refers to the components of actual, living animals and the interactions among those components that enable the animals to perform as they do.

Curiosity about mechanism is what inspires most physiologists to study animals, and studies of mechanism dominate physiological research. Physiology, in fact, is most clearly distinguished from other biological disciplines with which it is related, such as morphology or ecology, by its central focus on the study of mechanism. A physiologist typically begins an investigation by observing a particular capability that excites curiosity or needs to be understood for practical purposes. The capability of the human visual system to distinguish red and blue is an example. Another example is the ability of certain types of nerve cells to conduct nerve impulses at speeds of over 100 meters per second. Whatever the capability of interest, the typical goal of physiological research is to discover its mechanistic basis. What cells, enzymes, and other parts of the body are employed, and how are they employed, to enable the animal to perform as it does?

For a detailed example of a mechanism, consider how the light organ of a firefly emits flashes, starting with the biochemistry of light

(a) **Evolution** Today's animals are products of evolution and are still evolving

(b) **Chemistry and physics**

$$\text{Thrust} - \text{Drag} = \text{Mass} \times \text{Acceleration}$$

Animals must adhere to the laws of chemistry and physics—and sometimes they take advantage of them.

(c) **Physiology** depends on all levels of organization

◀ **FIGURE 1.2 The study of physiology integrates knowledge at all levels of organization** To understand the physiology of fish, physiologists consider (a) evolutionary biology, (b) the laws of chemistry and physics, and (d) ecological relations—as well as (c) body function at all levels of organization. All elements shown are for fish in a single genus, *Oncorhynchus*, the Pacific salmonid fish. In (c) the drawing in “Systems physiology” is a cross section of the body; the salmon in “Morphology” is a chinook salmon. (Graph in a—which pertains to populations of chum salmon—after Hendry et al. 2004; cross section, salmon, and biomechanics illustration in c after Videler 1993; graph in d—which pertains to sockeye salmon—after Crossin et al. 2004.)

production (Figure 1.3a). A chemical compound (a benzothiazol) named *firefly luciferin* first reacts with ATP to form luciferyl-AMP (AMP, adenosine monophosphate). Then, if O_2 —molecular oxygen—can reach the luciferyl-AMP, the two react to form a chemical product in which electrons are boosted to an excited state, and when this electron-excited product returns to its ground state, it emits photons. This sequence of reactions requires a protein catalyst, an enzyme called *firefly luciferase*. A question only recently answered is how cells within the light organ are controlled so that they flash at certain times but remain dark at others. When a firefly is not producing light (Figure 1.3b), any O_2 that reaches the insect’s light cells via its gas-transport tubules is intercepted (and thereby prevented from reacting with luciferyl-AMP) by mitochondria that are positioned between the gas-transport tubules and the sites of the luciferin reactions. The light cells produce light (Figure 1.3c) when, because of stimulation by the nervous system, the mitochondria become bathed with nitric oxide (NO). The NO blocks mitochondrial use of O_2 , allowing O_2 through to react with luciferyl-AMP. Facts like these form a description of the *mechanism* by which fireflies produce light.

The study of a mechanism may become so intricate that decades or centuries are required for a mechanism to be fully understood. By definition, however, the complete mechanism of any given function is present for study in the here and now. A scientist can, in principle, fully describe the mechanism of a process merely by studying existing animals in ever-finer detail.

The study of origin: Why do modern-day animals possess the mechanisms they do?

Suppose a youngster observes a firefly produce a flash of light and asks you to explain what he has seen. One way you could interpret the request is as a question about mechanism. Thus you could answer that the brain of the insect sends nerve impulses that cause the light cells to become bathed with nitric oxide, resulting in the production of excited electrons through the reaction of O_2 with luciferyl-AMP. However, the youngster who asks you to explain the flashing of a firefly is probably interested in something else. The *reason* the firefly makes light is probably what is on your young friend’s mind, rather than the mechanism. That is, the youngster is probably wondering *why* the firefly possesses a mechanism to make light.

For biologists, the answer lies in *evolutionary origins*. The mechanisms of modern-day animals are products of evolution, and thus the reasons for the existence of mechanisms lie in evolutionary processes. The study of evolutionary origins is a central aim of modern physiology because it promises to reveal the *significance* of mechanisms. If we can learn why evolution produced a mechanism, we will better understand what (if anything) animals gain by having the mechanism.

FIGURE 1.3 The mechanism of light production by fireflies (*Photinus*) (a) The chemistry of light production. (b,c) In the light cells—the cells that compose the light organ—the luciferin reactions are spatially separated from mitochondria. When a light cell is not flashing (b), the mitochondria intercept O_2 . However, when a cell is flashing (c), O_2 gets through to the luciferin reactions. Understanding of firefly flashing is a work in progress; thus, parts of this scenario are hypothetical. AMP = adenosine monophosphate; ATP = adenosine triphosphate.

Because modern-day mechanisms evolved in the past, the question of origins is fundamentally historical. The origins of a mechanism, unlike the mechanism itself, cannot usually be observed directly in the here and now. Instead, origins must usually be studied indirectly, by means of inferences about the past derived from observations we can make in the present. The reliance on indirect reasoning means that evolutionary origins are rarely understood with the same certainty as mechanisms.

Natural selection is a key process of evolutionary origin

Natural selection is just one of several processes by which animals acquire traits during evolution, as we discuss later in this chapter. Natural selection, however, holds a place of special importance for biologists because, of all the modes of evolutionary change, natural selection is believed to be the principal process by which animals become fit to live in their environments.

Natural selection is the increase in frequency of genes that produce phenotypes that raise the likelihood that animals will survive and reproduce. During evolution by natural selection, such genes increase in frequency—over the course of generations—because animals with the genes are differentially successful relative to other members of their species. If we find that a physiological mechanism originated by natural selection within the prevailing environment, we can conclude that the mechanism is an asset; that is, it improves an animal's chances of survival and reproduction within the environment the animal occupies.

Adaptation is an important sister concept to natural selection. Because we discuss adaptation at length later, here we simply state that an adaptation is a physiological mechanism or other trait that is a product of evolution by natural selection. Adaptations are assets; because of the way they originated, they aid the survival and reproduction of animals living in the environment where they evolved. When we speak of the **adaptive significance** of a trait evolved by natural selection, we refer to the reason *why* the trait is an asset: that is, the reason *why* natural selection favored the evolution of the trait.

The light flashes of fireflies usually function to attract mates. The males of each species of firefly emit light flashes in a distinctive, species-specific pattern as they fly, thereby signaling their species identity to females (Figure 1.4). Using various sorts of evidence, students of fireflies infer that the firefly light-producing mechanism evolved by natural selection because light flashes can be used to bring the sexes together. Thus the mechanism of light production is an adaptation, and its adaptive significance is mate attraction.

Mechanism and adaptive significance are distinct concepts that do not imply each other

Why have we stressed that physiology faces *two* central questions? We have emphasized both that physiology studies mechanism and that it studies evolutionary origins to understand adaptive significance. Why *both*? Physiologists must seek answers to both questions because *mechanism and adaptive significance do not imply each other*. If you know the mechanism of a process, you do not necessarily know anything about its adaptive significance. If you know the adaptive significance, you do not necessarily know anything about the mechanism. Thus, to understand both mechanism and adaptive significance, you must study both.

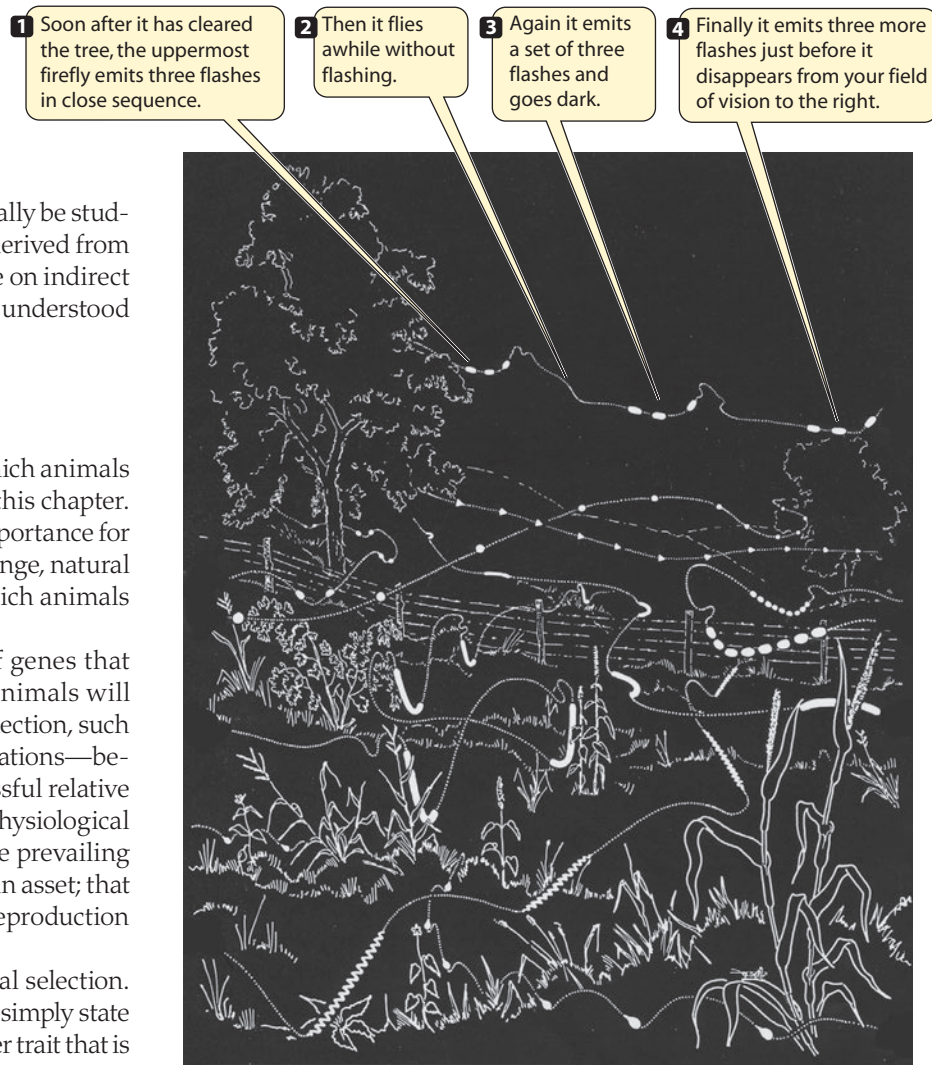

FIGURE 1.4 Male fireflies employ their mechanism of light production for an adaptive function: mate attraction. The drawing shows representative flashing patterns and flight paths of males of nine different species of fireflies of the genus *Photinus* from the eastern and central United States. Each line of flight represents a different species. For instance, the uppermost line represents *Photinus consimilis*, a species that flies high above the ground. To understand the format, imagine that you are watching the uppermost firefly as it leaves the tree and follows the numbered sequence. The differences in flashing and flight patterns among species allow males to signal their species to females. (From a drawing by Dan Otte in Lloyd 1966.)

As an example, consider light production by fireflies once again. Physiologists know of many mechanisms by which organisms can produce light.² Thus, even if fireflies were *required* to attract their mates with light, their mechanism of making light would not be limited theoretically to just the mechanism they use. The mechanism of light production by fireflies cannot be deduced from simple knowledge of the purpose for which the mechanism is used. Conversely, light flashes could be used for purposes other than mate attraction, such as luring prey, distracting predators, or

²The number of known mechanisms is partly obscured by the fact that *luciferin* and *luciferase* are generic terms, each used to refer to many distinctly different chemical compounds. For example, more than 30 distinctly different compounds are called *luciferin*. Accordingly, although many bioluminescent organisms are said to use a “luciferin–luciferase system” to make light, all such organisms are not by any means employing the same chemistry.

synchronizing biorhythms. The significance of light production cannot be deduced from the simple fact that light is made or from knowledge of the mechanism by which it is made.

François Jacob (b. 1920), a Nobel laureate, asked in a famous article whether evolution by natural selection more closely resembles engineering or tinkering. An engineer who is designing a machine can start from scratch. That is, an engineer can start by thinking about the very best design and then build that design from raw materials. A tinkerer who is building a new machine starts with parts of preexisting machines.

Evolution is like tinkering, Jacob argued: A population of animals that is evolving a new organ or process rarely starts from scratch; instead, it starts with elements that it already has on hand for other reasons. The lungs of mammals, for example, originated as outpocketings of a food-transport tube, the *esophagus*, in the ancient fish that gave rise to the tetrapods living on land today. Those fish, moreover, were not the only fish to evolve air-breathing organs. Today, as discussed in Chapter 23 (see page 593), there are various different groups of fish that use the *stomach*, *intestines*, *mouth cavity*,

or outpocketings of the *gill chambers* as air-breathing organs. This diversity reminds one of a tinkerer who, in the course of assembling a garden cart, might try to use axles and wheels taken from a discarded bicycle, an outdated trailer, or an old children's wagon.

Throughout evolution, animals in a sense have had to remain capable of living in their old ways even as they have developed new ways. Thus design from first principles—the engineering approach—has not been possible.

The tinkering aspect of evolution is a key reason why mechanism and adaptive significance do not imply each other. The mechanism employed to perform a particular function is not an abstraction but instead bears an imprint of the structures and processes that came before in any particular evolutionary line. Consider, for instance, the eyes of two groups of active aquatic animals: the cephalopod molluscs (squids and octopuses) and the fish. Both groups have evolved sophisticated eyes that permit lifestyles based on excellent vision. However, these eyes are built on very different retinal designs (**Figure 1.5**). The photoreceptors in the retinas of fish point *away* from the light; those of squids and octopuses point *toward* the light.

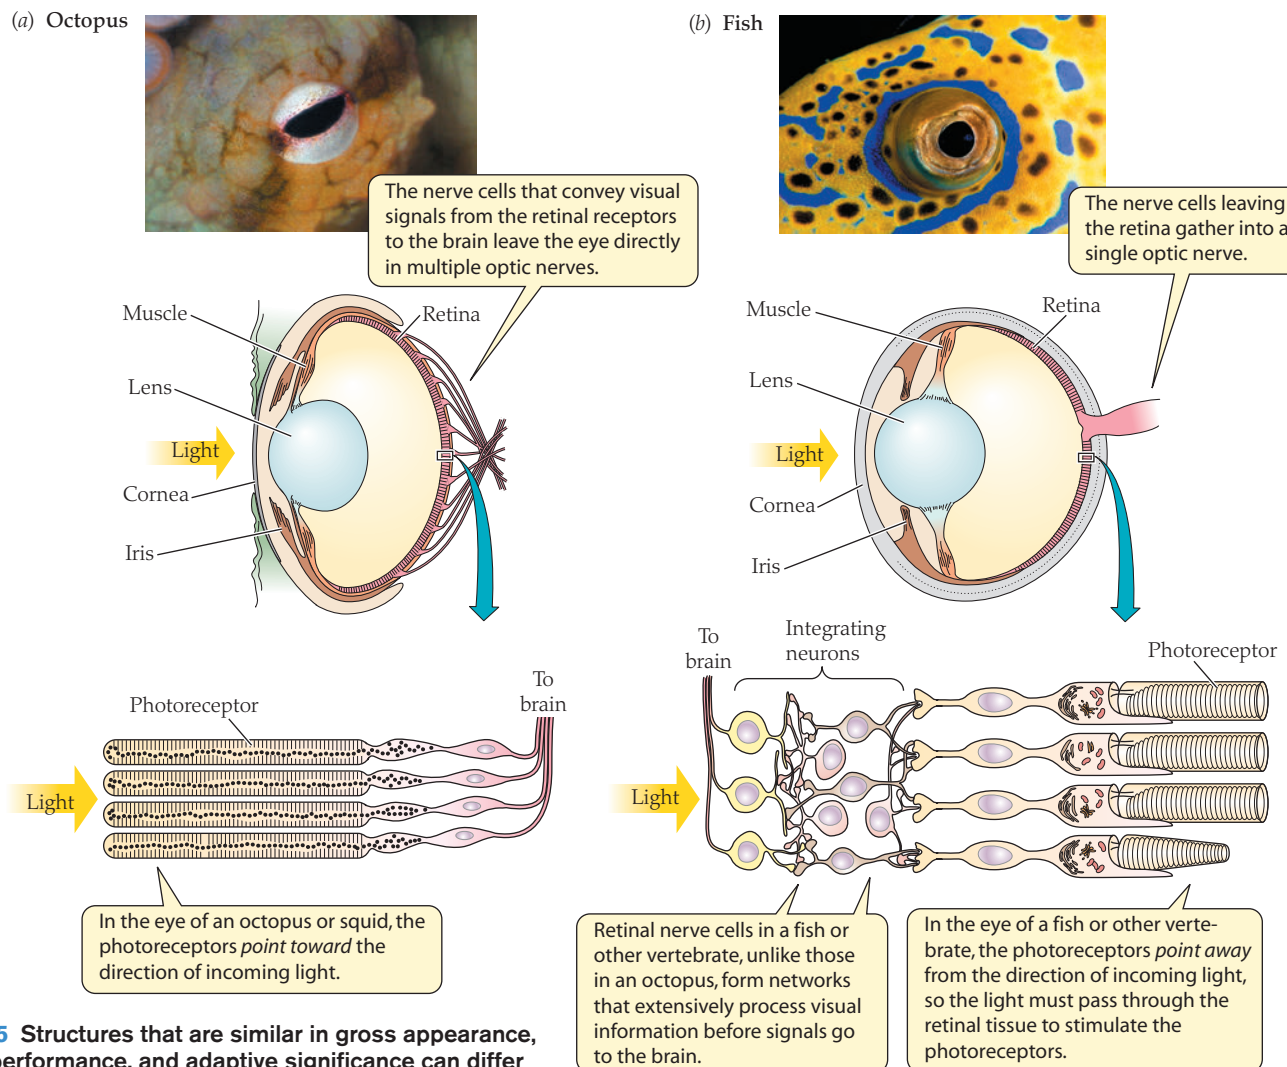

FIGURE 1.5 Structures that are similar in gross appearance, functional performance, and adaptive significance can differ dramatically in details of how they are assembled and work. Both cephalopod molluscs and fish have evolved excellent vision, but they see using different detailed mechanisms. (a after Wells 1966 and Young 1971; b after Walls 1942.)

Moreover, whereas visual signals from the fish photoreceptors are extensively processed by networks of integrating nerve cells *within* the retina before visual information is sent to the brain in a single optic nerve, in squids and octopuses the photoreceptors send their visual signals more directly to the brain in multiple optic nerves. The adaptive significance of excellent vision in the two groups of animals is similar, but the detailed mechanisms are not. A major reason for the differences in mechanisms is undoubtedly that the two groups built their eyes from different preexisting structures.

This Book's Approach to Physiology

Mechanistic physiology, which emphasizes the study of mechanism, and **evolutionary physiology**, which emphasizes the study of evolutionary origins, have become recognized as major approaches to the study of animal physiology in recent years. The two approaches share the same overall subject matter: They both address the understanding of animal function. They differ, however, in the particular aspects of physiology they emphasize. The viewpoint of this book, as stressed already, is that both approaches are essential for physiology to be fully understood.

Comparative physiology and **environmental physiology** are additional approaches to the study of animal physiology. These approaches overlap mechanistic and evolutionary physiology, and they overlap each other. Comparative physiology is the synthetic study of the function of all animals. It contrasts, for example, with *human physiology* or *avian physiology*, each of which addresses only a limited set of animals. Comparative physiology is termed *comparative* because one of its major goals is to compare systematically the ways that various sorts of animals carry out similar functions, such as vision, breathing, or circulation. Environmental physiology (also called *physiological ecology*) is the study of how animals respond physiologically to environmental conditions and challenges, or—more briefly—“ecologically relevant physiology.” **Integrative**

physiology is a relatively new term referring to investigations with a deliberate emphasis on *synthesis across levels of biological organization*, such as research that probes the relations between molecular and anatomical features of organs.

Our viewpoint in this book is mechanistic, evolutionary, comparative, environmental, and integrative. In other words, we stress:

- The mechanisms by which animals perform their life-sustaining functions
- The evolution and adaptive significance of physiological traits
- The ways in which diverse phylogenetic groups of animals both resemble each other and differ
- The ways in which physiology and ecology interact, in the present and during evolutionary time
- The importance of all levels of organization—from genes to proteins, and tissues to organs—for the full understanding of physiological systems

Overlapping with the classifications already discussed, physiology is divided also into various branches or disciplines based on the *types of functions* that are performed by animals. The organization of this book into parts and chapters is based on the types of function. As **Table 1.1** shows, the book consists of six major subdivisions, Parts I through VI, each of which focuses on a particular set of functions. The chapters within each part discuss particular aspects of the part topic. The last chapter in each part (except Part I) is an “At Work” chapter that takes a synthetic approach to a prominent, curiosity-provoking topic in the part. *The principal goal of the “At Work” chapters is to show how the material in each of the parts can be used in an integrated way to understand animal function.*

Now, as they say in theater, “Let the play begin.” As we consider the principal subject of this chapter—function on the ecological stage—the three major players are animals, environments, and evolutionary processes (see Figure 1.2). We now address each.

TABLE 1.1 The organization of this book

The “At Work” chapters, printed in italics, exemplify how the material covered in each part of the book can be used synthetically to understand a problem in animal physiology.

Parts	Topics within parts
Part I: Fundamentals of Physiology	• Animals and Environments (Chapter 1) • Molecules and Cells (Chapter 2) • Genomics and Proteomics (Chapter 3) • Physiological Development and Epigenetics (Chapter 4) • Transport of Solutes and Water (Chapter 5)
Part II: Food, Energy, and Temperature	• Nutrition, Feeding, and Digestion (Chapter 6) • Energy Metabolism (Chapter 7) • Aerobic and Anaerobic Metabolism (Chapter 8) • Exercise (Chapter 9) • Thermal Relations (Chapter 10) • <i>Mammals in Frigid Places (Chapter 11)</i>
Part III: Integrating Systems	• Neurons (Chapter 12) • Synapses (Chapter 13) • Sensory Processes (Chapter 14) • Nervous Systems; Biological Clocks (Chapter 15) • Endocrine and Neuroendocrine Physiology (Chapter 16) • Reproduction (Chapter 17) • <i>Animal Navigation (Chapter 18)</i>
Part IV: Movement and Muscle	• Control of Movement (Chapter 19) • Muscle (Chapter 20) • <i>Muscle Plasticity in Use and Disuse (Chapter 21)</i>
Part V: Oxygen, Carbon Dioxide, and Internal Transport	• Oxygen and Carbon Dioxide Basics (Chapter 22) • Breathing (Chapter 23) • Gas Transport in Blood (Chapter 24) • Circulation (Chapter 25) • <i>Diving by Marine Mammals (Chapter 26)</i>
Part VI: Water, Salts, and Excretion	• Water and Salt Basics (Chapter 27) • Water and Salt Physiology of Animals in Their Environments (Chapter 28) • Kidneys and Excretion (Chapter 29) • <i>Mammals of Deserts and Dry Savannas (Chapter 30)</i>

Animals

The animal properties that deserve mention in an initial overview are the properties that are of overriding importance. These include that (1) animals are *structurally dynamic*, (2) animals are *organized* systems that *require energy* to maintain their organization, and (3) both *time* and *body size* are of fundamental significance in the lives of all animals.

One of the most profoundly important properties of animals is that the atoms of their bodies—their material building blocks—are in dynamic exchange with the atoms in their environments throughout life. This structural dynamism—memorably termed “the dynamic state of body constituents” by Rudolf Schoenheimer, who discovered it³—is a fundamental and crucially important way in which animals differ from inanimate objects such as telephones. After a telephone is manufactured, the particular carbon and iron atoms that are built into its substance remain as long as the telephone exists. One might think by casual observation that the composition of a person, lion, or crab is similarly static. This illusion was abruptly dispelled, however, when Schoenheimer and others began using chemical isotopes as research tools.

Isotopes proved to be revealing because they permit atoms to be labeled and therefore tracked. Consider iron as an example. Because most iron atoms in the natural world are of atomic weight 56 (⁵⁶Fe), an investigator can distinctively label a particular set of iron atoms by substituting the unusual (but *stable*) alternative isotope of iron having an atomic weight of 58 (⁵⁸Fe). Suppose that we make a telephone in which all the iron atoms are of the unusual ⁵⁸Fe isotope, so that we can distinguish those iron atoms from the ones generally available. Years later, all the iron atoms in the telephone will still be of the unusual ⁵⁸Fe type. Suppose, however, that we create a ⁵⁸Fe-labeled person by feeding the person over the course of a year the unusual ⁵⁸Fe isotope, so that isotopically distinctive iron atoms are built into hemoglobin molecules and other iron-containing molecules throughout the person’s body. Suppose we then stop providing the unusual iron isotope in the person’s diet. Thereafter—as time goes by—the isotopically distinctive ⁵⁸Fe atoms in the body will leave and will be replaced with atoms of the ordinary isotope, ⁵⁶Fe, from the environment. Years later, all the unusual iron atoms will be gone. We see, therefore, that although the person may outwardly appear to be structurally constant like a telephone, the iron atoms in the substance of the person’s body at one time differ from those at another time.

The mechanistic reason for the turnover of iron atoms in an animal is that the molecular constituents of an individual’s body break down and are rebuilt. A human red blood cell, for example, typically lives for only 4 months. When a red blood cell is discarded and replaced, some of the iron atoms from the hemoglobin molecules of the old cell are excreted into the environment, and some of the iron atoms built into the new cell are acquired from food. In this way, even though the number of red blood cells remains relatively constant, the iron atoms of the cells are in dynamic exchange with iron atoms in the environment.

Essentially all the atoms in the substance of an animal’s body undergo similar dynamic exchanges. Calcium atoms enter an animal’s skeleton and later are withdrawn; some of the withdrawn atoms are replaced with newly ingested calcium atoms from the environment. Proteins and fats throughout an animal’s body are continually broken down at substantial rates,⁴ and their resynthesis is carried out in part with molecules newly acquired from the environment, such as amino acids and fatty acids from foods. Adult people typically resynthesize 2–3% of their body protein *each day*, and about 10% of the amino acids used to build the new protein molecules are acquired from food.

Have you ever wondered why you need to worry *every week* about whether you are eating enough calcium, iron, magnesium, and protein? The explanation is provided by the principles we are discussing. If you were an inanimate object, enough of each necessary element or compound could be built into your body at the start, and you would then have enough forever. Instead, because you are alive and dynamic—rather than inanimate and static—you lose elements and compounds every day and must replace them.

As this discussion has illustrated, the *material boundaries* between an animal and its environment are blurred, not crisp. Atoms cross the boundaries throughout life, so that an atom that is part of an animal’s tissues on one day may be lying on the forest floor or drifting in the atmosphere the next day, and vice versa. Possibly the most profound implication of these facts is that *an animal is not a discrete material object*.

The structural property of an animal that persists through time is its organization

If the atomic building blocks of an animal are transient, by what structural property is an animal *defined*? The answer comes from imagining that we can see the individual molecules in an adult animal’s body. If we could, we would observe that the molecular structures and the spatial relations of molecules in tissues are relatively constant over time, even though the particular atoms constructing the molecules change from time to time. A rough analogy would be a brick wall that retains a given size and shape but in which the bricks are constantly being replaced, so that the particular bricks present during one month are different from those present a month earlier.

The structural property of an animal that persists through time is the *organization* of its atomic building blocks, not the building blocks themselves. *Thus an animal is defined by its organization*. This characteristic of animals provides the most fundamental reason why animals require inputs of energy throughout life. As we discuss in detail in Chapter 7, the second law of thermodynamics says that for organization to be maintained in a dynamic system, use of energy is essential.

Most cells of an animal are exposed to the internal environment, not the external environment

Shifting our focus now to the cells of an animal’s body, it is important first to stress that the conditions experienced by most of an animal’s cells are the conditions *inside* the body, not those outside. Most cells are bathed by the animal’s tissue fluids or blood. Thus

³As chemists learned about and started to synthesize unusual isotopes in the 1930s, Rudolf Schoenheimer (1898–1941) was one of the first to apply the newfound isotopes to the study of animal metabolism. His classic book on the subject, published posthumously as World War II raged, is titled *The Dynamic State of Body Constituents*.

⁴See Chapter 2 (page 55) for a discussion of the ubiquitin–proteasome system that tags proteins for breakdown and disassembles them.

the *environment* of most cells consists of the set of conditions prevailing in the tissue fluids or blood. Claude Bernard (1813–1878), a Frenchman who was one of the most influential physiologists of the nineteenth century, was the first to codify this concept. He coined the term **internal environment** (*milieu intérieur*) to refer to the set of conditions—temperature, pH, sodium (Na^+) concentration, and so forth—experienced by cells within an animal's body. The conditions outside the body represent the **external environment**.

The internal environment may be permitted to vary when the external environment changes, or it may be kept constant

Animals have evolved various types of relations between their internal environment and the external environment. If we think of the organization of the body as being hierarchically arranged, the relations between the internal and external environments represent one of the potential hierarchical levels at which animals may exhibit organization. At a primary level, *all* animals consistently exhibit structural organization of their atoms and molecules. At this additional, secondary level, animals sometimes—but only sometimes—exhibit further organization by keeping their internal environment distinct from their external environment.

Animals display two principal types of relation between their internal and external environments. On the one hand, when the conditions outside an animal's body change, the animal may permit its internal environment to match the external conditions and thus change along with the outside changes. On the other hand, the animal may maintain constancy in its internal environment. These alternatives are illustrated with temperature in Figure 1.6. If the temperature of an animal's external environment changes, one option is for the animal to let its internal temperature change to match the external temperature (see Figure 1.6a). Another option is for the animal to maintain a constant internal temperature (see Figure 1.6b). If an animal permits internal and external conditions to be equal, it is said to show **conformity**. If the animal maintains internal constancy in the face of external variability, it shows **regulation**. Conformity and regulation are extremes; intermediate responses are common.

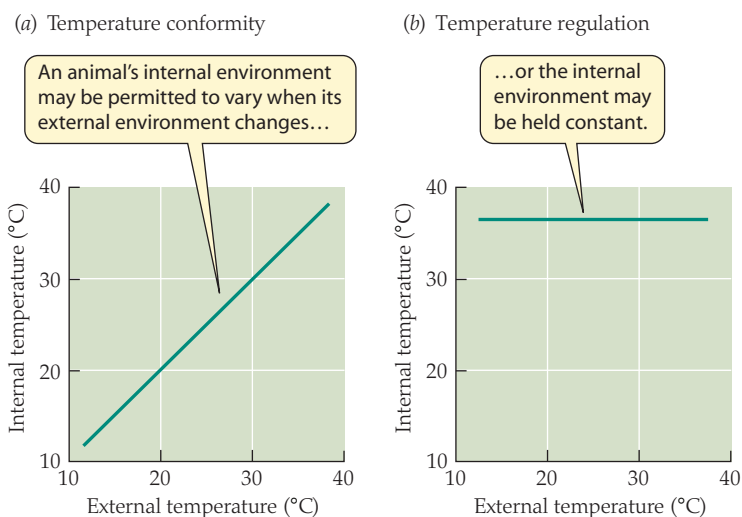

FIGURE 1.6 Conformity and regulation These examples from the study of temperature illustrate the general principles of conformity (a) and regulation (b).

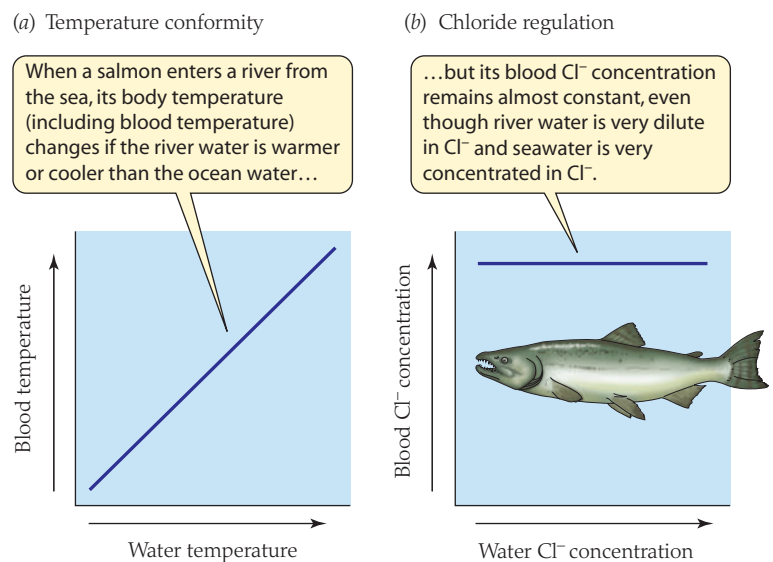

FIGURE 1.7 Mixed conformity and regulation in a single species Salmon are temperature conformers but chloride regulators. The presentation of Cl^- regulation is diagrammatic; the blood Cl^- concentration is not in fact absolutely constant but is a little higher when the fish are in seawater than when they are in freshwater.

Animals frequently show conformity with respect to some characteristics of their internal environment while showing regulation with respect to others. Consider a salmon, for example (Figure 1.7). Like most fish, salmon are *temperature conformers*; they let their internal temperature match the surrounding water temperature (see Figure 1.7a). Simultaneously, salmon are excellent *chloride regulators*; they maintain a nearly constant concentration of Cl^- ions in their blood, regardless of how high or low the outside Cl^- concentration is (see Figure 1.7b).

Regulation demands more energy than conformity because regulation represents a form of organization. During regulation, organization is manifested both by the maintenance of *constancy* inside the body and by the maintenance of a *distinction* between inside and outside conditions. A familiar analogy for the energy costs of regulation in animals is provided by home heating. A great deal of energy is required to keep the inside of a house at 22°C (72°F) during the cold of winter. This energy cost is entirely avoided if the inside temperature is simply allowed to match the outside temperature.

Homeostasis in the lives of animals: Internal constancy is often critical for proper function

Homeostasis is an important concept regarding the *nature* and *significance* of internal constancy. Soon we will define homeostasis using the words of Walter Cannon (1871–1945), who coined the term. To fully appreciate the concept, however, we must first recognize its historical roots in medicine. The two men who contributed the most toward developing the concept of homeostasis, Claude Bernard and Walter Cannon, were physicians and medical researchers, concerned primarily with human physiology. Healthy humans maintain remarkable constancy of conditions in their blood and tissue fluids. The notion of homeostasis was thus conceived during studies of a species that exhibits exceptional internal constancy, and later the notion was extrapolated to other animals.

BOX 1.1 NEGATIVE FEEDBACK

The type of control that Claude Bernard discovered in his studies of blood glucose is what today we call *negative feedback*. In any control system, the **controlled variable** is the property that is being kept constant or relatively constant by the system's activities. The **set point** is the level at which the controlled variable is to be kept. **Feedback** occurs if the system uses information on the controlled variable itself to govern its actions. In **negative feedback**, the system responds to changes in the controlled variable by bringing the variable back toward its set point; that is, the system *opposes deviations* of the controlled variable from the set point. There are many detailed mechanisms by which negative feedback can be brought about in physiological systems. Negative feedback, however, is virtually synonymous with homeostasis and occurs in all homeostatic systems.

In the case of the blood glucose level that so intrigued Claude Bernard, the control system adds glucose to the blood if the blood glucose concentration—the controlled variable—falls below its set-point concentration, thereby opposing the deviation of the blood concentration from the set point. The control system removes glucose from the blood if the glucose concentration rises too high, thereby again opposing the deviation of the concentration from its set point. Biologists and engineers who study control systems have established that no control system can maintain perfect constancy in a controlled variable; putting the case roughly, a controlled variable must be a moving target for a control system to act on it. Thus the blood glucose concentration is not kept perfectly constant by the glucose control system, but during normal health it is kept from varying outside a narrow range.

Box 10.2 will provide greater detail about control systems based on negative feedback.

In **positive feedback**, a control system *reinforces deviations* of a controlled variable from its set point. Positive feedback is much less common in physiological systems than negative feedback. It is more common during normal function than is usually recognized, however. For example, positive feedback occurs when action potentials (nerve impulses) develop in nerve cells (see Figure 12.16), and it also occurs during the birth process in mammals (see Figure 17.16). In the first case, a relatively small change in the voltage across the nerve-cell membrane modulates the properties of the membrane in ways that amplify the voltage change. In the second, muscular contractions acting to expel the fetus from the uterus induce hormonal signals that stimulate ever-more-intense contractions.

Claude Bernard was the first to recognize the impressive stability of conditions that humans maintain in their blood and tissue fluids. One of Bernard's principal areas of study was blood glucose in mammals. He observed that the liver takes up and releases glucose as necessary to maintain a relatively constant glucose concentration in the blood. If blood glucose rises, the liver removes glucose from the blood. If blood glucose falls, the liver releases glucose into the blood. Bernard stressed that, as a consequence, most cells in the body of a mammal experience a relatively constant environment with respect to glucose concentration (Box 1.1). Bernard's research and that of later investigators also revealed that most cells in a mammal's body experience relative constancy of temperature, O₂ level, osmotic pressure, pH, Na⁺ concentration, Cl⁻ concentration, and so on because various organs and tissues regulate these properties at consistent levels in the body fluids bathing the cells.

Claude Bernard devoted much thought to the *significance* of internal constancy in humans and other mammals. He was greatly impressed with how freely mammals are able to conduct their lives regardless of outside conditions. Mammals, for example, can wander about outdoors in the dead of winter, seeking food and mates, whereas fish or insects—in sharp contrast—are often driven into a sort of paralysis by winter's cold. Bernard reasoned that mammals are able to function in a consistent way regardless of varying outside conditions because the cells inside their bodies enjoy constant conditions. He thus stated a hypothesis that remains probably the most famous in the history of animal physiology: "*Constancy of the internal environment is the condition for free life.*" A modern translation might go like this: Animals are able to lead lives of greater freedom and independence to the extent that they maintain a stable internal environment, sheltering their *cells* from the variability of the outside world.

Walter Cannon, a prominent American physiologist who was born in the same decade that Claude Bernard died, introduced the concept of homeostasis to refer to internal constancy in animals. In certain ways, Bernard's and Cannon's views were so similar that

Bernard might have invented the homeostasis concept, but the implications of internal constancy were clearer by Cannon's time. Because animals dynamically interact with their environments, the temperature, pH, ion concentrations, and other properties of their bodies are incessantly being drawn away from stability. Cannon emphasized that for an animal to be internally stable, vigilant physiological mechanisms must be present to correct deviations from stability. Thus, when Cannon introduced and defined the term **homeostasis**, he intended it to mean not just internal constancy, but also the existence of regulatory systems that automatically make adjustments to maintain internal constancy. In his own words, Cannon at one point described homeostasis as "the coordinated physiological processes which maintain most of the [constant] states in the organism."

An essential aspect of Cannon's perspective was his conviction that homeostasis is good. Cannon argued, in fact, that homeostasis is a signature of highly evolved life. He believed that animal species could be ranked according to their degree of homeostasis; in his view, for example, mammals were superior to frogs because of their greater degree of homeostasis. Late in life, Cannon even argued that human societies could be ranked on a scale of homeostasis—self-regulatory and internally constant societies being inherently superior to others.

HOMEOSTASIS IN THE MODERN STUDY OF ANIMAL PHYSIOLOGY

The concept of ranking animals using degrees of homeostasis seems misguided to most biologists today. Bernard and Cannon, having focused on mammals, articulated ideas that are truly indispensable for understanding mammalian biology and medicine. However, the mere fact that mammals exhibit a high degree of homeostasis does not mean that other animals should be held to mammalian standards. Animals that exhibit less-complete homeostasis than mammals coexist in the biosphere with mammals. Indeed, the vast majority of animals thriving today do not achieve "mammalian standards" of homeostasis. Thus most biologists to-

day would argue that a high degree of homeostasis is merely one of several ways to achieve evolutionary and ecological success. In this view, Bernard and Cannon did not articulate universal requirements for success, but instead they clarified the properties and significance of *one particular road* to success.

Recent research has clarified, in fact, that organisms sometimes achieve success in the biosphere precisely by letting their internal environment *vary* with the external environment: the antithesis of homeostasis. Consider, for example, insects that overwinter within plant stems in Alaska. They survive by ceasing to be active, allowing their internal temperatures to fall to below -40°C , and tolerating such low tissue temperatures. Any attempt by such small animals to maintain an internally constant temperature from summer to winter would be so energetically costly that it would surely end in death; thus the tolerance of the insects to the *change* of their internal temperature in winter is a key to their survival. Even some mammals—the hibernators—survive winter by *abandoning constancy* of internal temperature; hibernating mammals allow their body temperatures to decline and sometimes match air temperature. For lizards in deserts, tolerance of profound dehydration is often a key to success.

Both constancy and inconstancy of the internal environment—regulation and conformity—have disadvantages and advantages:

- **Regulation.** The chief disadvantage of regulation is that it costs energy. The great legacy of Bernard and Cannon is that they clarified the advantage that animals enjoy by paying the cost: Regulation permits cells to function in steady conditions, independent of variations in outside conditions.
- **Conformity.** The principal disadvantage of conformity is that cells within the body are subject to changes in their conditions when outside conditions change. The chief advantage of conformity is that it avoids the energy costs of keeping the internal environment different from the external environment. Conformity is energetically cheap.

Neither regulation nor conformity is categorically a defect or an asset. One cannot understand mammals or medical physiology

without understanding homeostasis, but one cannot understand the full sweep of animal life without recognizing that physiological flexibility is sometimes advantageous.

Time in the lives of animals: Physiology changes in five time frames

Time is a critical dimension for understanding the physiology of all animals because the physiology of animals invariably changes from time to time. Even animals that exhibit homeostasis undergo change. Details of their internal environment may change. Moreover, the regulatory processes that *maintain* homeostasis must change from time to time so that homeostasis can prevail, much as day-to-day adjustments in the fuel consumption of a home furnace are required to maintain a constant air temperature inside the home during winter.

An important organizing principle for understanding the role of time in the lives of animals is to recognize *five major time frames* within which the physiology of an animal can change. The time frames fall into two categories: (1) responses of physiology to changes in the external environment and (2) internally programmed changes of physiology. **Table 1.2** lists the five time frames classified in this way. We will recognize these five time frames throughout this book as we discuss various physiological systems.

The concept of the five time frames overlies other ways of organizing knowledge about animal function. For example, the concept of time frames overlies the concepts of regulation, conformity, and homeostasis that we have just discussed. When we speak of regulation, conformity, and homeostasis, we refer to *types* of responses that animals show in relation to variations in their external environments. When we speak of the time frames, we address *when* those responses occur.

PHYSIOLOGY RESPONDS TO CHANGES IN THE EXTERNAL ENVIRONMENT IN THREE TIME FRAMES

Individual animals subjected to a change in their external environment exhibit *acute* and *chronic* responses to the environmental change. **Acute responses**, by

TABLE 1.2 The five time frames in which physiology changes

Type of change	Description
Changes in physiology that are responses to changes in the external environment	
1. Acute changes	Short-term changes in the physiology of individual animals: changes that individuals exhibit soon after their environments have changed. Acute changes are reversible.
2. Chronic changes (termed <i>acclimation</i> and <i>acclimatization</i> ; also termed <i>phenotypic plasticity</i> or <i>phenotypic flexibility</i>)	Long-term changes in the physiology of individual animals: changes that individuals display after they have been in new environments for days, weeks, or months. Chronic changes are reversible.
3. Evolutionary changes	Changes that occur by alteration of gene frequencies over the course of multiple generations in populations exposed to new environments.
Changes in physiology that are internally programmed to occur whether or not the external environment changes	
4. Developmental changes	Changes in the physiology of individual animals that occur in a programmed way as the animals mature from conception to adulthood and then to senescence (see Chapter 4).
5. Changes controlled by periodic biological clocks	Changes in the physiology of individual animals that occur in repeating patterns (e.g., each day) under control of the animals' internal biological clocks (see Chapter 15).

definition, are responses exhibited during the first minutes or hours after an environmental change. **Chronic responses** are expressed following prolonged exposure to new environmental conditions. You might wonder why an individual's immediate responses to an environmental change differ from its long-term responses. The answer is that the passage of time permits biochemical or anatomical restructuring of an animal's body. When an animal suddenly experiences a change in its environment, its immediate responses must be based on the "old," preexisting properties of its body because the animal has no time to restructure. A morphological example is provided by a person who suddenly is required to lift weights after months of totally sedentary existence. The sedentary person is likely to have small arm muscles, and his immediate, *acute* response to his new weight-lifting environment will likely be that he can lift only light weights. However, if the person lifts weights repeatedly as time goes by, restructuring will occur; his muscles will increase in size. Thus his *chronic* response to the weight-lifting environment will likely be that he can lift heavy weights as well as light ones.

A familiar *physiological* example of acute and chronic responses is provided by human reactions to work in hot weather. We all know that when we are first exposed to hot weather after a period of living in cool conditions, we often feel quickly exhausted; we say the heat is "draining." We also know that this is not a permanent state: If we experience heat day after day, we feel more and more able to work in the heat.

Figure 1.8 shows that these impressions are not merely subjective illusions. Twenty-four physically fit young men who lacked recent

FIGURE 1.8 Heat acclimation in humans as measured by exercise endurance Twenty-four fit young men without recent heat experience were asked to walk at 3.5 miles per hour in hot, dry air (49°C, 20% relative humidity). Their endurance was used as a measure of their physiological capability to engage in moderate work under hot conditions. The acclimation illustrated by the chronic response is reversible; if heat-acclimated men return to a life of no heat exposure, they gradually revert to the level of endurance evident on day 1. (After Pandolf and Young 1992.)

experience with hot weather were asked to walk at a fixed pace in hot, relatively dry air. Their endurance was measured as a way of quantifying their physiological ability to sustain moderate exercise under the hot conditions. None of the men had sufficient endurance to walk for 100 minutes (min) on the first day. However, as the days passed and the men had more and more experience with hot conditions, their endurance increased, as indicated by a steady increase in the number of men who could keep walking for 100 min.

From research on the physiology of human work under hot conditions, physiologists know that endurance under hot conditions changes because as people gain increased experience with heat, their rates of sweat secretion increase, their sweat glands are able to maintain high rates of sweat secretion for dramatically lengthened periods of time, their sweat becomes more dilute (so they lose less salt), the blood flow to their skin becomes more vigorous (improving delivery of internal heat to the body surface), and their heart rates during exercise in the heat become lower. Thus human physiology is restructured in many ways by repeated exposure to heat. For a person who has been living in cool conditions, the *acute* physiological responses to heat exposure are low exercise endurance, a low rate of sweat production, and so forth. Heat training poises a person to express *chronic* physiological responses to heat, such as high exercise endurance and a high capacity to sweat.

The acute and chronic responses are, by definition, phenotypic responses of *individual animals* to environmental change. *Populations* may exhibit a third category of response to environmental change: **evolutionary responses** involving changes of genotypes. Collectively, therefore, animals display responses to environmental change in three time frames:

- Individuals exhibit immediate, *acute* responses.
- Individuals exhibit long-term, *chronic* responses. The length of time that an individual must be exposed to a new environment for chronic responses to be fully expressed is usually a few days to a few weeks.
- Populations exhibit *evolutionary* responses.

Chronic responses by individual animals to environmental change are so common, diverse, and important that their study forms a special discipline with its own terminology. For many physiologists, the concepts of *acclimation* and *acclimatization* provide an important way to classify the chronic responses of individuals to environmental change. A chronic response to a changed environment is called **acclimation** if the new environment differs from the preceding environment in just a few highly defined ways.⁵ Acclimation is thus a laboratory phenomenon. **Acclimatization** is a chronic response of individuals to a changed environment when the new and old environments are different *natural* environments that can differ in numerous ways, such as winter and summer, or low and high altitudes. Thus animals are said to *acclimatize* to winter, but they *acclimate* to different defined temperatures in a laboratory experiment.

Acclimation and acclimatization are types of **phenotypic plasticity**: the ability of an individual animal (a single genotype) to express two or more genetically controlled phenotypes. Phenotypic plasticity is possible because an individual invariably possesses the genetic code

⁵ Some authors restrict use of the word *acclimation* to cases in which just one property differs between environments.

BOX 1.2 THE EVOLUTION OF PHENOTYPIC PLASTICITY

When animals express different genetically controlled phenotypes in different environments—when they acclimate and acclimatize—they require controls that determine which particular phenotypes are expressed in which particular environments. As an illustration, suppose that an individual animal has four possible phenotypes, *P1* through *P4*, and that there are four environments, *E1* through *E4*. One option is that the individual could express phenotype *P1* in environment *E3*, *P2* in *E4*, *P3* in *E1*, and *P4* in *E2*. This set of *correspondences* between phenotypes and environments constitutes the individual's **norm of reaction**; that is, if we think of the phenotypes as one list and the environments as a second list in a matching game, the *norm of reaction* is like the set of lines that we would draw between items on the two lists to indicate which item on one matches which on the other.

Because it is genetically determined, *the norm of reaction itself can evolve and is subject to natural selection*. To see this, suppose that an individual other than the one just discussed expresses phenotype *P1* in environment *E1*, *P2* in *E2*, *P3* in *E3*, and *P4* in *E4*. In this case, the two individuals would differ in their norms of reaction. Suppose, now, that there is a population—living in a variable environment—that is composed half of individuals with the first reaction norm and half of individuals with the second. If individuals of the first sort were to survive and reproduce more successfully as the environment varied, natural selection for the first reaction norm would occur. In this way the reaction norm itself would evolve in ways that would better adapt the animals to the variable environment in which they live.

A simple example is provided by tanning in people with light complexions. Suppose

that there are two possible integumentary phenotypes: *high melanin* and *low melanin*. Suppose also that there are two environments: *high sun* and *low sun*. One possible norm of reaction would be to express high melanin in low sun and low melanin in high sun. Another norm of reaction would be to express high melanin in high sun and low melanin in low sun. If both of these reaction norms once existed, it is easy to understand why individuals with the second reaction norm would have left more progeny than those with the first, leading to the evolution of the sort of reaction norm we see today among people with light complexions.

Phenotypic plasticity *itself* can evolve, and norms of reactions can themselves be adaptations.

to adopt multiple phenotypes (Box 1.2). Growth of the biceps muscle during weight training provides a simple example of a change in phenotype under control of genetically coded mechanisms. Another example is that the particular suite of enzymes active in an adult person may change from one time to another because the genes for one suite of enzymes are expressed under certain environmental conditions, whereas the genes for another suite are expressed under different conditions.⁶ Phenotypic plasticity is discussed in more detail—with several additional examples—in Chapter 4.

PHYSIOLOGY UNDERGOES INTERNALLY PROGRAMMED CHANGES IN TWO TIME FRAMES

The physiological properties of individuals sometimes change even if their external environment stays constant. For instance, the type of hemoglobin in your blood today is different from the type you produced as a newborn. This change in hemoglobin is internally programmed: It occurs even if your external environment stays constant. Sometimes internally programmed changes interact with environmental changes. For instance, an internally programmed change might occur sooner, or to a greater amplitude, in one environment than in another. However, the internally programmed changes do not require any sort of environmental activation. There are two principal types of internally programmed change: developmental changes and changes controlled by periodic biological clocks.

Development is the progression of life stages from conception to senescence in an individual. Different genes are internally programmed to be expressed at different stages of development, giving rise to **developmental changes in an animal's phenotype**. Puberty is a particularly dramatic example of internally programmed developmental change in humans. The environment

may change the timing of puberty—as when the advent of sexual maturity is delayed by malnutrition—but puberty always occurs, no matter what the environment, illustrating that internally programmed changes do not require environmental activation. Physiological development is one of the principal topics addressed in Chapter 4.

Biological clocks are mechanisms that give organisms an internal capability to keep track of the passage of time. Most biological clocks resemble wristwatches in being periodic; that is, after they complete one timing cycle, they start another, just as a wristwatch starts to time a new day after it has completed timing of the previous day. These sorts of biological clocks emit signals that cause cells and organs to undergo internally programmed, repeating cycles in their physiological states, thereby giving rise to **periodic, clock-controlled changes in an animal's phenotype**. An enzyme under control of a biological clock, for instance, might increase in concentration each morning and decrease each evening, not because the animal is responding to changes in its outside environment, but because of the action of the clock. The changes in enzyme concentration might mean that an animal is inherently better able to digest a certain type of food at one time of day than another, or is better able to destroy a certain type of toxin in the morning than in the evening. Biological clocks typically synchronize themselves with the external environment, but they go through their timing cycles inherently, and they can time physiological changes for days on end without environmental input. They are discussed in greater detail in Chapter 15.

Size in the lives of animals: Body size is one of an animal's most important traits

How big is it? is one of the most consequential questions you can ask about any animal. This is true because within sets of related species, many traits vary in regular ways with their body sizes. The

⁶Enzymes that vary in amount as a result of changes in environmental conditions are termed *inducible* enzymes. An excellent illustration is provided by the P450 enzymes discussed at length in Chapter 2 (see page 48).

FIGURE 1.9 Length of gestation scales as a regular function of body size in mammals The data points—each representing a different species—are for African herbivorous mammals weighing 5 to 1000 kg as adults. The line (fitted by ordinary least squares regression; see Appendix D) provides a statistical description of the overall trend and thus depicts the gestation length that is statistically expected of an average or ordinary animal at each body size. Both axes use logarithmic scales, explaining why the numbers along the axes are not evenly spaced (see Appendix E). (After Owen-Smith 1988.)

length of gestation, for example, is a regular function of body size in mammals (Figure 1.9). Brain size, heart rate, the rate of energy use, the age of sexual maturity, and hundreds of other physiological and morphological traits are also known to vary in systematic ways with body size in mammals and other phylogenetically related sets of animal species. The study of these relations is known as the study of **scaling** because related species of large and small size can be viewed as *scaled-up* and *scaled-down* versions of their type.

Knowledge of the statistical relationship between a trait and body size is essential for identifying specializations and adaptations of particular species. To illustrate, let's ask if two particular African antelopes, the bushbuck and mountain reedbuck, have specialized or ordinary lengths of gestation. Answering this question is complicated precisely because there is no single norm of mammalian gestation length to use to decide. Instead, because the length of gestation is a regular function of body size, a biologist needs to consider the sizes of the species to know what is average or ordinary.

Statistical methods can be used to derive a line that best fits a set of data. In the study of scaling, the statistical method that has traditionally been considered most appropriate is **ordinary least squares regression** (see Appendix D). The line in Figure 1.9 was calculated by this procedure. This line shows the average trend in the relationship between gestation length and body size. The line is considered to show the length of gestation *expected* of an ordinary species at each body size.

With this information on *expected* gestation lengths, now we can address the question asked earlier: Are the bushbuck and mountain reedbuck specialized or ordinary? Notice that the length of gestation

in the bushbuck is very close to what the line in Figure 1.9 predicts for an animal of its size. The bushbuck, therefore, adheres to what is expected for its size: It has an ordinary gestation length when its size is taken into account. The mountain reedbuck, however, is far off the line. According to the line, as shown in Table 1.3, an animal of the reedbuck's size is expected to have a gestation lasting 26.5 weeks, but actually the reedbuck's gestation lasts 32 weeks. Thus the reedbuck seems to have evolved a specialized, exceptionally long gestation. Similarly, the gray duiker seems to have evolved an exceptionally short length of gestation for *its* size (see Figure 1.9).

In the last 15 years, physiologists have recognized that ordinary least squares regression may not always be the best procedure for fitting lines to scaling data because the ordinary least squares procedure does not take into account the family tree of the species studied; it simply treats each data point as

being fully independent of all the other data points (see Appendix D). Increasingly, therefore, physiologists have fitted lines not only by the ordinary least squares procedure but also by an alternative procedure based on **phylogenetically independent contrasts**, a method that takes the family tree into account (see Appendix G).⁷ Although these two approaches sometimes yield distinctly different results, they most often yield similar results, and in this book, the lines we present for scaling studies will be derived from the method of traditional, ordinary least squares regression.

Body-size relations are important for analyzing almost all sorts of questions in the study of physiology, ecology, and evolutionary biology. If all one knows about an animal species is its body size, one can usually make useful predictions about many of the species' physiological and morphological traits by consulting known statistical relationships between the traits and size. Conversely, there is always the chance that a species is specialized in certain ways, and as soon as one has actual data on the species, one can identify potential specializations by the type of scaling analysis we have discussed.

⁷Appendix G explains the reasons why the family tree should ideally be taken into account, as well as providing a conceptual introduction to phylogenetically independent contrasts.

TABLE 1.3 Predicted and actual gestation lengths for two African antelopes of about the same body size

Species	Predicted gestation length (weeks) ^a	Actual gestation length (weeks)
Bushbuck (<i>Tragelaphus scriptus</i>)	27	26
Mountain reedbuck (<i>Redunca fulvorufula</i>)	26.5	32

^aPredicted lengths are from the statistically fitted line shown in Figure 1.9.

Environments

What is an environment? An important starting point in answering this question is to recognize that an *animal* and its *environment* are interrelated, not independent, entities. They are in fact defined in terms of each other, as noted more than 100 years ago by none other than Claude Bernard. The environment in any particular case cannot be specified until the animal is specified. A dog, for instance, is an animal from our usual perspective, but if the animal of interest is a tapeworm in the dog's gut, then the dog is the environment. All animals, in fact, are parts of the environments of other animals. The birds in the trees around your home are part of your environment, and you are part of theirs. The interdependence of animal and environment is reflected in standard dictionary definitions. A dictionary defines an animal to be a living organism. An **environment** is defined to be all the chemical, physical, and biotic components of *an organism's* surroundings.

Earth's major physical and chemical environments

The physical and chemical environments on our planet are remarkably diverse in their features, providing life with countless challenges and opportunities for environmental specialization. Temperature, oxygen, and water are the “big three” in the set of physical and chemical conditions that set the stage for life. Here we discuss the ranges of variation of temperature, oxygen, and water across the face of the globe. We also discuss highlights of how animals relate to these features. In later chapters, we return to these topics in greater detail.

TEMPERATURE The **temperature** of the air, water, or any other material is a measure of the intensity of the random motions that the atoms and molecules in the material undergo. All atoms and molecules ceaselessly move at random on an atomic-molecular scale. A high temperature signifies that the intensity of this atomic-molecular agitation is high. Although some animals are temperature regulators and (at a cost of energy) keep their tissue temperatures relatively constant whether they experience high or low environmental temperatures, most animals are temperature conformers. As we discuss temperature here, the conformers are our principal interest because the level of atomic-molecular agitation in their tissues matches the level in the environments where they live.

The lowest temperature inhabited by active communities of relatively large, temperature-conforming animals is -1.9°C , in the polar seas. The very lowest temperature at which *any* active communities of temperature-conforming animals live occurs *within* the sea ice near the poles; minute nematodes and crustaceans, as well as algae, live and reproduce within the sea ice at temperatures that, in some places, are a few degrees colder than in the surrounding water. The fish and other animals living in the open waters of the unfrozen polar oceans (Figure 1.10) are far better known than the sea-ice animals, however. The open waters of the polar oceans remain perpetually at about -1.9°C , the lowest temperature at which seawater is liquid. Thus the fish, the shrimplike krill, the sea stars, and the other invertebrates of these oceans have tissue temperatures near -1.9°C from the moment they are conceived until they die. They do not freeze. Whereas some do not freeze because their normal freezing points

FIGURE 1.10 Fish in the sea around Antarctica spend their entire lives at body temperatures near -1.9°C . These rock cod (*Pagotthenia borchgrevinki*) lay their eggs in holes or depressions in ice sheets. They hatch, grow, feed, and mate at body temperatures near -1.9°C . Metabolically synthesized antifreeze compounds keep them from freezing.

are similar to the freezing point of seawater,⁸ others have special protections against freezing. Because the tissues of these animals are very cold, one might imagine that the animals live in a sort of suspended animation. Actually, however, the communities of temperature-conforming animals in the polar seas are active and thriving. In the ocean around Antarctica, for example, a sure sign of the vigor of the populations of fish and krill is that they reproduce and grow prolifically enough to meet the food needs of the famous Antarctic abundance of whales, seals, and penguins.

Are the low tissue temperatures of polar fish and invertebrates actually challenging for them, or do they only seem challenging? One way to obtain an answer is to compare polar species with related nonpolar ones. Tropical species of fish clearly find low temperatures to be challenging. Many tropical species, in fact, die if cooled to $+6^{\circ}\text{C}$, even if they are cooled very gradually. Such observations emphasize that success at -1.9°C is not “automatic,” and that the polar species have had to evolve special adaptations to thrive with their tissues perpetually at -1.9°C . The polar species themselves often die if they are warmed to $+6^{\circ}\text{C}$, indicating that the tropical species also have special adaptations—adaptations that poise them to live at tropical temperatures. The evolutionary divergence of these fish is dramatized by the fact that a *single* temperature can be lethally *cold* for tropical species and yet be lethally *warm* for polar species!

Far greater extremes of cold are found on land than in aquatic environments. In Antarctica, the air temperature can drop to -90°C (-130°F); in the Arctic, it can descend to -70°C (-90°F).

⁸Dissolved salts and other dissolved compounds lower the freezing points of solutions. Most marine invertebrates have total concentrations of dissolved matter in their blood similar to the concentration in seawater. Consequently, their blood freezing points are about the same as the freezing point of seawater, and they do not freeze, provided that the seawater remains unfrozen.

FIGURE 1.11 Butterfly biogeography The diagram shows the number of species of swallowtail butterflies (family Papilionidae) at various latitudes. The reason there are relatively few species of animals at high latitudes may not be simply the low temperatures there, but may in part be a relay effect from the effects of cold on plants. Plants decrease in diversity and annual productivity toward the poles, affecting the food supplies of animals. (After Scriber 1973.)

The Canadian tiger swallowtail (*Papilio canadensis*) is one of the species of butterflies that lives farthest from the equator.

The extremes of animal adaptation to low tissue temperature are represented by certain extraordinary species of Arctic insects that spend winters inside exposed plant stems or on the surface of pack ice. The insects are quiescent, not active, at these times. Nonetheless, it is impressive that some endure tissue temperatures of -60°C to -70°C , either in a frozen state (which they have adaptations to tolerate) or in an unfrozen supercooled state. When we look at the diversity of terrestrial temperature-conforming animals, we find that it typically declines as latitude increases from the temperate zone toward the poles, as exemplified by a family of butterflies in **Figure 1.11**. The decline in diversity toward the poles indicates that the very cold terrestrial environments are demanding places for animals to occupy, despite evolutionary adaptability.

The temperature of the air or water on Earth usually does not go higher than $+50^{\circ}\text{C}$ ($+120^{\circ}\text{F}$). Animals on land may experience even higher heat loads, however, by being exposed simultaneously to hot air and the sun's radiation. Some temperature-conforming animals from hot environments—such as certain desert insects and lizards—can function at *tissue* temperatures of $45\text{--}55^{\circ}\text{C}$ (**Figure 1.12**).⁹ These are the highest tissue temperatures known for animal life, suggesting that the high levels of molecular agitation at such temperatures pose the greatest challenge that can be met by evolutionary adaptation in animal systems.

The hottest places in the biosphere are the waters of geothermally heated hot springs and underwater hot vents. These waters are often far above the boiling point when they exit Earth's crust. Although aquatic animals typically stay where the waters have cooled to $35\text{--}45^{\circ}\text{C}$ or lower, many prokaryotic microbes—bacteria and archaea—thrive at much higher temperatures than animals can. Some prokaryotes even reproduce at temperatures above 100°C .

OXYGEN The need of most animals for oxygen (O_2) is a consequence of their need for metabolic energy. The chemical reactions that animals use to release energy from organic compounds remove some of the hydrogen atoms from the compounds. Each adult person, for example, liberates about one-fifth of a pound of hydrogen every day in the process of breaking down food mol-

FIGURE 1.12 A thermophilic (“heat-loving”) lizard common in North American deserts The desert iguana (*Dipsosaurus dorsalis*) can often be seen abroad as the sun beats down on hot days. Although it does not usually expose itself to body temperatures higher than 42°C , it can survive 48.5°C , one of the highest body temperatures tolerated by any vertebrate animal.

⁹Normal human body temperature is 37°C .

ecules to obtain energy. Hydrogen liberated in this way cannot be allowed to accumulate in an animal's cells. Thus an animal must possess biochemical mechanisms for combining the hydrogen with something, and O_2 is the usual recipient. O_2 obtained from the environment is delivered to each cell, where it reacts with the free hydrogen produced in the cell, yielding water (see Figure 8.2).

The suitability of an environment for animals often depends on the availability of O_2 . In terrestrial environments at low and moderate altitudes, the open air is a rich source of O_2 . Air consists of 21% O_2 , and at low or moderate altitudes it is relatively dense because it is at relatively high pressure. Thus animals living in the open air have a plentiful O_2 resource. Even within burrows or other secluded places on land, O_2 is often freely available because—as counterintuitive as it may sound— O_2 diffuses fairly readily from the open atmosphere through soil to reach burrow cavities, provided the soil structure includes gas-filled spaces surrounding the soil particles.

High altitudes are among Earth's most challenging places, where the numbers of animal species are sharply reduced. Although high altitudes present animals with several stresses, their single greatest challenge is the decline in O_2 concentration with increasing elevation. Air at the top of Mount Everest—8848 m above sea level—is 21% O_2 , like that at sea level; but the total air pressure is much lower than at sea level, and gas molecules within the air are therefore so widely spaced that each liter of air contains only about one-third as much O_2 as at sea level.

At high altitudes, the maximum rate at which animals can acquire O_2 is often much lower than at sea level, and functions are consequently limited. At elevations above 6500 m (21,000 ft), for example, people breathing from the atmosphere find that simply walking uphill is a major challenge because of the limitations on their level of exertion imposed by the low availability of O_2 (Figure 1.13). Some animal species have evolved adaptations to succeed in the dilute O_2 of rarefied air in ways that humans cannot. One of the most remarkable species is the bar-headed goose (*Anser indicus*), which—in ways that physiologists still do not fully comprehend—is able to fly (without an oxygen mask!) over the crests of the Himalayas at 9000 m.

Water-breathing animals typically face a substantially greater challenge to obtain O_2 than air-breathing animals do because the supply of O_2 for water breathers is the O_2 dissolved in water, and the solubility of O_2 in water is not high. Because of the low solubility of O_2 , water contains much less O_2 per liter than air does, even when the water is fully aerated. For example, aerated stream or river water at sea level contains only 3–5% as much O_2 per liter as air at sea level does.

A common problem for animals living in slow-moving bodies of water such as lakes, ponds, or marshes is that the O_2 concentration may be even lower than in aerated water because dissolved O_2 may become locally depleted by the metabolic activities of animals or microbes. *Density layering* of water—which prevents the water from circulating freely—is a common contributing factor to O_2 depletion in the deep waters of lakes and ponds. Density layering occurs when low-density water floats on top of high-density water, causing distinct water layers to form. When this happens, there is often almost no mixing of oxygenated water from the low-density surface layer (where photosynthesis and aeration occur) into the high-density bottom layer. Thus O_2 in the bottom layer is not readily replaced when it is used, and as

FIGURE 1.13 Performance in an O_2 -poor environment Because of the difficulty of acquiring O_2 from rarefied air, the rate at which energy can be released from food molecules for use in work by humans is reduced at high altitudes, and the simple act of walking uphill becomes extremely arduous. Well-conditioned mountaineers are slowed to a walking rate of 100–200 meters per hour near the tops of the world's highest mountains if they are breathing from the air rather than from oxygen tanks. Shown here is Chantal Mauduit (1964–1998) during an unsuccessful attempt to reach the summit of Mt. Everest while breathing only atmospheric air. On an earlier expedition she had been the fourth woman to climb to the peak of K2 (8611 m), second highest mountain on Earth, without supplemental oxygen.

microbes and animals in the bottom layer consume O_2 , the O_2 concentration may fall to very low levels.

In lakes during summer, density layering occurs because of temperature effects: Sun-heated warm water tends to float on top of colder and denser bottom water.¹⁰ The lake studied by a group of university students in Figure 1.14 provides an example of this sort of density layering. The bottom waters of this lake contained essentially *no* dissolved O_2 on the July day when the data were collected. Deep-water O_2 depletion has become more common in recent decades in lakes, ponds, and estuaries as human populations have enriched waters with organic matter. The organic matter supports the growth of microbes that deplete dissolved O_2 . For animals in deep waters to survive, they must be able to tolerate low O_2 levels, or they must temporarily move to other places where O_2 is more available.

In certain sorts of water bodies, animals have faced the challenge of low O_2 concentrations for millennia. Unlike animals confronted

¹⁰ In estuarine bodies of water along seacoasts—where freshwater and seawater mix—layering can occur because of salinity effects as well as temperature effects. Low-salinity water is less dense than—and tends to float on top of—high-salinity water.

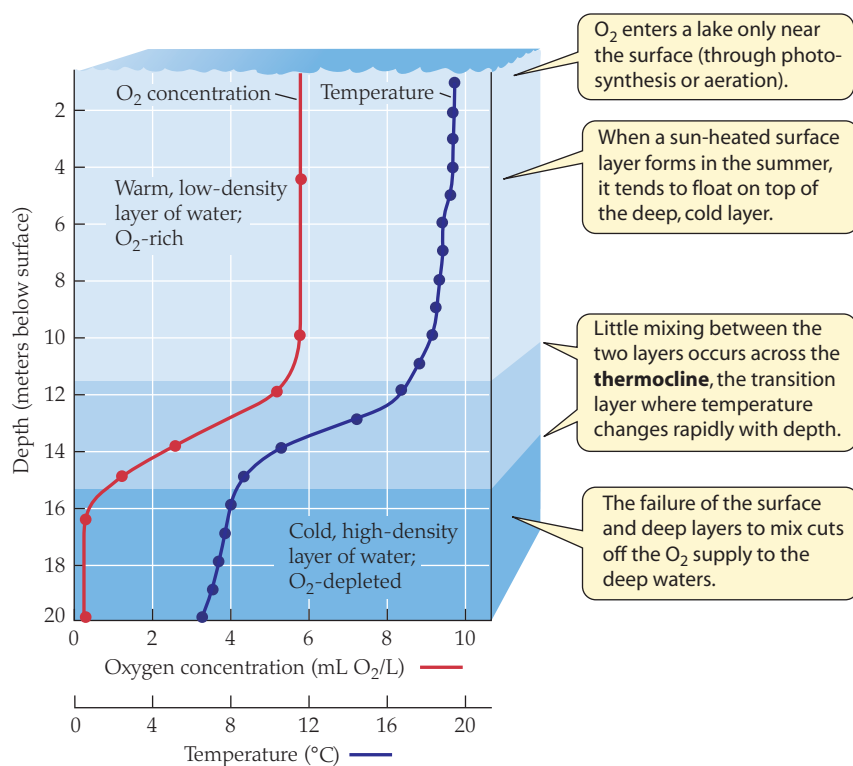

FIGURE 1.14 Density layering can cut off the O_2 supply to the deep waters of a lake. Different densities of water do not mix readily. The O_2 concentration in the deep waters of a lake may fall to near zero because the animals and microbes living there consume O_2 that is not replaced. (From data gathered by a group of animal physiology students on a lake in northern Michigan in July.)

with new, human-induced O_2 depletion, the animals living in primordially O_2 -poor waters have been able to undergo long-term evolutionary adaptation to low- O_2 conditions. Examples of such bodies of water include tropical rivers that are naturally very rich in organic matter, as in the Amazon basin. The warmth of these rivers not only lowers the solubility of O_2 in the water but also promotes rapid multiplication of microbes that use O_2 . In addition, thick forest canopies may create deep shade over the rivers, impeding algal photosynthesis that otherwise could replenish O_2 . Tropical rivers of this sort and their associated wetlands have experienced low levels of dissolved O_2 over eons of geological time.

Among the animals living in such waters, the evolution of air breathing is one of the most remarkable features. Hundreds of species of fish in these waters are air breathers, for example. Some take up inhaled O_2 across well-vascularized mouth linings or lunglike structures. Others swallow air and absorb O_2 in their stomachs or intestines, as mentioned previously. In one of nature's twists of fate, physiologists have discovered that it can be important for these fish to limit gas exchange across their gills because the O_2 they get from breathing air can escape across their gills into the O_2 -depleted waters they inhabit.

For animals confronted with short-term or long-term O_2 deficiency, whether in O_2 -depleted freshwater environments or elsewhere, a potential solution over evolutionary time is to adopt a biochemistry that can attach hydrogen to molecules other than O_2 . Many species—both air breathers and water breathers—have temporary options of this sort. Certain tissues in our own bodies,

for example, can live without O_2 for 10 minutes at a time by attaching hydrogen to pyruvic acid (making lactic acid). Suppose, however, that an animal's entire body must live without O_2 for many hours, days, weeks, or months. Doing so is possible for some animals, but as the period without O_2 lengthens, ever-fewer species have evolved biochemical specializations that enable them to survive. Some exceptional animals are able to meet the most extreme challenge of living indefinitely in O_2 -free environments. Most that are currently known to science are parasites (e.g., nematodes and tapeworms) that live in the O_2 -free environment of the vertebrate gut cavity.

WATER Water is the universal solvent in biological systems—and therefore is required for blood and all other body fluids to have their proper compositions. Water is also important for animals because H_2O bound to proteins and other macromolecules as *water of hydration* is often required for the macromolecules to maintain their proper chemical and functional properties.

Animal life began in Earth's greatest watery environment, the oceans. Most invertebrates that live in the open oceans today—sea stars, corals, clams, lobsters, and so forth—are thought to trace a continuously marine ancestry. That is, their ancestors never left the seas from the time that animal life began, and thus the salinity of the oceans has been a perennial feature of their environment. The blood of these invertebrates (Figure 1.15), although differing a bit from seawater in composition, is similar to seawater in its total salt concentration. These animals therefore do not tend to gain much H_2O from their environment by osmosis, nor do they tend to lose H_2O from their blood to the seawater. Because this situation is almost universal among these animals, we believe it is the

FIGURE 1.15 The sea star and the corals in this ocean scene have body fluids similar to seawater in their total concentration of salts, although the body fluids of the fish are more dilute than seawater. Most scientists believe that the difference between marine invertebrates and marine bony fish is based on their evolutionary histories. The invertebrates' ancestors always lived in the sea, but the fish's ancestors once lived in freshwater.

primordial condition of animal life. Thus we believe that for much of its evolutionary history, animal life lived in a setting where (1) H₂O was abundant in the environment and (2) little danger existed for an animal to be either dehydrated or overhydrated.

This benign situation was left behind by the animals that migrated from the oceans into rivers during their evolution. Freshwater has a very low salinity compared with seawater. When animals from the oceans, with their salty blood, started to colonize freshwater, they experienced a severe challenge: H₂O tended to seep osmotically into their bodies and flood their tissues because osmosis transports H₂O relentlessly from a dilute solution into a more-concentrated one. Today, lakes and rivers are populated by fish, clams, crayfish, sponges, hydras, and so forth, all descended from ocean ancestors. The process of invading freshwater from the sea is probably still continuing, in fact; some freshwater crabs, for example, are thought to be geologically recent immigrants to freshwater because they must return to the sea to breed. Over evolutionary time, freshwater animals reduced their tendency to gain H₂O osmotically from their environment, but they have not eliminated it. A 100-g goldfish, for example, osmotically gains enough water to equal 30% or more of its body weight every day.

Vertebrates and several groups of invertebrates invaded the land from freshwater. In so doing they came face to face with the most severe of all the water challenges on Earth: On land, evaporation of water into the atmosphere tends to dehydrate animals rapidly; moreover, some terrestrial habitats are so dry that replacing lost water borders on impossible. When animals first invaded terrestrial habitats, they probably possessed integuments (body coverings), inherited from aquatic ancestors, that provided little or no barrier to evaporative water loss. This problem ultimately had to be solved for animals to be able to live entirely freely in the open air.

Some of today's land animals have integuments that resemble the primordial types. Leopard frogs, earthworms, and wood lice, for example, have integuments that lack significant evaporation barriers and permit virtually free evaporation. In some cases, water evaporates across these sorts of integuments as fast as it evaporates from an open dish of water of the same surface area! Animals with such integuments dehydrate so rapidly that they cannot possibly live steadily in the open air. Instead, they must stay in protected places where the humidity of the air is high, or if they venture into the open air, they must return often to places where they can rehydrate. The danger of dehydration severely constrains their freedom of action.

For a terrestrial animal to be liberated from these constraints and lead a fully exposed existence in the open air, it must have evolved highly effective barriers to water loss across its integument. Only a few major groups of animals possess such novel water barriers: mammals, birds, other reptiles (see Figure 1.12), insects, and spiders. In each of these groups, excessive evaporation is prevented by integumentary lipids: thin layers of hydrocarbons deposited in the integument. The evolution of these hydrocarbons liberated animals to occupy the open air and was a prerequisite for animals to invade the driest places on Earth, the deserts. In hyperarid deserts, a year or two can pass without rain, yet there are populations of insects, lizards, birds, and mammals that succeed there.

Some terrestrial animals have adapted to land in part by evolving exceptional tolerance of dehydration. Although most terrestrial animals die if they lose half or more of their body water without replacing it, the exceptional types can dehydrate more. The most

extreme cases are certain invertebrates that can lose essentially all their body water and survive in a dormant, crystalline state until water returns. Certain tardigrades (“moss animals” or “water bears”), for example, dry completely when deprived of water and then can blow about like dust, ready to spring back to active life if water becomes available.

Contrary to what intuition might suggest, even some aquatic animals are threatened with dehydration. The bony fish of the oceans, such as the reef fish seen in Figure 1.15, are the most important example. These fish have blood that is only one-third to one-half as salty as seawater, probably because they are descended from freshwater ancestors rather than from ancestors that always lived in the sea. The ocean is a desiccating environment for animals with dilute blood because osmosis transports H₂O steadily from the blood to the more-concentrated seawater. These desiccating fish have an advantage over terrestrial animals desiccating in a desert—namely, that H₂O to replace their losses is abundant in their watery environment. To incorporate H₂O from seawater into their dilute bodies, however, they must in essence possess mechanisms to “distill” the seawater: They must be able to separate H₂O from the salty seawater solution.

The environment an animal occupies is often a microenvironment or microclimate

In a forest, lake, or any other large system, small places inevitably exist where physical or chemical conditions are significantly different from the average in the system. For instance, when the average temperature of the open air in a woodland is 30°C, the temperature under a pile of brush on the forest floor might be 24°C. Although large-bodied animals are often, by necessity, exposed to the statistically average conditions where they live, small-bodied animals may enter the small places—the nooks and crannies—where they may find conditions that are far from average. Places within an environment that potentially differ from the environment at large in their physical or chemical conditions are called **microenvironments**. A related concept is that of **microclimates**. A microclimate is the set of climatic conditions (temperature, humidity, wind speed, and so forth) prevailing in a subpart of a system.

Because we humans are large organisms, our perception of the prevailing conditions in a place may bear little relation to the microclimates that smaller creatures can find by entering distinctive subparts of the place. George Bartholomew (1919–2006), one of the founders of environmental physiology, expressed this important point well:

Most vertebrates are much less than a hundredth of the size of man . . . , and the universe of these small creatures is one of cracks and crevices, holes in logs, dense underbrush, tunnels and nests—a world where distances are measured in yards rather than miles and where the difference between sunshine and shadow may be the difference between life and death. Climate in the usual sense of the word is, therefore, little more than a crude index to the physical conditions in which most terrestrial animals live.¹¹

Desert environments nicely illustrate the point that Bartholomew makes (Figure 1.16). At head level (about 2 m aboveground), a human

¹¹From G. A. Bartholomew. 1964. The roles of physiology and behavior in the maintenance of homeostasis in the desert environment. *Symp. Soc. Exp. Biol.* 18: 7–29.

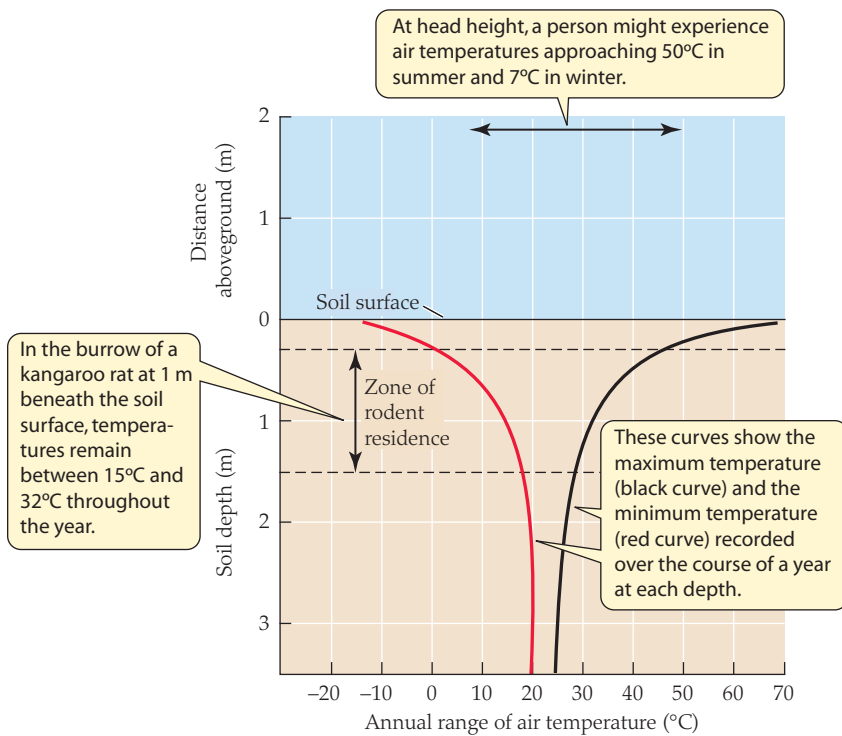

FIGURE 1.16 Microenvironments in the Arizona desert near Tucson The plot shows the *annual range of temperatures* in the soil and air and at the soil surface. (After Misonne 1959.)

or a horse standing in the Arizona desert may experience daytime air temperatures that reach almost 50°C during the summer, combined with intense solar radiation. Humans and horses typically have no choice but to cope physiologically with these conditions because they are too large to escape by going underground or squeezing into patches of shade cast by cacti or desert bushes. Small desert rodents such as kangaroo rats and pocket mice are in a very different situation, however, because they can burrow deep into the soil, where thermal conditions are far different from those that humans associate with deserts. On the surface of the desert soil, the annual temperature range is actually greater than that in the air above (see Figure 1.16); the soil surface becomes hotter than the air during the day as it absorbs solar radiation, and it becomes cooler than the air at night because it radiates infrared energy to the cold nighttime sky (see pages 232–233). Beneath the soil surface, however, the annual range of temperature decreases dramatically as depth increases. At a depth of 1 m, the temperature remains well below the maximum aboveground air temperature during summer and well above the minimum air temperature during winter. In fact, in certain desert regions, such as that shown in Figure 1.16, the rodents never face significant heat or cold stress throughout the year when they are in their burrows!¹²

Microenvironments must be considered in the study of virtually all the physical and chemical features of the places where animals live. In tall grass, for example, the wind speed is likely to be lower than in adjacent open areas, and because the weak wind permits moisture evaporating from the soil and grass to accumulate in the

¹²There are hotter desert regions where even the burrow environment presents thermal challenges in some seasons, but the burrow environment is still far more moderate than the environment aboveground (see Chapter 28).

air rather than being blown away, the humidity also tends to be higher than in adjacent open air. Animals that enter tall grass are thus likely to find a less-desiccating microenvironment than in open fields nearby. Along a river, any side pool cut off from free mixing with the flowing water is likely to form a distinctive microenvironment; the concentration of dissolved O₂ in such a pool might be lower than that in the river at large if there is a lot of microbial decay occurring in the pool, for example. On land in winter, spaces under deep snow in the far north form distinctive microenvironments, often warmer by 20°C (or more) than the open air above (Figure 1.17). Thus a lemming burrowing under the snow experiences a very different environment from a reindeer standing above.

Animals often modify their own environments

An important way in which *animal* and *environment* are interdependent is that animals modify their own environments. In the simplest case, animals behaviorally select the actual environments that they experience from the many that they *could* experience. A frog stressed by desiccation on open terrain, for example, can raise the humidity and lower the wind speed of its environment by hopping into tall grass. The environment of an animal is the animal's surroundings, and the surroundings depend on where the animal places itself.

A more subtle but equally important point is that the very presence of an animal in a place often alters the physical and chemical features of the place. The environmental alteration caused by the animal may then change that selfsame animal's behavior or physiology. Consider, for instance, a squirrel in a small cavity in a tree. In winter, the squirrel will warm the cavity to a higher tem-

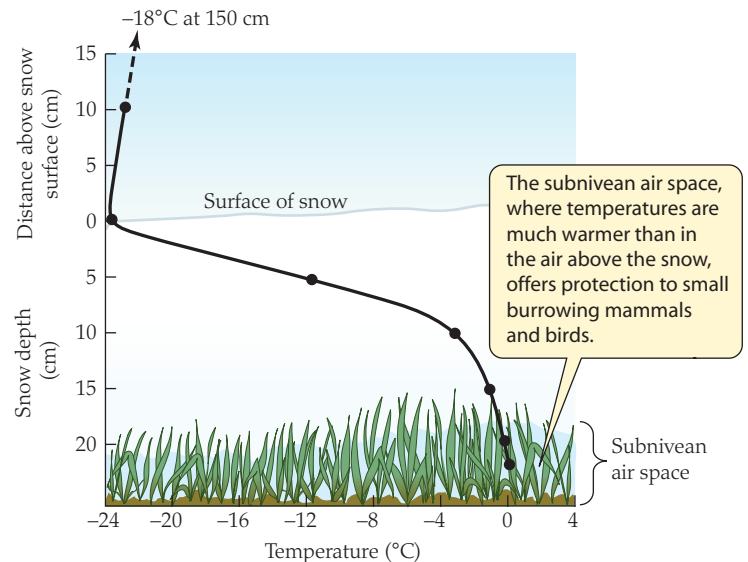

FIGURE 1.17 Microenvironments in deep snow in the far north An air space—termed the subnivean air space—is often trapped beneath deep snow. When lemmings, ptarmigans, or other small mammals or birds burrow under the snow into the subnivean air space, they enter a windless environment where the temperature may be 20°C warmer than in the air above the snow, and where they are protected by the overlying snow from losing heat radiatively to the frigid nighttime sky. The temperatures shown were measured on a March night in Sweden. (After Coulianos and Johnels 1963.)

perature than would prevail in the squirrel's absence. The squirrel will then respond physiologically to the elevated temperature in the cavity, by cutting back its rate of metabolic heat production. In a like manner, a school of fish can deplete water of dissolved O₂ and then must cope with low "environmental" O₂ levels.

Because of phenomena like these, the analysis of an animal–environment interaction often requires dynamic calculations that take into account that the interaction is of a two-way, back-and-forth sort. After an animal has initially altered an environment, the animal may function differently because it is in a changed environment, and thus the animal's future effect on the environment may be different from its original effect.

Global warming represents a planet-sized example of this phenomenon. Most scientists believe that the use of fossil fuels by the global human population is changing Earth's atmosphere toward a composition that increases planetary heat retention. Human activities are therefore raising the global temperature. The warming environment then will alter the ways in which human societies function in the future.

Evolutionary Processes

The evolutionary origins of physiological traits—and the continuing evolution of physiological traits in today's world—form the subject matter of *evolutionary physiology*, one of the two most important branches of the modern study of physiology, as stressed earlier. Physiologists have long recognized that the traits of species are often well matched to the environments they occupy. For example, polar bears are well suited to deal with cold, and dromedary camels with heat. Evolution by natural selection is believed by modern biologists to be the primary process that produces this match between species and the environments they inhabit.

Carefully defined, **evolution** is a *change of gene frequencies over time* in a population of organisms. Suppose a population of animals contains a gene that codes for the oxygen affinity of hemoglobin (the ease with which hemoglobin combines with O₂). The gene has two alleles (alternative forms), one coding for high oxygen affinity (H allele) and one for low oxygen affinity (L allele). At one time in the history of the population, 30% of all copies of this gene were of the H allele and 70% were of the L allele. After 1000 generations have passed, however, 60% of all copies are of the H allele and 40% are of the L allele. In this case, gene frequencies have changed. Therefore, evolution has occurred.

A more-complex question by far is whether *adaptation* has occurred. There are several known processes by which gene frequencies can change. Only one, natural selection, leads to adaptation.

Some processes of evolution are adaptive, others are not

Returning to the hypothetical example just discussed, suppose that in a population of animals occupying a particular environment, individuals with hemoglobin of high oxygen affinity are more likely to survive and reproduce than those with hemoglobin of low affinity. By this very fact, an allele that codes for high affinity will tend to increase in frequency in the population from one generation to the next (and an allele that codes for low affinity will tend to decrease). After many generations, the H allele might become so common that essentially all individuals born into the

population have it. You will recognize this as the process of *natural selection*. Natural selection creates a better match between animals and their environments.

The concept of *adaptation*, which is intimately related to that of natural selection, has a specific meaning in the study of evolutionary biology. By definition, a trait is an **adaptation** if it has come to be present at high frequency in a population because it confers a greater probability of survival and successful reproduction in the prevailing environment than available alternative traits. Thus adaptations are products of the process of natural selection. An adaptation is not necessarily an *optimum* or *ideal* state, because constraints on the freedom of natural selection may have precluded the optimum state from being an option (the optimum state, for instance, might never have arisen through mutation). As the definition stresses, an adaptation is the trait favored by natural selection from among the *available* alternative traits.

Now let's repeat our thought exercise but substitute different assumptions. Consider a population, in the same environment as analyzed before, in which the H and L alleles are both common. Suppose that the population experiences a drop in size, so that it contains fewer than 100 individuals. Suppose also that during this low point, a catastrophe strikes, killing individuals *at random*, regardless of whether they possess the H or L allele. In a small population of 100 or fewer animals, deaths at random could *by sheer chance* eliminate all individuals possessing one of the alleles. All copies of the H allele might, in fact, be eliminated. In a population subjected to this process, when the population later regrows in size, it will have only the L allele, the *less-adaptive* allele. In this case, the process of gene frequency change we have described is a process of **nonadaptive evolution**. Because of chance, an allele that provides a *lower* probability of survival and reproduction than an available alternative comes to be the predominant allele in the population.

Processes in which chance assumes a preeminent role in altering gene frequencies are termed **genetic drift**. We have described, in the last paragraph, one scenario for genetic drift: Gene frequencies may shift in chance directions because of random deaths (or other random blocks to individual reproduction) in populations transiently reduced to small size. Another scenario for genetic drift is that when a species enters a new area and founds a new population there, the new population may exhibit changed gene frequencies, relative to the parent population, simply because of chance—because the founding individuals may by chance be genetically nonrepresentative of the population from which they came (a so-called *founder effect*).

Students of allele frequencies in natural populations believe that they often observe evidence of genetic drift. For example, two populations of mice living 10 km (6 mi) apart in seemingly identical woodlots usually exhibit many differences in allele frequencies thought to be produced by drift of one sort or another. Often the genes affected by drift seem to be ones that have little or no fitness effect; drift, in other words, seems to have its greatest influence on genes not subject to strong natural selection. That is not always the case, however.

Additional processes are known by which evolution may lead to nonadaptive outcomes. These include:

- A trait may be common in a population simply because it is closely correlated with *another* trait that is favored by

natural selection. For instance, a trait that itself diminishes the fitness of animals (their ability to survive and reproduce) may occur because it is coded by a gene that is subject to positive selection because of other, fitness-enhancing effects. The control by an allele of a single gene of two or more distinct and seemingly unrelated traits is called **pleiotropy**. An example is provided by a recently discovered allele of an enzyme-coding gene in the mosquito *Culex pipiens* that simultaneously has two effects. The allele both (1) increases the resistance of the mosquitoes to organophosphate insecticides and (2) decreases the physiological tolerance of the mosquitoes to the cold of winter. When a population of mosquitoes is sprayed with insecticides, the population *may evolve toward a diminished physiological ability to survive winter* because of pleiotropy. Selection will favor alleles that confer insecticide resistance, but the particular allele we have described will also diminish the odds of winter survival.¹³

- A trait may have evolved as an adaptation to an ancient environment, yet persist even though the environment has changed. In the new environment, the trait may no longer be beneficial and thus may not be an adaptation. Traits of this sort are thought by some evolutionary biologists to be quite common, because animals often move to new places, and even if animals stay in one place, climates often change radically over relatively short periods of geological time.¹⁴ The need of many desert amphibians for pools of water to breed, and the possession of eyes by numerous species of arthropods that live obligatorily in caves, are two examples of traits that seem to exist today because they are carryovers from the past, not because they are adaptations to the animals' present environments. Similarly, the dilute blood of the bony fish of the oceans is probably a legacy of life in a different environment, not an adaptation to life in seawater.

A trait is not an adaptation merely because it exists

Prior to about 1980, many physiologists referred to *all* traits of organisms as adaptations. Traits were called *adaptations* merely because they existed, and stories (now sometimes recalled as “just-so” stories) were concocted to explain how the traits were beneficial. This habit ignored the possibility of genetic drift and other forms of nonadaptive evolution. The habit, in fact, reduced adaptation to a nonscientific concept because no empirical evidence was required for a trait to be considered an adaptation.

A major shift in the use of the concept of adaptation was precipitated by Stephen J. Gould and Richard C. Lewontin with the publication of a critique in 1979. They stressed that natural selection in the present environment is just one of several processes by which a species may come to exhibit a trait. A trait, therefore, is not an adaptation merely because it exists. Instead, when physiologists

call a trait an *adaptation*, they are really making a *hypothesis* that natural selection has occurred.

Just as is true of any other hypothesis, data must be gathered to assess whether a hypothesis of adaptation is true or false. Because scientists usually cannot actually witness the evolution of a trait, the data they can gather are often indirect. Nonetheless, Gould and Lewontin emphasized, scientists must attempt to gather the soundest evidence possible. With this objective in mind, the study of adaptation has been maturing gradually into an empirical (i.e., data-based) science.

Adaptation is studied as an empirical science

Biologists today are giving a great deal of attention to the question of how to obtain *data* that will guide a decision on whether or not a trait is an adaptation. Sometimes the biosphere presents a “natural experiment” that permits scientists to *observe* evolution taking place over multiple generations in a natural setting. Scientists cannot depend entirely on such natural experiments to study adaptation, because the natural experiments are uncommon and may not speak to questions of greatest interest. Nonetheless, a natural experiment may provide particularly useful insights into adaptation because it may allow the adaptiveness of a trait to be judged from all the angles that matter.

Industrial melanism is a famous phenomenon—with which you are likely familiar from your study of general biology—that exemplifies a natural experiment for adaptation. *Melanism* refers to a genetically coded dark body coloration. *Industrial melanism* is an evolutionary increase in the frequency of melanism in a population of animals living in an environment modified by human industries. A species of moth in the industrial regions of England has two genetically determined color states: light and dark. The moths were predominantly light-colored prior to the industrial era, when light-colored lichens covered the tree trunks on which they rested during the day. With increasing industrialization, the lichens on the trees were killed by pollutants, and soot from factories darkened the tree trunks. Within 50 years the moth populations in the industrial areas became predominantly dark-colored because, from generation to generation, genes for dark coloration increased in frequency. Studies demonstrated that on dark tree trunks, the dark-colored moths were less likely than light-colored ones to be seen by avian predators.

From the *direct observation* of this natural experiment, we can say the following: In an environment impacted by industrial pollution, dark coloration became common in the moth populations by way of natural selection because it increased an individual's likelihood of survival in comparison with the available alternative coloration. Dark coloration thus met all the standards of our formal definition of adaptation and could be judged, based on evidence, to be an adaptation to the sooty environment.

Usually biologists are not able to observe evolution in action in this way. Thus, to study adaptation empirically, they must adopt other approaches. Several techniques have been developed—or are being developed—to study the question of adaptation when nature fails to provide an ideal natural experiment:

- *The comparative method.* The **comparative method** seeks to identify adaptive traits by comparing how a particular function is carried out by related and unrelated species in

¹³In addition to causation by pleiotropy, traits may also evolve in tandem because of *linkage disequilibrium*, in which alleles of two or more genes on the same chromosome—because of being on a single chromosome—tend to be inherited together to a nonrandomly great extent.

¹⁴Just 18,000 years ago, the arid, warm deserts of Arizona and New Mexico were far more moist than today, and they were on average about 6°C cooler, because of the last ice age. About 10,000 years ago, large expanses of the Sahara Desert experienced far more rain than they do today and were savannas (prairielike landscapes) rather than desert.

similar and dissimilar environments. *This method is based on the premise that although we cannot see evolution occurring in the past, the many kinds of animals alive today provide us with many examples of outcomes of evolution, and patterns we identify in these outcomes may provide insights into processes that occurred long ago.* Figure 1.18 presents a simple example of the use of the comparative method. Terrestrial vertebrates have lungs for breathing. If we were to look *only* at terrestrial vertebrates, we would have just that single isolated bit of knowledge about breathing mechanisms. However, if we also examine other unrelated terrestrial organisms, we discover a pattern: In insects, in land snails, *and* in terrestrial vertebrates, the breathing surfaces are parts of *invaginated* structures that hold the air rather than projecting into the air. This pattern is striking because *evaginated* breathing surfaces, which project into the water, are nearly universal among aquatic animals (note the gills of fish or crayfish). The occurrence of invaginated structures in multiple independent lines of modern terrestrial animals suggests that if we could see into the distant evolutionary past, we would witness individuals with invaginated breathing organs outcompete ones with alternative breathing structures on land. The pattern suggests that natural selection was at work, and that the invaginated breathing organs are adaptations to life on land.

- *Studies of laboratory populations over many generations.* Changes in gene frequencies can be observed over multiple generations in laboratory populations of fast-breeding animals such as fruit flies. By exposing such populations to specific, controlled conditions (e.g., high or low desiccation stress), physiologists may observe which alleles are favored by selection when a particular condition prevails. An illustration is provided by studies of fruit fly populations exposed for many generations to high desiccation stress; in such populations, the genetically coded blood volume of flies increases dramatically, and the flies become able to tolerate desiccation for greatly enhanced lengths of time (see Box 28.6). The selection that occurs in cases like this is usually considered to be *laboratory selection* or *artificial selection* because humans are manipulating the circumstances. A concern, therefore, is to assess whether outcomes of *natural selection* in the wild would be likely to be similar.
- *Single-generation studies of individual variation.* Individuals in a natural population of a single species typically vary in their physiological properties. For example, various adult individuals in a single wild population of deer mice vary widely in the maximal rate at which they can take in and use O_2 —a rate that is a key determinant of how long and vigorously the various individuals can sustain metabolic effort (Figure 1.19). Such natural variation among individuals of a species can be exploited to carry out single-generation experiments to determine which traits are most advantageous. To illustrate, suppose we trap several hundred mice in a wild population and measure

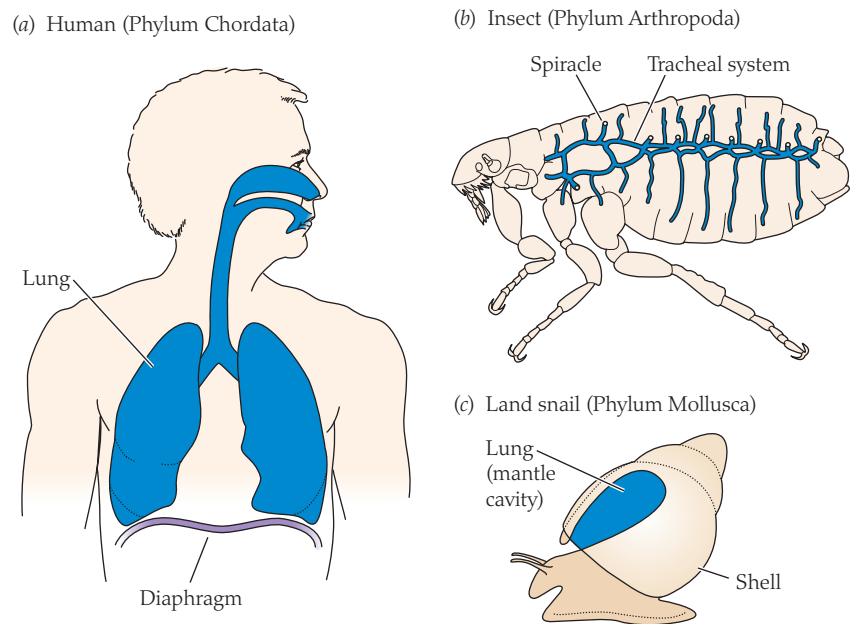

FIGURE 1.18 The comparative method Terrestrial vertebrates (a), insects (b), and land snails (c)—representing three phyla that separately colonized the land—have independently evolved breathing organs that are invaginated into the body. This convergence in the type of breathing organ suggests that invaginated breathing organs are adaptive for living on land.

the maximal rate of O_2 consumption of each, and then we release all the mice back into their natural population, where we monitor them until they die. If we find that individuals with particular O_2 -consumption capabilities produce more young before dying than individuals with

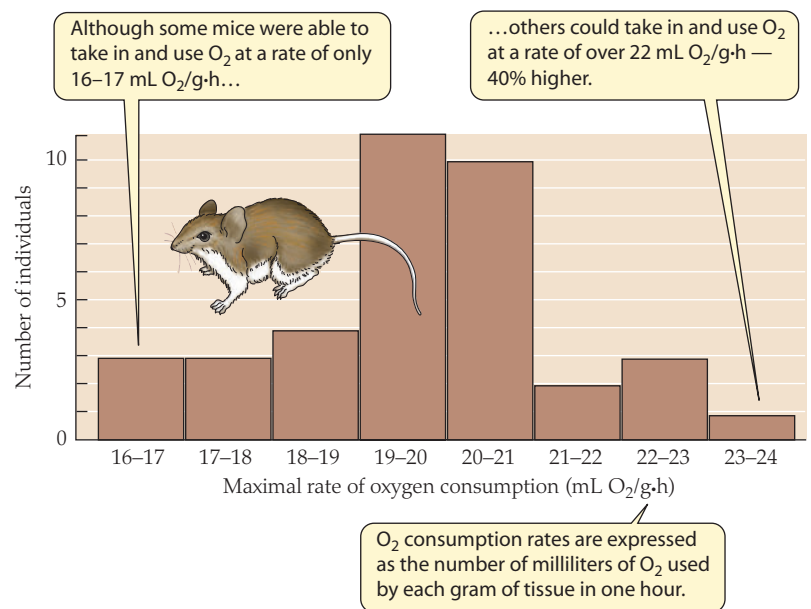

FIGURE 1.19 Physiological variation among individuals of a species This histogram summarizes the measured maximal rates of O_2 consumption of 35 deer mice (*Peromyscus maniculatus*) from a single natural population.

other O₂-consumption capabilities, we will have insight into which capabilities are adaptive.

- *Creation of variation for study.* Biologists may be able to create variation in a trait that shows little or no natural variation among individuals of a species. Then competitive outcomes in natural or laboratory settings may be observed. Years ago, the principal application of this approach was morphological; for instance, the size of the ear cavities of desert rats was morphologically altered to assess which ear-cavity dimensions allowed the surest detection of predators. One newer approach is to employ genetic manipulations. Suppose that the vast majority of individuals of a species have a certain allele for a digestive enzyme but that an unusual mutant allele is found that produces a different molecular form of the enzyme. By controlled breeding, one could create a population rich in both alleles and then observe the relative advantages of the two enzyme forms. Another genetic approach is to employ genetic engineering methods to silence genes. As we discuss in Chapter 3 (see page 79), **knockout animals** that lack functional copies of a gene of interest can be produced, or **RNA interference (RNAi)** can be employed to block transcription of a gene. Individuals manipulated in these ways are unable to synthesize the protein coded by the affected gene and thus can be used to evaluate the functional significance of the protein. Other forms of “engineering” are available for creating individual diversity that can be tested for effects. These include “allometric engineering,” in which the body sizes of individuals are artificially manipulated during development to create variation, and “hormonal engineering,” in which hormone injections are used.
- *Studies of the genetic structures of natural populations.* Natural populations are sometimes genetically structured in revealing ways. Genetic **clines** provide excellent examples. A genetic cline is a progressive change in allele frequencies or gene-controlled phenotype frequencies along an environmental gradient. Investigators find, for instance, that within certain species of fish of the East Coast of the United States, alleles that are common in warm-water Georgia individuals become progressively less common toward the north and are almost absent in cold-water New England individuals (see Figure 2.22). Genetic patterns of this sort often point to ways in which natural selection differs in its effects from place to place.
- *Phylogenetic reconstruction.* The goal of phylogenetic reconstruction is to determine the structure of the *family tree* (the ancestry) of groups of related species, often using molecular genetic data. The family tree is useful in two major ways. First, a family tree often facilitates the estimation of exactly *when* in evolutionary history each trait evolved; thus, for example, we might learn from a family tree whether the evolution of one trait preceded or followed the evolution of another—knowledge that can help us understand the context of the evolution of each trait. Second, a family tree clarifies whether a trait evolved independently more than once; several independent origins in one environment suggest that a trait is adaptive to the

environment. In this book we discuss several analyses of adaptation based on family trees. Chapter 3, for example, starts with a family-tree analysis of the icefish of Antarctic seas, fish that lack red blood cells and sometimes lack myoglobin, a key O₂-transport compound, in their heart muscle (see Figures 3.3 and 3.4).

Evolutionary potential can be high or low, depending on available genetic variation

A key determinant of the course of evolution of a trait in an animal population is the amount of genetic diversity for the trait in the population. If there is no genetic diversity for a trait—that is, if all the individuals in a population are homozygous for a single allele—then evolutionary change in the trait is essentially impossible. As an example, imagine a population of mammals in which all individuals are homozygous for an eye-color allele that codes for brown eyes. In this population as a whole, there would be no genetic diversity for eye color. Thus natural selection of alleles could not possibly alter eye color. By contrast, if the individuals in a population collectively have several different alleles of the gene for eye color—some alleles coding for brown, others for blue or olive—then the frequencies of the various alleles can be modified by natural selection, and eye color can evolve.

Physiologists are just beginning to take into full account the importance of genetic diversity in understanding evolutionary potential. **Figure 1.20** provides a model example of the sorts of insight that can be obtained from considering genetic diversity. House mice were collected from five locations in eastern North America, locations chosen to represent a progression in winter severity, from mild winters in the south to severe winters in the north. The mice collected were from wild populations that had presumably reproduced at the five locations for many generations and were subjected to natural selection. Mice from the five locations had litters in the laboratory, and their offspring were studied. The reason for studying the offspring rather than the wild-caught animals was to gain as clear insight as possible into *genetic* differences among the populations; because all the offspring were born and reared in one environment, their differences were likely to be mostly or entirely caused by differences in genetics, rather than differences in early upbringing.

Four traits of the offspring were measured: their body temperatures, the sizes of the nests they constructed, their body weights, and the fractions of their bodies occupied by *brown fat*, a tissue capable of intense heat production (see p. 257). The offspring of the mice from the five locations differed significantly in body size and nest size; both the body size and the nest size were higher in the colder, northern populations than in the southern ones, as one might expect (see Figure 1.20). However, the offspring from all five sets of mice had the same average body temperature and the same average amount of brown fat. In the abstract, one might expect animals in a cold climate to evolve a lower body temperature and a larger quantity of heat-producing tissue than ones in a warm climate, but neither of these expectations is fulfilled in reality. Why has adaptation occurred in only two of the four traits studied?

Genetic diversity provides an important part of the answer. House mouse populations exhibit relatively high genetic diversity in the genes that control body size and nest size; these two traits have responded to natural selection. However, house mouse populations

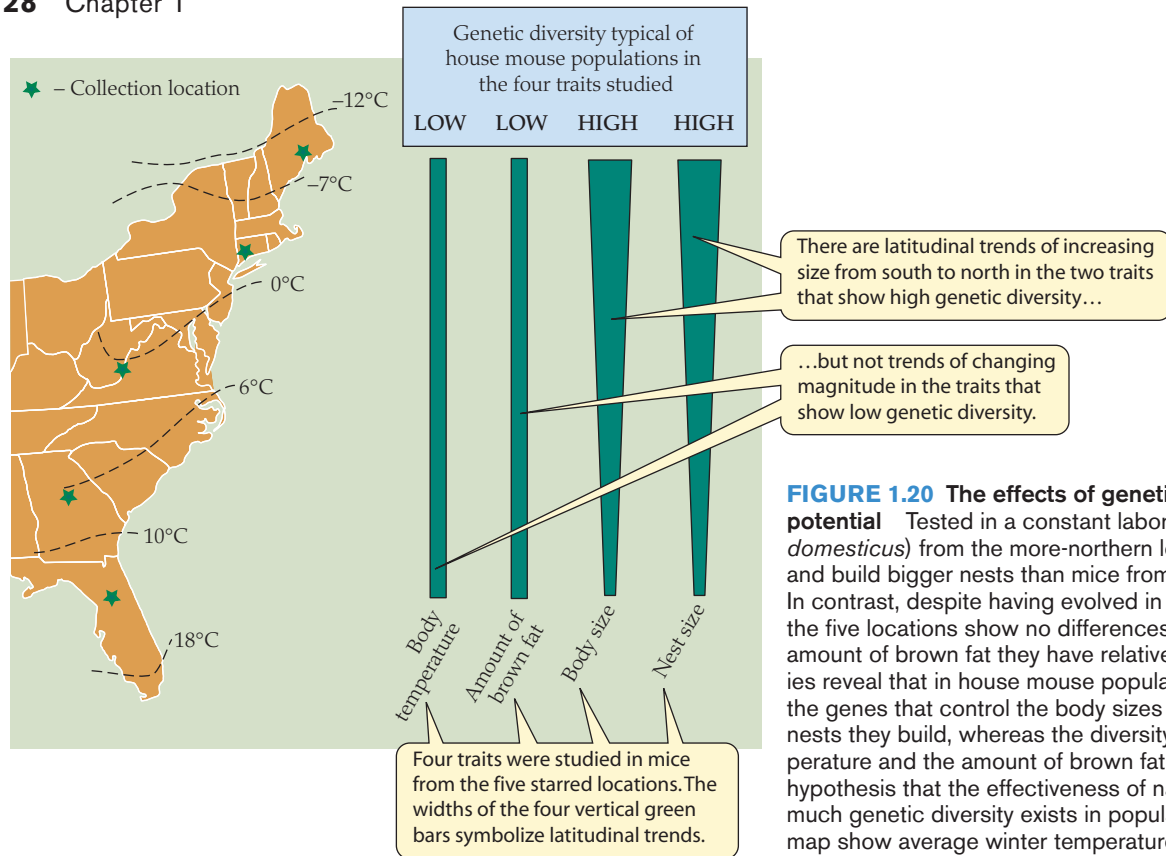

FIGURE 1.20 The effects of genetic diversity on evolutionary potential Tested in a constant laboratory setting, house mice (*Mus domesticus*) from the more-northern locations attain larger body sizes and build bigger nests than mice from the more-southern populations. In contrast, despite having evolved in different climates, mice from the five locations show no differences in body temperature or in the amount of brown fat they have relative to body size. Independent studies reveal that in house mouse populations, there is high diversity in the genes that control the body sizes of the mice and the sizes of the nests they build, whereas the diversity of genes controlling body temperature and the amount of brown fat is low. The results support the hypothesis that the effectiveness of natural selection depends on how much genetic diversity exists in populations. The dashed lines on the map show average winter temperatures. (After Lynch 1992.)

exhibit little diversity in the genes that control body temperature and the amount of brown fat; these two traits have failed to respond to natural selection in the very same mice. We do not know why genetic diversity is high for some traits and low for others. Examples such as this show, however, that evolution by natural selection depends on the underlying genetic structure of populations. It can be only as effective as genetic diversity permits it to be.

Study Questions

- There is a chance that a calcium atom or carbon atom that was once part of Caesar's or Cleopatra's body is now part of your body. Part of the reason is that most calcium and carbon atoms that were parts of these rulers' bodies did not go to their graves with them. Explain both statements. (If you enjoy quantifying processes, also see question 11.)
- Animals do not keep all their detoxification enzymes in a constant state of readiness. Thus they depend on phenotypic plasticity to adapt to changing hazards. An example is provided by the enzyme *alcohol dehydrogenase*, which breaks down ethyl alcohol. People who do not drink alcoholic beverages have little alcohol dehydrogenase. Expression of the enzyme increases when people drink alcohol, but full expression requires many days, meaning that people are incompletely defended against alcohol's effects when they first start drinking after a period of not drinking. Consider, also, that muscles atrophy when not used, rather than being maintained always in a fully developed state. Propose reasons why animals depend on phenotypic plasticity, instead of maintaining all their systems in a maximum state of readiness at all times.
- Whereas the larvae of a particular species of marine crab are bright orange, the adults of the species are white. An expert on the crabs was asked, "Why are the two different life stages different in color?" She replied, "The larvae accumulate orange-colored carotenoid pigments, but the adults do not." Did she recognize all the significant meanings in the question asked? Explain.
- Referring to Figure 1.9, do zebras, warthogs, and greater kudu have normal or exceptional gestation lengths? Justify your position in each case.
- At least three hemoglobin alleles in human populations alter hemoglobin structure in such a way as to impair the transport of O_2 by the blood but enhance resistance of red blood cells to parasitization by malaria parasites. Explain how such alleles exemplify pleiotropy, and discuss whether such alleles could lead to nonadaptive evolution of blood O_2 transport in certain situations.
- What are some of the microclimates that a mouse might find in your professor's home?
- Figure 1.14 seems at first to be simply a description of the physical and chemical properties of a lake. Outline how living organisms participate in determining the physical and chemical (i.e., temperature and O_2) patterns. Consider organisms living both in the lake and on the land surrounding the lake. Consider also a recent research report that shows that dense populations of algae sometimes change the temperature structure of lakes by raising the thermocline and thereby increasing the thickness of the deep, cold layer; how could algal populations do this, and what could be the consequences for deep-water animals?
- Do you agree with François Jacob that evolution is more like tinkering than engineering? Explain.
- Explain how the comparative method, knockout animals, and geographical patterns of gene frequencies might be used to assess whether a trait is adaptive. As much as possible, mention pros and cons of each approach.

10. Certain species of animals tolerate body temperatures of 50°C, but the vast majority do not. Some species can go through their life cycles at very high altitudes, but most cannot. What are the potential reasons that certain exceptional species have evolved to live in environments that are so physically or chemically extreme as to be lethal for most animals? How could you test some of the ideas you propose?
11. Using the set of data that follows, calculate how many of the molecules of O₂ that were used in aerobic catabolism by Julius Caesar are in each liter of atmospheric air today. All values given are expressed at Standard Conditions of Temperature and Pressure (see Appendix C) and therefore can be legitimately compared. Average rate of O₂ consumption of a human male during ordinary daily activities: 25 L/h. Number of years after his birth when Caesar was mortally stabbed near the Roman Forum: 56 years. Number of liters of O₂ per mole: 22.4 L/mol. Number of moles of O₂ in Earth's atmosphere: 3.7 × 10¹⁹ mol. Number of molecules per mole: 6 × 10²³ molecules/mol. Amount of O₂ per liter of air at sea level (20°C): 195 mL/L. Be prepared to be surprised! Of course, criticize the calculations if you feel they deserve criticism.

Molecules and Cells in Animal Physiology

The two slow-moving animals pictured here are able to consume fast-moving prey because they have evolved ways to defeat the function of essential molecules and cellular structures in their prey. The puff adder is one of the slowest moving of snakes. It feeds on fast-moving rats, however, because it needs only a split second of contact with its prey to set in motion processes that will destroy key molecular–cellular properties on which a rat depends for life. Like rattlesnakes and other adders, the puff adder sits and waits for an unsuspecting animal to come close enough for a strike. It then lunges at its victim, sinks its fangs in, and in less than 1–2 s, injects a complex mix of compounds that attack critical molecules and cells. The snake then immediately releases the rat and tracks the victim as the rat’s molecular–cellular mechanisms fall apart. Some of the injected compounds, for instance, strip the outer membranes from the rat’s muscle cells, whereas other compounds make tiny holes in the rat’s blood capillaries, permitting widespread internal hemorrhaging. When, finally, the molecular–cellular damage is so great that the victim can no longer function, the slow-moving adder moves in to eat.

The second example of a slow-moving animal that consumes fast-moving prey—the cone snail—feeds on fish. The snail lures fish to its vicinity by waving a wormlike body part that deceives the fish into coming close to eat. The snail then harpoons the fish with a hollow barbed tooth. The fish could easily tear itself loose if permitted just a moment’s time to do so. The snail preempts such escape by injecting the fish through the tooth with compounds that almost instantly disrupt the function of proteins that are essential for the function of the fish’s nerve and muscle cells. In this way the fish’s most promising defense, its ability to swim rapidly away, is immediately defeated. With the cells in its nervous system in disarray and its muscles paralyzed, the fish is ingested by the sedentary snail.

The actions of venoms and poisons remind us that all the higher functions of animals depend on molecules and on the *organization* of molecules into cellular structures and cells. An animal as spectacular as a racehorse or a mind as great as that of Socrates can be brought down in a moment if the function of key molecules is blocked or the normal organization of cells is disrupted.

A case can be made that the study of molecules and the cellular organization of molecules is the most fundamental study of biology, because molecules and cells are the building blocks of tissues and other higher levels of organization. Some scientists believe that all the properties of tissues, organs, and whole animals will eventually be fully predictable from knowledge of molecules and cells alone. Other scientists, however, believe that animals have **emergent properties**: properties of tissues, organs, or whole animals that will never, in principle, be predictable from mere knowledge of molecules and cells because the properties *emerge* only when cells are assembled into interactively functioning sets.

Two slow-moving predators that use molecular weapons to capture fast-moving prey A cone snail sits virtually motionless in the coral reef ecosystems it occupies, yet feeds routinely on fish. The puff adder is a notoriously sluggish, but deadly, African snake that resembles rattlesnakes in its strategy of hunting small mammals. Both predators produce venoms that disrupt vital molecular structures or mechanisms.

Regardless of the resolution of this important debate, molecules and cells are critically important.

The goal of this chapter is to discuss fundamental structural and functional properties of molecules and cells. Many of the properties discussed here will come up in more specific ways throughout the book. Four topics receive greatest attention:

- Cell membranes and intracellular membranes
- Epithelia—the sheets of tissue that line body cavities and form the outer surfaces of organs
- Enzyme function, diversity, and evolution
- Mechanisms by which cells receive and act on signals

In addition we will discuss fundamental properties of proteins, the ways that proteins are repaired or destroyed, and the abilities of some cells to produce light or modify an animal's external color.

Cell Membranes and Intracellular Membranes

Each animal cell is enclosed in a **cell membrane** (*plasma membrane*). Each cell also includes many sorts of **intracellular membranes** (*subcellular membranes*), such as the endoplasmic reticulum, the inner and outer membranes of each mitochondrion, and the two closely associated membranes that form the nuclear envelope. These membranes are exceedingly thin, measuring 6–8 nanometers (nm) from one side to the other. They play vitally essential roles nonetheless. They physically compartmentalize systems in functionally essential ways; the cell membrane, for instance, separates the inside of a cell

from the cell's surroundings, permitting the inside to have different properties from the outside. In addition, far from being inert barriers, the membranes are dynamic systems that *participate* in cellular and subcellular functions. For example, the cell membrane acts to receive and transmit signals that arrive at the cell surface.

The cell membrane is ordinarily composed primarily of a bilayer (double layer) of phospholipid molecules in which protein molecules are embedded (**Figure 2.1**). Similarly, the fundamental structure of the intracellular membranes is also a bilayer of phospholipid molecules with protein molecules embedded in it. Recognizing the ubiquity and importance of phospholipids, it is not surprising that they are targets of venoms. A principal weapon in the complex venom of a puff adder or a rattlesnake is a set of enzymes known as *phospholipases*, which break up phospholipids. Among other effects, these enzymes destroy the phospholipid matrix in the cell membranes of a victim's skeletal muscle cells, thereby exposing the insides of the cells, setting membrane proteins adrift, and wreaking other havoc.

To understand the molecular logic of the structure of cell membranes and intracellular membranes, it is necessary to consider the *polarity* of molecules and the attendant attributes of *hydrophilic* and *hydrophobic* interactions. Consider vinegar-and-oil salad dressing as an everyday example of the effects of molecular polarity. Vinegar consists of acetic acid and water. Thus the dressing has three principal components: oil, acetic acid, and water. If the dressing sits still for a while, the acetic acid remains in solution in the water, but the oil forms a separate layer. This outcome occurs because the acetic acid is **hydrophilic** ("water-loving"), whereas the oil is **hydrophobic** ("water-hating"). Why do the two substances behave in these

FIGURE 2.1 The structure of a cell membrane The cell membrane consists primarily of two layers of phospholipid molecules with protein molecules embedded and attached. Intracellular membranes also have a structure based on proteins embedded in a phospholipid bilayer.

different ways? A principal reason is the polarity of the molecules. Acetic acid is polar and because of its polar nature is attracted to water. Oil is nonpolar and therefore repelled from water.

The distribution of electrons in a molecule is the property that determines whether the molecule is polar or nonpolar. Within a **polar molecule**, electrons are unevenly distributed; thus some regions of a polar molecule are relatively negative, whereas others are relatively positive. Water is a polar molecule. Other polar molecules, such as acetic acid—and ions—intermingle freely with polar water molecules by charge interaction, forming solutions. Within a **nonpolar molecule**, electrons are evenly distributed and there are no charge imbalances between different molecular regions. Nonpolar molecules, such as the oil in salad dressing, do not freely intermingle with polar water molecules. Because of this—at the molecular level—after oil is dispersed into water by violent shaking, the water molecules tend to assemble *with other water molecules* into arrays that surround nonpolar oil molecules. These arrays are thermodynamically less stable than a complete separation of the water and nonpolar molecules. The nonpolar molecules therefore gradually separate into a distinct layer.

As we shall shortly see, these principles help explain the structure of the phospholipid bilayer in cell membranes and intracellular membranes, and they also help explain the positioning of other chemical constituents within the bilayer.

The lipids of membranes are structured, diverse, fluid, and responsive to some environmental factors

Phospholipids are lipids that contain phosphate groups (Figure 2.2a). They are the principal constituents of the matrix in which proteins are embedded in cell membranes and intracellular membranes. They are **amphipathic**, meaning that each molecule consists of a polar part (within which there are regional differences of charge) and a nonpolar part (which lacks regional differences of charge). A membrane phospholipid consists of a *polar head* and two *nonpolar tails* (Figure 2.2b). The polar head is composed of the phosphate group, which forms a region of negative charge, bonded to another group that forms a region of positive charge, such as choline (see Figure 2.2a). Each nonpolar tail consists of a long-chain hydrocarbon derived from a fatty acid.

(a) A phospholipid molecule (a phosphatidylcholine)

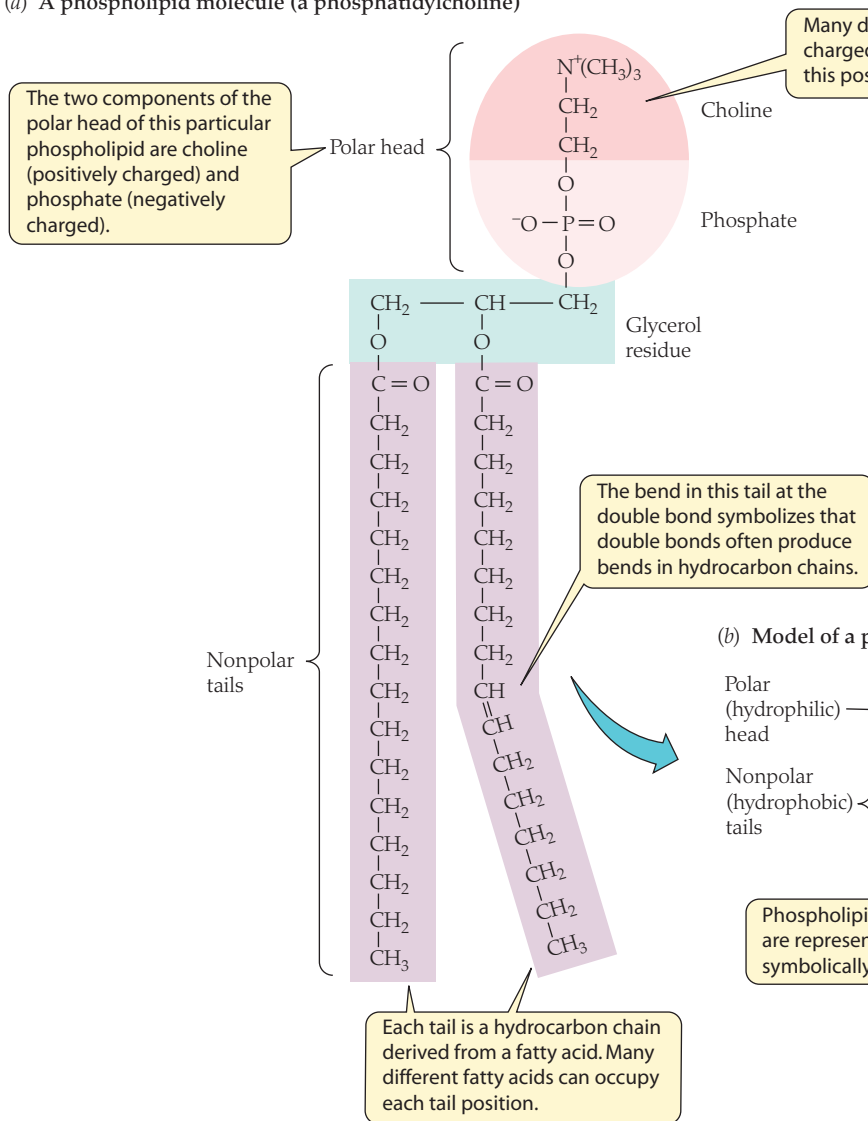

FIGURE 2.2 The structure of membrane phospholipid molecules

Phospholipid molecules are often described as having a polar head and two nonpolar tails, joined by way of ester linkages to glycerol. (a) The full chemical structure of a particular phospholipid, a phosphatidylcholine, that is common in animal cell membranes. Because many different chemical structures can occupy the two tail positions and the labeled position in the head, hundreds of kinds of membrane phospholipid molecules are possible. Any particular membrane typically consists of many different kinds of phospholipid molecules, and the kinds may change from time to time. (b) The way that a phospholipid molecule is usually symbolized to emphasize its polar head and lipid tails. (c) The assembly of phospholipid molecules into a lipid bilayer.

(b) Model of a phospholipid molecule

(c) Phospholipid molecules assembled into a bilayer with water on either side

Whereas the polar part of a phospholipid molecule or any other amphipathic molecule is hydrophilic, the nonpolar part is hydrophobic. When phospholipid molecules are placed in a system of oil layered on water, they collect at the interface of the oil and water in a predictable way, with their polar, hydrophilic heads in the water and their nonpolar, hydrophobic tails in the oil. Of greater importance for understanding living cells is the fact that when phospholipid molecules are placed simply in an aqueous solution, they spontaneously assemble into bilayers, adopting the same bilayer conformation they take in cell membranes and intracellular membranes (Figure 2.2c). This bilayer conformation forms because it is thermodynamically stable. All the hydrophobic regions (the hydrocarbon tails) get together in the interior of the bilayer (away from the water), whereas the hydrophilic heads associate with the water on either side of the membrane. The energy barrier to mixing polar and nonpolar regions in the membrane is so great that in a cell membrane, it is nearly impossible for a phospholipid molecule to “flip” its polar head through the nonpolar interior and move from one side of the bilayer to the other (unless specifically catalyzed to do so).

A striking attribute of membrane phospholipids is their great chemical diversity. Many different types of phospholipid molecules are possible because the two tails and the positively charged part of the head, as shown in Figure 2.2a, can differ widely in their specific chemical composition. The cell membranes of human red blood cells contain more than 150 different chemical forms of phospholipids, and similar diversity is seen in other cell membranes. The two layers of phospholipid molecules in any particular membrane, known as the two **leaflets** of the membrane, typically are composed of different mixes of phospholipid molecules.

The phospholipids in a cell membrane or intracellular membrane are **fluid**. Individual phospholipid molecules are not covalently bound to one another. Therefore, they move relative to each other. They are able to move about rather freely by diffusion *within each membrane leaflet*. The rate of this diffusion is great enough that a particular phospholipid molecule is able to travel, by diffusion, around the entire circumference of a cell in a matter of minutes. The ease of motion of the phospholipid molecules in a membrane leaflet is termed their **fluidity**.

Fluidity depends in part on the degree of *chemical saturation* of the hydrocarbons that make up the phospholipid tails. What do we mean by chemical saturation? A hydrocarbon is **saturated** if it contains no double bonds. It is **unsaturated** if it includes one or more double bonds; different degrees of unsaturation are possible because the number of double bonds can be high or low. As shown in Figure 2.2a, a double bond often imparts a bend to a hydrocarbon chain. Bent tails of membrane phospholipids prevent tight, crystal-like packing of the tails in the hydrophobic interior of the membrane. This disruption of tight packing helps keep the phospholipid molecules free to move. Accordingly, a greater proportion of unsaturated fatty acids in the tails of phospholipids results in a membrane with more fluidity.

In addition to chemical composition, temperature affects the fluidity of membranes; just as butter and other household lipids stiffen when they are chilled, the phospholipids in cell membranes tend to become stiffer at lower temperatures. During evolution, one important way in which cells have become adapted to different temperatures is alteration of the numbers of double bonds (the

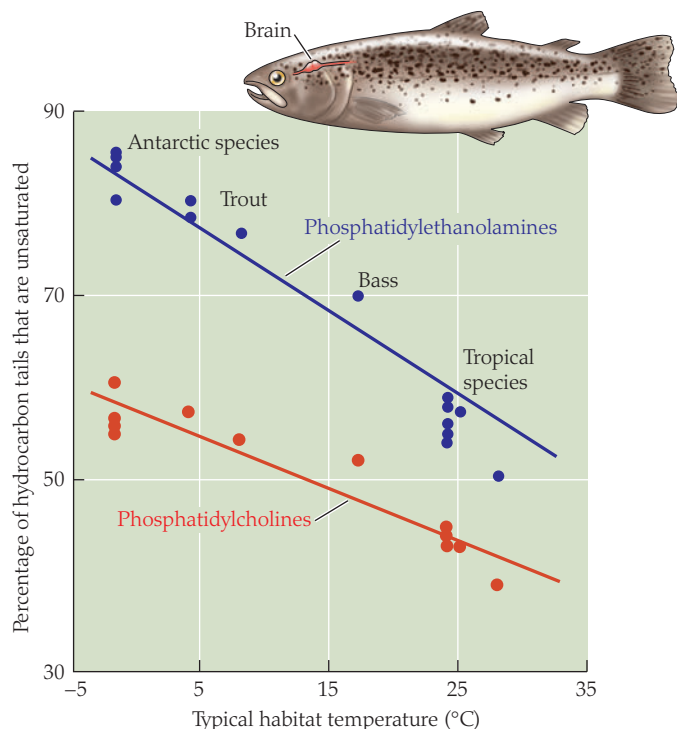

FIGURE 2.3 The degree of chemical unsaturation of the hydrocarbon tails of brain phospholipids in fish varies with habitat temperature. Brain synaptic membranes of 17 species of teleost (bony) fish were studied. Measurements were made of the composition of the hydrocarbon tails of two categories of cell-membrane phospholipids, the phosphatidylcholines and the phosphatidylethanolamines, which differ in whether the group at the top of the head in Figure 2.2a is choline [$-\text{CH}_2-\text{CH}_2-\text{N}(\text{CH}_3)_3$] or ethanolamine ($-\text{CH}_2-\text{CH}_2-\text{NH}_2$), respectively. Each plotted symbol corresponds to the average value for one species. (After Logue et al. 2000.)

degree of unsaturation) in their membrane phospholipids. This is evident in fish of polar seas, for instance. The fish experience tissue temperatures so low that their cell membranes could be overly stiff. This problem is avoided, however, because these fish have cell membranes constructed of phospholipids that are particularly rich in double bonds; the highly unsaturated phospholipids are inherently quite fluid and thus less likely than other phospholipids to become detrimentally stiff at low temperatures. Recent research on the cell membranes of brain cells in fish demonstrates that the degree of phospholipid unsaturation depends in a regular way on the environmental temperatures to which various species are adapted (Figure 2.3). Tropical species of fish, which face little risk of having their membranes rendered too stiff by low temperatures, have evolved relatively saturated phospholipids, but as the temperature of the habitat falls, the degree of unsaturation of the phospholipids increases.

Evidence is accumulating that individual animals sometimes restructure their membrane phospholipids in response to environmental factors. For example, lab mice alter the mix of membrane phospholipids in their heart muscle cells after just 4–12 h of fasting and reverse the changes when fed. At least some hibernating species of mammals substantially alter the mix of phospholipids in their cell and mitochondrial membranes as they approach hibernation, in ways thought to promote the hibernating physiological state (e.g., suppression of metabolism).

Besides phospholipids, cell membranes and intracellular membranes contain other classes of lipids, one of which is **sterols**. The principal membrane sterols are **cholesterol** and **cholesterol esters**. In cell membranes, which are typically much richer in sterols than intracellular membranes are, sterols collectively occur in ratios of 1 molecule per 10 phospholipid molecules, up to 8 per 10. Cholesterol is mildly amphipathic and positioned within the phospholipid leaflets (see Figure 2.1), where it exerts complex effects on membrane fluidity.

Proteins endow membranes with numerous functional capacities

Proteins are the second major constituents of cell membranes and intracellular membranes. According to the **fluid mosaic model** of membranes, a membrane consists of a mosaic of protein and lipid molecules, all of which move about in directions parallel to the membrane faces because of the fluid state of the lipid matrix. As we start to discuss proteins, an important fact to recall from the study of organic chemistry is that—in terms of their chemical makeup—proteins are considered to have primary, secondary, tertiary, and sometimes quaternary structure. This aspect of protein structure is reviewed in **Box 2.1**.

Membrane proteins are structurally of two principal kinds: integral and peripheral. **Integral membrane proteins** are parts of the membrane and cannot be removed without taking the membrane apart. Most integral proteins (see Figure 2.1) span the membrane and thus are called *transmembrane* proteins. These molecules have both hydrophobic and hydrophilic regions. As we will see in detail shortly, each hydrophobic region typically has an amino acid composition and a molecular geometry that allow it to associate with the hydrophobic hydrocarbon tails of the membrane interior. The hydrophilic regions of transmembrane protein molecules, by contrast, typically protrude into the aqueous solutions bathing the two sides of the membrane.

Peripheral membrane proteins are associated with the membrane but can be removed without destroying the membrane. They are bonded noncovalently (i.e., by weak bonds) to membrane components (e.g., integral proteins) and are positioned on one side of the membrane or the other (see Figure 2.1). Their positioning means

BOX 2.1 PROTEIN STRUCTURE AND THE BONDS THAT MAINTAIN IT

All protein molecules have *primary*, *secondary*, and *tertiary* structure (and some have *quaternary* structure). Primary structure refers to the string of covalently bonded amino acids. As essential as primary structure is, protein *function* depends most directly on secondary and tertiary structure—the three-dimensional conformation of the protein molecule. Because secondary and tertiary structure are stabilized by *weak* chemical bonds rather than covalent bonds, the three-dimensional conformation of a protein can *change* and *flex*—a process essential for protein function. *Denaturation* is a disruption of the correct tertiary structure; because primary structure is not altered, denaturation may be reversible (reparable). This box continues on the web at **Box Extension 2.1**. There you will find detailed information on—and illustrations of—all levels of protein structure, strong versus weak bonds, the types of weak bonds, denaturation, and potential repair of denaturation.

that *the two leaflets of a membrane differ in protein composition, as well as phospholipid composition*.

The proteins of cell membranes and intracellular membranes endow the membranes with capabilities to *do* many things. Five *functional* types of membrane proteins are recognized: **channels**, **transporters (carriers)**, **enzymes**, **receptors**, and **structural proteins**. Because these types are classified by function, the *actions* listed in **Table 2.1** define the five types. The categories are not mutually exclusive: A membrane protein can be both a receptor and a channel, or a transporter and an enzyme, for example.

The molecular structures of membrane proteins are complex and are diagrammed in several ways, depending on the degree of chemical detail to be shown. To illustrate, let's focus on a channel, which is a type of membrane-spanning integral protein. Channels provide paths for ions or other materials in aqueous solution to pass through membranes. In our example the channel is formed by a single protein molecule, the secondary structure of which is

TABLE 2.1 The five functional types of membrane proteins and the functions they perform

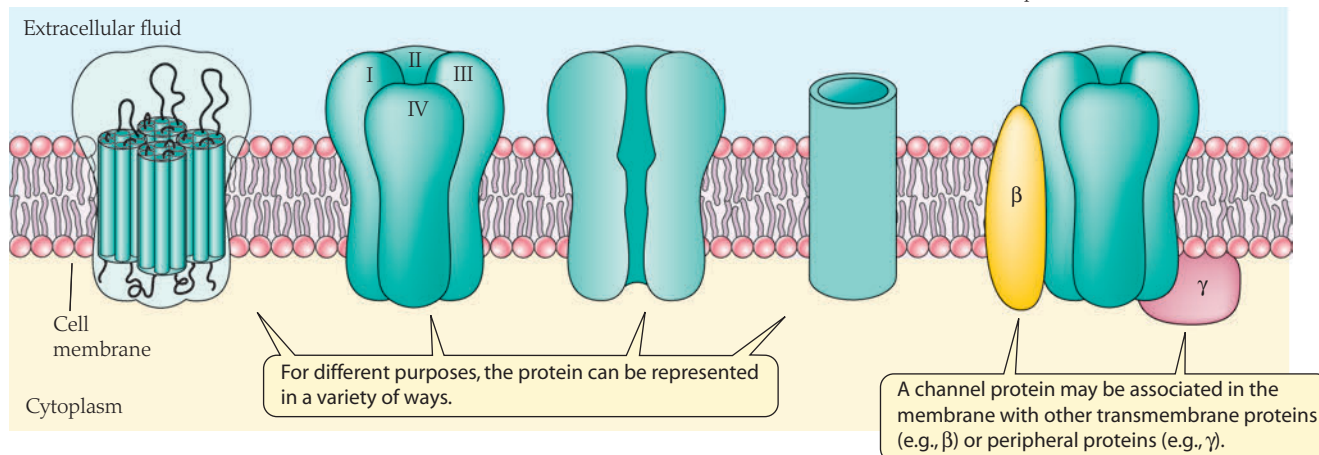

Functional type	Function performed (defining property)
Channel	Permits simple or quasi-simple <i>diffusion</i> of solutes in aqueous solution (see page 104)—or <i>osmosis</i> of water (see page 121)—through a membrane. A simplified view of a channel is that it creates a direct water path from one side to the other of a membrane (i.e., an aqueous pore) through which solutes in aqueous solution may diffuse or water may undergo osmosis.
Transporter (carrier)	Binds noncovalently and reversibly with specific molecules or ions to move them across a membrane intact. The transport through the membrane is <i>active transport</i> (see page 108) if it employs metabolic energy; it is <i>facilitated diffusion</i> (see page 108) if metabolic energy is not employed.
Enzyme	Catalyzes a chemical reaction in which covalent bonds are made or broken (see page 41).
Receptor	Binds noncovalently with specific molecules and, as a consequence of this binding, initiates a change in membrane permeability or cell metabolism. Receptor proteins mediate the responses of a cell to chemical messages (signals) arriving at the outside face of the cell membrane (see page 58).
Structural protein	Attaches to other molecules (e.g., other proteins) to anchor intracellular elements (e.g., cytoskeleton filaments) to the cell membrane, creates junctions between adjacent cells (see Figure 2.7), or establishes other structural relations.

shown in **Figure 2.4a** (see Box 2.1 for an explanation of secondary structure).

Each cylinder in **Figure 2.4a** represents a sequence of amino acids that forms a helix-shaped subunit, called an α -helix (see Box 2.1), within the protein structure. The whole protein molecule exemplifies a common property of membrane proteins, in that it consists of repeating structural patterns known as **domains**. To identify the domains, review the molecule from left to right. You will note five α -helices linked closely together, and then a sixth helix separated from the others by a longer string of amino acids; then you will note that this pattern of five closely spaced helices followed by a sixth more-separated helix is repeated three more times. On the basis of this repeating pattern, this molecule is said to show four domains, numbered I to IV, as illustrated in **Figure 2.4a**. The α -helices are predominantly hydrophobic and span the membrane by associating with the hydrophobic interior of the phospholipid bilayer. The strings of amino acids that connect successive helices are hydrophilic and protrude from the membrane into the aqueous solutions on either side. In its natural state in a membrane, this protein is believed to be shaped into a closed ring in which the four domains form cylinder-like structures surrounding a central pore, as diagrammed in **Figure 2.4b**.

- (b) Simplified tertiary (three-dimensional) structure enclosed in a sketch of the envelope of the molecule
- (c) Stylized version of chemical structure showing domains
- (d) Semirealistic symbol
- (e) Schematic symbol
- (f) Stylized version of chemical structure showing associated protein molecules

The three additional representations of the membrane protein that are shown in **Figure 2.4** are progressively simpler. The sort of representation in **Figure 2.4c**, which still shows that there are four domains, is a simplified way to represent the chemical structure of the molecule. The diagrammatic, semirealistic representation in **Figure 2.4d**, which leaves one guessing about the number of domains, is more simplified yet, and in **Figure 2.4e** the channel is represented schematically (without any intention of resembling the actual molecule).

The interrelations of the presentations in **Figure 2.4a–e** are important to note because all of these sorts of presentations are commonly used in biological literature. An important additional detail is that the major subunits of membrane proteins are not always parts of one molecule, as the four domains in our example are; sometimes the major subunits of a single channel, for example, are separate protein molecules. Moreover, the protein units that constitute the central pore-forming part of a channel may have other integral or peripheral proteins associated with them, as shown in **Figure 2.4f**.

Carbohydrates play important roles in membranes

Cell membranes and intracellular membranes also contain carbohydrates, which occur mostly in covalently bonded combination with lipids or proteins, or both (see **Figure 2.1**). *Glycolipids* (e.g., gangliosides), *glycoproteins*, and *proteoglycans* are some of the major categories of carbohydrate-containing membrane compounds.¹ Carbohydrate groups are hydrophilic and thus are associated with the membrane surface and adjacent aqueous solution. Carbohydrates reinforce the point, stressed earlier, that the two leaflets of a membrane are typically different.

¹The word fragment *glyco* refers to carbohydrates (after the Greek *glykeros*, “sweet”).

FIGURE 2.4 The structure of a transmembrane protein—a voltage-gated Na^+ channel—illustrating several modes of presentation

In cell membranes, for example, the carbohydrate groups always project from the outer, extracellular face, not the inner, cytoplasmic face (see Figure 2.1). These carbohydrate groups serve as attachment sites for extracellular proteins and as cell-recognition sites.

SUMMARY Cell Membranes and Intracellular Membranes

- The matrix of a cell membrane or intracellular membrane consists of a bilayer of phospholipid molecules. The phospholipids are chemically very diverse, even within a single membrane, and in a particular cell the phospholipid composition can undergo change in response to environmental or other factors. The phospholipids are fluid, meaning that individual molecules move about relatively freely by diffusion within each membrane leaflet.
- Animals exhibit adaptive trends in the phospholipid compositions of their cell membranes. Cells that function routinely at low temperatures tend to have a phospholipid composition that permits membranes to remain fluid under cold conditions (e.g., they have high proportions of double bonds in the hydrocarbon tails).
- Five functional categories of proteins occur in cell and intracellular membranes: channels, transporters, enzymes, receptors, and structural proteins. A single protein may engage in more than one function.
- In addition to phospholipids and proteins, which are the principal components, membranes often have other components such as cholesterol (a lipid) and glycoproteins (composed of covalently bonded carbohydrate and protein subunits).

Epithelia

An **epithelium** (plural *epithelia*) is a sheet of cells that covers a body surface or organ, or lines a cavity. Although epithelia are radically different from cell membranes and intracellular membranes, they—to some degree—perform parallel functions on a larger structural scale. Epithelia compartmentalize the body by forming boundaries between body regions. They also form a boundary between an animal and its external environment. Moreover, like cell membranes, epithelia have numerous functional capacities and play major functional roles in animal physiology.

A **simple epithelium** consists of a single layer of cells (Figure 2.5a). Simple epithelia are exceedingly common; in the human body, for instance, the intestines, kidney tubules, blood vessels, and sweat glands are all lined with a simple epithelium. Each cell in a simple epithelium has an **apical surface** (*mucosal surface*) facing into a cavity or open space, and a **basal surface** (*serosal surface*) facing toward the underlying tissue to which the epithelium is attached. An epithelium typically rests on a thin, permeable, noncellular, and nonliving sheet of matrix material, positioned beneath the basal cell surfaces. This sheet is called the **basement membrane** (*basal lamina*) and is composed of glycoproteins and particular types of collagen. It is secreted mostly by the epithelial cells, although the underlying cells also contribute. Simple epithelia are classified as *squamous*, *cuboidal*, or *columnar*, depending on how tall the cells are. The cells in a squamous epithelium are low and flat, whereas those in a columnar epithelium are high relative to their basal dimensions; the epithelium in Figure 2.5a is classed as cuboidal because the cells are about as tall as they are wide. Blood vessels usually do not enter epithelia. Instead, epithelial

FIGURE 2.5 Simple epithelia (a) A generalized simple epithelium covering a free surface of a tissue. (b) The specific simple epithelium lining the mammalian small intestine (midgut). This epithelium consists of several cell types. Most cells are the absorptive-digestive cells emphasized here. Scattered among these cells are mucin-secreting cells (not shown) and at least ten types of endocrine or endocrine-like cells. Each endocrine cell produces granules of secretory material; the granules move to juxtapose themselves with the basal or near-basal regions of the cell membrane and then release their secretions into the spaces outside the cell, after which the secretions enter the blood for transport elsewhere. Endocrine-like cells termed *paracrine cells* (not shown) are also present. Paracrine cells produce secretions that affect nearby cells rather than acting on distant cells by way of the circulation (see Figure 16.1).

cells exchange O_2 , CO_2 , and other materials through the underlying basement membrane with blood capillaries located on the opposite side of the basement membrane (see Figure 2.5a).

The epithelium that lines the small intestine (midgut) of a mammal (Figure 2.5b) is an example of a simple epithelium that will be featured prominently in this book (e.g., in Chapters 5 and 6) and that introduces additional aspects of epithelial morphology and function. The apical surfaces of the cells in this columnar epithelium face into the lumen (open central cavity) of the intestine. As digestion occurs, liberating food molecules from foods, the molecules pass through the epithelium and basement membrane to reach blood vessels and lymph passages that transport them to the rest of the body.

FIGURE 2.6 Tubules and follicles formed by simple epithelia

(a) Both tubules and follicles are formed by the wrapping of simple epithelia into closed curves. Cross sections of two important tubular structures are shown in (b) and (c); in each case the basal cell surfaces and basement membrane of the epithelium are on the outside. For historical reasons, the cells of blood capillaries are usually called *endothelial* cells, but they are a form of epithelium.

The intestinal epithelium illustrates that a simple epithelium can consist of two or more cell types. Whereas the epithelium is composed mostly of absorptive–digestive cells, it also includes endocrine cells (see Figure 2.5b) and additional cell types.

The intestinal epithelium also illustrates **microvilli** (singular *microvillus*), which are a common (but not universal) feature of epithelial cells. Microvilli are exceedingly fine, fingerlike projections of the apical cell membrane (see Figure 2.5b). In the intestinal epithelium, the microvilli greatly increase the area of contact between the epithelial cells and the contents of the gut. Microvilli are most often found in epithelia that are active in secreting or absorbing materials, such as the epithelia of certain kidney tubules and the pancreatic ducts, as well as the intestinal epithelium. Microvilli are often described collectively as a **brush border** because they look like the bristles on a brush when viewed microscopically.

Another significant aspect of diversity in simple epithelia arises from the geometric arrangement of the cells. *Tubules* or *follicles* (hollow globes) are often formed by the wrapping of a simple epithelium into a closed curve (Figure 2.6a) supported by the basement membrane on the outside. A tubule formed by cuboidal epithelium bearing microvilli forms the proximal region of each mammalian nephron (kidney tubule), for example (Figure 2.6b). Vertebrate blood capillaries are an especially important example. Each blood capillary consists of a single layer of highly flattened epithelial cells (lacking microvilli) supported by the epithelial basement membrane (Figure 2.6c). The basement membranes of capillaries are one of the important biochemical targets of the venoms of puff adders and rattlesnakes. The venoms contain enzymes (metalloproteases) that break down the basement membranes, destroying the integrity of blood capillaries. In this way the venoms cause widespread internal hemorrhaging.

Adjacent cells in an epithelium are physically joined by cell-membrane junctions of several sorts; the four most important of these are *tight junctions*, *septate junctions*, *desmosomes*, and *gap junctions* (Figure 2.7). In the paragraphs that follow, we look at each of these types of junction in turn.

A **tight junction** is a place where the cell membranes of adjacent cells are tightly joined so that there is no intercellular space between the cells; adjacent cells are perhaps 10–20 nm apart for the most part, but at tight junctions the cell membranes meet or fuse. Tight junctions typically occur between the sides of adjacent cells, just a short distance away from their apical surfaces (Figure 2.8). Any given epithelial cell has tight junctions with adjacent epithelial cells in a continuous ring around its entire perimeter. *This ring of tight junctions demarcates the apical surface of the cell from its lateral and basal surfaces, giving rise to one of the most important distinctions in the physiological study of epithelia, the distinction between the apical region and the basolateral region of each cell membrane* (see Figure 2.8). Many invertebrate groups have **septate junctions** instead of tight junctions. Septate junctions differ from tight junctions in their fine structure (see Figure 2.7), but they resemble tight junctions in

(a) Epithelial cells can form tubules and follicles

(c) Mammalian blood capillary in cross section

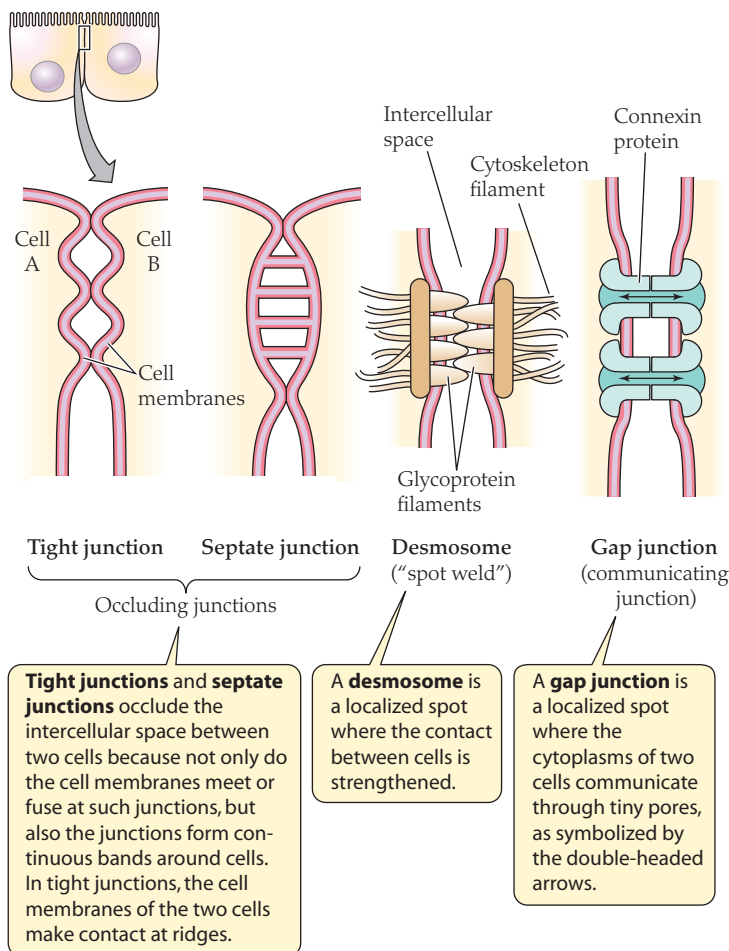

FIGURE 2.7 Types of junctions between cells At a pore in a gap junction, each cell has a ring of six connexin proteins that together form the pore, and the rings of the two cells line up to create continuity between cells. Each ring of connexin proteins is called a *connexon*.

their position and in the fact that they fully encircle each cell. Tight and septate junctions are sometimes aptly called **occluding junctions** because they block or occlude the spaces between adjacent epithelial cells, preventing open passage between the fluids on either side of an epithelium.

A **desmosome** (see Figure 2.7) is a junction at which mutually adhering glycoprotein filaments from two adjacent cells intermingle across the space between the cells. Desmosomes are often likened to rivets or spot welds because they occur as tiny isolated spots, not continuous bands, and their principal function is believed to be to strengthen and stabilize contacts between adjacent cells.

Gap junctions (see Figure 2.7) are like desmosomes in that they occur at discrete spots, but otherwise they are very different from all the other junctions we have discussed because within a gap junction there are open pores between cells. At these pores, which are formed by **connexin proteins** (see Figure 2.7), the two adjacent cells lack cell-membrane boundaries, and there is continuity between the cytoplasm of the cells. Molecules and ions smaller than 1000–1500 daltons (Da) in molecular mass are able to pass between cells at gap junctions, although large solutes such as proteins cannot. Gap junctions are important in cell–cell communication—including passage of intracellular signaling agents in some tissues and direct electrophysiological interactions between cells in nerve or muscle (gap junctions are treated in detail in Chapter 13 [see Figure 13.2]).

A central feature of epithelia is that *each epithelial cell is functionally asymmetric*. The proteins in the cell membrane of an epithelial cell are unable (for reasons only poorly known) to diffuse through tight junctions. Thus, the ring of tight junctions around each epithelial cell *acts as a fence* that keeps proteins from crossing between the apical and basolateral regions of the cell membrane. *The two regions of the cell membrane therefore have different sets of channels, transporters, membrane enzymes, and other classes of membrane proteins, and they are functionally different in many ways.* Differences also exist between the apical and basolateral regions in the membrane phospholipids composing the outer (but not inner) leaflet of the cell membrane.

One of the important functions of an epithelium is to control and mediate the transport of substances between the apical and basal sides of the epithelium and thus between different body regions. Substances—such as ions, nutrient molecules, or water—pass through a simple epithelium by two types of paths (Figure 2.9). They may pass *through* cells by **transcellular** paths. Alternatively,

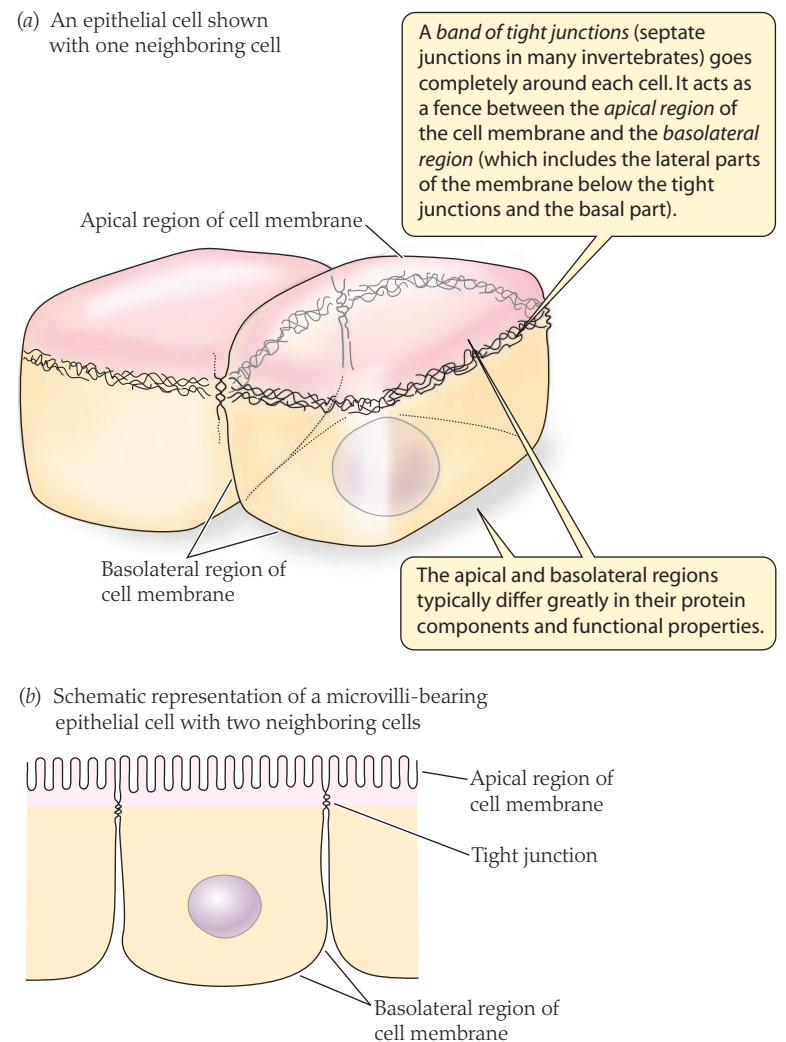

FIGURE 2.8 The organization of epithelial cells into apical and basolateral regions (a) The cell membrane of an epithelial cell is divided into apical (pink) and basolateral (orange) regions—which differ in their protein components and functions—by a band of tight junctions formed with adjacent epithelial cells. In this book, we will often use the schematic format shown in (b) to represent an epithelium. Microvilli do not always occur, but when they do, they are on the apical side only.

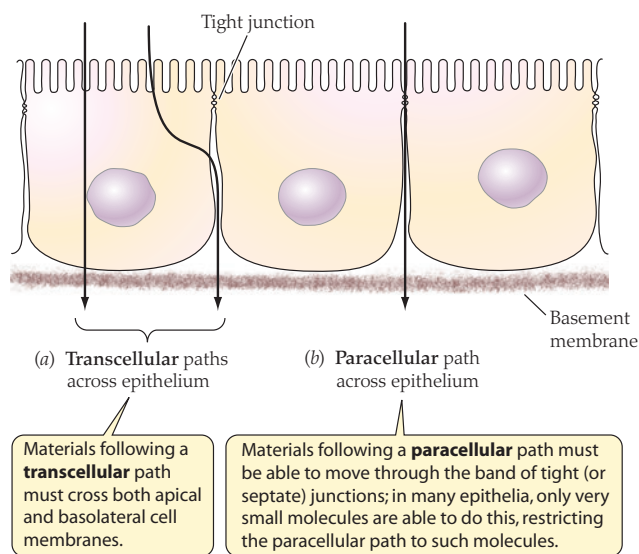

FIGURE 2.9 Transcellular and paracellular paths across an epithelium

they may pass *between* cells, in **paracellular** paths. Tight junctions interfere with or block the paracellular movement of substances across an epithelium. In some epithelia the tight junctions prevent almost all paracellular movement. In others, however, the tight junctions permit extensive paracellular movement of certain sorts of molecules or ions, and the epithelia are described as **leaky**.

A substance that crosses an epithelium by a transcellular path must pass through two *cell* membranes. One of the most important principles in the study of epithelia is that for scientists to understand the physiology of transcellular transport, they must understand the membrane proteins and functions of both the apical cell membranes and the basolateral cell membranes of the epithelial cells.

SUMMARY Epithelia

- An epithelium is a sheet of cells that lines a cavity or covers an organ or body surface, thereby forming a boundary between functionally different regions of the body or between the animal and the external environment.
- In a simple epithelium, each cell is fully encircled by a ring of tight or septate junctions formed with adjacent epithelial cells. These occluding-type junctions seal the spaces between adjacent cells. Moreover, the ring of junctions around each cell divides the cell membrane into chemically and functionally distinct apical and basolateral regions.
- An epithelium rests on a nonliving, permeable basement membrane secreted by the epithelial cells and underlying tissue. The apical membranes of metabolically active epithelial cells often bear a brush border of microvilli, greatly enhancing their surface area. In addition to the occluding junctions, adjacent epithelial cells are joined by structurally reinforcing “spot welds,” called desmosomes, and sometimes by gap junctions at which continuity is established between the cytoplasm of the cells.
- Materials pass through epithelia by paracellular paths between adjacent cells and by transcellular paths through cells. Materials traveling through a cell must pass through both the apical and the basolateral cell membranes of the cell.

Elements of Metabolism

At this point in the chapter, we shift toward even more of a focus on processes and less of a focus on morphology. The basics of metabolism constitute a good beginning for this new emphasis.

Metabolism is the set of processes by which cells and organisms acquire, rearrange, and void commodities in ways that sustain life. Metabolism involves myriad chemical and physical processes. To give order to their research, animal physiologists subdivide the study of metabolism. One way of doing this is according to specific commodities. For example, **nitrogen metabolism** is the set of processes by which nitrogen is acquired, employed in synthetic reactions to create proteins and other functional nitrogenous compounds, and ultimately transferred to elimination compounds such as urea or ammonia. **Energy metabolism** consists of the processes by which energy is acquired, transformed, channeled into useful functions, and dissipated.

Metabolism also may be subdivided according to the type of transformation that occurs. **Catabolism** is the set of processes by which complex chemical compounds are broken down to release energy, create smaller chemical building blocks, or prepare chemical constituents for elimination. **Anabolism**, by contrast, consists of the processes that synthesize larger or more complex chemical compounds from smaller chemical building blocks, using energy. Whereas catabolism is destructive, anabolism is constructive.

Metabolism depends on *sets* of biochemical reactions, such as the 30 or so linked reactions that cells employ to oxidize glucose into CO_2 and H_2O . The prominence of biochemistry in metabolism can give the impression that cells are just like test tubes: merely places where chemicals react. There is a massive distinction between cells and test tubes, however. Whereas test tubes are simply places where chemical reactions occur, cells orchestrate their own chemistry. The cellular orchestration of metabolism is directed by genes and mediated, in major part, by enzymes.

Enzyme Fundamentals

In his story “The Celebrated Jumping Frog of Calaveras County,” Mark Twain appealed to the imagination of his readers by extolling the awesome jumping abilities of a frog, probably a common leopard frog (*Rana pipiens*) (Figure 2.10a), named Dan’l Webster. Anyone who has ever tried to catch leopard frogs knows that when first disturbed, they hop away at lightning speed. Thus it is hard not to smile in knowing admiration as Twain describes Dan’l Webster’s celebrated jumping feats. Muscles can work only as fast as they are supplied with adenosine triphosphate (ATP). Amphibians, however, have only modest abilities to make ATP using oxygen (O_2), because they have relatively simple lungs and can supply their cells with O_2 only relatively slowly. For leopard frogs to hop along as fast as they do when fleeing danger, they need to make ATP faster than the O_2 supply to their muscles permits. That is, they must make ATP by *anaerobic* mechanisms not requiring O_2 . A crucial reason they can do this is that their leg muscles are well endowed with the enzyme *lactate dehydrogenase*.

Compared with leopard frogs, toads such as the common western toad of North America (*Bufo boreas*) (Figure 2.10b) are not nearly as well endowed with lactate dehydrogenase. Thus they cannot make ATP to a great extent without O_2 , and the slow rate of O_2 delivery to

(a) A fast-jumping amphibian: the leopard frog (*Rana pipiens*)(b) A slow-jumping amphibian: the western toad (*Bufo boreas*)

FIGURE 2.10 Two amphibians with different jumping capabilities based in part on different levels of a key enzyme, lactate dehydrogenase

their muscle cells means a slow rate of ATP production, explaining why they cannot hop along as fast as frogs. Mark Twain could not have known this, because the study of enzymes was just beginning during his life, but when he searched his mind for an amphibian that could inspire his readers as a “celebrated” jumper, he chose a frog rather than a toad in major part (we now know) because frogs have more of the enzyme lactate dehydrogenase.

Enzymes are protein catalysts that play two principal roles: They *speed* chemical reactions, and they often *regulate* reactions.² To appreciate the extreme importance of enzymes, it is crucial to recognize that the vast majority of the biochemical reactions that occur in animals *do not take place on their own at significant rates* under physiological conditions. Cells are biochemically complex enough that, in principle, tens of thousands of reactions might occur in them. However, because reactions in general require catalysis to occur at significant rates, the particular reactions that do take place in a cell—out of all those that *could* take place—depend on the cell’s own biosynthesis of enzyme proteins. *Enzymes represent one of the foremost means by which cells take charge of their own biochemistry.*

When we say that an enzyme is a **catalyst**, we mean that it is a molecule that accelerates a reaction without, in the end, being altered itself. The reaction catalyzed by lactate dehydrogenase (LDH) that is important for escape by frogs is the reduction of pyruvic acid to form lactic acid, a reaction in which each pyruvic acid molecule is combined with two hydrogen atoms (Figure 2.11a). Although the presence of LDH speeds this reaction, LDH is not itself altered by the reaction. Thus a molecule of LDH persists as it catalyzes the reduction of many pyruvic acid molecules, one after another.

Enzymes are described as having *substrates* and *products*, and often there are two or more of each. To be exact about the substrates and products of LDH, a chemically complete presentation of the LDH-catalyzed reaction is needed (Figure 2.11b). The hydrogen atoms that reduce pyruvic acid are taken from a molecule we symbolize as NADH_2 . NAD is an enzyme cofactor (nicotinamide adenine dinucleotide) found in all animal cells; and NADH_2 symbolizes

the reduced form of this cofactor, the form that is combined with hydrogen. The **substrates** of an enzyme are the initial reactants of the reaction that the enzyme catalyzes; the **products** of the enzyme are the compounds produced by the reaction. Thus, in the reaction we are discussing—the left-to-right reaction in Figure 2.11b—the substrates of LDH are pyruvic acid and NADH_2 , and the products are lactic acid and NAD. Chapter 8 discusses how this reaction aids not only rapid jumping by frogs, but also other forms of sudden, intense vertebrate exercise, such as sprinting by people. Put simply,

(a) Simplified reaction

(b) Full reaction

FIGURE 2.11 The reaction catalyzed by lactate dehydrogenase (LDH) The enzyme cofactor nicotinamide adenine dinucleotide (NAD) acts as an electron (or hydrogen) shuttle by undergoing reversible reduction (forming NADH_2) and oxidation (forming NAD). As (b) shows, when the reaction catalyzed by LDH proceeds from left to right, NADH_2 produced elsewhere is converted to NAD, renewing the supply of NAD. The reaction catalyzed by LDH is reversible, but the NAD reaction involved in the reverse direction is not shown. Chapter 8 discusses the important role of the LDH-catalyzed reaction in ATP production.

²Research over the past three decades has shown that protein catalysts—enzymes—are not the only catalysts. Some types of RNA molecules also play roles as catalysts.

the way the reaction helps is precisely that it produces NAD, an essential compound for ATP synthesis by glycolysis.

There are many kinds of enzymes. Mammalian cells, for instance, typically synthesize several thousand kinds. Usually, the names of enzymes end in *-ase*. Thus, when you see a biochemical term that ends in *-ase*, it usually refers to an enzyme. Later we will see that a single enzyme may exist in multiple molecular forms in different tissues or different animal species. The name of an enzyme typically refers to the *reaction catalyzed*. Lactate dehydrogenase, for example, is defined to be an enzyme that catalyzes the reaction in Figure 2.11b. All molecular forms that catalyze this reaction are considered to be forms of lactate dehydrogenase, even though they vary in their exact molecular structures and detailed functional properties.

Enzyme-catalyzed reactions exhibit hyperbolic or sigmoid kinetics

For an enzyme molecule to catalyze a reaction, it must first combine with a molecule of substrate to form an **enzyme–substrate complex**. (Here, for simplicity, we assume there is only one substrate.) This complexing of enzyme and substrate, which usually is stabilized by *noncovalent* bonds, is *essential* for catalysis because the enzyme can alter the readiness of the substrate to react only if the two are bonded together. Substrate is converted to product *while united with the enzyme*, forming an **enzyme–product complex**, also usually held together by *noncovalent* bonds. The enzyme–product complex then dissociates to yield free product and free enzyme. Symbolically, if E, S, and P represent molecules of enzyme, substrate, and product, the major steps in enzyme catalysis are:

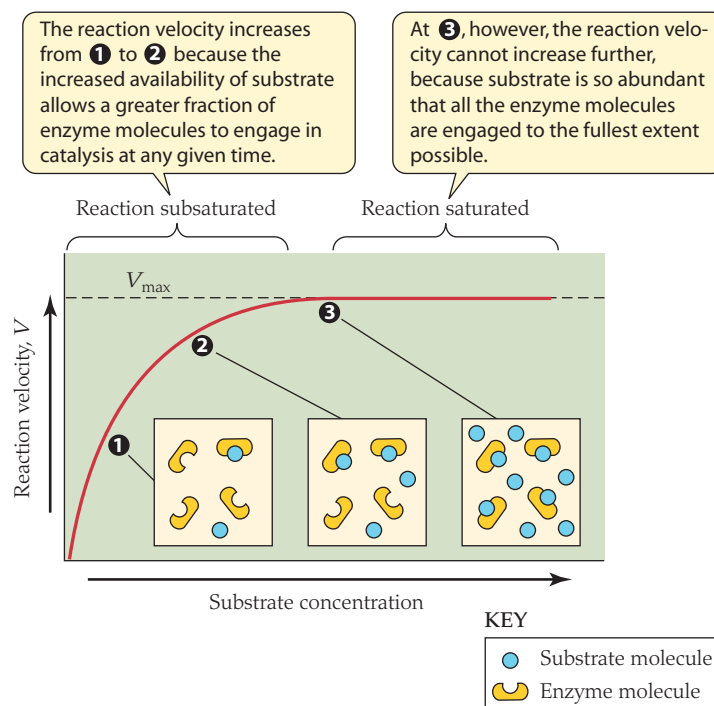

Note that, as stressed earlier, the enzyme emerges unaltered.

An enzyme-catalyzed reaction occurs at a rate that is affected by the relationship between the available number of enzyme molecules and the concentration of substrate. The **reaction velocity** (*reaction rate*) is the amount of substrate converted to product per unit of time. At relatively low substrate concentrations, the reaction velocity increases as the substrate concentration increases. However, this process does not go on indefinitely: As the substrate concentration is raised, the reaction velocity eventually reaches a maximum. The reason for this overall behavior is precisely that substrate must combine with enzyme molecules to form product. As shown in [Figure 2.12a](#), when the substrate concentration is low (as at ①), all of the available enzyme molecules are not occupied by substrate at any given time and the amount of substrate available is therefore the limiting factor in determining the reaction velocity. Raising the substrate concentration (as from ① to ②) increases the reaction velocity by using more of the available enzyme molecules. At high substrate concentrations (as at ③), however, the amount of enzyme is the limiting factor in determining the reaction velocity. When the substrate concentration is high, the population of available enzyme molecules becomes **saturated**, meaning that each enzyme molecule is occupied by a substrate molecule nearly all of the time. Increasing the substrate concentration, therefore, cannot increase the reaction velocity further.

Because of the principals just discussed, enzyme-catalyzed reactions are one of the types of reactions that exhibit *saturation kinetics*. **Kinetics** refers to the velocity properties of reactions. A reaction exhibits **saturation kinetics** if it is limited to a maximum velocity

(a) Hyperbolic kinetics

(b) Sigmoid kinetics

FIGURE 2.12 Reaction velocity as a function of substrate concentration (a) Some enzymes exhibit hyperbolic kinetics, in which the reaction velocity increases as shown, asymptotically approaching a maximum velocity, called V_{max} . The reaction velocity increases from ① to ② because the increase in availability of substrate allows a greater fraction of enzyme molecules to be engaged in catalysis at any given time. At ③, however, the reaction velocity cannot increase further because substrate is so abundant that all the enzyme molecules are engaged to the fullest extent possible. (b) Some enzymes exhibit sigmoid kinetics, in which the approach to V_{max} follows an S-shaped (sigmoid) trajectory; the reaction velocity cannot exceed V_{max} for the same reason as in hyperbolic kinetics.

because there is a limited supply of a molecule (the enzyme in the case of enzyme-catalyzed reactions) with which other molecules must reversibly combine for the reaction to take place.

Two types of saturation kinetics are exhibited by various enzyme-catalyzed reactions. One is **hyperbolic kinetics** (*Michaelis–Menten kinetics*), illustrated by the reaction we have been discussing in Figure 2.12a. The second is **sigmoid kinetics**, seen in [Figure 2.12b](#). Whether the kinetics are hyperbolic or sigmoid depends in major

part on the chemical properties of the enzyme. Hyperbolic kinetics occur when each enzyme molecule has just one substrate-binding site for the particular substrate of interest, or alternatively, such kinetics can occur when there are multiple sites but the sites behave independently. Sigmoid kinetics occur when each enzyme molecule has multiple substrate-binding sites and the multiple sites influence each other by way of ripple effects within the enzyme molecule (discussed later) so that catalytic activity at any one site depends on whether binding has occurred at other sites.

A mathematical description of hyperbolic kinetics was first provided by Leonor Michaelis and Maude Menten in 1913. Their equation, after being revised by other chemists about a decade later, is called the **Michaelis–Menten equation**:

$$V = \frac{V_{\max} [S]}{[S] + K_m} \quad (2.2)$$

where V is the reaction velocity at any given substrate concentration $[S]$, V_{\max} is the maximum reaction velocity (assuming a certain fixed amount of enzyme to be present), and K_m is a constant that is usually termed the **Michaelis constant**.³ This equation describes the curve plotted in Figure 2.12a.

Maximum reaction velocity is determined by the amount and catalytic effectiveness of an enzyme

Two properties determine the **maximum velocity** (V_{\max}) at which a saturated enzyme-catalyzed reaction converts substrate to product (see Figure 2.12). One is the number of active enzyme molecules present. The second is the catalytic effectiveness of each enzyme molecule.

The catalytic effectiveness of an enzyme molecule is expressed as its **turnover number** (k_{cat}), the number of substrate molecules converted to product per second by each enzyme molecule when saturated. Different enzymes vary enormously in turnover number. Indeed, even the molecular variants of a single enzyme can vary substantially in this crucial property. Some enzymes are so catalytically effective that when they are saturated, each enzyme molecule converts 10,000 substrate molecules to product each second, whereas others convert only 1 substrate molecule to product per enzyme molecule per second.

The catalytic effectiveness of an enzyme depends partly on the **activation energy of the enzyme-catalyzed reaction**. To understand the implications of activation energy, it is necessary to recognize that a substrate molecule must pass through an intermediate chemical state termed a **transition state** to form a product molecule. Thus one can think of any reaction, whether or not it is enzyme catalyzed, as involving first the conversion of the substrate to a transition state, and second the conversion of the transition state to the product. For a substrate molecule to enter the transition state, its content of energy must increase. The amount by which it must increase is the **activation energy** of the reaction. Molecules gain the energy they need by random collisions with other molecules. Any particular substrate molecule has a continuously fluctuating energy content as it gains and loses energy through intermolecular collisions; as its energy content rises and falls, it undergoes reaction when its energy content is boosted by an amount at least equal to the activation energy. An enzyme accelerates a reaction by lowering the activation energy (Figure 2.13). The *extent* to which it lowers

FIGURE 2.13 Enzymes accelerate reactions by lowering the needed activation energy Starting at their average energy level, substrate molecules must gain sufficient energy to enter a transition state before they can react to form product. The amount of energy required, the activation energy, is lowered by enzyme catalysts. Catalysts do not, however, alter the average free energy of either substrates or products; nor do they affect the relative concentrations of substrates and products at equilibrium. Vertical arrows indicate the activation energy.

the activation energy is one factor that determines the enzyme's catalytic effectiveness.

According to modern theories of how enzymes work, catalytic effectiveness also depends critically on the rates at which enzyme molecules can go through molecular conformational changes required for catalysis. As we discuss below, enzyme molecules change shape when they bind with substrate and again when they release product. There is reason to believe that different enzymes vary in the rates at which they can go through these necessary conformational changes, and differences in these rates may be as important as differences in activation energy in determining the relative turnover numbers of different enzymes.

Enzyme–substrate affinity affects reaction velocity at the substrate concentrations that are usual in cells

In a cell, a collision between an enzyme molecule and substrate molecule does not necessarily result in the formation of an enzyme–substrate complex. The two molecules may instead collide and “bounce apart” (i.e., separate). The outcome of a collision depends on a property of the enzyme called **enzyme–substrate affinity**, which refers to the proclivity of the enzyme to form a complex with the substrate when the enzyme and substrate meet. An enzyme that is highly likely to form complexes with substrate molecules it contacts has a *high* enzyme–substrate affinity. Conversely, an enzyme that is unlikely to form complexes has a *low* enzyme–substrate affinity.

The affinity of an enzyme for its substrate affects the shape of the velocity–concentration relation at *subsaturating* concentrations of substrate (concentrations too low to saturate the reaction), as illustrated in Figure 2.14a by three enzymes with hyperbolic kinetics. Curve x in the figure represents an enzyme having a high affinity for its substrate; curve z represents one having a low affinity. All three enzymes represented in the figure have the same maximum velocity. The key difference among them is that, at any

³Square brackets signify concentration. Thus $[S]$ is the concentration of compound S .

(a) Three enzymes with high, intermediate, and low affinity for substrate

Although V_{\max} is the same in all cases, the reaction rate at subsaturating substrate concentrations is greater when the enzyme–substrate affinity is higher.

FIGURE 2.14 The approach to saturation depends on enzyme–substrate affinity

given subsaturating substrate concentration, the reaction velocity more closely approaches V_{\max} if the enzyme has high substrate affinity (x) rather than low substrate affinity (z).

A convenient numerical expression of enzyme–substrate affinity for reactions showing hyperbolic kinetics is the **apparent Michaelis constant** or **half-saturation constant**, K_m , defined to be the substrate concentration required to attain one-half of the maximal reaction velocity. **Figure 2.14b** shows how K_m is determined for both the high-affinity enzyme x and the low-affinity enzyme z from **Figure 2.14a**. Note that the low-affinity enzyme has the greater K_m value. Thus K_m and enzyme–substrate affinity are related inversely: A high K_m means low affinity, and a low K_m means high affinity. K_m is one of the parameters in the Michaelis–Menten equation (see Equation 2.2). For enzyme-catalyzed reactions that follow sigmoid kinetics, the measure of affinity is once again the substrate concentration required to half-saturate the enzyme, but it is calculated in technically different ways and symbolized like this: $(S_{0.5})_{\text{substrate}}$.

Substrate concentrations in cells are usually subsaturating. Thus the affinities of enzymes for substrates are important determinants of reaction velocities in cells.

In sum, therefore, reaction velocities in cells depend on all three of the enzyme properties we have discussed: (1) the number of active enzyme molecules present (which affects V_{\max}), (2) the catalytic effectiveness of each enzyme molecule when saturated (which also affects V_{\max}), and (3) the affinity of enzyme molecules for substrate (which affects how close the velocity is to V_{\max}).

Enzymes undergo changes in molecular conformation and have specific binding sites that interact

Like any other protein, an enzyme depends on its three-dimensional molecular shape—its conformation—for its functional properties. One of the single most important attributes of enzymes and other proteins is that *their three-dimensional structure is stabilized mostly by weak, noncovalent*

(b) Determination of K_m for two of the enzymes from (a)

For an enzyme that exhibits hyperbolic kinetics, the enzyme–substrate affinity is quantified by the half-saturation constant K_m , which is the substrate concentration needed for the enzyme-catalyzed reaction to proceed at one-half of the maximal velocity ($1/2V_{\max}$).

K_m and enzyme–substrate affinity are inversely related.

bonds, such as hydrogen bonds, van der Waal’s interactions, and hydrophobic interactions (see Box 2.1). Weak bonds create flexible links between molecular regions that allow an enzyme’s three-dimensional structure to change its detailed shape while retaining its overall organization. Such shape changes, as already suggested, are crucial for proper enzyme function. For example, an enzyme changes shape when it binds with its substrate (**Figure 2.15**).

A substrate molecule binds with an enzyme molecule at a particular molecular region, at or near the surface of the enzyme, called the **active site** or **substrate-binding site**. The three-dimensional shape of the active site and the peculiarities of its chemical constituents complement a particular three-dimensional part of the substrate molecule (and its chemical constituents) such that the substrate molecule and the enzyme molecule match up and fit

Hexokinase changes shape to surround its substrate, glucose, when enzyme–substrate binding occurs.

FIGURE 2.15 Molecular flexibility is important for enzyme function

Hexokinase is the enzyme that ushers glucose into glycolysis by catalyzing glucose phosphorylation using a phosphate group from ATP (see **Figure 2.19**). The enzyme molecule is a single protein; the different shading of the two parts of the molecule is for visual clarity only.

together. The binding of the substrate and enzyme molecules is typically stabilized entirely by weak bonds, not covalent bonds. If an enzyme requires two or more substrates, the enzyme molecule has an active site specific for each. The active site(s) are said to exist within a **catalytic vacuole**, a part of the enzyme molecule that provides a suitable setting for catalysis to occur.

Enzyme–substrate binding is sometimes said to resemble a lock and key fitting together, but this analogy is flawed in two important respects. First, the binding between the substrate and the corresponding active site on an enzyme is principally chemical and electrochemical in nature, not mechanical. Second, the lock-and-key analogy erroneously suggests mechanical rigidity. In fact, as we have seen, the active site and other regions of an enzyme molecule are flexible and change conformation when enzyme–substrate binding occurs (see Figure 2.15). They also change conformation when product is released.

Many enzyme molecules consist of two or more noncovalently bonded proteins, and these often interact in important ways to determine enzyme properties. Enzyme molecules composed of two, three, or four protein subunits are called *dimeric*, *trimeric*, or *tetrameric*, respectively. All the subunits in a multisubunit enzyme may be chemically identical, or they may consist of two or more types. Multisubunit enzymes typically have multiple binding sites. The simplest version of this property is that a multisubunit enzyme may have an active site on each subunit. However, multisubunit enzymes often also have specific binding sites for molecules other than the substrate. These nonsubstrate-binding sites have important similarities to the active (substrate-binding) sites: They are at or near the surface of the enzyme molecule; they bind *noncovalently* and *reversibly* with specific molecules; and their specificity arises because they are complementary in three-dimensional shape and chemistry to parts of the molecules they bind. The substrates of enzymes and the molecules that bind to specific nonsubstrate-binding sites are collectively known as *enzyme ligands*. A **ligand** is any molecule that selectively binds by noncovalent bonds to a structurally and chemically complementary site on a specific protein; not just enzymes but also certain other sorts of proteins (e.g., transporters and receptors) are said to bind or combine with ligands, as we will see.

When an enzyme molecule has multiple binding sites, the binding of any one site to its ligand may facilitate or inhibit the binding of other sites to their ligands. Such interactions between the binding behaviors of different sites are termed **cooperativity**, whether they are facilitating or inhibiting. In **positive cooperativity**, ligand binding at one site facilitates binding of other sites on the same molecule to their ligands; in **negative cooperativity**, binding at one site inhibits binding at other sites on the same molecule. In addition to being classified as positive or negative, cooperativity is also categorized as *homotropic* or *heterotropic*. In **homotropic cooperativity** the binding of a particular type of ligand facilitates or inhibits the binding of other molecules of the *same ligand* to the same enzyme molecule; homotropic cooperativity occurs, for example, when the binding of a substrate molecule to one of the active sites on a multisubunit enzyme molecule facilitates or inhibits the binding of other substrate molecules to other active sites (this is the phenomenon that causes the kinetics to be sigmoid). In **heterotropic cooperativity** the binding of one type of ligand to an enzyme molecule influences the binding of other types of ligands.

An important point is that when cooperativity occurs, the interactions between binding sites on a molecule are interactions *at a distance*.

The various binding sites on a multisubunit enzyme—whether they are sites for substrates or nonsubstrates—are usually not immediately next to each other. Instead, they are found at separate locations in the multisubunit molecular structure. Cooperativity occurs because the binding of a ligand to its particular binding site causes the detailed conformation of the enzyme molecule to change in a way that ripples through the whole molecule, affecting the shapes and binding characteristics of all its other binding sites. The binding of a substrate molecule to an active site, for example, can cause shape changes that increase the affinity of all other active sites for the substrate.

A type of cooperativity that has great importance in the *control* of multisubunit enzymes is **allosteric modulation** (*allosteric modification*). Allosteric modulation means the modulation of the *catalytic* properties of an enzyme by the binding of *nonsubstrate ligands* to specific nonsubstrate-binding sites, which are called **regulatory sites** or **allosteric sites**. The nonsubstrate ligands that participate in this sort of modulation are called **allosteric modulators**. In **allosteric activation** the binding of an allosteric modulator to its binding site on an enzyme molecule increases the affinity of the molecule's active sites for the substrate or otherwise increases the *catalytic* activity of the enzyme. In **allosteric inhibition** the binding of an allosteric modulator impairs the catalytic activity of an enzyme, such as by decreasing its affinity for substrate. Allosteric modulation, as we will discuss, opens up vast regulatory possibilities.⁴

Enzymes catalyze reversible reactions in both directions

Like all other catalysts, enzymes accelerate reversible reactions in both directions. LDH, for example, can accelerate either the reduction of pyruvic acid (in Figure 2.11*b*, the reaction going from left to right) or the oxidation of lactic acid (in Figure 2.11*b*, the reaction going from right to left). Although all the reactions that take place within animals are reversible in principle, only some are reversible in practice. This is true because some reactions—for reasons unrelated to the enzymes that catalyze them—always proceed significantly in just one direction under the conditions that prevail in the body.

The direction of a reversible enzyme-catalyzed reaction is determined by the principles of **mass action**. Consider the following reversible reaction (where A, B, C, and D are compounds):

If the four compounds A, B, C, and D are mixed and then left alone, they will react until they reach equilibrium. The reaction equilibrium is characterized by a particular *ratio of concentrations* of the four compounds. This ratio— $[C][D]/[A][B]$ —always has the same value at equilibrium. The principles of mass action state that if compounds are out of equilibrium, the reaction will proceed in the direction of equilibrium as dictated by the ratios of concentrations. For example, if the reactants on the left, A and B, are collectively too concentrated relative to C and D for the equilibrium state to exist, the reaction will proceed to the right, thereby lowering the concentrations of A and B and raising those of C and D.

An enzyme does not alter the principles of mass action. The catalytic effect of an enzyme on a reversible reaction is to increase

⁴Although the term *allosteric* was originally used only in the context of allosteric modulation, its meaning has evolved. Today *allosteric* is often used to refer to *any* form of enzyme conformational change that results from the noncovalent bonding of ligands to ligand-specific sites, not just allosteric modulation.

the rate of approach to equilibrium from either direction. To see an important aspect of this action, consider that the substrate or substrates are different from the two directions. For instance, when LDH catalyzes the reaction in Figure 2.11 going from left to right, its substrates are pyruvic acid and NADH_2 ; when it catalyzes the reaction going from right to left, its substrates are lactic acid and NAD. The enzyme–substrate affinity of an enzyme and its other kinetic properties are typically different for the substrates of the reaction going in the left-to-right direction than for the substrates of the reaction going in the right-to-left direction. Thus, although an enzyme always catalyzes a reversible reaction in both directions, its catalytic behavior in the two directions may be very different.

Reversible reactions in cells are typically directional at any given time because they operate dynamically in a state that remains far from equilibrium. In a test tube, if A and B in Equation 2.3 are initially at high enough concentrations for the reaction to proceed to the right, the reaction itself will draw down the concentrations of A and B and create an equilibrium state. In a cell, however, the substrates of any one reaction are typically being produced by other reactions. Thus, in a cell, A and B are likely to be replaced as they are converted to C and D—meaning that their concentrations are not drawn down and a condition of disequilibrium in Equation 2.3 is maintained, driving the reaction steadily to the right (an example of a steady state). In this way, the enzyme-catalyzed reaction in a cell can display directionality, even though the enzyme itself catalyzes both directions of reaction.

Multiple molecular forms of enzymes occur at all levels of animal organization

A single enzyme often exists in multiple molecular forms, which all catalyze the same reaction, as stressed earlier. Dozens of described forms of lactate dehydrogenase are known, for example, in the animal kingdom. All the enzyme forms are called *lactate dehydrogenase* because they catalyze one reaction. In terms of primary structure (see Box 2.1), an enzyme can be thought of as a string of amino acids in which each amino acid occupies a specific position in the string; an enzyme composed of 300 amino acids has 300 positions, for example. Multiple molecular forms of an enzyme typically have similar string lengths and are identical in the particular amino acids that occupy most of the positions on the string. However, they differ in the amino acids at one or more of the positions, and these differences in their primary structures alter the details of their tertiary structures and function.

You might guess from what we have said that multiple molecular forms of enzymes are often related by evolutionary descent—that is, that certain forms evolved from others by mutations that caused changes in the amino acid sequence. As we will see, biochemists in fact know enough about the exact structures of many different LDH molecules to be almost certain that the various forms of LDH are related by evolutionary descent. It is probably a general rule that the multiple molecular forms of enzymes are families of evolutionarily related molecules.

LDH provides a good example for understanding multiple molecular forms of enzymes in greater detail. Among vertebrates, individuals have two or three different gene loci that code for LDH proteins. Thus two or three different forms of LDH protein are synthesized in any one individual; these are called LDH-A, LDH-B, and—if a third form is present—LDH-C. The various gene loci are not, however, expressed equally in all tissues. An additional

complexity is that each “finished” LDH molecule is a tetramer, consisting of four LDH protein molecules that are independently synthesized but linked together as subunits of the mature enzyme. The A and B forms are produced in all or nearly all vertebrates. Usually, skeletal muscle cells express the A genetic locus strongly and the B locus weakly. Thus, although some of the LDH tetramers produced in skeletal muscle consist of mixed A and B subunits, the principal type of LDH tetramer in the skeletal muscles consists of all A subunits, symbolized LDH- A_4 . In contrast, the cells of heart muscle express the B genetic locus strongly, and their principal type of LDH tetramer is composed entirely of B subunits: LDH- B_4 . In mammals, LDH-C is expressed in just a single organ, the mature testis; mammalian sperm LDH is mostly LDH- C_4 .

Both finer-scale and larger-scale variation occur in the forms of LDH. At a finer scale than we have already described, two or more alleles may exist at each genetic locus within a species. Thus, for instance, a species might have two alleles for the A locus, meaning that two different types of the A protein can be synthesized; the skeletal muscles of the species would then exhibit multiple molecular forms of the finished LDH- A_4 enzyme (i.e., LDH- A_4 in which all four A subunits are of the sort coded by one allele, LDH- A_4 in which all four A subunits are coded by the other allele, and LDH- A_4 in which some of the A subunits are coded by one allele and some by the other allele). On a larger scale, different species typically differ in the A, B, and C proteins. For example, although the A proteins synthesized by laboratory rats and by humans are similar, they are not identical, so rat LDH- A_4 differs from human LDH- A_4 .

Considering multiple molecular forms in general, researchers have developed a complex terminology to describe all the possibilities. For the purposes of an introduction to animal physiology, a simple dichotomy between *isozymes* (*isoenzymes*) and *interspecific enzyme homologs*, illustrated in Figure 2.16, is sufficient. **Isozymes** are the different molecular forms of an enzyme produced by a single species; an example is that the LDH- A_4 , LDH- B_4 , and LDH- C_4 produced in humans are three isozymes. **Interspecific enzyme homologs** are the different molecular forms of an enzyme coded by homologous gene loci in different species; an example is that human LDH- A_4 and rat LDH- A_4 are interspecific enzyme homologs. Functionally, isozymes and interspecific enzyme homologs often differ not only in their *catalytic* properties but also in their *regulatory* properties.

When functional differences exist between isozymes or interspecific enzyme homologs, they often seem to be adaptive differences; that is, they often seem to *assist* the proper functioning of the animal. For an example that pertains to isozymes, consider LDH- A_4 and LDH- B_4 , the two isozymes of LDH usually found in the skeletal and heart muscles, respectively, of a vertebrate. Of these two isozymes, LDH- A_4 is much more effective in using pyruvic acid as a substrate. As noted earlier, the reduction of pyruvic acid to lactic acid is an essential part of the mechanism by which skeletal muscles can at times make more ATP than their O_2 supply permits. Whenever people sprint for sport, cheetahs sprint for food, or frogs sprint for prizes in the Calaveras County races, the ability of their skeletal muscles to make ATP without O_2 allows the muscles to work exceptionally vigorously. Because this ATP production depends on the reduction of pyruvic acid, the particular isozyme of LDH found in the skeletal muscles—LDH- A_4 , the isozyme that is superior in reducing pyruvic acid—plays a key role in the performance of intense exercise. The heart muscle, in contrast, seldom makes ATP without O_2 , and its

FIGURE 2.16 Isozymes and interspecific enzyme homologs The forms of LDH in rats are interspecific enzyme homologs of the forms in humans.

isozyme, LDH-B₄, is more suited to other functions than to the rapid reduction of pyruvic acid.

Interspecific enzyme homologs are often instrumental in the adaptation of species to different habitats. For example, two closely related species of thornyhead rockfish (*Sebastolobus*)—both found in the ocean along the West Coast of the United States—possess different genetically coded homologs of LDH-A₄ in their skeletal muscles. One of the species is found in waters shallower than 500 m; the other lives at depths of 500–1500 m. A problem with the forms of LDH-A₄ found in shallow-water species of marine fish, including the shallow-water rockfish, is that their affinity for substrate is highly sensitive to water pressure; these enzyme forms lose their affinity for substrate as pressure increases—so much so that at the high pressures of the deep oceans, the forms become ineffective as enzymes. The homolog of LDH-A₄ synthesized by the deep-water species of rockfish is distinctive. It is relatively insensitive to water pressure and retains a suitably high affinity for substrate even when the pressure is high, helping to account for the adaptation of the species to live in the deep ocean.

SUMMARY Enzyme Fundamentals

- Enzymes are protein catalysts that accelerate reactions by lowering the activation energy required for reactants to reach transition state. For most reactions to occur in cells, they must be catalyzed by enzymes. Thus a cell controls which reactions occur within it by the enzymes it synthesizes.

- An enzyme must bind with its substrate to catalyze the reaction of substrate to form product. This binding, which is usually stabilized entirely by noncovalent bonds, occurs at a specific active site on the enzyme molecule, a site which is complementary in its three-dimensional chemical and electrochemical configuration to a portion of the substrate molecule. Enzyme molecules change shape when they bind to substrate or release product. These changes are permitted because the tertiary structure of a protein is stabilized by weak bonds.
- Enzyme properties that determine the velocity of an enzyme-catalyzed reaction in a cell are: (1) the number of active enzyme molecules present in the cell, (2) the catalytic effectiveness of each enzyme molecule when saturated, and (3) the enzyme–substrate affinity. Enzyme-catalyzed reactions exhibit saturation kinetics because the reaction velocity is limited by the availability of enzyme molecules at high substrate concentrations. The maximal reaction velocity (V_{max}) that prevails at saturation depends on properties 1 and 2: the amount and catalytic effectiveness of the enzyme. Property 3, the enzyme–substrate affinity, determines how closely the reaction velocity approaches the maximal velocity when (as is typical in cells) substrate concentrations are subsaturating. The enzyme–substrate affinity is measured by the half-saturation constant (i.e., the Michaelis constant, K_m , for enzymes displaying hyperbolic kinetics).
- Multisubunit enzymes often exhibit cooperativity, a phenomenon in which the binding of certain binding sites to their ligands affects (positively or negatively) the binding of other binding sites to their ligands. An important type of cooperativity is allosteric modulation, in which a nonsubstrate ligand called an allosteric modulator affects the catalytic activity of an enzyme by binding noncovalently with a specific regulatory (allosteric) binding site. Both allosteric activation and allosteric inhibition are possible.
- Enzymes catalyze reversible reactions in both directions because their action is to accelerate the approach toward reaction equilibrium (determined by principles of mass action), regardless of the direction of approach.
- Multiple molecular forms of enzymes occur at all levels of biological organization. Isozymes are multiple molecular forms within a single species; different isozymes may be coded by different alleles of one gene, or they may be coded by different genetic loci. Interspecific enzyme homologs are homologous forms of an enzyme in different species. Functional differences between isozymes and interspecific enzyme homologs often prove to be adaptive to different circumstances.

Regulation of Cell Function by Enzymes

The catalytic nature of enzymes often receives such exclusive attention that enzymes are viewed merely as molecules that speed things up. At least as important, however, is the role that cellular enzymes play as agents of *regulation* of cell function. The biochemical tasks in a cell are typically accomplished by sequences of enzyme-catalyzed reactions called **metabolic pathways**. Enzymes participate in the regulation of cell function in two principal ways. First, the types and amounts of enzymes synthesized by a cell determine which metabolic pathways are functional in the cell; any particular pathway is functional only if the cell synthesizes (through gene expression) all the enzymes the pathway requires. Second, the catalytic activities of the enzyme molecules that actually exist in a

cell at any given time can be modulated as a way of controlling the rates at which the functional metabolic pathways operate.

The types and amounts of enzymes present depend on gene expression and enzyme degradation

Essentially all cells in an animal's body have the same genome, and the genome includes the genetic code for all enzymes that the animal can produce. Cells of different tissues differ, however, in their suites of enzymes. Moreover, any one cell typically differs from time to time in the types and amounts of enzymes it contains. A gene that codes for an enzyme is said to be **expressed** in a cell if the cell actually synthesizes the enzyme. The reason that cells of various tissues differ in their enzymes—and that one cell can differ from time to time—is that only some genes are expressed in each cell at any given time. Gene expression is not all-or-none. Thus, for enzymes that are being synthesized by a cell, the rate of synthesis can be varied by modulation of the degree of gene expression.

The amount of a particular enzyme in a cell depends not just on the rate of enzyme synthesis but also on the rate of degradation of the enzyme. All enzymes are broken down in specific and regulated ways by various pathways, of which the ubiquitin–proteasome system discussed later in this chapter is best understood. Because of degradation, unless an enzyme is synthesized in an ongoing manner, the enzyme will disappear from a cell. The amount of an enzyme present in a cell depends, then, on an interplay of synthesis and degradation; the amount can be increased, for example, by either accelerated synthesis or decelerated degradation.

Variation in the rate of enzyme synthesis is the best-understood way that animal cells modify the amounts of their enzymes. The synthesis of an enzyme molecule requires several sequential steps: *transcription* of the stretch of DNA coding for the enzyme protein to form pre-messenger RNA, *posttranscriptional processing* to form mature mRNA, *exit* of the mature mRNA from the nucleus to associate with ribosomes in the cytoplasm, *translation* of the mature RNA into the amino acid sequence of the protein, and *posttranslational processing* that transforms the immature polypeptide chain into a mature protein. Each of these steps is potentially modulated by a cell to control the rate at which the enzyme is synthesized.

The first step, the transcription of DNA, for instance, is typically modulated by two types of specific regulatory regions of the DNA molecule that control whether, and how fast, transcription occurs in the relevant coding region of DNA. One type of regulatory region is the **promoter**, a DNA sequence located just upstream (toward the 5' end) from the site where transcription starts. The second type of regulatory region consists of one or more **enhancers**, DNA sequences that may occur at various locations, even thousands of nucleotide bases away from the promoter. Proteins called **transcription factors** bind with the promoter and enhancer regions of DNA by way of DNA-matching subparts of their molecular structures, and this binding controls the extent to which RNA polymerase attaches to and transcribes the DNA-coding region responsible for a given enzyme. Transcription factors are highly specific and often work in sets, permitting different genes to be independently and finely controlled.

The processes that control the rates of synthesis of enzymes act on a variety of timescales to determine which metabolic pathways are functional in a cell. A useful distinction for discussing timescales is that between *constitutive* and *inducible* enzymes. **Constitutive**

enzymes are present in a tissue in relatively high and steady amounts regardless of conditions. **Inducible enzymes**, however, are present at low levels (or not at all) in a tissue, unless their synthesis is activated by specific *inducing agents*.

The differentiation of tissues in an animal's body exemplifies the control of constitutive enzymes on a long timescale. Tissues become different in their sets of functional metabolic pathways during development, and they remain different throughout life, because of long-term controls on gene expression. For example, the bone marrow cells and skin cells of mammals differ in whether they express the genes that code for the enzymes required for hemoglobin synthesis. All the genes are relatively steadily expressed—and the enzymes are, therefore, constitutive—in marrow cells but not skin cells. Accordingly, the marrow cells have a functional metabolic pathway for hemoglobin synthesis at all times throughout life, whereas skin cells do not.

Inducible enzymes that undergo up- and downregulation on relatively short timescales are excellently illustrated by the **cytochrome P450 enzymes** found in the liver, kidneys, and gastrointestinal tract of vertebrates (and also found in most or all invertebrates). The P450 enzymes are a complex family of enzymes; more than 30 kinds occur in humans, for example. Their function is to help detoxify foreign compounds by oxidizing them. The foreign compounds themselves often serve as inducing agents for the enzymes.

Low levels of P450 enzymes are found in an individual animal that has not been exposed in the immediately preceding weeks or months to suitable inducing agents, because little or no enzyme synthesis occurs in such an individual and any preexisting P450 molecules are removed by being degraded. However, even a single exposure to an inducing agent will strongly induce increased synthesis of certain P450 enzymes. A mammalian example is provided by barbiturate anesthetics. If a person or other mammal is administered an identical dose of barbiturate on two occasions that are a few days or weeks apart, the second administration will have much less effect than the first. The reason is that P450 enzymes that break down barbiturates are induced by the first administration, and the levels of the enzymes are therefore higher when the second dose is given. Another example that is particularly well understood is induction by halogenated aromatic hydrocarbons (HAHs)—a class of modern pollutants. When an animal is exposed to HAHs, the HAHs enter cells and activate an *intracellular receptor*, which acts as a *transcription factor*, causing expression of P450-coding genes. Levels of P450 enzymes then rise, poisoning the animal to better detoxify HAHs if a second exposure occurs. Another control system for inducible enzymes that is well understood is the system for response to hypoxia (low O₂ levels) described in Box 23.1.

In Chapter 1 (see page 15), we discussed *acclimation* and *acclimatization*—the chronic (i.e., long-term) modifications of phenotype that individual animals commonly exhibit in response to changes in their environments. These important phenomena are often dependent at the cellular level on changes in the amounts of key enzymes.

Modulation of existing enzyme molecules permits fast regulation of cell function

Cells require speedier mechanisms of regulating their functions than are provided by even the fastest inducible enzyme systems. They achieve speedier regulation by modulating the catalytic activ-

ity of their *existing* enzyme molecules. A control mechanism that depends on changing the amounts of enzymes in cells usually requires many hours to be even minimally effective because increasing the synthesis or the degradation of enzymes cannot alter enzyme amounts more rapidly; if such mechanisms were the only controls, a cell would be like a car that could be accelerated or decelerated only once every several hours. Changes in the catalytic properties of already existing enzyme molecules, however, can often be brought about almost instantly, providing for moment-by-moment acceleration and deceleration of cell functions.

Some enzymes are better positioned than others in metabolic pathways to serve the requirements of rapid metabolic regulation. One category of well-positioned enzymes consists of those that catalyze **rate-limiting reactions**. In a linear metabolic pathway, it is possible in principle for the rate of one of the reactions to set the rate of the entire pathway. Suppose, for example, that of all the reactions in the pathway in **Figure 2.17a**, the conversion from B to C is inherently the slowest. Because the rate of the *entire pathway* would then be limited by the rate of that reaction, the conversion of B to C would be the *rate-limiting reaction* of the pathway. The catalytic effectiveness of enzyme enz_2 would then be crucial.

Enzymes that catalyze **branch-point reactions** in metabolic pathways are another category of enzymes that are well positioned to effect rapid metabolic regulation. A branching metabolic pathway permits two or more final products to be made from a single initial reactant. For instance, in **Figure 2.17b** either E or H can be made from A. The relative activities of the enzymes at the branch point— enz_2 and enz_5 —determine which product is favored.

ALLOSTERIC MODULATION OF EXISTING ENZYMES Although binding sites for allosteric modulators do not occur in all enzymes, they are a common feature of enzymes that play regulatory roles. Allosteric modulation is a principal mechanism by which cell func-

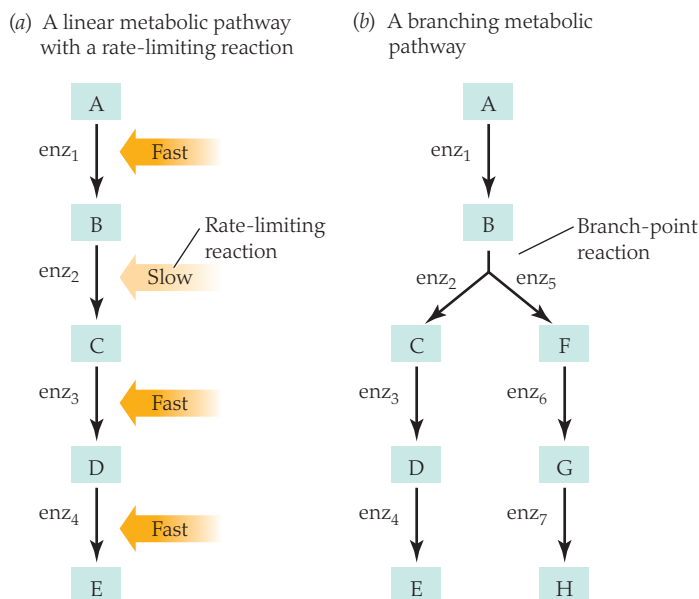

FIGURE 2.17 Enzymes that catalyze rate-limiting reactions and branch-point reactions are well positioned to exert control over metabolism. The two reaction sequences in (a) and (b) are independent. A–H are reacting compounds; enz_1 – enz_7 are enzymes. For example, B is the substrate of enz_2 , and C is its product.

FIGURE 2.18 An allosteric modulator follows the principles of mass action in binding with the enzyme it modulates. This figure shows how enz_2 in **Figure 2.17a** could (a) associate with an allosteric modulator, M, and (b) dissociate from the modulator. B and C are reacting compounds. Combination of enz_2 with M might promote or inhibit the action of the enzyme, depending on the exact nature of M, as exemplified in **Figure 2.19**.

tion is regulated. Recall that allosteric modulators are nonsubstrate molecules that bind noncovalently with specific sites, termed *allosteric sites* or *regulatory sites*, on enzyme molecules and that thereby affect the catalytic activities of the enzymes. The binding of an allosteric modulator with a regulatory site is *reversible* and follows the principles of *mass action*. To illustrate, suppose that enz_2 , in **Figure 2.17a**, the rate-limiting enzyme in the reaction sequence, is allosterically modulated by a compound M. The reaction between M and the regulatory site on enz_2 would then be

Increasing the concentration of M shifts the reaction to the right by mass action, causing more enz_2 molecules to form $M\text{-enz}_2$ complexes (**Figure 2.18a**). Decreasing the concentration of M shifts the reaction to the left, causing fewer enz_2 molecules to be in complexes with the allosteric modulator (**Figure 2.18b**). These adjustments, being driven by mass action, occur almost instantly, and they almost instantly affect the catalytic activity of the enzyme. Thus allosteric modulation can occur *very rapidly*.

As stressed previously, when an allosteric modulator binds with (or dissociates from) an enzyme, it alters the enzyme's ability to catalyze the conversion of *substrate* to *product*. This outcome occurs because the binding of the modulator to its *regulatory site* induces changes in the conformation of the enzyme molecule that ripple through the enzyme's molecular structure, affecting the *catalytically important properties* of the molecule, such as molecular flexibility or the conformation of the active site. An enzyme that has its catalytic activity increased by a modulator is said to be **upregulated**; conversely, one that has its catalytic activity decreased is said to be **downregulated**.⁵ A single enzyme molecule may have two or more regulatory sites, each specific for a different allosteric modulator. In this case, the individual modulators can exert reinforcing or canceling effects on the catalytic activity of the enzyme, offering elaborate regulatory possibilities.

When an allosterically modulated enzyme is the rate-limiting enzyme in a metabolic pathway, the *entire pathway* may be upregulated

⁵The concepts of *upregulation* and *downregulation* are used in additional contexts as well. Another application in the study of enzymes, for example, is to the amounts of inducible enzymes in cells. When the cellular concentration of an inducible enzyme is increased, the enzyme is said to be upregulated; when the enzyme is permitted to fall to low concentration, it is said to be downregulated. Common usage also refers today to the upregulation and downregulation of *processes* and *receptors*.

or downregulated by allosteric modulation. The downregulation of an entire pathway occurs, for example, during the phenomenon known as **feedback inhibition (end-product inhibition)**, a common process in which a product of a metabolic pathway decreases the catalytic activity of a rate-limiting enzyme earlier in the pathway. Feedback inhibition would occur in the pathway in Figure 2.17a, for example, if enz_2 , the rate-limiting enzyme, were downregulated by allosteric combination with compound E, the final product of the pathway. In this case, an abundance of E in the cell would diminish the further formation of E by slowing the entire pathway. Conversely, if E were scarce, the rapid dissociation of E– enz_2 complexes by mass action would accelerate the reaction sequence that produces E. A metabolic pathway of this sort would act to stabilize levels of E in the cell by negative feedback (see Box 1.1).

The potential complexity of allosteric modulation is illustrated by the reactions at the start of glycolysis, the metabolic pathway that converts glucose into pyruvic acid (see Figure 8.1). As shown in **Figure 2.19**, the third reaction in glycolysis is catalyzed by *phosphofructokinase*, an enzyme of pivotal regulatory significance. The form of phosphofructokinase that occurs in most mammalian tissues (PFK-2) is allosterically modulated by more than six different substances, of which citrate and adenosine monophosphate (AMP) are particularly influential. Binding of citrate to a citrate-specific regulatory site on the phosphofructokinase molecule inhibits catalysis. This modulation by citrate is essentially a case of *feedback inhibition* because in a cell with plenty of O_2 , the pyruvic acid produced by glycolysis forms citric acid in the tricarboxylic acid cycle; if the citrate concentration in a cell is high, allosteric downregulation of phosphofructokinase tends to restrain further entry of glucose into the glycolytic pathway that would produce more citrate. AMP potentially upregulates phosphofructokinase. A high concentration of AMP in a cell signals that the cell has depleted its ATP (because AMP is formed from the use of ATP). Under such circumstances, the allosteric modulation of phosphofructokinase by AMP can increase the catalytic activity of the enzyme 100-fold, accelerating the use of glucose to make more ATP.

COVALENT MODULATION OF EXISTING ENZYMES In addition to allosteric modulation, **covalent modulation** (also called *covalent modification*) is the second major way that the function of cells is regulated by changes in the catalytic activity of existing enzymes. Covalent modulation occurs by way of chemical reactions that make or break **covalent bonds** (strong bonds) between modulators and enzymes. Although allosteric modulators are chemically very diverse, just a few principal chemical entities are employed in covalent modulation. Of these, the most common is phosphate.

The most important processes of covalent modulation are **phosphorylation** and **dephosphorylation**—the covalent attachment and removal of orthophosphate groups (HPO_4^{2-}). In discussions of these processes, the orthophosphate groups are usually called simply “phosphate” groups and symbolized P_i or PO_4^{2-} . The phosphate groups are added to and removed from specific parts of modulated enzyme molecules, usually bonding with units of serine, threonine, or tyrosine in the protein structure. When a phosphate group forms a covalent bond with an enzyme that is covalently modulated, the enzyme’s activity is modulated because the shape of the protein changes, leading to changes in the catalytically important properties of the molecule. Often phosphorylation and dephosphorylation act as a very rapid type of *on–off* switch. That is, for example, an

FIGURE 2.19 Phosphofructokinase, an allosterically modulated enzyme, is a key regulatory enzyme for glycolysis The first three reactions of the glycolytic metabolic pathway are shown. The enzymes catalyzing the three reactions are in red print. Citrate and adenosine monophosphate (AMP) are allosteric modulators of the mammalian phosphofructokinase known as PFK-2. The first and third reactions are not reversible under physiological conditions and thus are symbolized with single, rather than double, arrows. Although the reactions shown consume ATP, subsequent reactions in glycolysis produce more ATP than is consumed, so the catabolism of glucose brings about a net production of ATP. ADP = adenosine diphosphate; ATP = adenosine triphosphate.

enzyme molecule might be completely inactive (“turned off”) when it lacks a phosphate group and become activated (“turned on”) when it bonds with a phosphate group. The transition between the downregulated “off” form and the upregulated “on” form can occur almost instantaneously.

A crucial property of covalent modulation is that, unlike allosteric modulation, it *requires the action of enzymes* to catalyze the making and breaking of covalent bonds. The enzymes that catalyze phosphorylation belong to a large class called **protein kinases**, which are enzymes that covalently bond phosphate to proteins using ATP as the phosphate donor (see the inset of Figure 2.20).⁶ The enzymes that catalyze dephosphorylation are *protein phosphatases*, which break covalent bonds between proteins and phosphate, liberating phosphate in the simple form of inorganic phosphate ions. Here we emphasize the protein kinases because they typically play a far larger role than the phosphatases in *controlling* the phosphorylation status of covalently modulated enzymes.

A significant question with regard to covalent modulation that you may have already wondered about is this: If phosphate

⁶A breaking area of research concerns new and unexpected actions of protein kinases, some of which play nonenzymatic roles in transcription regulation.

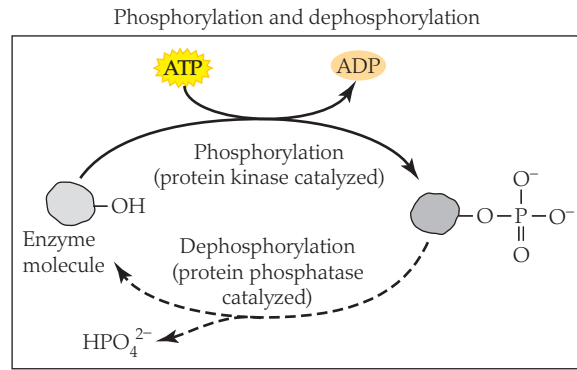

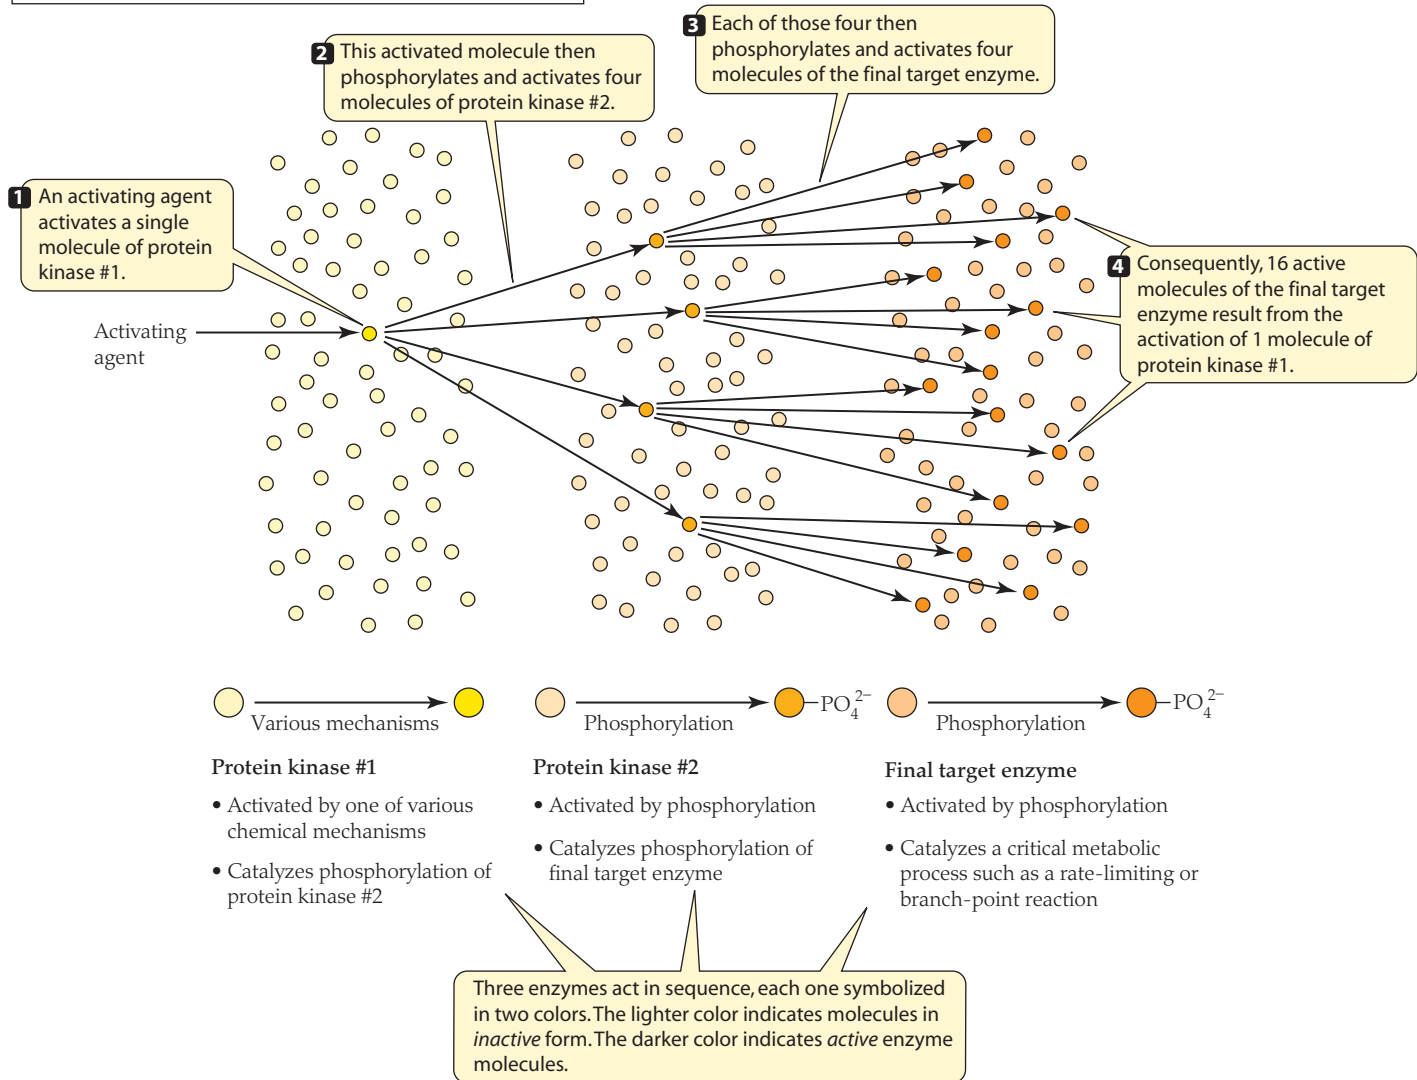

FIGURE 2.20 Protein kinases often function in multi-enzyme sequences that bring about amplifying effects

is nearly always the modulator in covalent modulation, how does a cell prevent the simultaneous modulation of all of its covalently modulated enzymes? A key part of the answer is that the protein kinases required for phosphorylation are *specific to the enzymes being modulated*. Hundreds of major types of protein kinases are known. Two different enzymes that are modulated by phosphorylation require the action of two different protein kinases to bind with phosphate, meaning that each can be controlled independently of the other. Some protein kinases phosphorylate proteins other than enzymes, as we will see later.

Protein kinases often act in *multiple-enzyme sequences* in carrying out their control functions. That is, one protein kinase often activates another protein kinase! Then the second protein kinase

may activate a different sort of enzyme or possibly even a third protein kinase. The principal advantage of such sequences is **amplification** of the final effect. Amplification occurs because each molecule of an activated protein kinase can catalyze the activation of *many* molecules of the enzyme following it.

To see how amplification takes place, consider **Figure 2.20**, which presents a simple example of an amplifying sequence of enzymes, consisting of two protein kinases and a final target enzyme that controls a critical metabolic process. The sequence is set in motion by an initial activating agent that activates a single molecule of the first protein kinase. That one protein kinase molecule then catalyzes the phosphorylation—and thus the activation—of four molecules of the second protein kinase. Each of the four activated molecules of

the second protein kinase then catalyzes the phosphorylation—and activation—of four molecules of the final target enzyme. In total, therefore, 16 target-enzyme molecules are activated. The initial activating agents of such sequences are often signaling compounds that arrive at cells in amounts that are so minute they could not by themselves exert large effects. A multi-enzyme sequence like that in Figure 2.20 allows a tiny quantity of a signaling compound to have a 16-fold greater effect than otherwise would occur.

SUMMARY Regulation of Cell Function by Enzymes

- The metabolic pathways active in a cell depend on which enzymes are present in the cell, as determined by the processes of enzyme synthesis (dependent on gene expression) and enzyme degradation. The presence or absence of enzymes in a cell is regulated on long and short timescales. During individual development (an example of a long timescale), tissues acquire tissue-specific patterns of gene expression that establish tissue-specific suites of enzymes and metabolic pathways. Inducible enzymes, such as the cytochrome P450 enzymes, exemplify shorter-term regulation of the presence or absence of enzymes and metabolic pathways.
- Very fast regulation of enzyme-catalyzed metabolic pathways is achieved by the modulation (upregulation or downregulation) of the catalytic activity of enzyme molecules already existing in a cell. Enzymes that catalyze rate-limiting or branch-point reactions are well positioned to mediate the rapid regulation of entire metabolic pathways in this way.
- Allosteric modulation and covalent modulation are the two principal types of modulation of existing enzyme molecules. Allosteric modulation occurs by way of the noncovalent binding of allosteric modulators to regulatory sites, governed by the principles of mass action. Covalent modulation requires the enzyme-catalyzed making and breaking of covalent bonds—most commonly with phosphate. Phosphorylation is catalyzed by enzyme-specific protein kinases, which usually are the principal controlling agents in covalent modulation.

Evolution of Enzymes

A great achievement of modern molecular biology is that the evolution of proteins can now be studied at the biochemical level. One major approach to this sort of study is to use data on the genes that code for proteins. We discuss that approach in Chapter 3. A second major approach, discussed here, is to use data on the proteins themselves. In studies of proteins, two principal evolutionary scales—investigated with different scientific objectives and techniques—have been of interest. We discuss these with an emphasis on enzymes.

One scale of interest in the study of enzyme protein evolution is the *evolutionary relationships of the multiple enzyme forms found in sets of related species*. The goal of research on these relationships is to reconstruct the family tree of the enzyme forms, so as to clarify enzyme evolution over geological scales of time. In research directed at this goal, scientists extract homologous enzymes from all the species of interest and determine the sequence of amino acids in each enzyme. They then employ the amino acid sequences to estimate the evolutionary relationships among the enzymes by drawing logical conclusions from similarities and differences in

the sequences. **Figure 2.21a** illustrates this approach using a set of five simplified enzymes; note, for example, that it is logical to conclude that the enzyme forms with red + green and red + blue mutations are descended from a form with only the red mutation because all the red mutations are identical.

Figure 2.21b presents a far more elaborate evolutionary tree of 24 vertebrate lactate dehydrogenases (LDHs). The evidence available indicates that there was just a single LDH gene when vertebrates first arose. All the modern, vertebrate LDH enzyme forms are coded by genes descended from that original gene and belong to a single family tree. According to amino acid sequence data, all the A forms of LDH in modern vertebrates are relatively closely related to each other (and thus all fall on one major branch—the upper branch—of the family tree in Figure 2.21b). Moreover, all the B forms are also relatively closely related to each other (and fall on a second major branch of the tree). This pattern indicates that the single original LDH gene duplicated (i.e., gave rise to two genes) early in vertebrate evolution at the point marked *. After that early duplication, each individual vertebrate animal had two LDH genes. The two diverged evolutionarily to give rise to two lineages (two evolutionary families) of genes: one coding for the A forms of LDH, and the other for the B forms. The analysis also indicates that the A gene itself duplicated prior to the appearance of mammals at the point marked **. Following that duplication, one copy of the gene continued to code for the A form, whereas the other diverged to produce the C form. According to the amino acid sequence data, the C forms of LDH in fish and amphibians are only distantly related to the C forms in mammals (these were all named “C” forms long ago, before their relationships were known). In sum, the study of the 24 LDHs illustrates that important features of the family tree of enzymes can be elucidated by the study of the amino acid sequences of the enzyme forms in modern animals.

The second scale of interest in the study of enzyme evolution focuses on the *evolution of allele frequencies within single species*. An important goal of this *microevolutionary scale* of research is to study evolution in action. Changes in allele frequencies within species can be highly dynamic and occur on relatively short scales of time. A case can often be made, therefore, that when differences in allele frequencies are observed—from place to place, or time to time—within a living species, the differences reflect the *present-day action* of natural selection or other evolutionary mechanisms.

A famous example of research on the evolution of allele frequencies comes from studies of the killifish *Fundulus heteroclitus*, a small fish (5–10 cm long) found commonly in estuaries along the Atlantic seaboard. The waters along the coast from Georgia to Maine represent one of the sharpest marine temperature gradients in the world; killifish living in Georgia experience body temperatures that, averaged over the year, are about 15°C higher than those of their relatives in Maine. In killifish, there are two major alleles of the B form of LDH (the form that occurs in the heart, red blood cells, liver, and red swimming muscles of fish). Killifish in the coastal waters of Georgia have mostly the *a* allele (symbolized B^a), whereas those in Maine have only the *b* allele (B^b). Moreover, the *a* allele becomes progressively less frequent from Georgia to Maine, as shown in **Figure 2.22**.

Several sorts of studies indicate that *modern-day natural selection maintains this geographical gradient of allele frequencies*. Individual killifish, for instance, have been demonstrated to travel substantial distances. Because of these long travels, interbreeding would rapidly even out the frequencies of the *a* and *b* alleles along the entire Atlantic

(a) The arrangement of five molecular forms of an enzyme protein into a logical family tree based on similarities and differences in their amino acid sequences

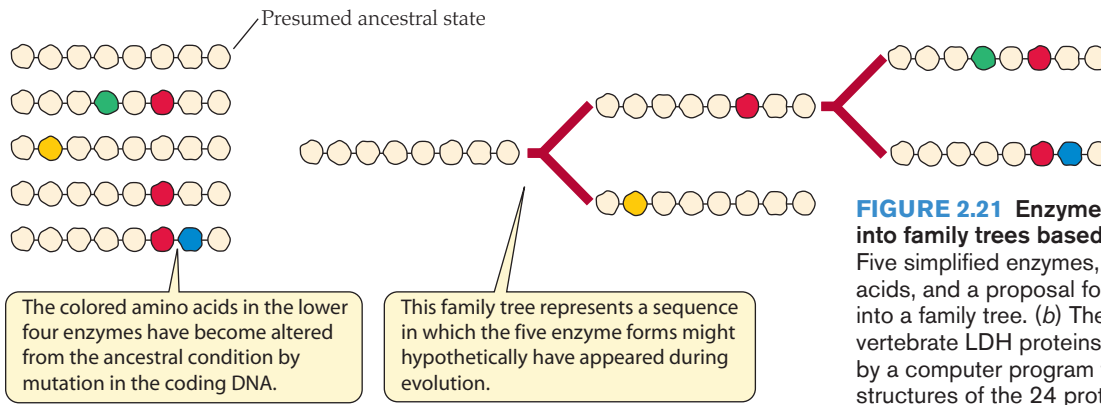

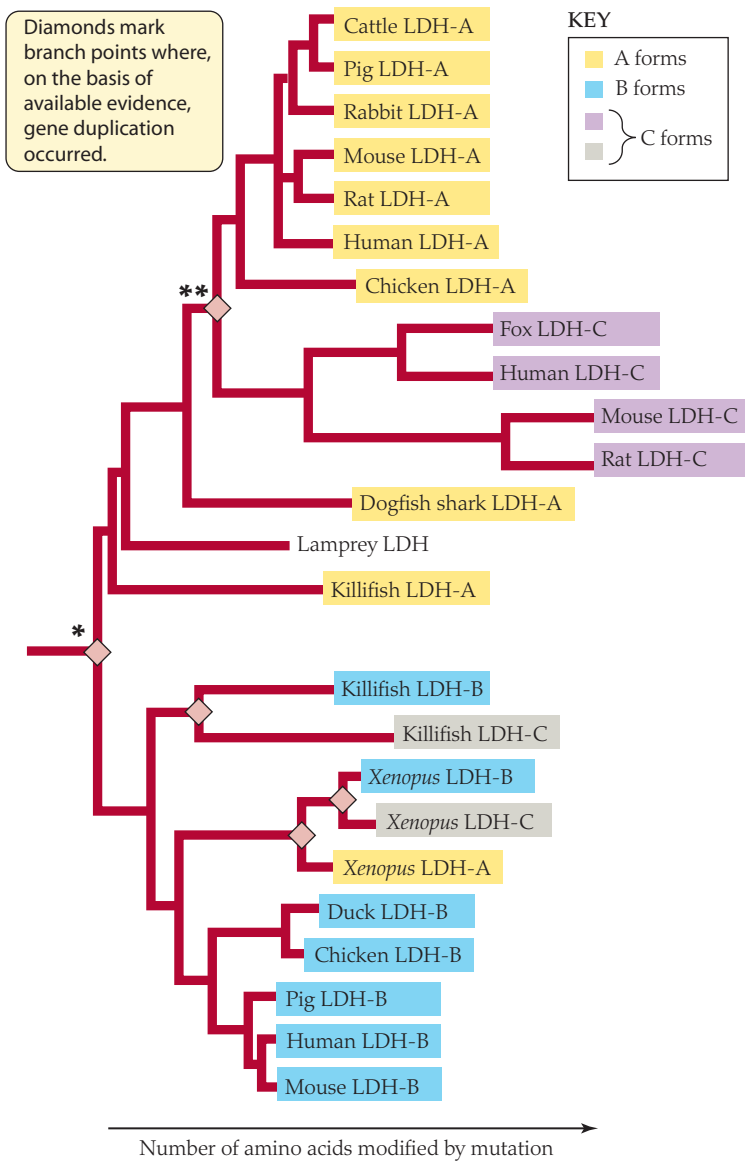

FIGURE 2.21 Enzymes and other proteins can be arranged into family trees based on their amino acid sequences (a) Five simplified enzymes, each consisting of a string of eight amino acids, and a proposal for how they could logically be arranged into a family tree. (b) The most logically cogent arrangement of 24 vertebrate LDH proteins into a family tree. The tree was determined by a computer program that took into account the primary chemical structures of the 24 proteins (300+ amino acids per protein) but was provided with no information on the presumed relationships of the animals sampled. Each horizontal line segment is proportional in length to the number of amino acids altered in that segment of the tree. Asterisks are referred to in the text. At the time this analysis was carried out, 24 LDH proteins had been sequenced, and all are included here. (b after Stock et al. 1997.)

(b) Twenty-four vertebrate LDH proteins arranged into a family tree based on their amino acid sequences

seaboard if simply left to its own devices. The fact that different allele frequencies persist from place to place indicates that fish with different alleles undergo differential survival and reproduction: Those with the *b* allele, for example, survive and reproduce better than those with the *a* allele in Maine. Evidently we are witnessing natural selection right before our eyes because otherwise there would be no differences in allele frequencies!

Trying to gain a better understanding of the natural selection that is involved in the distribution of allele frequencies in killifish,

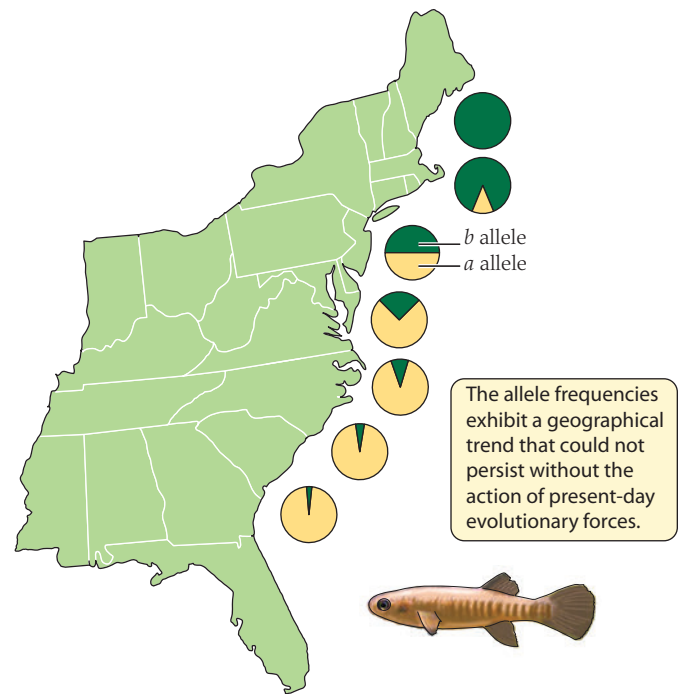

FIGURE 2.22 Contemporary evolution of an enzyme in the killifish *Fundulus heteroclitus* The pie diagrams show the frequencies of the *a* and *b* alleles of the gene for the B form of lactate dehydrogenase in fish of this one species collected at seven latitudes from Georgia to Maine. The green region in each diagram is the frequency of the *b* allele; the yellow region is the frequency of the *a* allele. (After Powers et al. 1993.)

physiologists have explored how the two isozymes of the B protein, coded by the *a* and *b* alleles, differ in their functional properties as enzymes. They have found that the isozyme coded by the *b* allele has several functional advantages at low temperatures, and that the one coded by the *a* allele has advantages at high temperatures. Thus mutation has given rise to two forms of this one enzyme protein, and both forms are retained because each is superior to the other in certain environments where the fish live.

Enzymes Are Instruments of Change in All Time Frames

Enzymes are primary instruments of physiological change in all five of the time frames identified in Chapter 1 (see Table 1.2). Three of the time frames, you will recall, refer to changes in animal physiology that are *responses to changes in the external environment*. The first of these three is *acute physiological responses by individuals*, the responses that occur rapidly after the environment changes. Allosteric modulation and covalent modulation of existing enzymes are major mechanisms of acute enzyme responses. For instance, if an animal is frightened by a predator and runs rapidly away, allosteric upregulation of phosphofructokinase by accumulation of adenosine monophosphate (AMP) in its muscle cells will immediately increase the rate that glucose is processed to manufacture more ATP to sustain muscular work (see Figure 2.19).

The second major time frame of response to the environment, the *chronic (long-term) physiological responses of individuals*, depends on reconstructions of physiological systems requiring hours, days, or longer periods to complete. Environmentally induced changes in the expression of enzyme-coding genes constitute a major mechanism of chronic responses. For an example, consider a fish acclimated to toxin-free water. If the fish encounters toxins, it will be unable to defend itself immediately using P450 enzymes, because the enzymes must be synthesized, a process requiring many hours or days. In the long term, however, the fish will assume a new phenotype—characterized by superior toxin defenses—because of induction of its P450 enzymes.

The third time frame of response to the environment, *evolutionary change*, depends on shifts of gene frequencies in entire populations over multiple generations. Genes that code for enzymes are frequently known to evolve by mutation, natural selection, and other mechanisms on both long and short scales of evolutionary time, as we have seen in Figures 2.21*b* and 2.22. In this way, populations of animals take on new catalytic and regulatory phenotypes by comparison with their ancestors.

In addition to the responses of animals to their environments, there are two time frames in which the physiology of individual animals is internally programmed to change, and enzymes are primary participants in these time frames as well. One time frame of internally programmed change consists of *developmental (ontogenetic) changes in an animal's physiology*, the changes that occur in a programmed way as an animal matures from conception to adulthood. The expression of particular enzymes is often programmed to start at particular stages of development, as we discuss in Chapter 4 (see Figure 4.5).

Individual animals also undergo *periodic physiological changes—such as changes between day and night—under control of internal biological clocks*.⁷ Enzymes often mediate these changes, as shown

by the fact that—in the tissues of animals—the catalytic activities of many enzymes rise and fall in rhythms that parallel the daily day–night cycle even when the animals have no external information on the prevailing time. Some of these enzymes affect the abilities of animals to metabolize particular foodstuffs. Others affect capabilities for detoxifying foreign chemicals, including medications as well as toxins. Thus food metabolism and responses to foreign agents vary between day and night because of internally programmed enzyme changes.

The Life and Death of Proteins

Physical and chemical stresses in the lives of animals can denature enzymes and other proteins. Such stresses include high tissue temperatures, low cellular levels of O₂, and exposure to toxic chemicals such as certain alcohols or heavy metals. When we say a protein is *denatured*, we mean that its three-dimensional conformation—its tertiary structure—is altered in a way that disrupts its ability to function (see Box 2.1). Usually, the primary structure—the string of amino acids—remains intact. Because the primary structure remains intact, the denatured state is potentially reversible.

One of the stunning discoveries of the last 20 years is that cells synthesize proteins termed **molecular chaperones** that can repair damage to other proteins by correcting reversible denaturation. The molecular chaperones use ATP-bond energy to guide the folding of other proteins. They are often active when proteins are first synthesized, and they are active in the repair of “old” but damaged proteins as emphasized here. Molecular chaperones assist repair by preventing protein molecules that are in unfolded states from aggregating with each other and by promoting folding patterns that restore damaged proteins to their correct three-dimensional structures. Because ATP is used, repair by molecular chaperones has a metabolic cost.

Heat-shock proteins are the most famous and best understood molecular chaperones. They are called *heat-shock proteins* because they were initially discovered in cells of organisms that had been exposed to stressfully high but nonlethal tissue temperatures. We realize now, however, that “heat-shock” proteins often function as molecular chaperones following many other types of cell stress, sometimes even including cold stress! An alternative name is **stress proteins**. The heat-shock proteins belong to several protein families of characteristic molecular weights (especially 70 and 90 kilodaltons, kDa) and display highly conserved amino acid sequences, indicating that they are evolutionarily related in most or all animals. Often they are identified by combining the prefix *hsp* with the molecular weight; thus *hsp70* and *hsp90* refer to heat-shock proteins with molecular weights of 70 and 90 kDa. Although some are constitutive proteins, heat-shock proteins are principally inducible proteins: Most are absent except during times when a stress has elicited expression of the genes that encode them.

Rocky shores along seacoasts are known from recent research to be one of the ecological settings in which heat-shock proteins routinely play critical roles. Mussels, snails, and other attached or slow-moving animals living on the rocks can experience heat stress on clear, hot days when the tide goes out and they are exposed to the sun. During or soon after such events, these animals express heat-shock proteins.

Of course, repair is not always possible, or proteins once needed may become unnecessary, or regulatory processes may require that

⁷Biological clocks are discussed at length in Chapter 15.

FIGURE 2.23 The ubiquitin–proteasome system tags proteins and then inevitably destroys those that are tagged. Note that ATP is used by both the initial reactions leading up to tagging and the proteasome reactions that break up a protein into peptides. Tagged proteins are repeatedly tagged, a process termed *polyubiquitination*.

proteins be lowered in concentration. That is—speaking metaphorically—enzymes and other proteins in cells often die. Biochemists have discovered in the last 20 years that cells possess metabolic processes that specifically target enzymes and other proteins for destruction.

The most important known protein–degradation mechanism is the **ubiquitin–proteasome system**. There are three major players or sets of players in this complex system. One is a small protein called **ubiquitin**. Another is a multiprotein complex, termed a **proteasome**, which functions as an enzyme. The third is a suite of additional enzymes that catalyze steps in the process. These include *E1*, an enzyme that activates ubiquitin; *E2*, an enzyme that conjugates activated ubiquitin to a lysine unit within the protein that is destined to be broken down (sometimes aided by another enzyme, *E3*); and *cytoplasmic peptidases*.

A stunning (and almost scary) attribute of the ubiquitin–proteasome system is that it *tags* proteins prior to destroying them. Tagging occurs by the attachment of ubiquitin molecules to a protein molecule that is targeted to be degraded—a process termed **ubiquitination**. After the ubiquitin molecules are attached, the ultimate destruction of the targeted protein is inevitable: No reprieve or reversal is possible. Ubiquitination is the kiss of death.⁸

As shown in **Figure 2.23**, after a protein is tagged, it is recognized by a proteasome, which breaks the protein into peptides (short strings of amino acids). The cytosolic peptidases then break up the peptides into amino acids, which can be used in anabolic reactions or oxidized (forming, among other things, nitrogenous wastes). Ubiquitin is released unaltered and can be reused.

Light and Color

The ability of cells to produce light biochemically—called **bioluminescence**—is widespread in animals. It is most common in the ocean, where bioluminescent species are found in most of the principal animal groups, including coelenterates, comb jellies, annelids, sea stars, squids, krill, and fish—as well as bacteria and protists. On land, the more-than-2000 species of beetles in the family Lampyridae—known as fireflies—are bioluminescent (see Figures 1.3 and 1.4), as are some other types of beetles, and some flies, millipedes, and earthworms. Few bioluminescent animals are known in freshwater, however. Based on analysis of chemical mechanisms, bioluminescence has evolved independently more than 40 times, indicating that it confers functional advantages. Animals employ bioluminescence to attract mates, lure prey, camouflage themselves where there is ambient light of similar intensity, frighten predators, and in other functions.

The animal cells in which bioluminescence occurs are called **photocytes**. *Bioluminescence* must be distinguished from *fluorescence*. Both processes can occur within a photocyte. In bioluminescence, light is produced *de novo*. In fluorescence, light is not produced *de novo*; instead, preexisting light is absorbed and re-emitted at longer wavelengths (although, as soon noted, actual events may not exactly follow this dictionary definition). *Green fluorescent protein (GFP)*, discovered in a bioluminescent species of jellyfish (genus *Aequorea*), provides a prominent example of fluorescence. Photocytes in the jellyfish have a biochemical pathway that, in isolation, generates

⁸The one exception is that histone molecules in the chromosomes are routinely combined with ubiquitin and yet not degraded. Histones in the nucleus are the only proteins that are tagged with ubiquitin and live to tell about it (paraphrasing a lecture by Michael S. Brown).

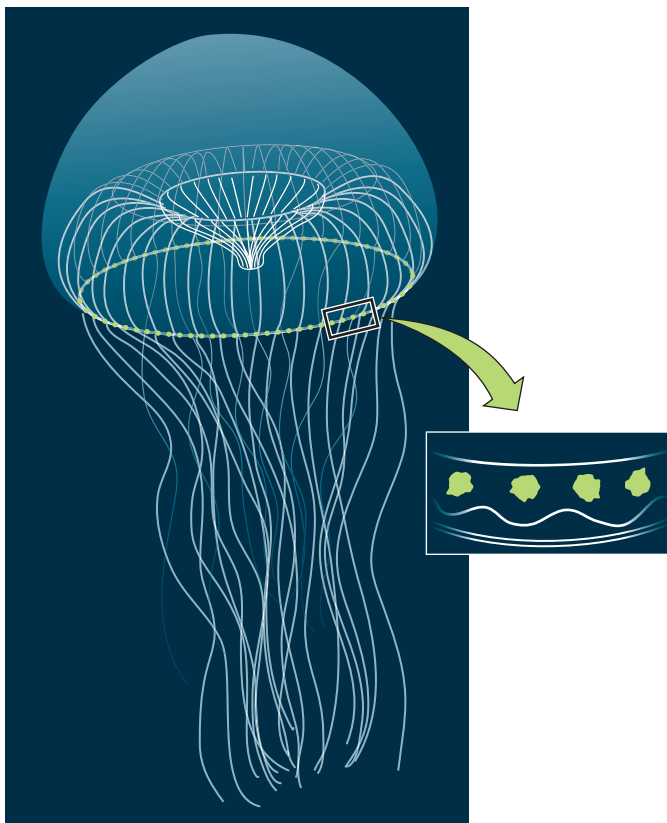

FIGURE 2.24 Bioluminescence and fluorescence in *Aequorea victoria*, a hydromedusan jellyfish found along the West Coast of the United States Clusters of light-producing cells are found on the margin of the bell. Although the light-producing mechanism generates blue light, the light emitted is green because of the presence of green fluorescent protein (GFP), which converts the emission wavelengths from blue to green. The light-producing photoprotein is Ca^{2+} -activated. Both the photoprotein and the GFP, discovered in this jellyfish, have revolutionized biology because of their widespread use as molecular probes.

light at blue wavelengths. In the intact cells, however, the pathway is intimately associated with GFP, and in the final step of light production, energy from the light-producing pathway is transferred by resonance—a radiation-less process—to the GFP. The GFP emits light at green wavelengths, so the clusters of photocytes on the margin of the bell of the jellyfish glow green (Figure 2.24).

In a very general sense, light is often said to result from a *luciferin–luciferase reaction*. That is, light is said to be generated when a **luciferin**—a compound capable of light emission—is oxidized by the action of a **luciferase**—an enzyme that catalyzes luciferin oxidation. This statement is valid, but it hides the fact that there are many chemically different luciferins and luciferases, and thus an enormous diversity of light-producing reactions exists. The luciferases are particularly diverse. Typically, the luciferase catalyzes combination of the luciferin with O_2 to form a peroxide intermediate compound, which then spontaneously decomposes to generate a singlet electronically excited product, which in turn decays, emitting a photon of visible light. The color of the light depends on the particular luciferin–luciferase reaction and on fluorescent proteins if present. Marine animals most commonly emit at blue wavelengths—the wavelengths that travel farthest in clear seawater.

In some marine animals—notably the *Aequorea* jellyfish (see Figure 2.24)—luciferin, O_2 , and an inactive form of the catalyzing protein are assembled into a complex called a **photoprotein**. Light production in these cases is initiated by exposure of the photoprotein to Ca^{2+} or Mg^{2+} (or another agent), which induces a conformational change that activates catalysis.

Bioluminescent animals probably, in most cases, synthesize their own luciferin and luciferase—and produce their own light. However, many departures from this straightforward scenario are known in marine animals. Some obtain their luciferin in their diet. A more common variant is that some animals depend on symbiotic bacteria for light production, rather than having endogenous photocytes. This phenomenon is best understood in the Hawaiian bobtail squid (*Euprymna scolopes*), in which each generation must acquire specific light-emitting bacteria (*Vibrio fischeri*) from the water in its ocean environment. As discussed in **Box 2.2**, the squid and their bacteria provide probably the greatest insight available today on the mechanisms by which animal–microbial symbioses are established—as well as being a striking example of how an animal can achieve bioluminescence by the use of microbial light.

Although bioluminescence affects an animal’s color, the subject of *animal color* is more generally a quite different matter, depending most commonly on pigments in the skin (or other outer integument) and the wavelengths that those pigments absorb or reflect when illuminated by solar light. If the skin is rich in a pigment that absorbs wavelengths other than green, for example, the animal looks green when viewed in solar light because only the green wavelengths are reflected into our eyes.

Speaking of animal color in this sense, a process of great physiological interest and ecological importance is *rapid color change* (*physiological color change*)—the ability of individuals to change color (or color pattern) in seconds, minutes, or at most a few hours. For example, in many species of frogs, flatfish, and crayfish, individuals darken rapidly when placed on a dark substrate, and lighten on a light substrate. Such color change depends on the function of **chromatophores**—flattened pigment-containing cells—in the skin or other integument. An individual may have several types of chromatophores that differ in their pigment colors. Thus, chromatophores containing brown–black pigments, ones containing red pigments, and still others containing yellow or white pigments may be present. The pigment in a chromatophore is in the form of **pigment granules** (pigment-containing organelles), each about 0.3–1.0 micrometer (μm) in diameter. As a first approximation, each chromatophore *cell* has a *fixed size* in these animals. Color change is achieved by *dispersing* or *aggregating* the pigment granules within the cell. When the granules are dispersed throughout the cell, the cell as a whole takes on the color of the granules and imparts that color to the skin. When the granules within a cell are aggregated tightly together at a tiny spot in the center of the cell, the color of the granules may be essentially invisible and exert hardly any effect on the color of the skin.

The process of fully dispersing or fully aggregating pigment granules takes as little as 2–8 s in some flatfish but as long as a few hours in some frogs. Several mechanisms—still being elucidated even in vertebrates, where they are best understood—are involved. One is that the pigment granules within a chromatophore move along microtubules (part of the cytoskeleton) that radiate out to the cell periphery from the cell center in complex geometries (Figure 2.25a). Movement of the granules toward the periphery disperses

BOX 2.2 SQUID AND BIOLUMINESCENT BACTERIA, A STUDY IN CROSS-PHYLUM COORDINATION: THE *EUPRYMNA SCOLOPES*–*VIBRIO FISCHERI* SYMBIOSIS

Margaret McFall-Ngai

The Hawaiian bobtail squid *Euprymna scolopes* forms a life-long symbiotic relationship with the Gram-negative bioluminescent bacterium *Vibrio fischeri*. The animal houses populations of the bacterium in a bi-lobed *light organ* in the center of its mantle (body) cavity (Figure A). This squid is nocturnally active and uses the light produced by the bacterial symbiont as an

Bacteria in the light organ, in the center of the mantle cavity of the squid, emit bioluminescent light downward so that at night, the squid blends in with moon- or starlight when viewed from below.

FIGURE A The ecological function of the symbiosis for the squid (Photo courtesy of Margaret McFall-Ngai.)

antipredatory mechanism. Specifically, bacterial light is emitted from the ventral surface of the squid at an intensity that matches the intensity of moonlight and starlight shining down through the water (a phenomenon termed *counterillumination*), so that the animal does not cast a shadow that can be perceived by a predator looking up from below. Each squid acquires its own bacteria from its environment early in life: A juvenile squid recruits *V. fischeri* cells from the seawater in which it develops within hours of hatching from its egg. Careful studies have revealed that this recruitment—the formation of the symbiosis—entails an intimate interaction between the squid and the bacteria (Figure B). A young squid presents specialized epithelia to its seawater environment to acquire the specific bacterial symbionts, which populate deep crypts within its light organ. Once acquired, the symbionts initiate the life-long loss of those very epithelia, making further acquisition impossible! For more on this fascinating story, see **Box Extension 2.2**.

FIGURE B Acquisition of bacterial symbionts Both images were obtained by use of immunocytochemistry and confocal microscopy. (Images courtesy of J. Foster [upper] and E. Ziegelhoffer [lower].)

Soon after a squid hatches, *Vibrio fischeri* bacteria specifically attach to key epithelial surfaces that the bacteria, after they are acquired, promptly induce to be lost. Simultaneously, ...

... the bacteria enter ciliated pores to populate the squid's light organ.

(a) Microtubules

Microtubules are seen here as fibrous white material. Note that they radiate out from the cell center.

Pigment granules are tightly aggregated at the center in this cell but can travel outward along microtubules to disperse.

10 μm

(b) Aggregation and dispersal

FIGURE 2.25 Pigment aggregation and dispersal within black-pigmented chromatophores (melanophores) from the skin of a codfish (*Gadus morhua*) (a) Photomicrograph of a cell treated so that the microtubules are visible. Pigment granules are transported along the microtubules during dispersal and aggregation. In this cell, the black pigment granules are aggregated at the cell center. (b) Diagram of a cell in aggregated and dispersed states. Note that the branched shape of the cell ensures that pigment granules will be widely spread out when in the dispersed state. (a photo courtesy of Helén Nilsson Sköld; from Nilsson and Wallin 1998.)

(a) A young squid

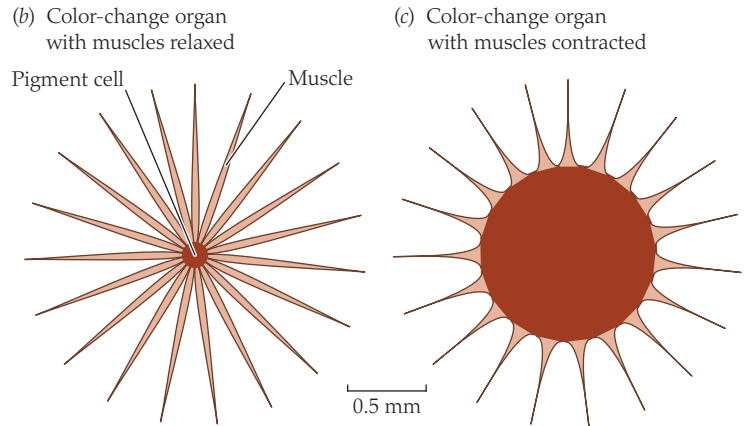

FIGURE 2.26 Color-change organs in squid (a) A juvenile Hawaiian bobtail squid, *Euprymna scolopes*. The entire squid is only 2 mm long, accounting for the large size of the color-change organs relative to the size of the animal. The pigment cells, seen here, are expanded because the muscles of the color-change organs are contracted. (b,c) Diagrams showing a color-change organ with muscles relaxed and con-

tracted. (b) Relaxation of the muscles allows the pigment cell to contract to a small, barely visible size. (c) Contraction of the muscles expands the pigment cell so it has a prominent effect on integumentary color. Although the pigment cell in this case contains red pigment, neighboring pigment cells contain yellow or brown pigments. (Photo in a courtesy of Margaret McFall-Ngai; b,c after Bozler 1928.)

them, whereas movement toward the cell center aggregates them (Figure 2.25b). Movement is driven by ATP-using intracellular motor proteins such as kinesin and dynein. Chromatophores are signaled to disperse or aggregate their pigment granules by hormones, such as (i) melanocyte-stimulating hormone in amphibians and fish and (ii) several well-defined peptide hormones (e.g., red-pigment-concentrating hormone) in crustaceans. Chromatophores in some fish are also directly innervated, poising them for relatively fast neuronally-stimulated responses. In addition to exhibiting extrinsic controls, chromatophores in some crustaceans exhibit intrinsic rhythms of pigment movement controlled by biological clocks.

The most rapid color change in the animal kingdom is displayed by squids, cuttlefish, and octopuses—the cephalopod molluscs. Their color change is based on an entirely different principle than that in amphibians, fish, and crustaceans. It occurs so rapidly in some species that an individual can switch from a fully dark to a fully light coloration in less than 1 s! Color change in cephalopod molluscs is mediated by tiny *color-change organs* (Figure 2.26a; these organs are often called chromatophores, although this usage of “chromatophores” is entirely different from the usage we have just been discussing in the preceding paragraphs). Each of the color-change organs consists of a pigment cell of *variable size* that is surrounded (in three dimensions) by dozens of radially arranged muscles that are innervated directly from the brain. Relaxation of the muscle cells allows the pigment cell to contract to minimal size (e.g., 0.1 mm in diameter; Figure 2.26b). By contrast, contraction of the muscles—which can be very fast (as is typical of muscles)—expands the pigment cell (to a diameter of 1.5 mm in some cases) so the pigment inside is spread out and easily visible (Figure 2.26c), imparting its color to the integument.

Reception and Use of Signals by Cells

Cells send signals to each other that serve to coordinate cell functions throughout the body. Nerve cells, for example, signal muscle cells to contract, employing neurotransmitter molecules. Moreover, endocrine cells, employing hormones, signal chromatophores to disperse or aggregate pigment granules, and they signal liver cells

to release glucose into the blood. When a signal arrives at a target cell, the cell must have mechanisms of **signal reception** to detect the signal. It must also have mechanisms of **signal transduction**—meaning mechanisms by which it modifies its intracellular activities in appropriate ways in response to the extracellular signal. Here we address signal reception and transduction.

Extracellular signals initiate their effects by binding to receptor proteins

Extracellular signaling molecules such as neurotransmitters or hormones initiate their actions on a cell by binding with certain protein molecules of the cell, called **receptors**. A molecule that binds specifically and noncovalently to a receptor protein is considered a *ligand* of the receptor. Ligand binding occurs at a specific *receptor site* (or sites) on the receptor protein and results in a change in the molecular conformation of the protein, a process that sets in motion a further response by the cell.

Receptors may be categorized into four functional classes: (1) ligand-gated channels, (2) G protein-coupled receptors, (3) enzyme/enzyme-linked receptors, and (4) intracellular receptors (Figure 2.27). Receptors in the first three categories reside in the cell membrane. This prevalence of receptors at the cell surface reflects the fact that *most signaling molecules cannot enter cells*. For the most part, signaling molecules are proteins or other *hydrophilic* molecules that are unable to pass through the hydrophobic interior of the cell membrane. Instead of entering cells, these signaling molecules bind to receptors on the cell-membrane surface, and the receptors then mediate their intracellular effects. Only hydrophobic or very small signaling molecules can enter a cell at meaningful rates through the cell membrane; once inside, such molecules bind to intracellular receptors. Now let's discuss the properties of the four principal classes of receptors.

LIGAND-GATED CHANNELS A **ligand-gated channel** is a cell-membrane protein that acts as both a receptor and a channel.⁹ This sort of channel opens to create a passageway for specific solutes, typically inorganic ions, through the cell membrane when the recep-

⁹Table 2.1 defines the functional categories of membrane proteins.

(a) Ligand-gated channel

(b) G protein-coupled receptor and associated G protein system

(c) Enzyme/enzyme-linked receptor

(d) Intracellular receptor

FIGURE 2.27 The four types of receptor proteins involved in cell signaling (a) A ligand-gated channel. The particular example shown, a muscle cell acetylcholine receptor, must bind a ligand molecule at two sites for the channel to open. (b) A G protein-coupled receptor. Details of the molecular interactions symbolized by the yellow, double-headed arrows are discussed later in this chapter. (c) Enzyme/enzyme-linked receptors are themselves enzymes or, when activated, interact directly with other membrane proteins that are enzymes. Either way, binding with the ligand activates an enzyme catalytic site inside the cell. The example shown is the atrial natriuretic peptide receptor, which is particularly simple because it consists of just a single protein with both a ligand-binding site and a catalytic site. (d) Intracellular receptors are effective only for ligands that can dissolve in and diffuse through the lipid bilayer of the cell membrane. After a ligand enters the cell, it forms a complex with the receptor to initiate cellular responses. The example shown is a steroid hormone receptor, a type of receptor protein that is composed of a hormone-binding region and a region capable of binding with DNA. Binding with the hormone activates the receptor, and the activated hormone-receptor complex functions as a transcription factor. ATP = adenosine triphosphate; cyclic AMP = cyclic adenosine monophosphate; cyclic GMP = cyclic guanosine monophosphate; GTP = guanosine triphosphate.

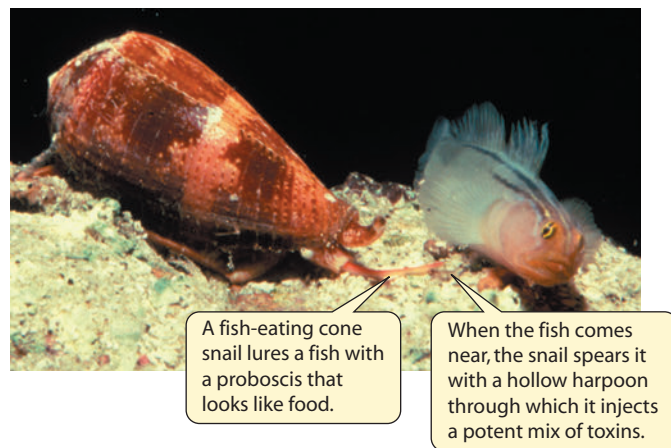

tor site or sites on the protein bind to specific signaling molecules, as diagrammed in Figure 2.27a. Ligand-gated channels function mostly in the transmission of nerve impulses across synapses, the narrow spaces between interacting nerve cells or between nerve and muscle cells (see Chapter 13). The signaling molecules that carry signals across synapses are called *neurotransmitters*. When a neurotransmitter is released by one cell into a synaptic gap, it diffuses across the gap to the receiving cell. The initial response of the receiving cell is that ligand-gated channels in its cell membrane open because of binding of the neurotransmitter to the channels. The opened channels permit increased flux of inorganic ions

through the cell membrane, thereby changing the voltage difference across the membrane.

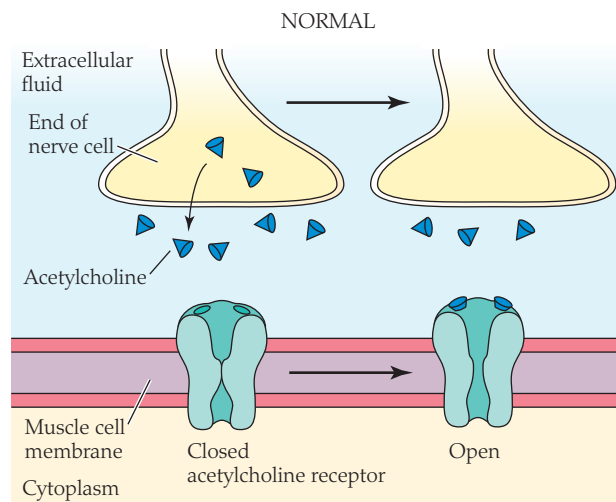

An example of synaptic transmission is provided when a nerve cell stimulates a skeletal muscle cell to contract. In this case, the specific neurotransmitter *acetylcholine* is released by the nerve cell and binds noncovalently to the receptor sites of acetylcholine receptors—which are ligand-gated channels—on the surface of the muscle cell. The channels then open and allow sodium (Na^+) and potassium (K^+) ions to flow through the cell membrane of the muscle cell, initiating a change in voltage across the membrane and a series of subsequent changes culminating in muscle contraction. Fish-eating cone snails, which we introduced at the opening of this

chapter, incapacitate their prey in part by using toxins that block these ligand-gated channels. One of the most potent of a cone snail's *conotoxins* is α -conotoxin, which specifically binds to the receptor sites on muscle cell acetylcholine receptors, preventing the receptors from binding with or responding to acetylcholine, as shown in **Figure 2.28**. Because α -conotoxin binds to the receptors very rapidly and tightly, the swimming muscles of a fish attacked by a cone snail are promptly blocked from responding to nervous stimulation, and the fish becomes paralyzed. Thus the whole fish is condemned to death by the incapacitation of a crucial ligand-gated channel protein in its body. Certain Asian krait snakes and the poison-dart frogs of Latin America have independently evolved toxins that also incapacitate this channel in their prey.

(a) A fish-hunting cone snail in action

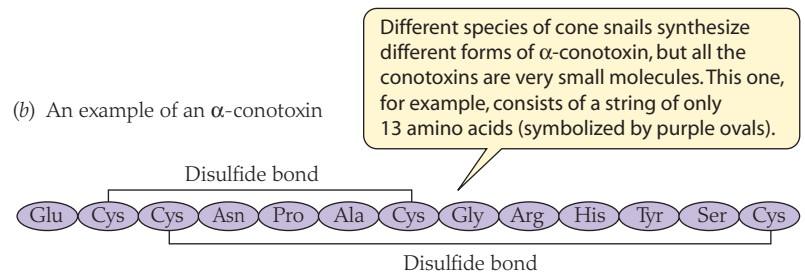

(c) Block of receptor action by α -conotoxin

In a normal fish, when a nerve cell releases acetylcholine, the muscle cell receptors bind the acetylcholine, causing the receptors, which are ligand-gated channels, to open, thereby stimulating the muscle cell to contract.

(b) An example of an α -conotoxin

In a poisoned fish, the muscle cell receptors are unable to bind the acetylcholine because the receptor sites are blocked by the α -conotoxin. The receptors thus fail to open in the normal way. Consequently, the muscle cell is not stimulated and does not contract—the fish is paralyzed.

FIGURE 2.28 The defeat of a vital molecule by a venom (a) The speed of action in this cone snail's capture of a fish is imperative because the slow-moving snail could not pursue a fish that had even seconds to swim away. (To see an electron micrograph of the harpoon the snail uses, see Figure 6.11*d*.) (b) One of the most important toxins for the quick immobilization of the fish is α -conotoxin, a small polypeptide.

G PROTEIN-COUPLED RECEPTORS G protein-coupled receptors in cell membranes mediate cellular responses to many hormones and neurotransmitters. They also mediate many responses of sensory neurons. When a G protein-coupled receptor in the cell membrane of a cell is activated by binding its ligand, it activates a separate cell-membrane protein termed a **G protein**. The activated

(See Appendix I for three-letter codes for amino acids.) (c) α -Conotoxin binds quickly and tightly to the receptor sites on the acetylcholine receptors of the fish's swimming muscles. Consequently, as shown in the "Poisoned" side of the diagram, the receptors become incapable of binding acetylcholine.

G protein may then directly exert an intracellular effect, or more commonly, it interacts with still another cell-membrane protein, usually an enzyme, and activates it so that a distinctive intracellular signaling compound is synthesized in the cytoplasm of the cell by the catalytic activity of the enzyme (see Figure 2.27b).

A major difference between reception based on G protein-coupled receptors and reception based on ligand-gated channels is that in general, *no sort of chemical passes through the cell membrane in the case of G protein-mediated reception*. In the most common type of such reception, one chemical brings the cell-signaling message to the extracellular side of the cell membrane, and a second, different, chemical is produced on the intracellular side to carry the signal onward to the interior of the cell. The molecules that bring signals to the cell membrane from the outside—such as hormones or neurotransmitters—are called **first messengers**, whereas the *intracellular* signaling molecules that carry the signals to the interior of the cell are called **second messengers**. The action of the G protein-mediated mechanism in the cell membrane is analogous to a relay race in which the first messenger brings the message to a certain point but then can go no farther and must activate a second messenger for the message to go on. An example is provided by the action of epinephrine (adrenaline) on a liver cell. Epinephrine, the first messenger, binds to a G protein-coupled receptor in the cell membrane, which initiates steps resulting in intracellular synthesis of the second messenger **3'-5'-cyclic adenosine monophosphate (cyclic AMP, or cAMP)**. Cyclic AMP then activates the intracellular responses to the epinephrine signal. Shortly we will return to this and other second-messenger systems in greater detail.

ENZYME/ENZYME-LINKED RECEPTORS Enzyme/enzyme-linked receptors are cell-membrane proteins that either are enzymes themselves or that interact directly with enzyme proteins when activated. They are a more structurally and functionally diverse class of receptors than the two types of cell-membrane receptors we have already discussed. As in the case of G protein-mediated reception, molecules or ions do not pass through the cell membrane in this sort of reception, and enzyme/enzyme-linked receptors often activate the formation of second messengers. The simplest sort of enzyme/enzyme-linked receptor is a receptor protein that is itself an enzyme; such a protein is composed of an extracellular receptor region, a membrane-spanning region, and an intracellular catalytic region (see Figure 2.27c). Binding of the extracellular signaling molecule to the receptor site activates the catalytic site at the other end of the molecule. The hormone atrial natriuretic peptide (ANP) acts on target cells in the kidney of a person to increase Na^+ excretion by way of this sort of receptor. When ANP binds to the receptor region on the outside of a cell, the receptor molecule catalyzes the formation of a second messenger, **3'-5'-cyclic guanosine monophosphate (cyclic GMP, or cGMP)**, inside the cell.

INTRACELLULAR RECEPTORS Intracellular receptors are the only class of receptors not localized at the cell surface. As noted earlier, most signaling molecules cannot enter cells. Those that do are typically relatively small, hydrophobic molecules that can dissolve in and diffuse through the core of the lipid bilayer of the cell membrane. These signaling molecules include steroid hormones, thyroid hormones, retinoic acid, vitamin D, and the gas nitric oxide (NO). The receptors for these substances are located intracellularly, in the cyto-

plasm or nucleus. The usual pattern for intracellular receptors is that, after they are activated by binding with their ligands, they interact with DNA (see Figure 2.27d) to activate specific primary-response genes, the products of which may secondarily activate other genes.

When the steroid hormone estrogen arrives at a cell, for example, it passes through the cell membrane and binds to an estrogen-specific intracellular receptor protein, forming a hormone-receptor complex. The complex is itself a transcription factor that activates specific promoter and enhancer regions of the nuclear DNA, causing the expression of specific genes. The resulting effects can alter much of a target cell's metabolism, often promoting female cellular phenotypes.

RECEPTORS OCCUR AS MULTIPLE MOLECULAR FORMS RELATED BY EVOLUTIONARY DESCENT In terms of molecular diversity, receptor proteins of any given type follow the same general principles as enzyme proteins: Each type of receptor exists in multiple molecular forms that typically are related by evolutionary descent. Most of the ligand-gated channels in modern-day animals, for example—although they vary in molecular details—have very similar chemical structures and are coded by a single lineage of genes that diversified over evolutionary time to give rise to the channels seen today. Similarly, all the G protein-coupled receptors belong to a single family tree, as do the intracellular steroid receptors.

Cell signal transduction often entails sequences of amplifying effects

When signaling molecules bind to cell-membrane receptors, *sequences of amplifying effects*—analogous to a chain reaction—are often involved between the moment that signal reception occurs and the moment that the final intracellular response occurs. For a classic example of this widespread pattern, let's look at the process by which epinephrine leads to the activation of glycogen breakdown to produce glucose in vertebrate liver cells, shown in **Figure 2.29**.

When a human or other vertebrate experiences stress, such as the stress that occurs in anticipation of physical conflict, the adrenal glands secrete epinephrine into the blood. The circulation carries the epinephrine to the liver, where the hormone bathes liver cells, which contain abundant supplies of glycogen, a glucose-storage compound. The epinephrine itself cannot cross the cell membranes of the liver cells. "News" of its arrival reaches the inside of each cell, instead, by way of a G protein-coupled receptor system.

The receptor system itself has important amplifying properties. To set the stage for discussing these, we need to note some details of G-protein function. Recall that a G protein-coupled receptor activates a cell-membrane G protein. G proteins get their name from the fact that they are modulated by binding with guanine nucleotides. A G protein bonded with **guanosine diphosphate (GDP)** is inactive. A G protein is activated when it is induced to change from being bonded with GDP to being bonded with **guanosine triphosphate (GTP)**. However, G proteins exhibit intrinsic GTP-destructive activity: When bonded with GTP, they tend to break down the GTP to GDP by hydrolysis. In this way, a G protein that has been activated by binding with GTP *tends to inactivate itself* by reverting to the inactive GDP-bonded form. The membrane G proteins, which are our focus here, are trimers in their inactive state. They dissociate into two parts when activated by GTP binding.

When epinephrine binds to its specific G protein-coupled receptor in the cell membrane of a liver cell, what first occurs is a series of

FIGURE 2.29 Amplifying signal transduction of an extracellular epinephrine signal results in enzymatic release of glucose inside a liver cell Because five steps in the epinephrine signal transduction pathway are amplifying, a very low epinephrine concentration can trigger a very large increase in glucose concentration. The cyclic AMP signal is

amplifying reactions *within the cell membrane*, diagrammed across the top of Figure 2.29. The activated receptor first interacts with molecules of G protein in the membrane to activate them by promoting loss of GDP in exchange for GTP. The G protein–coupled receptor and the G protein are separate, however, and both diffuse freely and independently in the fluid mosaic of the cell membrane. Accordingly, as an activated receptor diffuses about in the membrane, it must randomly bump into a G-protein molecule to activate it, a situation that sounds inefficient until one realizes that it *makes amplification possible*. During its active life, a *single* activated receptor can bump into and activate *many* (perhaps 100) G-protein molecules. Each activated G-protein molecule then remains active for a period of time, the duration of which depends on how long it takes to inactivate itself (tens of seconds to several minutes), and while it is active, it can activate a cell-membrane enzyme, **adenylyl cyclase** (also called

ultimately terminated by the action of a cytoplasmic enzyme, phosphodiesterase. ATP = adenosine triphosphate; cyclic AMP = cAMP = cyclic adenosine monophosphate; GDP = guanosine diphosphate; GTP = guanosine triphosphate.

adenylyl cyclase), which it bumps into by diffusion in the membrane; probably each activated G-protein molecule activates just one adenylyl cyclase molecule because the activation requires steady linkage of the two proteins. Adenylyl cyclase has an active site on the cytoplasmic side of the cell membrane, and when it is activated, it catalyzes the formation of the second messenger cyclic AMP (cAMP) from ATP inside the cell. Further amplification occurs at this step because a *single* activated molecule of adenylyl cyclase can catalyze the formation of *many* molecules of cAMP during its active life.

The cAMP signal inside a liver cell triggers the activation of a series of intracellular enzymes (see Figure 2.29). *Multiple amplifying steps occur in this series*. The series starts with two protein kinases and is a classic example of the type of amplification sequence shown in Figure 2.20. The cAMP second messenger activates a protein kinase named *cAMP-dependent protein kinase (cAMPK)* by causing it

to dissociate, forming two active enzyme units. The activated cAPK units phosphorylate, and thereby activate, a second protein kinase called *glycogen phosphorylase kinase (GPK)*. Finally, the active GPK molecules phosphorylate and activate the ultimate target enzyme, *glycogen phosphorylase (GP)*. Great numbers of activated GP molecules are produced. Each of them catalyzes the removal of glucose units from the glycogen polymers stored in the cell, and the glucose is then released into the blood for distribution throughout the body.

Because of the cumulative effect of all the amplifications that occur in this cell signal transduction pathway, a *minute quantity* of epinephrine can cause a *flood* of blood glucose. A cumulative amplification of about 10,000-fold can occur between the binding of an epinephrine molecule to a G protein-coupled receptor molecule and the formation

of cAMP. Accordingly, a blood epinephrine concentration of 10^{-10} molar (M) can result in an intracellular concentration of cAMP of 10^{-6} M . Then the protein-kinase cascade within the cell can result in a further amplification of about 1000, so that the concentration of activated GP is 10 million times the blood concentration of epinephrine that initiated the signal transduction process!

Several second-messenger systems participate in cell signal transduction

Several compounds—not just cyclic AMP—act as second messengers. The common second messengers, in addition to cyclic AMP, are cyclic GMP (cGMP); inositol 1,4,5-trisphosphate (IP_3); 1,2-diaclyglycerol (DAG); and Ca^{2+} ions. **Figure 2.30** provides

FIGURE 2.30 Second messengers in overview The production and the actions of five important second messengers are shown: cyclic AMP, cyclic GMP, diacylglycerol, inositol trisphosphate, and calcium ion. This figure includes only some of the major cell signal transduction pathways that employ second messengers. **1** Some G protein-coupled receptor systems employ cyclic AMP as a second messenger, as seen previously in Figure 2.29. **2** Receptor systems based on guanylyl cyclase enzymes employ cyclic GMP as a second messenger. When activated, a guanylyl cyclase produces cyclic GMP from guanosine triphosphate (GTP). In some cases, as in the atrial natriuretic peptide receptor system (see Figure 2.27c), the guanylyl cyclase is a cell-membrane enzyme. **3** Some guanylyl cyclase enzymes are cytoplasmic. Many of the actions of nitric oxide (NO) are mediated by cyclic GMP produced by the activation of a cytoplasmic guanylyl cyclase. **4** Some

G protein-coupled receptor systems employ diacylglycerol and inositol trisphosphate as second messengers. When such receptor systems are activated, the two second messengers are synthesized simultaneously from a cell-membrane phospholipid, PIP_2 (phosphatidylinositol 4,5-bisphosphate), by the catalytic action of activated phospholipase C, a membrane-associated enzyme. **5** Diacylglycerol stays in the cell membrane because it is hydrophobic. **6** Inositol trisphosphate, which is hydrophilic, enters the cytoplasm, where its major action is to open ligand-gated channels that release Ca^{2+} from intracellular stores such as the endoplasmic reticulum. **7** Ca^{2+} ions sometimes act as second messengers, as when Ca^{2+} released by action of inositol trisphosphate activates the cytoplasmic protein calmodulin, which then can activate protein kinases or other enzymes.

an overview of some prominent second-messenger systems in which these compounds participate. For the most part, all of the second messengers share with cyclic AMP the property that their immediate intracellular effect is to activate a protein kinase that is already present in the cell in an inactive form, as Figure 2.30 shows. The protein kinase then activates or inactivates its target protein or proteins by phosphorylation. The target proteins are often enzymes, but *they may be cell-membrane channels or receptors, channels in intracellular membranes, transcription factors that regulate gene expression, or virtually any other sort of protein.* Sequences of multiple signal-amplifying reactions are a common feature of the signal transduction pathways involving second messengers.

SUMMARY Reception and Use of Signals by Cells

- Extracellular signals such as hormones initiate their actions on cells by binding noncovalently with specific receptor proteins. Receptor proteins activated by binding with their signal ligands set in motion cell signal transduction mechanisms that ultimately cause cell function to be altered.
- Most extracellular signaling molecules are chemically unable to enter cells because they are hydrophilic, or otherwise unable to pass through the hydrophobic, lipid interior of cell membranes. The receptors for these molecules are cell-membrane proteins that fall into three principal functional classes: ligand-gated channels, G protein-coupled receptors, and enzyme/enzyme-linked receptors. Extracellular signaling molecules that readily pass through cell membranes, such as steroid hormones, thyroid hormones, and nitric oxide (NO), have receptors that belong to a fourth functional class: intracellular receptors.
- Activation of ligand-gated channels by their ligands most commonly results in changed fluxes of inorganic ions, such as Na⁺ and K⁺, across cell membranes, thereby altering voltage differences across the membranes. The altered voltage differences may then trigger other effects.
- Activation of G protein-coupled receptors and enzyme/enzyme-linked receptors by their extracellular signaling ligands typically initiates the formation of second messengers, such as cyclic AMP or cyclic GMP, on the inside of the cell membrane. The second messengers, in turn, often trigger sequences of additional intracellular effects in which preexisting enzymes are modulated, most notably protein kinases. A function of these sequences is dramatic amplification of the ultimate effect.
- Intracellular receptors, when activated by their ligands, usually bind with nuclear DNA and directly activate specific primary-response genes.

Study Questions

1. It is becoming possible for molecular biologists to synthesize almost any protein desired. Suppose you use a phylogenetic tree of modern-day enzymes (e.g., Figure 2.21*b*) to predict the amino acid sequence of a now-nonexistent ancestral enzyme form. What insights might you obtain by synthesizing the ancestral enzyme protein?
2. Using lactate dehydrogenase as an example, explain why it is true to say that “multiple molecular forms of enzymes occur at all levels of animal organization.”
3. Pollutants such as halogenated aromatic hydrocarbons (HAHs) are usually spotty in their distributions in bodies of water. Thus, even if HAHs are present, fish might be able to avoid being exposed to them. Suppose you want to determine if the fish living in an industrialized harbor are in fact more exposed to HAHs than fish in a more pristine harbor. Why might a study of liver P450 enzymes be particularly useful for your purposes?
4. What is cooperativity, and why does it not require that “cooperating” sites affect each other directly?
5. Explain why G protein-mediated receptor systems depend on membrane fluidity.
6. Describe the possible roles of allosteric modulation in the regulation of metabolic pathways.
7. Venoms nearly always consist of complex mixes of compounds. Suggest evolutionary and physiological reasons why *mixes* are employed rather than pure compounds. Assume that mixes imply lower amounts of individual components; for instance, assume that if a venom is composed of two compounds, each will be present in only about half the quantity than if it alone were the only component.
8. What are your views on the two sides of the debate over whether emergent properties exist? Explain and justify.
9. Outline the functional roles of conformational changes in proteins, being sure to consider the various categories of proteins such as enzymes, channels, and receptors.
10. Present additional plausible family trees for the enzyme forms in Figure 2.21*a*, and explain which tree you judge to be most likely.
11. Cone snails, krait snakes, and poison-dart frogs (dendrobatid frogs) have independently evolved venoms that block the muscle acetylcholine receptor. Why do you suppose this receptor has so often become a target of venoms? Explain your answer in terms of the cellular mechanisms involved.

Genomics, Proteomics, and Related Approaches to Physiology

CHAPTER 3

Old-time Antarctic whalers believed that some of the fish in the polar seas had no blood because when they lifted the opercular flaps of the fish to see their gills, the gills were white, and when they cut the fish, only a whitish fluid ran out. A young Norwegian named Johan Ruud, a recent graduate with an undergraduate degree in biology, was introduced to these fish by whalers during an Antarctic voyage in the late 1920s. His curiosity whetted, he remembered the unique fish throughout the middle years of his life and, 20 years later, seized an opportunity to investigate them. Convinced of their distinctive properties, he then brought the fish to the attention of biologists worldwide. That was in the 1950s, and by now the fish have become the focus of one of the most startling and instructive efforts to fuse studies of physiology and genetics.

Although Johan Ruud originally referred to the fish using the whalers' term *bloodless fish*, his studies revealed that they in fact have blood. Their blood lacks hemoglobin, however, and is virtually devoid of red blood cells. Thus the blood is translucent and whitish, rather than dense red like most vertebrate bloods (Figure 3.1). Today the fish are usually called *icefish*, a reference to their clear blood and the icy seas they inhabit. There are about 25,000 species of fish alive today—and more than 53,000 species of vertebrates of all kinds—yet the icefish are the only vertebrates that do not have red blood as adults.

The icefish function, overall, as quite ordinary fish even though one might imagine that their lack of blood hemoglobin would be a crippling defect. They are neither rare nor small. Some species have been sufficiently common at times in the past to form commercially valuable fisheries, and several species grow to be 0.5–0.6 m long. Some are active swimmers that move between deep and shallow waters each day.

If icefish have any sort of obvious limitation, it is that they are restricted to the Antarctic seas,¹ where the waters are persistently very cold (often -1.9°C) and saturated with dissolved oxygen (O_2). The coldness tends to depress their metabolic needs for O_2 , and it tends to make O_2 particularly soluble in both the seawater and their body fluids. The Antarctic seas became functionally isolated from most of the world's oceans about 30 million years ago because of dramatically altered global patterns of ocean circulation. Thereafter, the seas became much colder than they had been earlier, and the icefish evolved in that frigid context.

A question that immediately arises in considering icefish is how they came to lose their ability to synthesize blood hemoglobin. Physiologists recognize that studies of genetics can often provide

¹One species, of undoubted polar ancestry, occurs in adjacent cold waters near the southern tip of South America.

This Antarctic fish differs from most fish in that it has no hemoglobin in its blood, giving it an almost ghostlike appearance The fish is one of 16 species known as *icefish* because their blood is clear like ice and they live in the icy polar seas around Antarctica. The icefish differ dramatically from most fish in the proteins they synthesize: They fail to synthesize blood hemoglobin, explaining why their blood is clear instead of red, but they produce antifreeze glycoproteins that are not made by the great majority of fish. (The photo is of *Chaenocephalus aceratus*; courtesy of William J. Baker.)

FIGURE 3.1 Freshly drawn blood from two species of Antarctic fish Both species belong to a single suborder, the Notothenioidei, the dominant group of fish in Antarctic waters. Most species in this group, such as the yellowbelly rockcod (*Notothenia coriiceps*) represented on the right, are red-blooded. The icefish, represented here by the blackfin icefish (*Chaenocephalus aceratus*) on the left, lost blood hemoglobin during their evolution. (Photo courtesy of Jody M. Beers.)

insight into such questions. Do the icefish still have the genes that code for hemoglobin and not transcribe those genes? Or have the genes become nonfunctional, or possibly entirely lost? Modern molecular genetic studies can answer these sorts of key questions.

Studies of genetics from an evolutionary perspective also may help to clarify the adaptive significance of the loss of blood hemoglobin. Fewer than 20 species of icefish exist today; most authorities say 16. If the fish in this small group turn out to lack functional genes for synthesis of blood hemoglobin, can we trace the loss of the genes back to a single common ancestor of all members of the group, meaning the genes were lost a single time? Or did certain species lose the genes independently of others during evolution? The answer, as discussed later, might help us think more confidently about whether the loss of blood hemoglobin was a disadvantageous accident or an advantageous change favored by natural selection.

The protein portion of the blood hemoglobin of vertebrates consists of alpha (α) and beta (β) globin units. Specifically, each hemoglobin molecule is composed of two α -globin units and two β -globin units (see Figure 24.1c). The genes that code for the α - and β -globin units are members of an evolutionarily ancient *gene family*. Biologists know the family is ancient, in part, because genes with a clear structural similarity are found in bacteria and yeasts, indicating that genes of this basic type existed before the time that animals branched off from other life forms. The ancestral genes became duplicated during evolution. Because of this duplication, each individual vertebrate animal today has multiple copies. Over the course of millions of years of

animal evolution, copies of the genes in different species diversified by accumulating changes, and the multiple copies within a single species also underwent diversification. All the genes retained their family resemblance nonetheless. In modern birds and mammals, the two distinct—but structurally similar—genes that code for the α - and β -globin units are located on different chromosomes. In fish, by contrast, the two genes are found on a single chromosome, relatively close to each other.

Physiologists reasoned that if they could look at the exact DNA structure of the α - and β -globin genes in icefish—and compare those genes with ordinary fish globin genes—they might be able to determine how the DNA of icefish became modified during evolution to produce the hemoglobin-free condition. The physiologists employed knowledge of the basic DNA structure of fish globin genes to find the relevant stretches of DNA in icefish. Then they used the polymerase chain reaction (PCR) to make enough copies of the icefish DNA so that they could determine the sequences of nucleotide bases in the DNA. From research of this type carried out in just the last 15 years, the researchers found that in 15 of the 16 species of icefish, the DNA is modified in exactly the same way!²

The relevant DNA in ordinary fish, as shown in Figure 3.2a, consists of a complete α -globin gene separated by an intermediate stretch of DNA from a complete β -globin gene. In the icefish, however, as shown in Figure 3.2b, the β -globin gene is completely gone, and the α -globin gene is missing parts, rendering it nonfunctional. A substantial stretch of DNA was deleted during the evolution of the icefish from their red-blooded ancestors.

To visualize *when* an event occurred during the evolution of a set of species, biologists often plot the event at the most logical position on an evolutionary tree of the species concerned. Figure 3.3 shows the most likely evolutionary tree of the icefish and some of their closest red-blooded relatives. This tree is itself based principally on genetic information. To construct the tree, biologists determined the nucleotide base sequences of mitochondrial DNA in all the fish involved. Then they used the sequences of the

²The 16th species, although it does not contradict the conclusions described herein, is a special case. If you are interested in more detail, see Near et al. (2006).

FIGURE 3.2 Genes and pseudogenes for blood hemoglobin The diagrams depict homologous stretches of DNA in (a) ordinary fish and (b) icefish. In ordinary fish (exemplified here by *Notothenia coriiceps*, an Antarctic red-blooded fish), functional genes for α - and β -globin are found near each other on a single chromosome; each globin gene consists of three exons (coded green) and two introns (coded yellow). In nearly all icefish, the entire β -globin gene, most of the α -globin gene, and the DNA between the original globin genes have been deleted. The icefish retain only a nonfunctional pseudogene, a fragment of the α -globin gene consisting of exon 3 and a part of the adjacent intron. (After Near et al. 2006.)

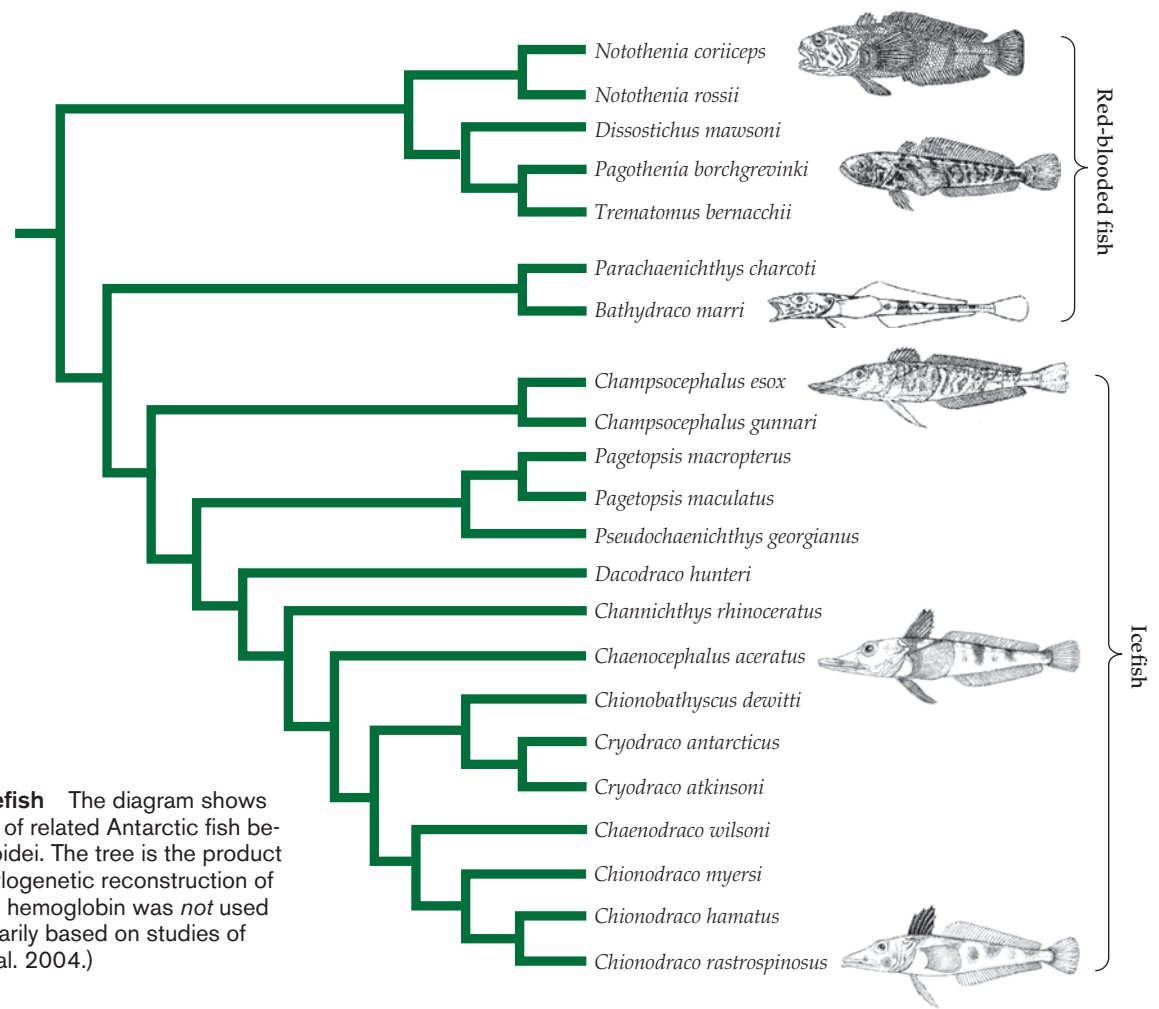

FIGURE 3.3 The evolution of icefish The diagram shows the evolutionary tree of 22 species of related Antarctic fish belonging to the suborder Notothenioidei. The tree is the product of the most recent research on phylogenetic reconstruction of this suborder. Information on blood hemoglobin was *not* used to construct the tree, which is primarily based on studies of mitochondrial DNA. (After Near et al. 2004.)

various species to identify logical relationships among the species, based on the same principles we discussed in Chapter 2 (see Figure 2.21) for interpreting amino acid sequences. No information on hemoglobin or the α - or β -globin gene was used in constructing the evolutionary tree.³ The tree is therefore *completely independent of our knowledge of the globin genes*.

The most logical spot on the evolutionary tree to plot the loss of the globin genes is shown in Figure 3.4. All the lines of evolution drawn in red in Figure 3.4 end in species that have functional genes for both α - and β -globin and that synthesize blood hemoglobin. All the lines of evolution drawn in gray end in species that lack functional globin genes because of DNA deletions. Moreover, *all the species with deletions exhibit the same deletions*, those evident in Figure 3.2b. Therefore, the most logically coherent proposition is that the deletions occurred at the spot marked in Figure 3.4, in an ancestor of modern-day icefish. Later, as the various existing species of icefish evolved, all inherited the deletions from their common ancestor.

A deeper appreciation of these conclusions is reached by looking at another property of icefish that is similar in certain respects but dissimilar in others. In most vertebrates, the blood is not the only place in the body where hemoglobin is found (see Chapter 24). Hemoglobin of distinctive structure is found also within the

cells of muscles—particularly many of the skeletal muscles and the heart muscle—where it imparts a red color to the muscle tissue. Hemoglobin within muscle cells helps increase the rate at which O_2 diffuses into the cells, and it sometimes acts as an important internal store of O_2 for the cells. Muscle hemoglobin is known as *myoglobin* (*myo*-, “muscle”).

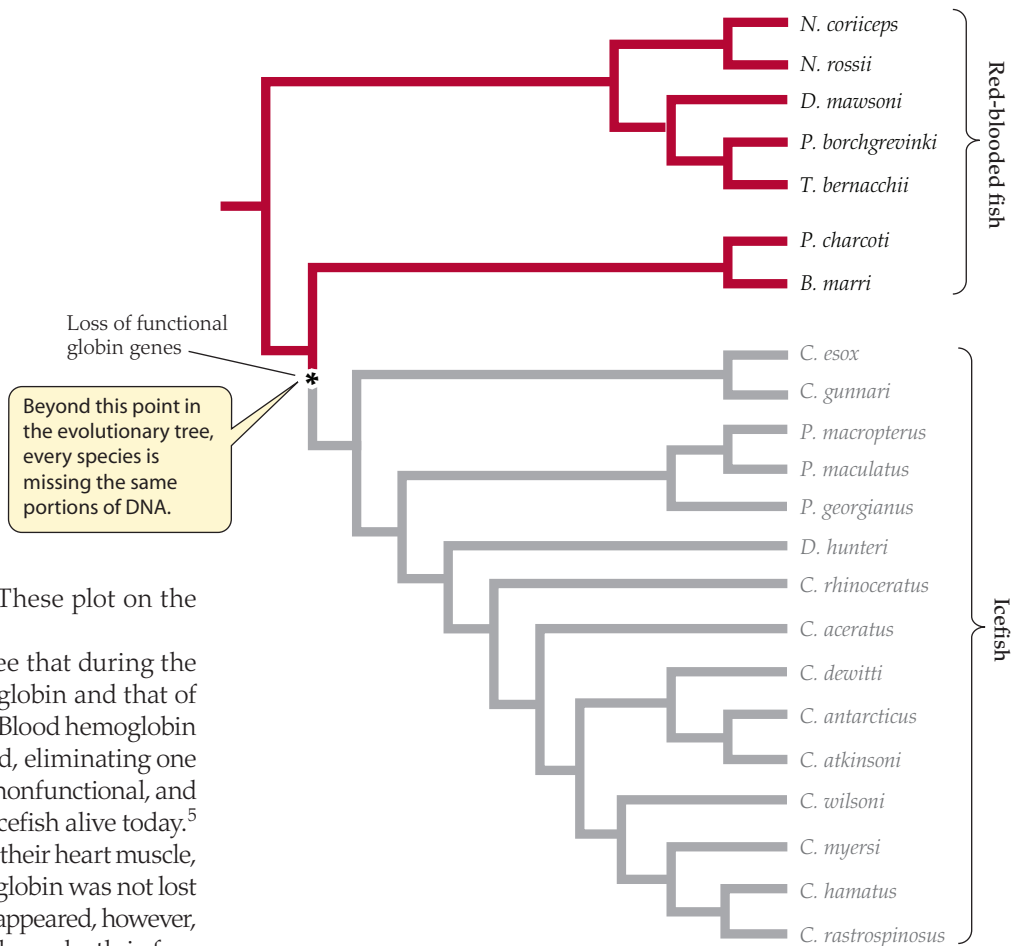

Six of the 16 species of icefish lack myoglobin in the cells of their ventricular heart muscle. The ventricle in these species is cream-colored, in contrast to the ventricle in the other 10 species of icefish, which have ventricular myoglobin.⁴ Figure 3.5a shows examples of these two sorts of icefish (left and middle images). To increase understanding of the evolution of the myoglobin-free condition, physiologists took the same approach as in the study of blood hemoglobin. They examined the DNA sequences of the genes for myoglobin and asked what had happened to render the genes nonfunctional in the icefish that lack ventricular myoglobin.

The physiologists found that the myoglobin genes in some species of myoglobin-free icefish are altered in distinctly different ways from the genes in other of the myoglobin-free species. This discovery indicates that the myoglobin-free condition evolved independently more than once. In fact, based on the evidence currently available, there were four independent occasions when

³The globin genes are found in chromosomal DNA in the cell nucleus, not in the mitochondrial DNA used to construct the tree.

⁴Fish with red blood almost always have ventricular myoglobin.

FIGURE 3.4 The most likely point at which the ability to synthesize blood hemoglobin was lost during the evolution of icefish. Red and gray are used to symbolize which species and lines of evolution are characterized by the presence of functional globin genes (red) and which are not (gray). All of the 15 icefish species shown exhibit the condition diagrammed in Figure 3.2b: They lack the β -globin gene and possess only a nonfunctional fragment of the α -globin gene. One species of icefish (*Neopagetopsis ionah*) is omitted because, although it does not contradict the conclusions described here, it represents a special case. See Figure 3.3 for full species names.

the myoglobin genes became nonfunctional. These plot on the evolutionary tree as shown in Figure 3.5b.

Comparing Figures 3.4 and 3.5b, you can see that during the evolution of the icefish, the loss of blood hemoglobin and that of muscle myoglobin followed very different paths. Blood hemoglobin was lost once: A large stretch of DNA was deleted, eliminating one globin gene and rendering the other irretrievably nonfunctional, and this deletion was passed on to all the species of icefish alive today.⁵ By contrast, most icefish synthesize myoglobin in their heart muscle, just like most of their red-blooded relatives; myoglobin was not lost when blood hemoglobin was. After the icefish first appeared, however, mutations that eliminated myoglobin occurred independently in four of the lines of icefish evolution, and today six of the species exhibit one of those mutations and have myoglobin-free ventricular muscle.

Trying to decide if the loss of blood hemoglobin and myoglobin was advantageous or disadvantageous is a complicated matter. Surely biologists will debate some aspects long into the future. Here let's look just at blood hemoglobin.

Most researchers conclude that the initial loss of blood hemoglobin was almost surely a disadvantage for the ancestors of icefish. The genetic discovery that the loss occurred once—rather than multiple times—enhances the plausibility of this conclusion. Evolution by natural selection tends to weed out deleterious mutations. If geneticists found that blood hemoglobin had been lost multiple, independent times in icefish evolution, we would have to explain how multiple deleterious mutations were able to survive the immediate selection against them in order to argue that the loss of hemoglobin was a disadvantage. Instead, we need only argue that a single loss was able to survive despite being disadvantageous. Dramatic morphological and physiological specializations of icefish provide the most compelling evidence that the loss of blood hemoglobin was a disadvantage. Compared with related red-blooded fish of the same body size, existing icefish have very large hearts, and they circulate their blood at rates that are far higher than usual.⁶ These specializations strongly suggest that the original loss of blood

hemoglobin was a defect that significantly decreased the ability of the circulatory system to transport O_2 , and the circulatory system thereafter became modified to make up for the defect by evolving a capacity to circulate the blood exceptionally rapidly. Looking at the evidence from both genetics and physiology, a persuasive case can be made that the loss of blood hemoglobin initially decreased the fitness of icefish and thereby favored the subsequent evolution of other attributes that compensated for the shortcoming.⁷

The *antifreeze glycoproteins* are a final set of proteins of icefish that raise intriguing genetic and evolutionary questions. All species of ocean fish with bony skeletons, including icefish, have body fluids that are more dilute in total dissolved matter than seawater is (see Chapter 28). Because of this, the body fluids of ocean fish tend to freeze at a higher temperature than seawater freezes.⁸ The seawater in the frigid polar seas, in fact, is often cold enough to freeze fish even though the seawater itself remains unfrozen. Antarctic species of fish typically differ from the great majority of fish species in that

⁵The overall change from normal to altered DNA, diagrammed in Figure 3.2, probably involved several sequential mutations, not just a single large and simultaneous deletion. The change is described as occurring once because from the viewpoint of the species existing today, there was a single net alteration in the DNA, regardless of the intermediate steps involved in its occurrence.

⁶The distinctive cardiovascular physiology of icefish is discussed further in Chapter 24 (see page 638). You can see that the icefish hearts are enlarged in Figure 3.5a.

⁷An obvious question is how the fish that initially exhibited hemoglobin loss were able to survive. Researchers working on the subject argue that survival occurred in part because of the particular conditions existing in the Antarctic seas at the time, including relatively little overall competition and the existence of ecological refuges from competition. The arguments rest on studies of the ancient oceanography and plate tectonics of the region, as well as studies of biology.

⁸Typically, in aqueous solutions, the freezing point depends on the concentration of dissolved entities: The higher the concentration, the lower the freezing point. More specifically, doubling the concentration of dissolved entities (e.g., Na^+ ions or glucose molecules) approximately doubles the extent to which the freezing point of a solution is lowered below $0^\circ C$ (see page 117). Antifreeze proteins and glycoproteins are unusual, compared with other dissolved materials, in that they exert a far greater effect on freezing point than can be accounted for by just their concentrations (see page 248).

(a) Hearts of two species of icefish and a red-blooded Antarctic fish

Six species of icefish have cream-colored hearts because they lack ventricular myoglobin...
 ... whereas the other icefish have ventricles colored red by the presence of myoglobin.
 In red-blooded fish, the ventricle is nearly always red with myoglobin.

FIGURE 3.5 Presence and absence of myoglobin in the ventricular heart muscle (a) Three hearts—representing three species of Antarctic fish—removed from individuals of approximately the same body size. Because blood has been drained from the hearts, the color of the tissues depends on whether or not myoglobin is present in the cardiac muscle cells. The left and middle hearts are from two species of icefish; the species at the left (*Chaenocephalus aceratus*) has a cream-colored ventricle because it lacks ventricular myoglobin, whereas the species in the middle (*Chionodraco rastrospinosus*) has a reddish ventricle because it synthesizes ventricular myoglobin. The heart at the right, red with ventricular myoglobin, is from a red-blooded species of Antarctic fish (*Notothenia coriiceps*). (b) The points in evolution at which the genes for myoglobin synthesis in the heart ventricle became nonfunctional. The mutations at three of the four points are known to be different from each other; those at the fourth (*Dacodraco hunteri*) are presumed also to be distinct but remain to be described. See Figure 3.3 for full species' names. (a from Moylan and Sidell 2000; b after Sidell and O'Brien 2006.)

(b) The points at which the myoglobin genes became nonfunctional

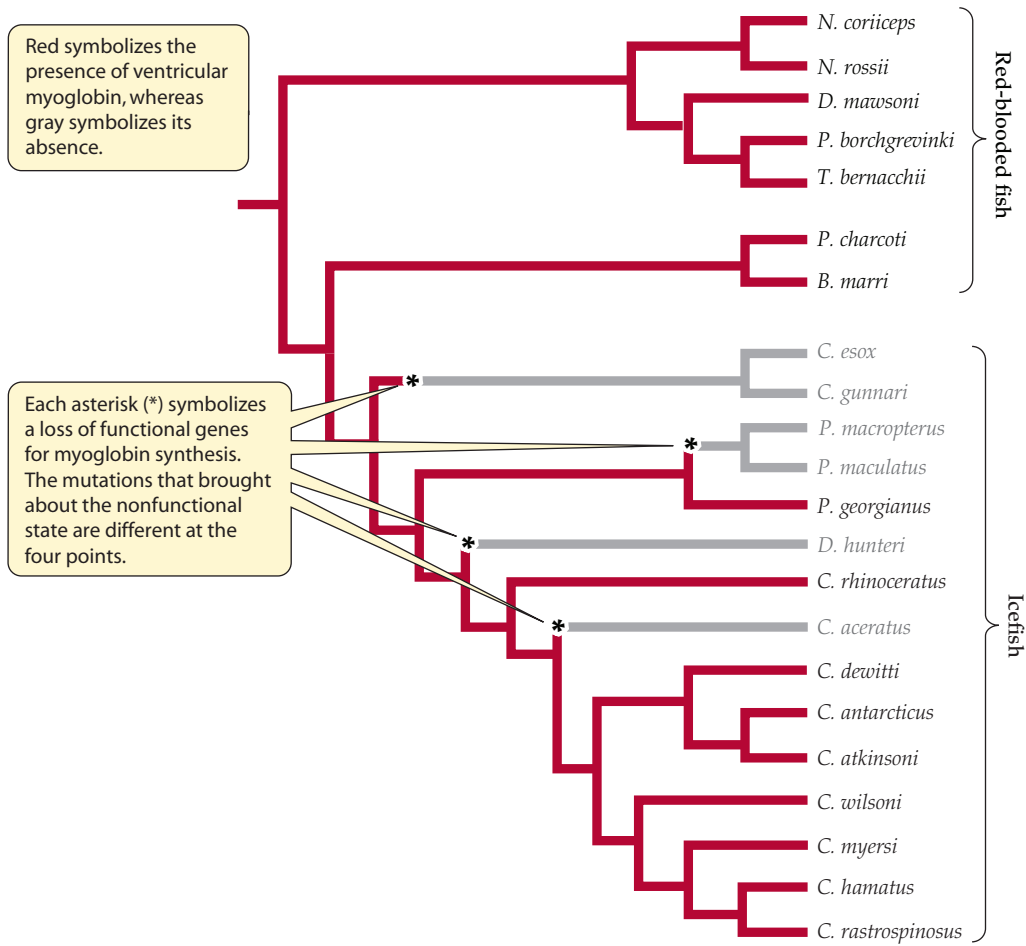

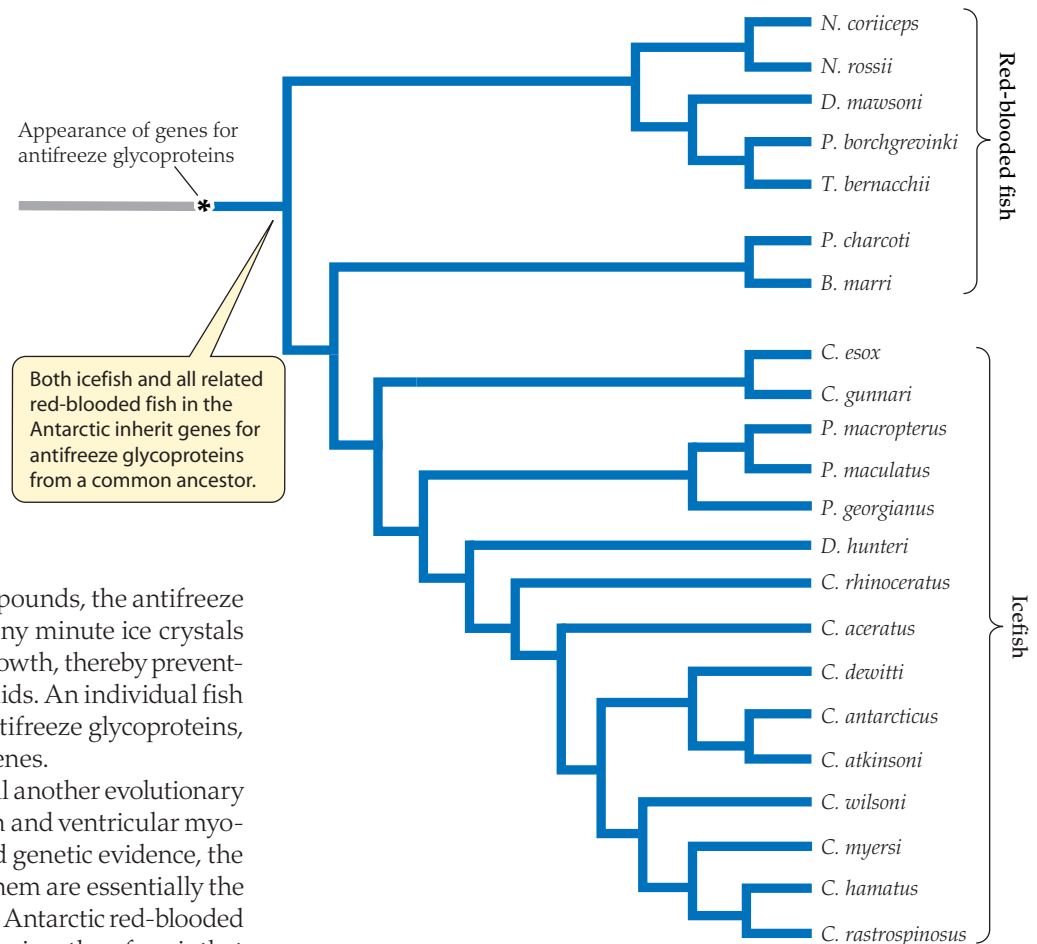

FIGURE 3.6 Evolution of antifreeze glycoproteins Blue symbolizes the species and lines of evolution characterized by antifreeze glycoproteins. Genes coding for the glycoproteins appeared prior to the evolution of icefish. See Figure 3.3 for full species' names. (After Cheng et al. 2003.)

they synthesize specialized antifreeze compounds, the antifreeze glycoproteins. These compounds bind to any minute ice crystals that appear in the body and arrest crystal growth, thereby preventing freezing of the blood and other body fluids. An individual fish synthesizes a suite of chemically similar antifreeze glycoproteins, coded by a suite of evolutionarily related genes.

The antifreeze glycoproteins present still another evolutionary scenario, compared with blood hemoglobin and ventricular myoglobin. According to available chemical and genetic evidence, the glycoproteins and the genes that code for them are essentially the same not only in all icefish but also in all the Antarctic red-blooded fish related to icefish. The most logical conclusion, therefore, is that the genes for antifreeze synthesis evolved before icefish appeared, as shown in **Figure 3.6**. When blood hemoglobin became deleted, giving rise to the first ancestors of icefish, those early hemoglobin-free fish already had the types of antifreeze compounds that their descendants still display today.

Modern research on icefish dramatically illustrates the fruitful use of genome science to help understand questions in animal physiology. We will return to the icefish examples several times as we now look more systemically at genomics and the disciplines related to genomics.

Genomics

Genomics is the study of the genomes of organisms. The **genome** of a species is the species' full set of genes, or—more broadly put—its full set of genetic material.

Probably the most famous aspect of genomics at present is *genome sequencing*, in which the DNA sequence of the entire genome of a species is determined. Because individuals of a species differ genetically to some degree (e.g., whereas some people have genetically coded brown eyes, others have blue eyes), the DNA sequence for a species depends a bit on the particular individual from which the DNA for sequencing was acquired. The sequence is enormously useful nonetheless, even if based on just one individual. At present, complete genome sequences have been determined for many, diverse animal species. Probably thousands of animal species' genomes will be fully sequenced within the next decade.

The study of genomics is not limited to species for which the entire genome has been sequenced. Sequencing of just a limited set of individual genes—a subpart of the genome—can sometimes

set the stage for major new insights into a physiological system. An example is provided by research on the evolutionary origins of the genes that code for the antifreeze glycoproteins of Antarctic fish. Sequence comparisons of those genes with a limited but relevant set of other genes reveal that the antifreeze genes are derived from genes that in ordinary fish code for pancreatic proteins similar to trypsinogen, the precursor of the digestive enzyme trypsin. That is, copies of genes that originally coded for pancreatic digestive proteins evolved to code for the antifreezes! Like the unfolding of a good mystery story, this strange revelation from genomics has lately been joined by an equally strange revelation from the study of organ physiology to point to a dramatic, unexpected conclusion. Researchers have recently obtained evidence that the antifreeze glycoproteins—long assumed to be secreted directly into the blood by the liver—are in fact secreted by the exocrine pancreas into the intestines, only later making their way to the blood. The genomic and physiological evidence taken together suggest that when the antifreeze glycoproteins first evolved in Antarctic fish, they were pancreatic secretions homologous to the preexisting pancreatic digestive secretions.

Genomics is inextricably linked with advanced methods of information processing

Genomics, especially when entire genome sequences are studied, involves the processing of massive quantities of information. The genome of a single species, for example, may consist of a string of more than 1 billion nucleotide bases. To compare the genomes of two species, researchers often need to search for stretches of similar and dissimilar DNA in two sequences that each exceed 1 billion

bases in length. Modern genomics is defined in part by massive information processing.

Progress in genomics relies typically on the use of computer programs and robots that carry out great numbers of steps without direct human attention. The computer programming is itself sufficiently demanding that it is carried out by scientists in new specialties termed *computational biology* and *bioinformatics*. One key task for these specialties is the organization of data: The great masses of information gathered in genomic studies need to be recorded in ways that permit reliable retrieval by multiple users, many of whom were not involved in the original data collection. A second key task is to articulate the operational meaning of similarity and difference among base sequences within stretches of DNA and write algorithms that efficiently identify similarities and differences. Algorithms of this sort are used, for example, to locate apparently homologous strings of nucleotides in DNA—similar DNA sequences—in two or more genomes.

Much of genomic research is carried out by what are called **high-throughput methods**. The term refers to methods of the sort we have been discussing, in which computer programs and robots—after being designed to be as effective and error-free as possible—are “turned loose” to carry out procedures and generate results without moment-to-moment human attention or detailed human quality control. The process of adding direct human interpretation is known as **annotation**. To illustrate the interplay between high-throughput methods and annotation, consider a genome composed of 20,000 genes. When the genome is first fully sequenced, both the sequencing itself and the initial identification of individual genes will be carried out largely by high-throughput methods. Thereafter, experts on various genes in the global scientific community will directly or indirectly (e.g., by use of data catalogs) assess and add annotations to the information on genes of interest, but this time-consuming process is never complete. Possibly, therefore, the information on just 6000 of the genes will be annotated within the first few years. Knowledge of the other 14,000 genes would then consist, for the moment, only of the decisions of computer programs.

The World Wide Web is the primary vehicle by which the vast quantities of genomic information are shared among scientists worldwide. Gene and genome sequences are posted at dedicated websites (e.g., National Center for Biotechnology Information, GenBank, FlyBase, and WormBase). Web-based tools—notably BLAST programs—are available online to search for similarities among nucleotide base sequences in two or more stretches of DNA of interest.⁹ Web-based tools, such as the Gene Ontology, are also available to facilitate and standardize annotation.

One overarching goal of genomics is to elucidate the evolution of genes and genomes

Genomics, whether based on entire or partial genome sequences, can be said to have two overarching goals:

- First, elucidate the evolution of genes and genomes.
- Second, elucidate the current functioning of genes and genomes.

Genomics does not proceed in isolation in the pursuit of either of these goals. Instead, progress is most effective when genomics is integrated with physiology, biochemistry, and other disciplines.

In the study of the evolution of genes and genomes, one central topic is the elucidation of *mechanisms of gene modification*. The genome of each species is descended from the genomes of ancestral species, and genomes become modified as they evolve. Genomic studies help clarify the mechanisms by which genes and genomes become modified. One mechanism documented by genomic research is that genes sometimes become modified during evolution by the accumulation of beneficial base substitutions or other mutations favored by natural selection. This process can occur to such a significant extent that certain genes come to code for new proteins, as we have seen in the evolution of the genes for antifreeze glycoproteins in Antarctic fish from genes for pancreatic proteins such as trypsinogen. Another mechanism of modification is that genes sometimes become duplicated during evolution, and following duplication, the multiple copies within a single species often come to code for different proteins (illustrated by the evolution of the α - and β -globin genes in red-blooded vertebrates). Genes also sometimes become nonfunctional as they evolve, by partial or full deletion or by mutations that block transcription (illustrated by the icefish hemoglobin and myoglobin genes). The *coding* regions of genes are not the only parts that change by the operation of these and other mechanisms. *Regulatory* regions also sometimes change, thereby affecting the circumstances in which genes are transcribed.

Besides analyzing mechanisms of gene change, another central topic in the study of the evolution of genomes is the *reconstruction of paths of evolution in the past*. In research of this sort, the evolutionary tree of species of interest is first determined as accurately as possible from genomic, morphological, and biochemical evidence. Then, as illustrated by Figures 3.4–3.6, the most likely points of occurrence of particular evolutionary developments are located on the tree. Methods exist to add a time scale, so that the amount of time between events can be approximated. Reconstructions of the sort described are useful in several ways. One is that they clarify the order of evolutionary events. For example, as physiologists reason about why certain icefish lost ventricular myoglobin, they can be virtually certain that blood hemoglobin was already gone (compare Figures 3.4 and 3.5b): To hope to explain accurately the myoglobin-free condition in icefish, one needs to think of the loss of myoglobin as having occurred, not in fish with ordinary vertebrate blood, but in ones with hemoglobin-free blood.

A second overarching goal of genomics is to elucidate the current functioning of genes and genomes

Because of the evolutionary continuity of life, when a new genome is sequenced, many of the genes found in the new genome are likely to be similar to genes observed already in genomes that were sequenced at earlier times. One may therefore be able to predict the function of genes in the new genome by extrapolating from preexisting knowledge of homologous genes. Suppose, to illustrate, that a particular gene of physiological importance is known to occur in the laboratory mouse (one of the most intensively studied mammals), and suppose that the mouse gene has been extensively annotated with information on how it is regulated and the physiological roles it plays. Suppose also that when researchers sequence the genome of a new mammal species, they find a gene that has a DNA sequence

⁹BLAST stands for *basic local alignment search tool*. BLAST programs are available to search for similarities among amino acid sequences in different proteins, as well as similarities among base sequences in samples of DNA. See “tools” at the National Center for Biotechnology Information website (www.ncbi.nlm.nih.gov) for useful tutorials on BLAST programs.

closely similar to the mouse gene. It would then be reasonable for the researchers to predict that the gene in the newly sequenced species has a function like that of the gene already known. Not all such predictions prove to be accurate when tested, because genes evolve and can take on new properties. Nonetheless, homologous genes in different species often have similar functional properties.

The existence of *gene families* creates opportunities for large-scale interpretations based on the same sort of logic as just described. We have already seen an example of a gene family, namely the set of genes that code for vertebrate globin proteins. You will recall that the various globin genes within a single vertebrate species bear a family resemblance, and the globin genes in different species also do—all being related through evolutionary descent. All these genes are considered to belong to one gene family. The property that defines a **gene family** is that all the genes in a family share distinctive DNA base sequences. All the genes in a family also *tend* to code for functionally similar proteins; for example, just as the genes in the globin family code for hemoglobin proteins, the genes in another family might code for a particular type of enzyme, and those in still another family might code for a particular type of voltage-gated channel protein. With these concepts in mind, it is clear that when the genome of a species is initially sequenced, the simple process of scanning the genome for distinctive DNA sequences—the signature sequences of gene families—can be instructive. The process can provide a great deal of tentative insight into the functions of the genes present and the types of proteins likely to be synthesized.

An illustration is provided by the genome of the purple sea urchin. **Figure 3.7** lists just six of the many major insights into urchin biology that arise from surveying this genome. Consider, first, observations ❶ and ❷, which state that when the urchin genome is surveyed, no genes are found that would be expected to code for gap-junction proteins or mediate the synthesis or use of melatonin and adrenaline. These observations suggest that the cellular communication system of sea urchins is unusual, compared with that of other animals, in that it lacks gap junctions and certain of the common neurotransmitter compounds. Observations ❸ and ❹ highlight that there seem to be lots of genes in the urchin genome for immune and detoxification proteins; these observations suggest that sea urchins have unusually elaborate immune and detoxification systems, possibly helping to explain why urchins are exceptionally long-lived. Observation ❺ points to a functional explanation for why the skeletons of sea urchins differ from those of vertebrates in the chemistry of their mineral composition. Sea urchins and vertebrates are thought to belong to closely related phyla (see the endpapers at the back of the book). Observation ❻ suggests that certain vertebrate genes in fact evolved in a common ancestor of sea urchins and vertebrates, rather than being exclusive to vertebrates as previously thought.

Genomes must ultimately be related empirically to phenotypes

Although the genome of an animal reveals what genes are present in the animal's tissues, the *phenotype*¹⁰ of any particular tissue at

¹⁰The *phenotype* of a tissue consists of its outward characteristics—its structure, activities (such as contraction or secretion), biochemical constituents, and metabolic pathways—as opposed to its genetic material. Its *genotype* is its genetic material, its genome.

In the genome of the sea urchin, analysis of gene families indicates that:

- ❶ No genes are present that code for connexins or other gap-junction proteins.
- ❷ No genes are present that code for the enzymatic synthesis or use of adrenaline or melatonin, although such genes exist for many other common neurotransmitters.
- ❸ Genes that code for elements of the innate immune response—such as genes for innate pathogen-recognition proteins—are extraordinarily numerous in comparison with other known genomes.
- ❹ Genes that code for cytochrome P450 detoxification enzymes and other types of detoxification proteins are also unusually numerous.
- ❺ In the gene families that control skeleton mineralization, the genes differ in major ways from those in vertebrates.
- ❻ Many genes are observed that previously had been thought to exist only in vertebrates.

FIGURE 3.7 Characteristics of the genome of a sea urchin

The six observations listed here arise from a close study of the genome of the purple sea urchin (*Strongylocentrotus purpuratus*), a common echinoderm in shallow coastal waters and tidal pools along the West Coast of the United States. Sequencing of the urchin's genome was completed in 2006. (After Sea Urchin Genome Sequencing Consortium 2006.)

any given time is not a simple, deterministic consequence of the genes present, the tissue *genotype*. Thus efforts to predict proteins, metabolic processes, and other phenotypic traits from the genome represent just the first step in a long and essential process, namely that the genome must be related by empirical studies to the phenotype. When predictions are made from just the genome, they may ultimately prove to be wrong for several reasons. These include that (1) the actual functions of newly discovered genes may in fact not match the functions predicted by extrapolation from already-known genes and (2) even if the true function of a new gene is known, the gene may not be expressed when and where predicted. When all is said and done, predictions from the genome are *hypotheses*, and they must be tested before they can be accepted or rejected.

The process of testing genomic predictions entails, in part, the study of *which genes are transcribed and expressed* under various circumstances. It also entails the study of the *actual proteins synthesized* as a consequence of gene expression, and the *metabolites*¹¹ that are synthesized, used, and otherwise processed by the proteins. We will return to these sorts of studies—transcriptomics, proteomics, and metabolomics—after looking at important issues in research strategy in the next two sections of this chapter.

¹¹A *metabolite* is an organic compound of modest to low molecular weight that is currently being processed by metabolism. An example would be glucose that is being processed by glycolysis.

The study of a species is said to enter a **postgenomic era** after the genome of the species has been sequenced. *Postgenomic* does not mean that the genome can be relegated to history. Quite the contrary, it emphasizes that in the era “after the genome is known,” the study of a species’ biology is forever altered. In the postgenomic era, the sequence of a species’ genetic material is entirely known. The monumental task of empirically evaluating the full *significance* of this knowledge remains, however.

SUMMARY Genomics

- Genomics is the study of the genomes—the full sets of genes—of organisms. Because of the large numbers of genes, genomics depends on high-throughput methods to collect data and on advanced information processing to catalog and use data.
- One of the two major goals of genomics is to elucidate the evolution of genes and genomes. In pursuit of this goal, students of genomics seek to understand the mechanisms of evolutionary modification of genes and genomes (e.g., deletion and duplication). They also seek to reconstruct the paths followed by evolution in the past so that, for example, the order of evolutionary events is better defined.
- The second major goal of genomics is to elucidate the current functioning of genes and genomes. In pursuit of this goal, genomics uses information on already-known genes and gene families to predict the likely functions of newly identified genes and the likely ranges of action and competence of newly sequenced genomes.
- Although knowledge of an animal’s genome permits many useful predictions to be made about the animal’s biochemical phenotype, these predictions must ultimately be tested empirically. For example, although the suite of proteins synthesized in an animal’s tissues can be predicted from the genome, the proteins must ultimately be studied directly, as by proteomic methods.

Top-down versus Bottom-up Approaches to the Study of Physiology

The traditional approach to the study of the multiple levels of organization in animal physiology can be described as *top-down*. To see this, consider the diagram of levels of organization and the chain of causation in **Figure 3.8a**. In the traditional approach, shown at the left in **Figure 3.8b**, the order of study of a phenomenon proceeds from the top of the diagram to the bottom. Physiologists first recognize an attribute of animal function of interest; a human example would be the *exercise training effect*, loosely defined as the improved ability of previously sedentary people to engage in exercise when they participate in a program of athletic training. After the attribute of animal function is specified, physiologists seek to identify the aspects of tissue function that are involved. In the case of the exercise training effect, a key aspect of tissue function is that skeletal muscles increase their capacity for physical work, and sometimes their size, when they are trained. Physiologists then look for the specific proteins—and the properties of the proteins—that are responsible for the tissue functions they have identified. Finally, physiologists identify the genes coding for the proteins, and they study how the expression

of the genes is controlled, and the evolution of the genes. In the traditional, **top-down order of study**, investigation proceeds from animal function to tissue function, then to tissue biochemistry, and finally to genes.

Genomics sets the stage for physiologists to adopt a new *bottom-up* approach to the study of physiological phenomena, shown at the right in **Figure 3.8b**. In this approach, physiologists first sequence the genome of a species, or they approximate the genome by extrapolating from other, related species. Actually, the entire genome need not be known or approximated; physiologists need only have information on the portion of the genome that is relevant to them. After the genomic information is available, physiologists study the transcription of the genes in key tissues. For example, in research on athletic training, physiologists would study gene transcription in the skeletal muscles to determine which genes are transcribed to a greater extent after training than before (i.e., genes upregulated by training), and which genes are transcribed less than before training (downregulated). After changes in gene transcription are known, physiologists employ their knowledge of the affected genes to predict changes in tissue proteins. They also look directly at extensive suites of tissue proteins to see which are increased and decreased in amount. Then, physiologists seek to understand how the changes in proteins alter tissue function, and how the changes in tissue function are likely to affect animal function. In the new, **bottom-up order of study**, investigation proceeds from genes to gene expression, then to tissue biochemistry, and finally to tissue and animal function.

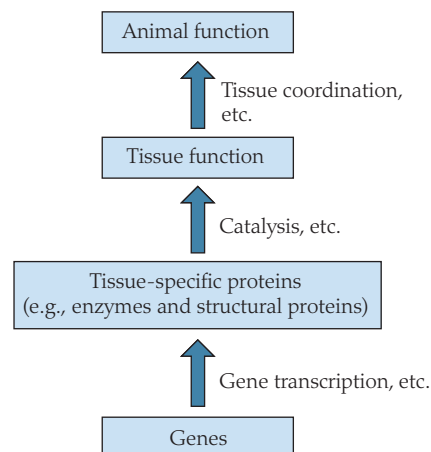

What would be the potential advantage of the bottom-up approach? The answer depends on recognizing the methods used. Researchers who employ the bottom-up approach have developed *high-throughput* methods to study all the genetic and biochemical steps. Thus not only the genes, but also the gene transcripts, proteins, and metabolites, are surveyed and monitored in great numbers simultaneously.

The bottom-up approach pursued with high-throughput methods has two distinctive assets: (1) It can be extremely thorough in searching for the genes, proteins, and metabolites that are instrumental in a physiological process; and (2) precisely because it is thorough, it can proceed without preexisting biases regarding which genes or proteins are likely to be involved. Advocates of the bottom-up approach point to examples in which the traditional top-down approach missed important genes or proteins because investigators looked only at the small subsets that they imagined would be important. With the high-throughput methods employed in the bottom-up approach, investigators can, in principle, look at everything and therefore miss nothing.

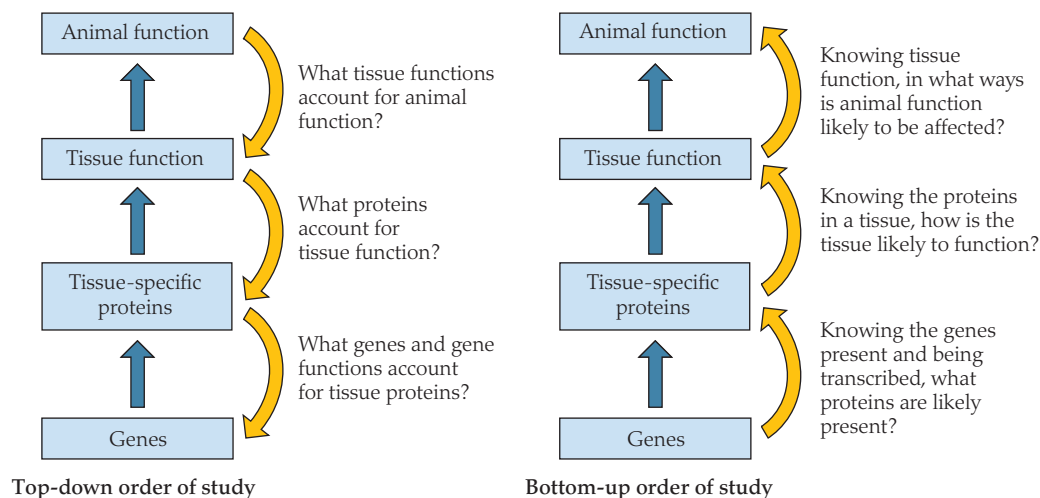

Defenders of the top-down approach emphasize that looking at everything is not always an advantage. For example, when dozens or even hundreds of genes prove to be up- or downregulated during a physiological process—as is often the case—sorting through the implications for tissue function and animal function can be, literally, mind-boggling. Advocates of the top-down approach stress that it brings a needed focus to research because it starts with a defined phenomenon of known importance to whole organisms.

The top-down and bottom-up approaches seem certain to coexist for the foreseeable future. Each has advantages. Thus the two approaches can work together synergistically.

(a) The levels of organization and chain of causation in animal physiology

(b) The order of questions posed in top-down and bottom-up studies

Screening or Profiling as a Research Strategy

At each stage of a bottom-up research program, as already suggested, the most common strategy today—termed **screening** or **profiling**—is for investigators to look as comprehensively as possible at the class of compounds of interest, whether the compounds are messenger RNAs (produced by transcribed genes), proteins, or metabolites. Screening or profiling capitalizes on the existence of high-throughput methods. This strategy also creates a demand for ever more efficient and cost-effective high-throughput methods.

In screening or profiling studies, the most common type of research design is to compare a tissue of interest before and after a change of interest. An example would be screening skeletal muscle before and after exercise training. Other examples include studies of a tissue before and after stress, or at different times of day, or in young individuals versus old. In all cases, the full suite of compounds present before a change is compared with the full suite after the change.

FIGURE 3.8 Top-down versus bottom-up (a) Four of the principal levels of organization that must be taken into account in the study of animal physiology. Arrows show cause–effect relationships among the levels of organization: the order of causation. Arrows are labeled with just a few of the processes that are instrumental in the cause–effect relationships. (b) The order in which investigators pursue questions (yellow arrows) in top-down versus bottom-up studies.

An important challenge for screening studies is the *statistical* challenge of deciding which observed changes are likely to be physiologically significant and which are likely to be mere artifacts of chance. We often read that statistical tests are carried out “at the 5% level,” meaning that the probability of error (i.e., of thinking we see a change when in fact there is none) is 5% or less. In standard computer programs used for statistical calculations, however, this probability level is calculated on the assumption of an *a priori hypothesis*, that is, a hypothesis stated prior to data collection. Screening or profiling studies typically gather the data first, then articulate hypotheses; the hypotheses from such studies, in other words, are

not a priori. Suppose a screening study examines 1000 genes and—among the 1000—identifies 100 genes that seem to exhibit increased transcription when a tissue is stressed in some particular way. Of those 100, if an investigator has simply used a standard statistical program and an error probability of 5%, there will be no doubt that 50 of the instances of increased transcription (5% of 1000) are not real and repeatable changes but chance events—false positives. Specialized statistical methods already exist and are used to reduce false positives. Moreover, research is ongoing to develop improved methods that will deal in superior ways with the problem that when great numbers of genes, proteins,

or metabolites are surveyed, some of the effects observed are bound to be artifacts of chance.

The Study of Gene Transcription: Transcriptomics

The study of gene transcription—that is, the study of which genes are being transcribed to make messenger RNA (mRNA) and the rates at which they are transcribed—is known as **transcriptomics** or **transcription profiling**.¹² Because physiologists have recognized for decades that the genes that matter are those that are transcribed, physiologists have studied transcription and mRNA synthesis for a long time. *Transcriptomics* and *transcription profiling* are new terms. One of their key connotations is that they imply

¹² **Expression profiling** is another commonly used term. However, *expression* is sometimes used to mean protein synthesis. *Transcription profiling* is a more exacting term to use when *transcription* per se is the process under study. See Nikinmaa and Schlenk (2009) for a discussion.

(a) The type of exercise performed

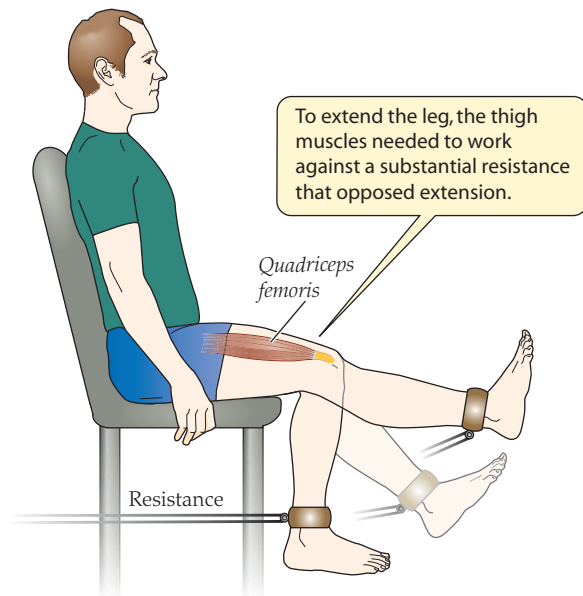

FIGURE 3.9 Exercise is followed by increased transcription of groups of genes (a) Subjects performed a 90-min bout of leg-extension exercise once each day for 5 days. Only one leg was exercised; the other remained at rest. On the fifth day, biopsy samples were taken repeatedly from the *quadriceps femoris* muscles of the two legs, and concentrations of many messenger RNAs were measured in the samples. (b) Based on the mRNA data—and using the unexercised leg as a control for the exercised one—investigators identified three groups of genes that exercise causes to be upregulated. During and after exercise

(b) Changes in three categories of mRNAs in the exercised leg

of the sort performed, one group of genes—termed the *stress-response genes*—quickly exhibits highly enhanced transcription. Another group—dubbed the *metabolic priority genes*—is slower to be upregulated but also exhibits a dramatic increase in transcription. The third group—the *metabolic/mitochondrial enzyme genes*—is the slowest to be upregulated and exhibits only modest (but long-duration) increases in transcription. Note that times are not evenly spaced on the x axis. (b after Booth and Neuffer 2005.)

the simultaneous study of great numbers of mRNAs, often by use of highly automated methods.

Changes in gene transcription during and after exercise nicely illustrate the transcriptomic approach. Investigators have found that numerous genes are upregulated—transcribed at an increased rate—in exercising muscles each time a person engages in an extended period of endurance exercise. In one study (Figure 3.9a), subjects performed 90 minutes (min) of leg extension (kicking) exercise with one leg while the other leg remained at rest. For 24 h following the exercise, biopsy methods (see Figure 21.3) were used to remove tiny samples of muscle tissue from thigh muscles periodically, and the levels of dozens of mRNAs in the exercised leg were compared with those in the unexercised leg. Three groups of genes were identified that underwent upregulation in the muscles of the exercised leg during and following exercise (Figure 3.9b).

One of the groups of upregulated genes—termed the *metabolic/mitochondrial enzyme genes*—is especially interesting. These genes code for mitochondrial proteins. As seen in Figure 3.9b, the metabolic/mitochondrial enzyme genes undergo just a small degree of upregulation after a single bout of exercise and thus boost mitochondrial protein synthesis just a bit. The mitochondrial proteins, however, have long half-lives; once synthesized, they last for a long time. The investigators believe they have found a key mechanistic reason for why muscles keep increasing their exercise capability, day after day, over many weeks of daily endurance training. Each day's training produces just a modest increase in transcription of the mitochondrial genes and a modest increase in synthesis of mitochondrial proteins, but these small effects cumulate when training is repeated day after day.

DNA microarrays (also called *DNA microchips* or *gene chips*) are the basis for a set of particularly important, high-throughput methods for the study of gene transcription. A single microarray can permit investigation of thousands or tens of thousands of genes at a time.

As a physical object, a microarray consists of a grid of spots of DNA placed on a glass plate or other solid substrate by a robot (Figure 3.10a). Each spot might, for instance, consist of a stretch of DNA that represents a single gene or presumptive gene.¹³ Given the minute physical size of each bit of DNA and the technology used to apply the spots, a grid of 10,000 spots—representing 10,000 different genes—will fit within an area of only 1 cm², or less.

In one common type of experiment using a DNA microarray, a single array is used to carry out a direct comparison of the mRNAs produced by a tissue under two different conditions.¹⁴ For illustration, let's assume that we are doing a microarray study of muscle before and after exercise. The mixes of mRNA molecules present under the two conditions are extracted (● in Figure 3.10b), and all the mRNA molecules in each extract are then labeled with a distinctive fluor,

¹³The nature of the DNA spots depends on the method used to prepare them, and several methods are in common use. One method is to reverse-transcribe mRNA molecules to produce DNA sequences (cDNA) that code for the mRNA molecules; this method, you will note, does not require a sequenced genome. Another method is to start with the entire genome and essentially cut it up into many, often overlapping, pieces of DNA (producing a *tiling array*). Still another method is to synthesize DNA sequences from scratch (essentially from raw nucleotides) using knowledge of the genome to select the sequences made.

¹⁴This experimental design is said to employ a *two-color spotted microarray*.

(a) A fluorescent image of a DNA microarray, greatly magnified

FIGURE 3.10 With DNA microarrays, the transcription of thousands of genes can be studied at once (a) A DNA microarray. Each spot represents one gene. The color of a spot after processing indicates whether the gene was transcribed under either or both of two conditions being investigated. (b) An outline of the procedure followed to compare directly the mRNAs produced by a tissue under two different conditions, I and II. The mRNAs extracted from the tissues of animals exposed to the two conditions are labeled with two different fluorors (green and red) prior to hybridization with spots of DNA on the microarray. Each mRNA hybridizes with the specific DNA that represents the specific gene that codes for the mRNA. When the fluorors are visualized, spots emit either green or red fluorescence if they represent genes that were transcribed under just one of the conditions. Spots that represent genes that were transcribed about equally under both conditions emit yellow (the combination of green and red). Spots emit nothing and appear black if they represent genes that were transcribed under neither condition.

a compound that has the potential to emit light by fluorescence.¹⁵ A common approach (2) in the figure) is to label one extract (e.g., that from muscle before exercise) with a fluor that will emit green light after it is fully processed, and the other extract (e.g., that from muscle after exercise) with a different fluor that will emit red light. The two fluor-labeled mRNA preparations are then permitted to hybridize with the microarray. Each mRNA hybridizes with the DNA spot representing its specific gene (3) in the figure). Thus, at this step, each spot in the microarray potentially becomes labeled. A spot is labeled with mRNA from both preparations if the gene it represents was being transcribed under both conditions. A spot is labeled with mRNA from only one preparation if the gene it represents was being transcribed under only one of the two conditions. A spot that represents a gene that was not transcribed under either condition is not labeled at all. Finally, the fluorors bonded to the microarray are visualized by laser scanning (4) in the figure) so they emit their distinctive fluorescent wavelengths: green or red. If the gene represented by a spot on the microarray was not being transcribed under either condition, the spot emits nothing and appears black. If the gene was being transcribed approximately equally under both conditions, the spot emits both green and red and thus appears yellow. The most interesting spots are those that emit only green or only red, because those represent the genes that were being transcribed under only one of the two conditions studied.

Transcription profiling often identifies large numbers of genes that exhibit altered transcription in response to environmental or other conditions

Table 3.1 illustrates that animals routinely modify the transcription of hundreds of genes—by up- or downregulating them—in

¹⁵For conceptual simplicity, we here describe the procedure as if the raw mRNA itself were used, although in reality, technical steps must be taken to stabilize the mRNA.

(b) A study to compare gene transcription under two different conditions

response to environmental changes of many sorts, or in response to other changes such as exercise or hormone exposure. Physiologists never imagined until recently that such large numbers of genes would be involved. Determining the *significance* of gene transcription changes numbering in the hundreds will obviously be a challenging and revelatory phase in the advance of physiological knowledge. One of the “At Work” chapters in this book, Chapter 21, provides considerably greater detail on exercise responses.

Transcription profiling reveals that many genes routinely undergo daily cycles of transcription

Periodic cycles of gene transcription—*transcription rhythms*—are common, based on recent research. Most known cycles in gene transcription are daily cycles in which the pattern of falling and rising transcription repeats approximately every 24 h. For example, in

TABLE 3.1 Numbers of genes studied and discovered to be up- or downregulated in transcriptomic research on seven phenomena using DNA microarrays

Phenomenon and tissue studied (reference in parentheses)	Number of genes studied	Number of up- or downregulated genes ^a	Some of the functions controlled by affected genes
Endurance exercise in humans: Thigh muscle 3 h following lengthy (~75 min), high-intensity bicycling compared with before bicycling (Mahoney et al. 2005)	8432	126	Mitochondrial biogenesis, tolerance of oxidative stress, membrane ion transport, nuclear receptor function (all categories mostly upregulated)
Tissue freezing in freeze-tolerant wood frogs: Heart muscle after frogs experienced extracellular freezing compared with before (Storey 2004)	>19,000	>200	Glucose metabolism, antioxidant defense, membrane ion transport, ischemia-related signaling (all categories mostly upregulated)
High water temperature in killifish: Liver after fish were exposed to high temperature compared with ordinary temperature (Podrabsky and Somero 2004)	4992	540	Heat-shock protein synthesis, cell membrane synthesis, nitrogen metabolism, protein biosynthesis
Continuous swimming for 20 days in rainbow trout: Ovaries in fish that swam compared with resting fish (Palstra et al. 2010)	1818	235	Protein biosynthesis, energy provision, ribosome functionality, anion transport (all categories mostly downregulated)
Transfer from freshwater to seawater in eels: Several tissues in eels after transfer to seawater compared with before (Kalujnaia et al. 2007)	6144	229	Transport across membranes, cell protection, signal transduction, synthesis of structural proteins
Exposure to juvenile hormone in developing honeybees: Animals treated with a juvenile hormone analog compared with ones not treated (Whitfield et al. 2006)	5559	894	Foraging behaviors, RNA processing, protein metabolism, morphogenesis
Ocean acidification in sea urchin larvae: Larvae exposed to high CO ₂ and low pH compared with ones not exposed (Todgham and Hofmann 2009)	1057	178	Biom mineralization, energy metabolism, cellular defense responses, apoptosis

^aThe numbers of affected genes are quoted from the references cited; different criteria might have been used in different studies.

a recent study of gene transcription in the lung tissue of laboratory rats, more than 600 genes exhibited clear 24-h cycles in their transcription. These genes participate in just about every aspect of lung function. Some, for example, play roles in tissue maintenance, others in defense against airborne foreign materials, and still others in the genesis of asthma. Because the genes are transcribed more rapidly at some times in the 24-h daily cycle than at others, lung repair and defense are likely to occur more effectively at some times of day than others, and treatments for asthma may be more effective at certain times. All the genes are not synchronous; some reach their peaks and troughs of transcription at different times than others. Some of these transcription cycles are undoubtedly under control of biological clocks (see page 410). Other cycles, however, are probably direct responses to day–night changes in the outside environment.

Additional studies in a wide variety of animals indicate, similarly, that 2–40% of genes exhibit cycles in their transcription on approximately 24-h periodicities. For example, hundreds of genes in the malaria mosquito *Anopheles gambiae* exhibit daily cycles (Figure 3.11). Inasmuch as some of these genes play roles in defending the mosquitoes against toxic environmental agents, the mosquitoes

may be inherently more vulnerable at some times of day than others to agents (e.g., insecticides) used to combat them (see Figure 3.11).

Manipulations of protein synthesis can be used to clarify gene function

We are concerned in this chapter mostly with the unmanipulated chain of events by which genes are naturally transcribed and translated, leading to changes in proteins and other aspects of the biochemical phenotype. A significant aspect of gene expression, nonetheless, is that it can be manipulated experimentally as a way of gaining insight into gene function.

One strategy of this sort is **gene deletion** or **gene knockout**, in which a gene is manipulated so that experimental animals lack functional copies of the gene. The animals, therefore, cannot synthesize the mRNA ordinarily associated with transcription of the gene, and consequently they do not synthesize the protein (or proteins) coded by the gene. In principle, such animals will be deficient or inferior in one or more phenotypic traits, and their deficiencies will reveal the function of the missing gene. A converse strategy is **forced overexpression**, in which tissues are subjected to

FIGURE 3.11 Daily cycles in three mRNAs coding for detoxification enzymes in the malaria mosquito *Anopheles gambiae*. The mRNAs produced by transcription of three genes—*agCYP6P3*, *agCYP6M2*, and *CYP6Z1*—were measured over 2 day–night cycles (see scale at bottom: yellow = day, black = night). The genes and mRNAs code for three detoxification enzymes in the P450 system (see page 48). Because the enzymes help the mosquitoes resist pyrethrin-based insecticides, the cycles in gene transcription suggest that vulnerability to such insecticides is likely cyclic. mRNA levels are expressed on the y axis as multiples of the gene-specific median concentration (e.g., 2× for a particular gene indicates a concentration twice as high as that gene’s median concentration over the course of the study). Because the mosquitoes studied here could not actually see day and night, biological clocks probably controlled the transcription cycles shown. (After Rund et al. 2011.)

experimentally increased synthesis of the mRNA associated with a gene of interest.¹⁶

Several considerations can cloud the interpretation of gene knockout or overexpression studies. *Compensation* is one of the most important: When animals artificially lack a certain protein, for example, they often exhibit other phenotypic alterations that tend to make up for the loss of function they would otherwise exhibit. Mice engineered to lack functional genes for myoglobin,¹⁷ for example, have more blood capillaries in their cardiac muscle than ordinary mice, and they circulate blood faster through the muscle. These compensations, and others, prove that the lack of myoglobin is physiologically significant. Because of the compensations, however, the lack of myoglobin does not have a simple deterministic effect on the overall phenotype of the animals, and the mice are actually quite normal in their overall vigor and appearance.

RNA interference (RNAi) is a recently discovered cellular process that, among other things, has great promise for being manipulated to gain insight into gene function. When selected double-stranded RNA molecules are introduced into cells and processed by the RNAi pathway, specific mRNA molecules that are naturally produced by the cells are destroyed. In effect, the genes that produce the targeted mRNAs are silenced because the mRNAs produced by transcription of the genes are rendered inoperative before they lead to protein synthesis. The consequence is in many ways similar to that of gene deletion: Certain proteins are not synthesized, providing an opportunity to learn what the proteins normally do. Unlike the case when gene deletion is used, however, animals with *normal*

¹⁶This might be achieved, for example, by genetically engineering a tissue to have an unusually large number of copies of the gene.

¹⁷Myoglobin aids intracellular O₂ transport and storage, as discussed earlier in this chapter.

genomes can be manipulated with RNAi because gene action is blocked following gene transcription.

SUMMARY The Study of Gene Transcription: Transcriptomics

- Transcriptomics or transcription profiling (also sometimes called expression profiling) is the study of which genes are transcribed in a tissue and the degrees to which they are transcribed. Transcription is evaluated by measuring the messenger RNAs (mRNAs) produced in the tissue.
- DNA microarrays are a major tool in modern transcriptomic research. A microarray consists of a grid of thousands of DNA spots, each representing a particular gene. Each mRNA produced by a tissue binds to the DNA that corresponds to the gene that produced the mRNA. The DNA spots that thus become labeled with mRNA when exposed to the mix of mRNAs produced by a tissue collectively mirror the genes being transcribed in the tissue.
- DNA microarrays are often used to carry out a direct comparison of the mRNAs produced by a tissue under two different conditions. The mRNAs produced under the two conditions are labeled with green and red fluor. Gene-specific DNA spots in the microarray then glow with green light, red light, or yellow light (the result of green + red), depending on whether the corresponding genes were transcribed under just one of the two conditions or both.
- Studies using microarrays often identify hundreds of genes that undergo changes of transcription when an animal is exposed to a change in conditions. Many genes also routinely exhibit daily cycles of transcription.
- One way to study gene function is to manipulate gene transcription or translation and observe the consequences. Gene knockout, gene overexpression, and RNA interference are three of the major methods used. All modify the capacities of cells to produce specific proteins.

Proteomics

Proteomics is the study of the proteins being synthesized by cells and tissues. The term implies the simultaneous study of large numbers of proteins, even to the extent of screening all proteins that can be detected. One reason for the study of proteomics as a separate discipline is that the proteins coded by many genes are unknown, and therefore biologists cannot *predict* the full list of proteins in a cell from knowledge of gene transcription alone. A second reason for studying proteomics as a separate discipline is that, even if the proteins coded by mRNAs are known and the mRNAs have been quantified, protein concentrations cannot necessarily be predicted because protein synthesis is sometimes only loosely correlated with mRNA synthesis. Cell proteins constitute a part of the cell phenotype. Proteomics is thus a branch of the study of the *biochemical phenotype*.

The set of proteins assayed in a proteomic study can be narrowed down by a variety of methods. For example, a particular proteomic study might examine just the set of proteins that bind ATP—such as ATPase enzymes—or just the set of phosphorylated protein kinases (types of regulatory proteins; see Chapter 2).

Two-dimensional (2D) gel electrophoresis is a particularly common proteomics method. In this method, the proteins in a

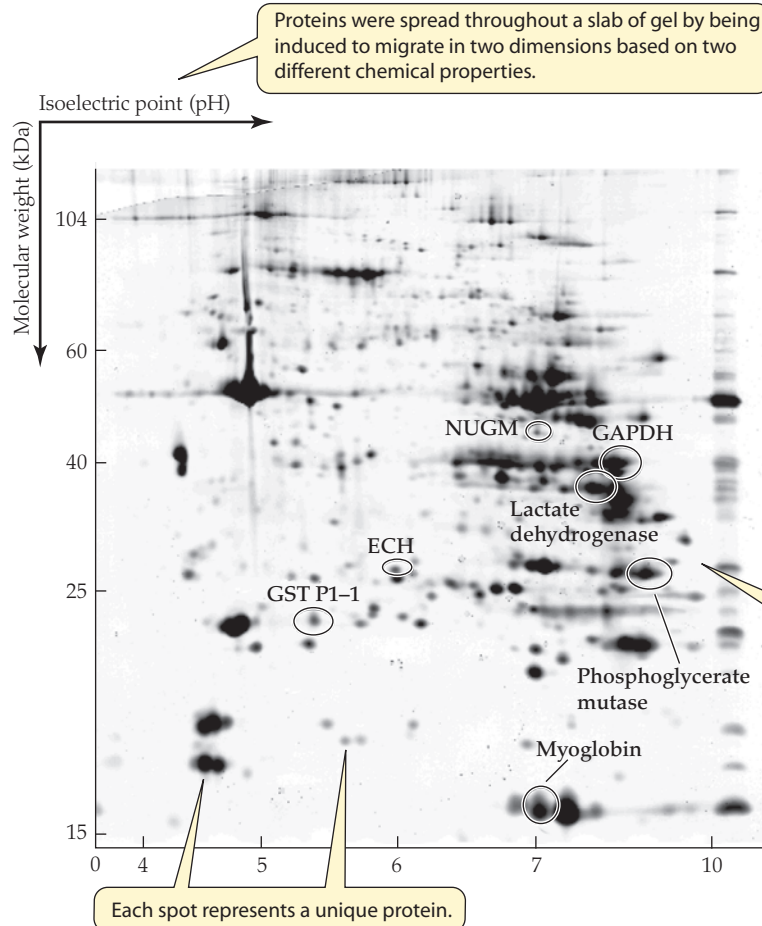

tissue sample, after being extracted, are first forced to migrate linearly through a gel material that separates them according to their isoelectric points, and thereafter the proteins are forced to migrate at a right angle to the first migration through a second gel material that separates them according to their molecular weights. In this way, the proteins in the original mixture are spread out in two dimensions—based on two different chemical properties—as seen in **Figure 3.12**. The proteins are then chemically identified by, first, excising spots of interest from the gel and, second, analyzing the spots by mass spectrometry or another analytical method.

Figure 3.12a is a gel from a proteomic study carried out to understand how Tibetan Sherpas are able to climb with great endurance—often carrying heavy loads—at altitudes above 5500 m (18,000 ft) in the Himalaya Mountains. Tissue was taken by biopsy from a thigh muscle of six Tibetans who had spent their entire lives at altitudes of at least 3500–4500 m and from six Nepal natives who had lived at 1300 m. Proteins in the muscle samples were

then subjected to 2D electrophoresis. Seven of the proteins—those circled in Figure 3.12a—proved to be different in concentration in the high- and low-altitude people. One of these, myoglobin, was hardly a surprise; the high-altitude people had relatively high levels of myoglobin, which as we earlier discussed, helps O_2 diffuse into muscle cells. The discovery of very high levels of another protein, the enzyme glutathione-S-transferase (GST P1-1), in the high-altitude people was a surprise, however. Investigators now must learn what role this protein plays at altitude; possibly it helps defend against oxidative damage that can cause muscle deterioration at high elevations. When biologists first started to study high-altitude physiology, they focused on breathing and blood circulation. Later, they realized that tissue biochemistry is also of great importance, as discussed in Box 23.1. Proteomics now promises to expand rapidly our understanding of which tissue proteins are important.

A proteomic study of host-behavior modification by a parasite provides a second example. A hairworm that parasitizes certain

(a) A gel employed for protein identification

(b) A modern-day Sherpa carrying a heavy load at high altitude

FIGURE 3.12 Proteomics: A study of tissue protein response to life at high altitude (a) For a proteomic study of muscle proteins in high-altitude human populations, tiny (15-mg) samples of muscle tissue were cut by biopsy from the *vastus lateralis* muscles in the thighs of volunteers and subjected to two-dimensional gel electrophoresis. This gel resulted from the processing of one sample. The proteins in the sample were induced to migrate both from left to right and from top to bottom. When the proteins migrated from left to right, they were separated by isoelectric point (measured in pH units). When they migrated

from top to bottom, they were separated by molecular weight (measured in kilodaltons, kDa). The proteins were in solution and invisible during migration. Afterward, however, they were visualized in the gel by staining, as seen here. The seven circled proteins were found to be present in significantly different concentrations in high- and low-altitude people. (b) An individual typical of the two human populations studied. ECH = Δ^2 -enoyl-CoA-hydratase; GAPDH = glyceraldehyde-3-phosphate dehydrogenase; GST P1-1 = glutathione-S-transferase; NUGM = NADH-ubiquinone oxidoreductase. (a after Gelfi et al. 2004.)

(a) Proteome

FIGURE 3.13 Proteomics: Parasites sometimes alter the protein profile of the central nervous system in their hosts (a) Proteins in the brains of katydids (*Meconema thalassinum*) were separated in two dimensions by the methods described in the caption of Figure 3.12a. Unlike in Figure 3.12a, however, the image seen here is not just that of a single gel. Instead, this image is a computer-generated synthesis of evidence from multiple gels, some from control katydids and some from katydids that were in the act of seeking water. Orange-colored proteins

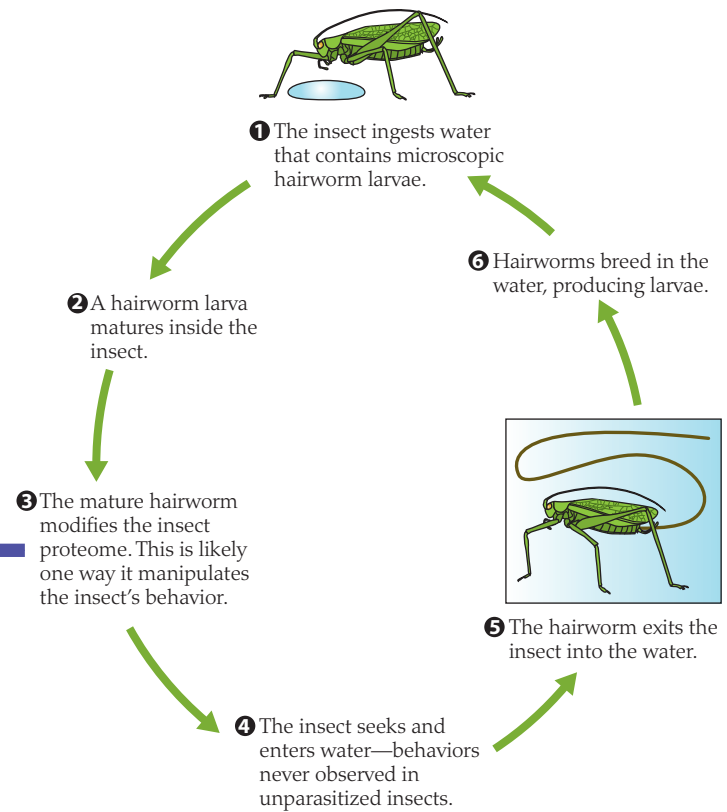

were at elevated concentrations during water-seeking behavior. Green-colored proteins were at reduced concentrations. Water-seeking occurs only when katydids are parasitized by hairworms (*Spinochordodes tellinii*), which manipulate the katydids' behavior in ways advantageous to the parasites. Although the insects are called katydids in the United States, they are more often called grasshoppers in Europe, where this study was done. (b) The life history of the parasite-host relationship. (a after Biron et al. 2005.)

katydids is known to manipulate the behavior of the insects, so that—entirely contrary to their normal behavior—the katydids jump into bodies of water at night. This strange behavior is induced when the hairworm within a katydid has grown to full size, and the behavior enables the hairworm to exit its host into water. Investigators reasoned that the parasite might exert its effect on the behavior of its host, in part, by increasing or decreasing the levels of brain proteins. They also reasoned that the host might upregulate defensive proteins. The proteomic study confirmed that many proteins are increased or decreased in the brain of a parasitized katydid at the time it bizarrely seeks water and jumps in. All the proteins colored orange or green in **Figure 3.13** are significantly altered. The next step will be to determine the roles the protein changes are playing.

Metabolomics

Metabolomics parallels and complements proteomics. Like proteomics, metabolomics seeks to describe the biochemical phenotype. Unlike proteomics, metabolomics does not focus on gene products.

(b) Life history of the host–parasite relationship

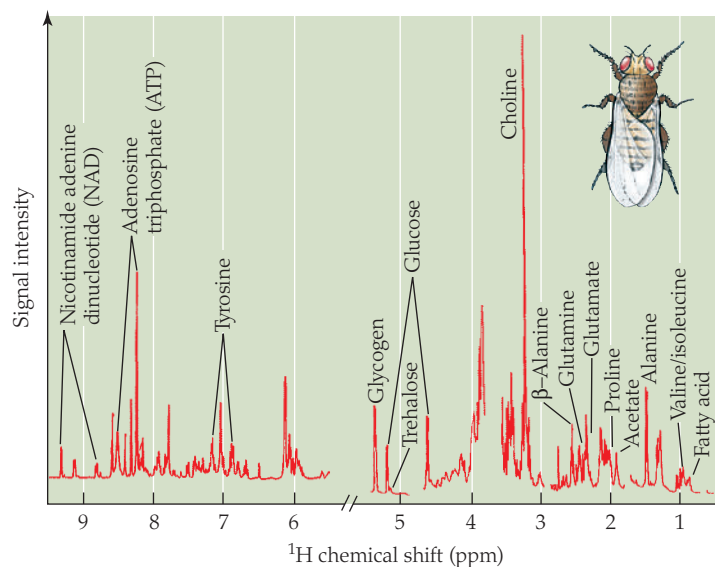

were at elevated concentrations during water-seeking behavior. Green-colored proteins were at reduced concentrations. Water-seeking occurs only when katydids are parasitized by hairworms (*Spinochordodes tellinii*), which manipulate the katydids' behavior in ways advantageous to the parasites. Although the insects are called katydids in the United States, they are more often called grasshoppers in Europe, where this study was done. (b) The life history of the parasite-host relationship. (a after Biron et al. 2005.)

Metabolomics, in a few words, is the study of all the organic compounds in cells and tissues other than macromolecules coded by the genome. The compounds encompassed by metabolomics are generally of relatively low molecular weight (roughly <1500 daltons). They include many types of small molecules found in cells and tissues, such as sugars, amino acids, and fatty acids. Most of these molecules are metabolites, that is, compounds currently being processed by metabolism. A central goal of metabolomics is to clarify the metabolic pathways operative in cells and the ways the pathways are modulated. A shortcoming of metabolomics is that when tissues are extracted for a study, compounds from various cell compartments typically become mixed, meaning that additional research is required to clarify whether the compounds measured were together, in certain cell compartments, in the native cell.

To illustrate metabolomics, let's consider a study of fruit flies subjected to heat stress (**Figure 3.14**). Some flies were exposed for 1 h to a heat-stress temperature of 38°C. Their tissues and the tissues of control flies were then extracted with solvents and analyzed by nuclear magnetic resonance (NMR) spectroscopy, a method capable of detecting and quantifying a great diversity of compounds. Nu-

(a) The NMR spectrum obtained from analysis of a single fruit fly

(b) Average concentrations of 10 metabolites that were compared in control and heat-stressed flies.

FIGURE 3.14 Metabolomics of heat stress Fruit flies (*Drosophila melanogaster*) were exposed to 38°C—a stressfully high temperature—for 1 h and compared with control flies that lived always at 25°C. Whole flies from both groups were analyzed immediately after the heat-stress period. (a) The NMR spectrum obtained from a single fly. The signatures of multiple metabolites are readily seen, and the amplitudes of the signatures can be used to calculate metabolite concentrations. The portion of the spectrum at 5.5 and higher was recorded at greater amplification than the portion at 5.4 and lower. (b) The average concentrations in control and heat-stressed flies of 10 metabolites that exhibited statistically significant changes in heat-stressed flies as compared with control flies, based on the NMR data. The concentrations are in arbitrary units and should be compared only *within* metabolites because different metabolites are scaled differently. The metabolite labeled “fatty acid” was identified only in general terms, as being a fatty acid–like compound. (After Malmendal et al. 2006.)

merous metabolites could be observed—because of their distinctive signatures—in the NMR spectrum obtained from each fly (see Figure 3.14a). Researchers therefore could paint a very broad picture of metabolite changes in the cells of the flies (see Figure 3.14b). The results obtained have been used to generate new hypotheses that will

need to be tested in future research. For instance, the rise in alanine (see Figure 3.14b) in the heat-stressed flies suggests that flies might depend to an increased extent on anaerobic catabolism when they are under heat stress, because alanine is a product of the anaerobic pathways in flies. From the rise in tyrosine, one might hypothesize that synthesis of several hormones is accelerated during heat stress, because tyrosine is involved in the synthetic pathways.

The metabolomic approach differs from traditional metabolite studies in that traditionally just one, two, or three compounds would typically have been studied and the others disregarded. In a metabolomics study, however, as many compounds as possible are measured, so effects are studied without preconceived limits. A metabolomics study often leads to hypotheses for future research rather than to definitive conclusions. In part, this is true precisely because metabolomics measures any and all effects that are detectable, including ones for which there may be no existing background knowledge. All the areas of *-omics* biology discussed in this chapter are characterized by similar assets and limits.

Study Questions

1. A case can be made that the sedentary way of life characteristic of many people today is a very recent development in human history, dating from at most a century or so ago. According to this line of argument, physical exertion was a regular part of daily life for most people during most of human evolution. From this point of view, in what way do recent gene-transcription data suggest that physical exertion is in fact probably essential for full health? (For reading on this question, see the article by Booth and Neuffer in the References.)
2. Geneticists can synthesize any gene—any stretch of DNA—desired. Suppose you use a tree of genome evolution to predict the structure of a now nonexistent, ancient gene. What insights might you obtain by synthesizing the ancient gene and inserting it into a living animal?
3. The solubility of O₂ in aqueous solutions—such as seawater or blood plasma—increases as temperature decreases. Moreover, the rates at which tissues metabolically consume O₂ tend to decrease as temperature decreases. With these facts in mind, explain why—in the world’s oceans—polar seas are the most likely place where fish could survive a mutation that deletes their ability to synthesize blood hemoglobin.
4. Suppose you carry out genomic, transcriptomic, and proteomic studies on a single tissue. What type of information would you obtain from each sort of study? For understanding physiology, what are the uses and shortcomings of each type of information?
5. Compare and contrast the top-down and bottom-up approaches to the study of physiology.
6. One of the most famous quotes in the history of inquiry is Francis Bacon’s statement: “The truth emerges more readily from error than confusion.” What did he mean? High-throughput methods are sometimes accused of producing such an information overload that they generate confusion. Carefully consider the pros and cons of high-throughput methods as viewed from Bacon’s perspective.
7. We tend to think that each expressed gene has a particular effect on an animal’s phenotype. Why, therefore, if a gene is knocked out by genetic engineering methods, is the consequent change in an animal’s phenotype not necessarily a direct reflection of the gene’s effect? For example, how is it possible to knock out a gene that in fact has a phenotypic effect and yet not, in some cases, see

- any measurable change in an animal's overall ability to function? How might your answer to Study Question 2 be affected by the considerations raised here?
8. The icefish alive today that lack ventricular myoglobin are often cited as examples of “natural knockout animals” because they lack functional genes for myoglobin synthesis. Suppose geneticists engineer some ordinary, modern-day fish to lack functional genes for myoglobin synthesis. Compare the icefish—the “natural knockout animals”—with the first generation of engineered knockout animals. Explain how these two groups of animals would be likely to differ in the mechanisms available for compensating for their lack of myoglobin.
 9. Suppose you want to determine if excessive lipid ingestion alters gene transcription. Describe and explain all the steps you would carry out to do a microarray-based study of the question. Include your choice of subjects and tissues to be investigated. (The statement of the problem to be studied—effects of “excessive lipid ingestion”—is deliberately vague, and you should refine it by specifying and explaining an operational procedure.)
 10. Suppose you want to determine if dehydration changes the types or amounts of enzymes. Describe and explain all the steps you would carry out to do a two-dimensional gel study of the question. As in Study Question 9, refine the experimental objectives, and include your choice of subjects and tissues.

Physiological Development and Epigenetics

The Australian sea lion (*Neophoca cinerea*) is an endangered species of diving mammal endemic to the southwestern seacoasts of Australia. Although the adults do not engage in particularly long dives compared with many other diving mammals (see Chapter 26), they are highly accomplished divers in their own way. They feed on fish, squids, octopuses, lobsters, and other prey that they capture by diving to the bottom, or near the bottom, of modestly deep (e.g., 70–100 m) offshore waters. They spend approximately half their time at sea. When they are at sea, they forage incessantly by undertaking about 10 to 11 dives every hour, thereby spending almost 60% of their time at depths in excess of 6 m. With all these considerations in mind, the intensity of foraging effort by Australian sea lions ranks as exceptionally high. Because the sea lions forage underwater, their unusually intense foraging places high demands on their physiological capacities for functioning without breathing.

Infant Australian sea lions cannot dive at all (they depend on their mother to feed them). Thus, a dramatic change in diving capacity occurs in the life of each individual as it grows and matures. Each sea lion starts life with essentially no diving capacity but must develop a sophisticated diving capacity by the time it is a mature adult.

Oxygen stores play a crucial role. During many dives—although not all (see Chapter 26)—the tissues of a diving mammal maintain their metabolism by using O_2 that the animal stored in its body while it was at the surface, breathing air. Oxygen is stored in three major ways. First, during diving, an animal's lung air contains O_2 , which can potentially be transported from the lungs to other tissues. Second, O_2 is combined with hemoglobin in the blood; as a dive progresses, this O_2 is released from the blood hemoglobin and taken up by tissues. Third, within the cells of the heart and skeletal muscles, O_2 is combined with myoglobin, a red, iron-containing protein that gives red muscles their reddish color. Myoglobin is a specialized form of hemoglobin. The O_2 combined with myoglobin is released for use in muscle metabolism during a dive.

Biologists studying the individual development of Australian sea lions have discovered that the capacity of a young animal to store O_2 undergoes a major developmental change as the animal matures to adulthood. This can be seen in [Figure 4.1](#). Note that the amount of O_2 that can be stored at the start of a dive—plotted on the y axis—is expressed per unit of body weight. By use of this form of expression, body size is removed as an immediate consideration. As you can see, by the time an individual has grown to be an adult, it is able to store almost three times as much O_2 as it could store when it was 6 months old. This is not because the animal is bigger. Instead, what the data show is that the amount of O_2 that can be stored *per unit of tissue* triples during development.

Australian sea lions (*Neophoca cinerea*) searching for prey near the bottom of the coastal ocean As adults, these sea lions dive 10–11 times per hour in search of fish, squids, octopuses, lobsters, and other prey. Young Australian sea lions are more limited than adults in their physiological capacities for diving, and they only gradually acquire adult competence as they mature.

FIGURE 4.1 The maximum O₂ stores of Australian sea lions at four different ages The total O₂ available per kilogram of body weight at each age is estimated by adding (from bottom to top) the O₂ in blood (mostly bound to hemoglobin), the O₂ bound to myoglobin in muscles, and the O₂ in lung air. (After Fowler et al. 2007.)

Some of the reasons for this change are known. A young sea lion increases the concentration of hemoglobin in its blood by about 1.4 times as it matures from 6 months of age to adulthood. The greater concentration of hemoglobin enables each volume of blood to combine with more O₂. In addition, the volume of blood increases. Blood volume per unit of body weight is more than twice as great in an adult as in a 6-month-old. These two developmental changes—the increase in amount of hemoglobin per unit volume of blood and the increase in blood volume—mean that an animal has more and more blood hemoglobin per unit of body weight as it grows older. The capacity for O₂ storage by myoglobin also increases. In fact, myoglobin accounts for the most dramatic of all the changes in O₂ storage capacity. Muscles become more than three times more concentrated with myoglobin (and become strikingly redder) as a sea lion develops from 6 months of age to adulthood.

Each individual sea lion must pass successfully through all the stages of maturation, from infancy to adulthood, if it is ever

to reproduce. Each individual must therefore function with the physiological capabilities of a 6-month-old, then the physiological capabilities of a 15-month-old, and so forth.

Recognizing that the O₂ storage capacities of immature sea lions are limited (see Figure 4.1), we might well expect that when a sea lion is young, its diving capabilities are also limited, compared with an adult. This expectation is supported by the available evidence. Young sea lions at 6, 15, and 23 months of age do not dive as long or as deep as adults (Table 4.1). Six-month-olds exhibit very limited diving performance and get most of their food from nursing. Even 23-month-olds dive to depths averaging only 62% as deep as those attained by adults. A youngster does not have as much hemoglobin or myoglobin per unit of body weight as an adult. Consequently, its O₂ store is lower, and its capacity to function without breathing is more limited. Its capacity to gather food in each dive is therefore also more limited. Despite such constraints, the animal must find ways to succeed as a youngster, or it will never be a reproductive adult. In this way, the physiology of all the successive stages of individual development—**developmental physiology**—is a life-and-death matter for every individual.¹

The Physiology of Immature Animals Always Differs from That of Adults

Universally, the physiology of youngsters differs in important ways from that of the adults of their species, gradually changing in age-specific ways as postnatal development takes place. For one way to see these points, consider the maturation of three categories of tissues in humans, shown in Figure 4.2a. The brain matures rapidly. Already by 7 years of age, a person's brain has reached its full adult size, whereas general body tissues are less than half developed at that age and the reproductive organs have hardly started to grow. For comparison, note that this developmental program differs dramatically from that in rats, in which reproductive maturity is attained before full brain growth (Figure 4.2b).

The developmental program evolved by humans is unique because of the rate of brain maturation, which is far higher than in any other species of mammal. A consequence of this fast brain development is that young children are in a dramatically different

¹Another, commonly used term for individual development is *ontogeny*.

TABLE 4.1 Diving durations and depths observed at four different ages in Australian sea lions (*Neophoca cinerea*)^a

Age	Maximum duration (min)	Mean duration (min)	Maximum depth (m)	Mean depth (m)
6 months	2.7	0.4	29	7
15 months	5.8	3.2	68	40
23 months	5.8	2.8	78	44
Adult	7.5	3.3	103	71

Source: Fowler et al. 2006.

^aAverages are listed. Statistically, all the values for subadult ages are significantly different from the corresponding adult values (bold text), with the exception of the mean duration for 15-month-olds. Numbers of animals studied were 7–9 in each subadult category and 25 in the adult category.

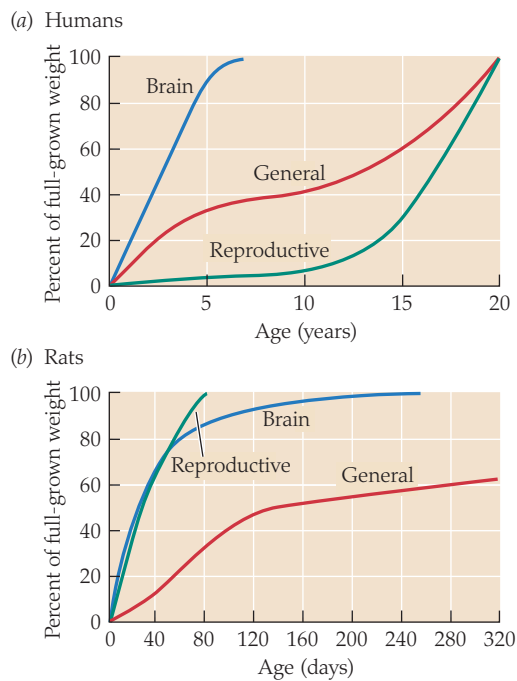

FIGURE 4.2 Growth of the brain, reproductive organs, and other (“general”) tissues in humans and laboratory rats Each tissue type is plotted, at each age, as a percentage of its full-grown weight. (After Bogin 1999.)

position from adults in the challenge they face to meet their brain’s energy needs. Brain tissue in mammals has a particularly high metabolic rate per gram—and therefore a particularly high need for fuel per gram—compared with most tissues; the metabolic rate per gram of brain is more than 10 times that of skeletal muscle, for example. The high per-gram metabolic rate of brain tissue explains why, in human adults, the brain accounts for about 20% of total body metabolism (see p. 181) even though brain weight is only 2% of body weight. In young children, the brain accounts for far more than 20% of total metabolism. Because of the rapid, early development of the brain in humans, a youngster who is 4 to 5 years old has a brain that is almost full size (see Figure 4.2a) even though the youngster’s body is small. Biologists have calculated that in children of that age, the brain accounts for approximately 50% of total body metabolism! Half of the food metabolized by a 4- or 5-year-old is for his or her brain! One implication is that childhood starvation—a common phenomenon around the world—is a particular threat to the most crucial of all human tissues.

Beyond brain energetics, countless cases are known in which brain performance undergoes maturation during the normal development of young animals, with long-term consequences for each individual. Striking examples come from the study of birds that employ the stars to help guide them during nocturnal migration, such as indigo buntings (*Passerina cyanea*), which breed in North America, and garden warblers (*Sylvia borin*), which breed in Europe. In both of these species, youngsters hatch and undergo their early development in the Northern Hemisphere. As adults, these birds migrate to warmer latitudes each winter. They migrate at night, and during their migration they are able to determine compass directions—such as whether they are flying north or

south—by looking at the stars. Obviously, the stars, *in and of themselves*, do not provide compass information. When a person determines north and south from the stars, the person does so by having learned that particular stars serve this purpose. Birds must do much the same thing. Experiments have shown that young indigo buntings and garden warblers, during their first summer of life, observe the rotation of the stars in the sky (Figure 4.3) and undergo a maturational change whereby thereafter they possess a brain record of the stars at the center of the rotation. They then associate those stars with north. Without this maturation during their early weeks of life, they cannot determine compass directions from the stars. Normally, of course, they are able to observe the stars during their early development, and consequently, when they head south for the first time in the autumn of their first year of life, they possess a fully functional star compass to guide them. The necessity for star observations during early development was discovered by manipulative experiments in a planetarium, where the stars can be made artificially to rotate around any spot in the sky. If birds undergo their early development in a planetarium where the stars rotate around a spot in the eastern sky, they later treat the eastern stars as if those stars are in the northern sky, so when they travel north based on their internal calculation of direction, they actually travel east.

Thermoregulation is another aspect of physiology that undergoes postnatal development. Adult mammals and birds are noted for physiological regulation of body temperature, termed **homeothermy**. Placental mammals, for example, typically maintain a deep body temperature of about 37°C as adults (see p. 250). Universally, however, newborn mammals are not as effective in maintaining homeothermy as adults of their species. Individuals develop their full capacity for homeothermy as they mature from birth to adulthood.

FIGURE 4.3 The apparent rotation of the stars when looking north in the Northern Hemisphere The stars seem to make circles around the northern end of Earth’s axis because of Earth’s rotation. This apparent movement of the stars is evident in a long exposure of the northern sky, as in this photograph. During early development, indigo buntings and garden warblers use the apparent rotation of the stars to identify north (the center of the apparent circles), and they undergo a maturational change whereby they thereafter possess a brain record of the stars positioned at the north.

An example is provided by the white-footed mouse (*Peromyscus leucopus*), one of the most common native rodents in North America (see Chapter 11 for additional examples). Individual adult white-footed mice can maintain a deep body temperature near 37°C when the air temperature is below freezing. Individual newborns, however, quickly cool to the environmental temperature; in a near-freezing environment, their tissues cool to near-freezing temperatures (which they tolerate). As young white-footed mice grow and mature during their 3-week-long nestling period, the peak rate per gram at which they can metabolically generate heat increases dramatically (Figure 4.4a). In addition, they develop

FIGURE 4.4 Development of thermoregulation in white-footed mice (*Peromyscus leucopus*) Four properties are shown as functions of age between birth (age 0) and 3 weeks of age, when weaning occurs. (a) Peak thermogenic rate. (b) Whole-body insulation (*I*) (see Equation 10.10). (c) The lowest air temperature at which an isolated individual can thermoregulate for 2.5–3.0 hours. (d) The number of hours per day that nestlings spend out of the nest when the air temperature outside is 7–10°C or 16–20°C. In all parts, the data are means for all individuals studied. (After research by Richard W. Hill; photos courtesy of Robert J. Robbins.)

fur, and their resistance to heat loss (their whole-body insulation) increases (Figure 4.4b). The mice therefore become increasingly able to thermoregulate as isolated individuals, away from their nest and siblings (Figure 4.4c). By 18 days of age, a lone youngster can thermoregulate for several hours even in freezing-cold air, and it capitalizes on this newfound ability by making its first excursions outside its nest (Figure 4.4d).

Physiological development occurs at all scales. The scale of individual proteins is particularly fundamental, because proteins determine the structural and metabolic properties of a tissue.

One class of proteins of great importance is the enzymes. A common pattern during development is for enzymes in a tissue to be upregulated—increasing their amounts and activities—in an almost stepwise fashion, under genetic control, as the tissue matures. For example, Figure 4.5 shows such stepwise upregulation of three enzymes in a single tissue, the liver, of developing rats. As new enzymes appear in cells (and old ones disappear), their

FIGURE 4.5 Sequential upregulation of enzymes during development in laboratory rats Activities of three enzymes in the developing liver are shown. Day 0 on the *x* axis is the day of birth; negative times are days before birth. (After Walker 1983.)

collective catalytic and regulatory properties alter cell metabolism. For instance, although early fetal rats cannot synthesize liver glycogen because they lack glycogen synthetase, newborn rats *can* because the required enzyme is suddenly expressed during the 5 days before birth.

The tissues in which a protein is highly expressed may also undergo developmental change. To illustrate this phenomenon, we will use a fish example. In many species of fish, the importance of the physiology of young animals is particularly evident because over 99% of individuals die before they complete their embryonic and larval life. In such cases, if you want to know the physiological characteristics that help to determine whether *most* individuals live or die, you need to look at the physiology of embryos and larvae.

Many species of fish complete a substantial portion of their early development before their gills form, raising the question of how and where gill functions are met before the gills develop. For fish living in seawater, Cl^- ions need to be transported out of the body to prevent the body fluids from becoming overly salty. In adults, this transport is carried out by the gills, but where does this transport occur in embryos and larvae? Often, eggs are spawned into the ambient water, where fertilization occurs. The embryos and larvae thus develop in seawater and have a need to transport Cl^- out of the body, like adults do, despite having no gills or only partly developed gills.

The cells that transport Cl^- ions out of the body, known as **chloride cells** (see Box 28.1), can be identified because they express the transporter protein $\text{Na}^+-\text{K}^+-\text{ATPase}$ (see page 110) in abundance (the protein is crucial for their ion-transport function). Because these cells profusely express this specific protein, they can be located using immunocytochemistry. In this technique, an antibody is made against a protein of interest— $\text{Na}^+-\text{K}^+-\text{ATPase}$ in this case—and when tissues are exposed to this antibody, the antibody binds wherever its target protein occurs. By visualizing the binding sites, one can learn the locations where the target protein is

expressed (and how abundant it is). This method has revealed the fascinating developmental patterns depicted in **Figure 4.6**. In the species shown, a killifish, young that are 8 days old or younger do not have gills.² They do, however, have chloride cells, which—at these early ages—are found in the yolk sac membrane and scattered over the surface of the skin (see **Figure 4.6a**). By 15 days of age, the young have emerged from the egg membrane (typically at 11 days), and the yolk sac has been reabsorbed. Still, chloride cells are found widely on the skin surface (see **Figure 4.6b**). In addition the gills have started to develop in 15-day-olds and are populated to some extent with chloride cells (see **Figure 4.6c**). Later, as killifish progress to adulthood, chloride cells cease to be found on the general skin surface and become mostly localized in the gills (and inner opercular membranes). In all, a major shift occurs in the location of outward Cl^- transport as a killifish develops. At first, the yolk sac and skin are the principal sites of transport. Later, the skin and gills become the principal sites, and still later, transport becomes localized principally to the gills.

Lately, investigators have become able to study gene transcription itself during the course of development by using DNA microarrays and other transcriptomic methods (see Chapter 3). For an example, we return to the developing lab rat, one of the most intensely studied model systems. **Figure 4.7** shows the temporal pattern of expression of spinal cord mRNAs. As you can see, different sets of mRNAs are upregulated sequentially during development, confirming that different sets of genes are transcribed at different times in a developmental program. Some of the mRNAs in the studied sets code for enzymes. Programmed transcription of the sort observed in **Figure 4.7** can thereby give rise to sequences of enzyme upregulation such as those seen in **Figure 4.5**.

²Ages are counted from conception.

FIGURE 4.6 Early development of chloride cells in killifish (*Fundulus heteroclitus*) living in seawater. The chloride cells are responsible for transporting Cl^- ions out of the body so the tissue fluids do not become overly salty. In these images, the chloride cells have been labeled with an antibody that glows green in the light used to produce the images. Ages are measured from conception. (a) The cells occur in the yolk sac membrane (which is highly vascularized) and skin at 8 days of age, when the gills have yet to develop. At 15 days of age, chloride cells (b) still occur widely on the skin and (c) occur in the gills, which have started to develop. (After Katoh et al. 2000; images courtesy of Toyoji Kaneko.)

FIGURE 4.7 Developmental programming of gene transcription in fetal and newborn rats The graph shows quantities of three sets of mRNAs in the developing spinal cord. Almost 120 mRNAs were monitored in this study. Some (not shown here) were steady or declined. Note that time is scaled differently before and after birth. Day 0 on the x axis is the day of birth; negative times are days before birth. (After Wen et al. 1998.)

Phenotypic Plasticity during Development

Phenotypic plasticity, as discussed in Chapter 1 (see pages 15–16), is the ability of a single animal—with a fixed genotype—to express two or more genetically controlled phenotypes. Phenotypic plasticity is frequently observed during development. An animal's adult phenotype, for instance, often differs if the animal matured in one type of environment rather than another. Two human examples will provide a good starting point for discussing this highly significant phenomenon.

The first example concerns the age at which **menarche**—first menstruation—occurs in girls. Many European countries have historical records on menarche dating back to at least the nineteenth century. Analyses of these records show that, on average, girls did not attain menarche until 16 to 17 years of age in the mid-nineteenth century, whereas they attained menarche at about 13 years of age in the second half of the twentieth century. Most scholars have concluded that this dramatic shift toward earlier menarche between the mid-nineteenth and late twentieth centuries was a consequence of improved nutrition, public health, and medical care. That is, population genotypes did not change in ways that caused the recorded shifts in menarche. Instead, changes in the environment were responsible. Girls in the late twentieth century reached reproductive maturity when they were several years younger than girls in the mid-nineteenth century because they enjoyed a more benign childhood environment.

The second human example concerns the restriction of growth that is often observed in people who live in a relative state of nature. Based on recent, detailed studies, 4- to 12-year-old children in

populations of Maya people in Guatemala are, on average, 5.5 cm (2 inches) shorter at each age than children in populations of the *same* ethnic group who recently settled in the United States. From every perspective—public health, sufficiency of the food supply, access to medical care, and political security—Maya populations in Guatemala face greater environmental challenges than do those in the United States. Evidently, the environmental stresses in Guatemala impair growth, and when those stresses are relaxed, children attain greater stature at each age.

Several historical comparisons—although not as well documented as that of the Maya—also point to a strong environmental effect on human growth. Medieval armor on display in museums, for example, is often striking for how small it is. Clearly the medieval people who wore the armor were smaller than the modern people who today look at it. **Figure 4.8** compares the stature of youngsters in two early populations in the British Isles with the stature of recent British youngsters. The factory children studied in 1833 were far shorter than modern children at each age—16–20 cm (6–8 inches) shorter in their teenage years. A 14-year-old factory child in 1833 was about as tall as a 10- or 11-year-old today! The factory children were, in fact, dramatically shorter than aristocratic children living at the same time they lived; Francis Galton (1822–1911) commented that working-class children and aristocratic children of that time could be told apart by their heights, and the fact that the elite grew faster helped reinforce their social status. As seen in Figure 4.8, youngsters in a medieval English rural population were even a bit shorter than the nineteenth-century factory children. The rude conditions of life that existed for medieval people and nineteenth-century factory children are believed to have been responsible for their short statures.

Examples such as these emphasize that the developmental environment can exert strong effects on an individual's phenotype. The developmental program does not unfold as a strictly genetic process, and the phenotype is not simply a fixed property set by genes (as some popularizations of genetic determinism argue). The phenotype, instead, is a product of interaction between genes and environment—with the developmental environment often being particularly important.

FIGURE 4.8 Height as a function of age in three groups of children in England The “Recent children” and “Factory children in 1833” were living subjects when measured. The “Children in the medieval village” (Wharram Percy) had died in childhood, and their skeletons were later excavated; height was calculated from bone lengths, and age was estimated from dental features. (After Mays 1999.)

Phenotypic plasticity is known today to occur in such a wide range of contexts that the question arises of whether a single term—“phenotypic plasticity”—is appropriate. Possibly several distinct types of phenomena are being lumped under that one rubric. Here, nonetheless, we use the global term “phenotypic plasticity” because a consensus has not yet emerged on an alternative terminology.

Environmental effects during development may arise from programmed responses to the environment or may be forced by chemical or physical necessity

Now we need to focus on a significant question that arises in all studies of phenotypic plasticity—the question of whether environmental effects develop as programmed responses or are forced on the animal. Two further examples—deliberately chosen to illustrate extremes—will set the stage.

Recent research has shown that when marine periwinkle snails *Littorina obtusata* or blue mussels (*Mytilus edulis*) grow in the presence of crabs over a period of weeks, they upregulate shell deposition and develop thicker shells than members of the same species that grow without predators being present. No contact is required between the crabs and molluscs. For example, when snails share the same water with crabs, the snails develop shells that are more than 10% thicker, even when the snails and crabs are kept separate; the snails detect that crabs are nearby by use of chemical cues in the water. To eat the flesh of a snail or mussel, a crab must first crack the mollusc’s shell with its claws. A thicker shell therefore protects against crab predation.

A different effect of the environment on development is seen when studies are directed at brain function following malnutrition. Particularly rigorous studies can now be conducted on *spatial learning*—the ability to learn and remember locations—in rats and mice, by using two devices, the *Morris water maze* and *radial-arm maze* (see page 497). In the Morris water maze, a small platform is positioned beneath the water surface in a pool in which a test animal swims (rats and mice swim readily). An opaque dye is added to the water so that the animal cannot see the platform. When an animal is first introduced into the water maze, it swims at random until it finds the platform and can crawl out of the water. Later, as the procedure is repeated over and over, the animal will exhibit learning with each repetition. The rat or mouse will arrive at the platform sooner and travel less distance to find it. Many studies have shown that when recently born rats or mice are subjected to a low-protein diet during their postnatal development, they exhibit impaired performance in the water maze, even long after being returned to a fully adequate diet. Thus, deficiencies in an animal’s nutritional environment during development cause an easily demonstrated, long-term deficit in capacity to learn.

A persistent question in studies of phenotypic plasticity is whether adaptive evolution in the past is responsible for the pattern of phenotypic plasticity observed. In the case of snails having their development altered by the presence or absence of predators, the pattern of phenotypic plasticity is summarized as follows: When predators are absent, a snail grows an ordinary shell, but when predators are present, a snail grows a thickened shell.³ This pattern of

plasticity could readily be advantageous in all respects, in that a snail does not expend extra energy to synthesize and carry a thickened shell when such a shell is unneeded, but it develops an augmented shell in the presence of danger. Accordingly, natural selection could well have favored the evolution of this pattern of plasticity. That is, the plasticity might well be genetically programmed because it has become inbuilt over evolutionary time by positive selection.

In contrast, in the case of rats having their brain development altered by availability of dietary protein, the pattern of plasticity is summarized as follows: When dietary protein is adequate, a rat develops a normal capacity for learning, but when dietary protein is inadequate, a rat grows up to be deficient in its ability to learn. Probably, this pattern of plasticity, instead of being a product of adaptive evolution, simply represents pathology. In a protein-poor environment, the relevant part of a rat’s brain (the hippocampus) may simply be unable to develop normally, and in that case the observed learning deficiency would be *forced* on the rat by chemical or physical necessity.

In many cases of developmental phenotypic plasticity, no means presently exist to resolve the question of causation. Accordingly, different biologists sometimes take opposite stances. Recall, for example, the low growth rates and delay of menarche in human populations living under stressful environmental conditions. Most biologists tend to think that these effects are simply pathologies; according to this reasoning, poor public health and uncertain nutrition prevent normal growth and maturation. Some biologists, however, argue that when environmental conditions are harsh, growth and maturation are programmed to be slowed because there are advantages to being small-bodied when food is scarce, and there are advantages to delaying reproduction when daily life is difficult.

Insect polyphenic development underlies some of the most dramatic cases of phenotypic plasticity

Many species of insects exhibit **polyphenic development**, a phenomenon in which *genetically identical* individuals can assume two or more distinct body forms, induced by differences in the environment. The body forms of a polyphenic species can be so dramatically different that anyone but a specialist would think they represent different species. In **Figure 4.9**, for example, both butterflies shown

FIGURE 4.9 Polyphenic development In the western white butterfly (*Pontia* [*Pieris*] *occidentalis*), any one individual can express either of the phenotypes shown; the difference between phenotypes represents phenotypic plasticity and is not caused by differences in genotype. This species goes through more than one generation each year, and the phenotype changes with the season in which an individual develops—a case of seasonal polyphenism. (Courtesy of Tom Valente.)

³In technical terms, this sentence is a statement of the norm of reaction discussed in Box 1.2.

belong to one species, and indeed either of the individuals could have developed either of the wing patterns. Polyphenic development is a particularly striking form of phenotypic plasticity.

The species shown in Figure 4.9 exemplifies a particular type of polyphenic development. Many species, including the one shown in the figure, go through two or more generations each year, and individuals that develop in one season differ in body form from those that develop in another season—a phenomenon termed **seasonal polyphenism**. Day length and temperature during development often serve as cues that help determine which body form an individual will assume. Two hormones, juvenile hormone and ecdysone (see Table 16.5)—and the timing of their secretion relative to endogenously timed sensitive periods—are frequently implicated in the control of seasonal polyphenism.

Extensive studies have established that in the western white butterfly (*Pontia [Pieris] occidentalis*) shown in Figure 4.9—and in several other butterflies—seasonal polyphenism aids thermoregulation. In these butterflies, an individual requires a high thoracic temperature to fly; if the thorax is too cool, the flight muscles cannot develop sufficient power. The required high body temperature is achieved by complex sun-basking behaviors. Owing to seasonal polyphenism, adults have different amounts and patterns of dark pigment (melanin) in their wings during different seasons as exemplified by Figure 4.9. Careful studies have shown that seasonal timing of the different phenotypes aids thermoregulation in that (1) during cool seasons, the prevailing wing phenotypes aid absorption of solar radiation for warming (as in the spring butterfly in Figure 4.9, which has dark wings), whereas (2) during hot seasons, the prevailing wing phenotypes offer more options for avoiding solar overheating.

Probably the most stunning examples of phenotypic plasticity in the animal kingdom are provided by migratory locusts—notorious since ancient times for their capacity to descend from the sky in incomprehensible numbers. Swarms are large and fast-moving—capable of decimating vegetation over large swaths of land (Figure 4.10). In some cases, a swarm may comprise tens of millions of locusts per square kilometer, and it may extend at any single time over a total land area of 100 km² or more.

Both *Locusta migratoria* and *Schistocerca gregaria*, the species of migratory locusts that have been best studied, exhibit polyphenic development. They have two behavioral phenotypes—*solitary* and *gregarious*. These two phenotypes, besides differing in behavior, also differ strikingly in their morphology (e.g., coloration). No genetic difference exists between individuals that show the solitary and gregarious phenotypes. Instead, any individual can exhibit either phenotype. When an individual exhibits the solitary phenotype, it avoids other individuals. Solitary individuals are inconspicuous and difficult to find in their natural setting. However, when circumstances bring individuals displaying the solitary phenotype into contact with each other for a few hours, they transform to the gregarious phenotype and begin to associate avidly with other locusts. That transformation is the starting point for swarm formation. The adaptive advantage is

FIGURE 4.10 Migratory locusts in their gregarious phenotype move across the landscape in voracious, fast-moving swarms

postulated to be that the fast-moving, voracious behavior of swarms enables locusts in a swarm to collect large quantities of food. When locusts in the solitary phenotype become crowded together—signaling that numbers in their population may be outstripping their food supply—the transformation to swarming poises them to collect food at an enhanced rate.

Recent research has pinpointed two biogenic amines (see Table 13.2) as key agents that physiologically mediate the transformation from solitary to gregarious. In *Schistocerca gregaria*, serotonin is both necessary and sufficient to induce transformation to the gregarious phenotype. In *Locusta migratoria*, dopamine is the principal agent of phenotype change, although serotonin also plays a role.

SUMMARY Phenotypic Plasticity during Development

- Phenotypic plasticity is the capacity for an individual of fixed genotype to exhibit two or more genetically controlled phenotypes. Because the phenotype expressed is often dependent on the prevailing environment, phenotypic plasticity is a process by which genotype and environment interact to determine the phenotypic characteristics of an individual.
- Phenotypic plasticity is often programmed by a genetically coded, physiological control system that determines which specific phenotypes are expressed under which specific environmental conditions. Such control systems are subject to natural selection over evolutionary time and may, therefore, in themselves represent adaptations. At the opposite extreme, changes of phenotype in different environments may simply be forced by chemical or physical necessity. A major challenge for biologists is to develop empirical ways to determine whether instances of phenotypic plasticity represent adaptations or products of chemical or physical forcing.

■ Polyphenic development in insects is perhaps the most striking form of phenotypic plasticity. In a species with polyphenic development, an individual with a fixed genotype can express two or more highly distinct phenotypes. Solitary and gregarious forms of migratory locusts provide an example.

Epigenetics

Epigenetics refers to modifications of gene expression—*with no change in DNA sequence*—that are transmitted when genes replicate.⁴ Although we usually think of *genes* being transmitted during gene replication, *gene expression* differences are transmitted when epigenetic effects are at work. Some epigenetic modifications of gene expression are environmentally induced. Some, having been environmentally induced in embryonic cells during the early development of an animal, are passed to all the cells in the adult animal that arise, during development, from the cell lineages initially affected. Some are passed, many researchers argue, from parents to offspring—meaning that epigenetics provides a mechanism whereby environmental effects can be transmitted from one generation to the next. The existence of this stunning phenomenon discredits the old dogma that, in the transmission of hereditary material, the genes are isolated from environmental influences. Interest in epigenetics has soared in the past 15 years, as evidenced by a 10-fold increase in the number of pertinent scientific papers published each year. Because most of the flurry of interest is focused on human disease processes and effects of toxic chemicals,⁵ the degree to which epigenetics is a factor in normal animal physiology is only starting to be clarified. A great deal of attention from physiologists can be expected in the near future.

Epigenetics provides an entirely new dimension in which genes and environment interact. To see this, let's first reflect again on programmed phenotypic plasticity, which—as we have just seen—is another process that mediates interaction between genes and environment in the determination of phenotype. In cases of programmed phenotypic plasticity, although genes control the program, the genes themselves are not modified in any way. For example, consider the case of snails and crabs discussed earlier. Snails develop an ordinary shell when crabs are not present in their environment, but they develop a thickened shell when crabs are present in their environment. A genetic program orchestrates the control sequence by which snails use sensory information from their environment to modulate shell formation. However, the genes responsible for this program—speaking loosely—*use* the environmental information *without being modified* by it.

By contrast, in some forms of epigenetic modification, the expression of genes is semi-permanently altered by interaction with the environment. An affected gene is said to be **marked** in such a way that its expression is modified, and when the gene replicates, its marking also replicates so that the resulting gene copies also have their expression modified in the same way. The environmental modification of gene expression is thereby passed along as gene replication

⁴In the research literature, other definitions can be found, but this is the definition around which the greatest consensus now exists.

⁵Strong evidence for transmission of epigenetic effects across generations, from parents to offspring, comes mostly from studies of the effects of toxic agents—putting these effects outside the scope of this text.

takes place. All the while, the DNA sequence of the gene remains unaltered. Phenotype is modified by the sort of gene–environment interaction seen in epigenetics, but it is modified in a different way than in programmed phenotypic plasticity. In the case of epigenetics, phenotype is altered because genes are directly modified in a transmissible way by marking, and the marking causes their expression to be different than it was before the environmental effect.

Phenotypes arising from epigenetic modification (similarly to ones arising from phenotypic plasticity) may, in principle, be adaptive for the organism or not. If a particular epigenetic modification has been subject to natural selection over evolutionary time, it may prove to be a product of positive selection and advantageous. However, when environmental agents chemically force epigenetic marking (as is known to occur), the epigenetic modifications may have negative effects. Adaptive effects cannot be assumed.

Two major mechanisms of epigenetic marking are DNA methylation and covalent modification of histones

One of the most widely observed and best-understood mechanisms of epigenetic marking is DNA methylation: the attachment of methyl ($-\text{CH}_3$) groups by covalent bonds to cytosine residues in the structure of DNA. In the most common version of this process, methylation is at a promoter region of DNA, and when it occurs there, the gene regulated by the promoter is repressed or silenced. When a marked cell replicates, an enzyme (usually the DNA methyltransferase DNMT1) acts to *perpetuate* the mark by methylating the same cytosine residues in each daughter cell (**Figure 4.11**), meaning that

FIGURE 4.11 Methylation of DNA, a type of epigenetic mark, is perpetuated during DNA replication. In this way, the gene expression modification caused by methylation is transmitted to daughter cells.

the affected gene is repressed or silenced in the daughter cells. The end result is that a modification of gene expression in the initial cell is transmitted to the daughter cells during cell replication, while the DNA sequence remains unchanged.

Another important mechanism of epigenetic marking is covalent modification of the histones (basic proteins) around which DNA is wrapped in the nucleosomes of the chromatin of a cell. Modification can be by methylation, acetylation, phosphorylation, or other binding of modulators, and it usually occurs on the NH_2 -terminal tails of the histone molecules. Distinctive histone variants, resulting from covalent modification, act as epigenetic marks.

Additional mechanisms of epigenetic marking also exist. Small RNA molecules play roles, for example.

Epigenetic marking during an animal's early development affects the animal's lifelong phenotype

Epigenetic effects are often instrumental in ordinary tissue differentiation. During early development, the developmental program places epigenetic marks on genes in various cell lineages, this being one of the mechanisms whereby different patterns of gene expression are established in different tissue types. The divergent patterns of gene expression help give cells their divergent tissue-specific phenotypes. When a marked cell divides, its epigenetic marks are passed to each daughter cell (see Figure 4.11), serving (along with other mechanisms) to perpetuate the cell's tissue-specific phenotype.

A fascinating recent study has illustrated how an *environmental* epigenetic effect can be added to the sort of ordinary

epigenetic developmental effects just discussed. During the winter of 1944–1945, a food embargo was imposed on part of The Netherlands as one of the final spasms of World War II. The citizens were exposed to severe famine in what has come to be called the Dutch Hunger Winter. Studies of pregnant laboratory rats subjected to malnutrition throughout conception and pregnancy have shown that certain genes in their offspring have fewer methylation marks than in ordinary rats. To see if this same phenomenon occurs in humans, researchers tracked down 60 people, all now over 60 years old, who were conceived during the Dutch famine and compared them with same-sex control siblings who were not conceived during the famine. DNA was extracted from the whole blood of each subject and analyzed for methylation marks associated with cytosine residues in a gene of particular relevance. As Figure 4.12 shows, there is a statistically strong tendency for the individuals who were conceived during the famine to exhibit a lower percentage of marked DNA sites than their sibling controls. As noted already, methylation marks are generally associated with reduced gene expression. Accordingly, reason exists to expect that the reductions of methylation marks induced by famine are allowing greater expression of some genes.

A stunning consideration to recognize in this study of Dutch people conceived in famine is the timescale. The original environmental effect was exerted on their cells when they were embryos. That effect is now evident more than 60 years later in their current blood cells, probably having been transmitted through a great many cell divisions in the cells that multiply to produce blood cells.

FIGURE 4.12 Conception during famine exerts an epigenetic effect

Each of the 60 red symbols on the plot represents a person conceived in famine during the Dutch Hunger Winter of 1944–1945. Along the x axis, the symbol is plotted at the time of conception. The scale on the y axis shows the difference in percent methylation of sites in a focal gene between the famine-conceived individual and a same-sex sibling not conceived in famine. The red line, depicting the average response, is below zero (0) to a statistically significant extent ($P < 0.00002$), indicat-

ing that famine-conceived individuals tend to exhibit a reduced extent of DNA methylation. The daily ration of food per person was tightly regulated and recorded, and is shown at the bottom; note that during the famine (December 1944 to May 1945), the daily ration per person was far below 2000–2500 kcal, the range of values considered ordinary. The two people in the photograph were victims of the food embargo in the winter of 1944–1945. (After Heijmans et al. 2008.)

An additional important consideration is the association that researchers have discovered between (1) early famine or malnutrition and (2) later cardiovascular and metabolic disease. This association is one of the best-documented examples of epigenetic control of individual phenotype. The association has been extensively investigated by means of epidemiological studies of humans and experimental studies of other mammals, most notably lab rats. Famine or malnutrition during pregnancy—especially early pregnancy—predisposes offspring to a variety of disease states that often develop relatively late in life, including cardiovascular diseases and metabolic diseases (e.g., diabetes and obesity). Although the mechanism of this association is not fully understood, strong evidence indicates that epigenetic marks play a role. Possibly, therefore, the alteration of marks observed in the 60-plus-year-old Dutch people is not merely of abstract, academic interest. The research on those people may have directly revealed epigenetic changes—wrought when they were embryos—that now, late in their lives, affect their odds of developing coronary artery disease, hypertension, and other ailments. In fact, separate studies have shown that these people show an unusually high prevalence of obesity and coronary artery disease.

Effects of maternal care represent another of the best-documented examples of epigenetic control of individual phenotype. After genetically homogeneous female lab rats have given birth, they exhibit two patterns of maternal care during their offsprings' first week of life. One pattern—termed *low-LG*—is characterized by low amounts of licking and grooming of the young; the other—*high-LG*—is characterized by high amounts of licking and grooming. Although the young of these two types of mothers are homogeneous in their DNA sequences, they develop into adults that display multiple differences. In adulthood, the high-LG offspring are less behaviorally fearful and show lesser endocrine responses to stress than the low-LG offspring. Direct chemical measurements on genes in hippocampal tissue from the brain show that the high-LG offspring differ significantly in epigenetic marking from the low-LG offspring. The results of extensive experiments show that the differences in maternal behavior between the two types of mothers epigenetically program their offspring to differ in fearfulness and endocrine responsiveness to stress in adulthood!

One of the most striking of all epigenetic effects in the lives of individual animals, an effect just discovered, is the control of caste in honeybees. Worker honeybees and queen honeybees develop from the same genotype. They have radically different phenotypes, however—a case of polyphenic development (discussed earlier). Workers, for example, do not produce offspring, whereas queens produce thousands. A remarkable recent experiment has shown that if DNA methylation—a type of epigenetic marking—is blocked, an individual originally destined to develop into a worker develops, to a great extent, into a queen. This evidence—bolstered by additional observations—points to gene-expression differences, arising from differences in epigenetic marking, as being the cause of caste differentiation. More than 20% of genes in the brains of developing worker and queen bees are expressed differently, depending on epigenetic marks. The differences in epigenetic marking (DNA methylation pattern) between the two castes arise, during early development, based on whether or not an individual is fed extensively with *royal jelly*. The royal jelly, which is fed principally to individuals that are

developing into queens, is a complex chemical substance made by glands in the mouths of young nurse bees.

There is a dramatic common denominator to all the effects discussed in this section. Namely, the origin of adult differences is in early development—mediated by epigenetic gene-expression modification.

Epigenetic marks on paternal and maternal copies of genes set the stage in mammals and insects for the two copies to exert nonequivalent effects

An embryo receives one copy of each gene from its father and a second from its mother. Incidental, exceptional examples have long been known in which the two copies—alleles—are unequally expressed. Recent research, however, has brought nonequivalent expression to the fore by demonstrating that a phenomenon termed **genomic imprinting** occurs in some types of organisms. In genomic imprinting, the allele inherited from the father may be expressed exclusively (or predominantly), or the allele from the mother may be expressed exclusively (or predominantly)—because of epigenetic marks. At present, genomic imprinting is known to occur only in mammals, insects, and flowering plants. In mammals, the number of genes subject to imprinting is not particularly great, being roughly in the range of 100 to 1000 (different species are not entirely identical in which genes these are). Although genomic imprinting thus has a restricted distribution, it is nonetheless emerging as a phenomenon likely to be of great importance in certain contexts. Reason exists to believe that genomic imprinting evolved in mammals in association with the evolution of the placenta, although placental functions for imprinting are not yet well known.

An essential feature of genomic imprinting is that *the transcription mechanism recognizes epigenetic imprinting marks during the transcription process*. Suppose, for example, that in the cells of an animal, the allele of a particular gene inherited from the animal's father is marked. The transcription mechanism recognizes this. Accordingly, transcription of the paternal allele may be regulated differently than that of the maternal allele. For example, only the paternal allele might be transcribed, or only the maternal allele might be. In general, marking is by DNA methylation. The usual assumption is that marks are added in the germ line (cells that give rise to sperm and eggs) in the parental generation. Then, after zygote formation—and during growth of an offspring—the marks are maintained and are present in the cells of the offspring, permitting the transcription mechanism to recognize which allele is paternal and which is maternal.

Although most research on genomic imprinting in animals has focused on human diseases, recent papers have suggested that imprinting may play a major role in normal brain development and function. By studying embryonic and adult lab mice using cutting-edge transcriptomic methods, researchers have established that expression of imprinted genes is far greater in some parts of the brain than in others. Moreover, a bias exists for preferential expression of *maternal* alleles during embryonic development, whereas in adults, a bias exists for expression of *paternal* alleles. And there is an effect of offspring gender: Females exhibit three times more expression of imprinting effects from their parents in certain critical brain regions than males. Surveying all these known effects, we can see that imprinting—differential expression of the alleles from mother and father—is implicated in region-

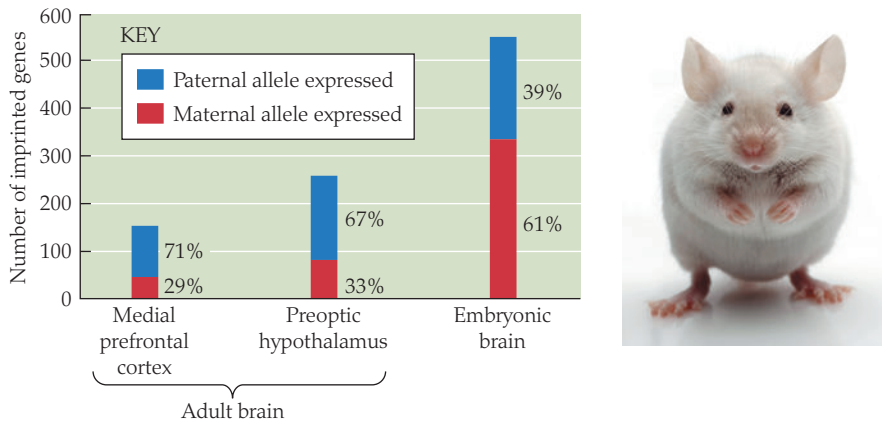

FIGURE 4.13 In the brain of the laboratory mouse, genomic imprinting exhibits differences from region to region and from one stage of development to another. In the adult brain, the number of genes showing imprinting differs to a statistically highly significant extent from one region of the brain to another (e.g., medial prefrontal cortex versus preoptic hypothalamus). Comparing the adult and embryonic brain, in genes where genomic imprinting is evident, the paternal allele is expressed in well over half the cases in the adult brain (67–71%), whereas the maternal allele is expressed in over half the cases in the embryonic brain (61%). This difference is also highly significant statistically. (After Gregg 2010.)

specific, time-of-development-specific, and gender-specific brain function (Figure 4.13). Imprinting therefore has the potential to be richly involved in the processes by which the brain develops and functions, although only further research will resolve how much this potential is actually realized.

SUMMARY Epigenetics

- Epigenetics refers to changes in gene expression that are transmitted during gene replication despite the lack of any alteration in the DNA sequence. The mechanism of epigenetic control is that genes are marked in ways (e.g., DNA methylation or histone modification) that modify their expression and the marks are replicated when the genes are replicated.
- Epigenetic marking is often initiated by environmental conditions because of the action of programmed control systems or of chemical or physical forcing. Accordingly, epigenetic control is a specific mechanism by which genotype and environment interact to determine phenotype.
- Because epigenetic marks are replicated from cell to cell as cells divide in an individual, epigenetic marks induced by the environment early in development can be perpetuated throughout life and affect the adult phenotype.
- Genomic imprinting, presently known only in mammals and insects among animals, is a particular case of epigenetic control in which maternal or paternal alleles in an individual are marked and therefore can be differentially transcribed, resulting in nonequivalent expression in determining the individual's phenotype.

Study Questions

1. You are asked to give a 20-minute talk to high-school students on why nutrition matters in a child's first years of life. Your assignment is to present a biologist's perspective. Write your talk.
2. Genotype and environment interact to produce the phenotype of an animal. Explain comprehensively the types of mechanisms by which this interaction takes place.
3. Rigorously define phenotypic plasticity, polyphenic development, and epigenetics. Outline how they relate to each other.
4. Explain why the physiological properties of individual animals *at each stage of their development* are crucially relevant for their ecological and evolutionary success.
5. As seen in Figure 24.20, freshwater water fleas (*Daphnia*) develop without hemoglobin (Hb) and are whitish when living in well-aerated water but produce abundant Hb and are red in O₂-depleted water. Explain how each of these phenotypes could be advantageous (relative to the other) in the environment where it is expressed.
6. Regarding the water fleas in Question 5, describe experiments you could carry out to test empirically whether (1) the low-Hb phenotype is more advantageous than the high-Hb one in well-aerated water and (2) the high-Hb phenotype is superior to the low-Hb one in O₂-poor water.
7. After studying Box 1.2, state in your own words the meaning of norm of reaction. Give an example.
8. Write a short explanatory essay on the following statement: "In cases of genetically programmed phenotypic plasticity, natural selection acts on the norm of reaction. Thus the norm of reaction as a whole—rather than any one phenotype—determines if selection is positive or negative."
9. In northern latitudes, a variety of birds and mammals create storage depots of food, termed *caches*, in the autumn and later can find the caches in winter to obtain food. What experiments could be done to determine if the ability to find caches is fully innate at birth or must undergo postnatal development?
10. Some molecules found in foods are known to be capable of driving DNA methylation or DNA demethylation. For example, folic acid (a vitamin), vitamin B₁₂, and choline are thought to increase methylation. Based on this consideration, why would it be important to avoid eating *excessive* quantities of such molecules (while being certain to eat sufficient quantities for health)?
11. In principle, what consequences might be expected to arise from an environmentally induced shift in the age of reproductive maturation? Think as broadly as possible. Answer the question for the human populations, discussed in this chapter, in which menarche shifted to occur more than 3 years earlier between the mid-nineteenth and late twentieth centuries. Also answer for a nonhuman mammal such as a species of squirrel or antelope.

Transport of Solutes and Water

Hummingbirds are dietary specialists that feed almost exclusively on flower nectars, which are principally solutions of sucrose (table sugar), plus other sugars, notably glucose and fructose. When sucrose itself is digested, it yields glucose and fructose. Thus a hummingbird has an abundance of glucose and fructose in its intestines after digesting a meal, and these simple sugars represent its immediate reward for feeding. The sugars, however, are in solution in the lumen—the hollow central core—of the intestines, and for them to do the bird any good, they must move into the bloodstream to be carried throughout the body.

You might at first imagine that glucose and fructose in the lumen of a hummingbird's intestines could simply diffuse across the intestinal epithelium into blood vessels. However, the hydrophilic or hydrophobic nature of the molecules is a factor (see Chapter 2). Glucose and fructose are hydrophilic, and because hydrophilic molecules tend not to mingle with hydrophobic ones, the sugars can be expected to have difficulty dissolving in the highly hydrophobic interior of the apical and basolateral cell membranes of the epithelial cells lining the intestine. In fact, the glucose and fructose from a meal cannot diffuse into a hummingbird's bloodstream at significant rates. How then do they move into the blood? Questions of this sort are among the most common and important faced in the study of animal physiology.

In the life of any animal, many materials must move across cell membranes and epithelia in substantial quantities to resupply cells or tissues with needed raw materials, to void wastes, to maintain the proper composition of body fluids, and to otherwise maintain the animal's integrity. The **solutes**—that is, the dissolved materials—that move across cell membranes and epithelia are chemically very diverse, and the mechanisms by which solutes and water cross are numerous. Thus a question that quickly arises is this: What term should be used to describe the movements globally? In this book we use the term **transport** to refer, in an entirely general way, to any and all movements of solutes or water across cell membranes or epithelia, regardless of the mechanisms of movement.

Three examples in which transport is important to animals will help define the subject of this chapter and provide a focus for our study of transport. Here we describe the examples. Later, as the chapter unfolds, we will return to all three to elucidate the specific transport processes involved.

1. One of our focal examples is a *single cell inside an animal's body*. A typical animal cell is bathed by extracellular fluid. Thus we can think of the cell membrane as separating an *intracellular fluid* on the inside from an *extracellular fluid* on the outside (Figure 5.1 a). The solutions on the inside and outside of a cell are normally similar in their *sum-total* concentrations of dissolved matter; speaking more exactly, they have similar osmotic pressures.¹ Consequently, the solutions inside and outside a typical cell do not tend to exchange water in net fashion by osmosis to a great degree.

¹Osmotic pressures and osmosis are discussed later in this chapter.

Mechanisms must exist to transport sugars from the open central cavity of a hummingbird's intestines into its blood following a meal Nectars are unusually rich in sugars. We may well wonder if sugar-transport mechanisms are exceptionally developed in hummingbirds because of the birds' nectar diets.

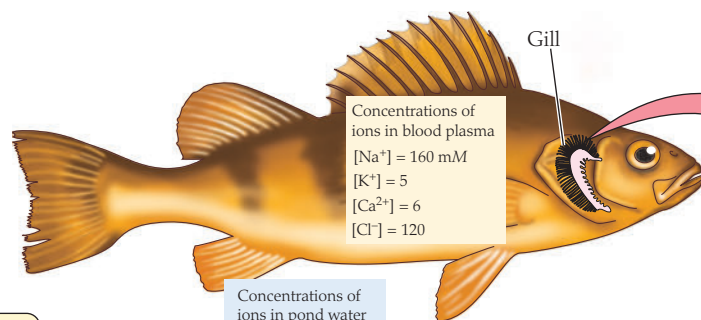

(a) A single animal cell: relative ion concentrations inside and outside

The size of the lettering symbolizes relative ion concentrations inside and outside the cell. Na^+ , K^+ , and Cl^- differ substantially in their concentrations inside and outside.

(b) The gill epithelium of a freshwater fish: relative ion concentrations on the two sides

Concentrations of ions in blood plasma
 $[\text{Na}^+] = 160 \text{ mM}$
 $[\text{K}^+] = 5$
 $[\text{Ca}^{2+}] = 6$
 $[\text{Cl}^-] = 120$

Concentrations of ions in pond water
 $[\text{Na}^+] = 0.5 \text{ mM}$
 $[\text{K}^+] = 0.1$
 $[\text{Ca}^{2+}] = 0.2$
 $[\text{Cl}^-] = 0.3$

Ion concentration differences across the gill epithelium are important because, unlike most body surfaces, the gill epithelium is permeable to ions.

(c) The epithelium of the small intestine: glucose transport across the epithelium

Glucose and other nutrient molecules from digested food must be transported across the intestinal epithelium to enter the blood.

Cross section of small intestine

FIGURE 5.1 Three focal examples in which transport occurs. Study of the three examples shown in this figure will bring to light most of the basic principles of solute transport. (a) A typical cell in an animal's body, surrounded by extracellular fluid. A^- represents anionic (negatively charged) proteins and other solutes that cannot cross the cell membrane and thus are trapped inside the cell. (b) A freshwater fish, showing representative ion concentrations in the blood plasma and surrounding pond water. A thin epithelium is all that separates the blood plasma and water in the gills of the fish. (c) A diagram of the small intestine of a bird or mammal, emphasizing the intestinal epithelium lining the lumen. In reality the epithelium is microscopically thin.

However, the *solute compositions* of the two solutions differ dramatically. The concentration of potassium ions (K^+) is much higher inside an animal cell than outside, for instance, whereas sodium (Na^+) and chloride (Cl^-) ions are typically less concentrated inside than outside. These differences in solute composition suggest that the intracellular fluid of a cell is not at equilibrium with the extracellular fluid bathing the cell. What are the transport mechanisms by which ions such as Na^+ and K^+ move toward equilibrium across a cell membrane, and what are the transport processes that keep the intracellular fluid different in composition from the extracellular fluid?

2. Our second focal example is the *outer gill membrane of a freshwater fish living in a pond or stream*. The fluid portion of the blood of a freshwater fish—known as the fish's *blood plasma*—is much more concentrated in Na^+ , Cl^- , and other inorganic ions than the surrounding pond or stream water is (Figure 5.1b). In the fish's gills, the relatively concentrated blood plasma is separated from the dilute pond water by just a thin epithelium. Because the gill epithelium is a permeable rather than impenetrable barrier, the blood

plasma tends to lose ions such as Na^+ and Cl^- to the pond water across the epithelium, and H_2O tends to enter the plasma from the pond water across the epithelium. What are the transport mechanisms by which inorganic ions and H_2O cross the gill epithelium? Are there transport mechanisms in the epithelium that help maintain the difference in composition between the fish's blood plasma and the environmental water?

3. Our third focal example is the *intestinal epithelium of the small intestine of a bird or mammal*. As we saw in Chapter 2 (see Figure 2.5b), this epithelium consists of a single layer of cells bearing microvilli on their apical cell membranes (Figure 5.1c). As stressed already in our discussion of hummingbirds, dissolved sugar molecules such as glucose and fructose must cross this epithelium from the intestinal lumen to the blood after a meal if they are to be of use to an animal. The same is true of dissolved amino acids and other compounds. What are the transport mechanisms that move each of these materials across the epithelium?

As we start our study of transport mechanisms, an important organizing principle is the distinction between *passive* transport

mechanisms and *active* ones. To define *passive* and *active* in this context, we first need to define **equilibrium**. Be cautious of the term, because it is commonly used in nonscientific ways, such as when people say that an angry child has “recovered his equilibrium” or that a city has reached “equilibrium size.” These sorts of uses tend to confuse rather than clarify the scientific meaning of the term.

An accurate definition of *equilibrium* is based on the second law of thermodynamics, which describes the behavior of systems, termed **isolated systems**, that have no inputs or outputs of energy or matter.² The second law of thermodynamics states that when an isolated system undergoes change, it is not able to change in all conceivable ways. Instead, an isolated system can change in only certain, limited ways. Equilibrium is, by definition, the state toward which an isolated system changes; that is, it is the state toward which a system moves—internally—when it has no inputs or outputs of energy or matter. A system is *at equilibrium* when internal changes have brought it to an internally stable state from which further *net* change is impossible without system inputs or outputs. *The state of equilibrium is a state of minimal capacity to do work under locally prevailing conditions.* Thus a change toward equilibrium is always in the direction of decreasing work potential.³

Passive-transport mechanisms, by definition, are capable of carrying material only in the direction of equilibrium. **Active-transport mechanisms**, by contrast, *can* carry material in the direction opposing equilibrium. The word *can* is emphasized for an important reason: An active-transport mechanism does not *necessarily* carry materials in the direction opposing equilibrium, but it is *capable* of doing so.

Passive Solute Transport by Simple Diffusion

Simple diffusion is the most straightforward form of passive solute transport. To understand simple diffusion, consider a beaker divided by a nonliving membrane that is penetrated by many microscopic pores through which the sugar glucose, but nothing else, can pass. A solution of glucose in water is placed on each side of the membrane, with the solution on the left having a higher glucose concentration than that on the right. Viewing this beaker *macroscopically* (Figure 5.2a), we know from everyday experience what will happen: Glucose will move in net fashion from left to right across the membrane until ultimately the concentration of glucose is equal on both sides. However, what is the *mechanism of motion* that carries glucose from left to right? In addition, why do the concentrations of glucose on the two sides *stay equal* once they have become equal?

Answering these questions will reveal the nature of simple diffusion. To answer them, we need to look at the beaker *microscopically*. At temperatures above absolute zero, all atoms and molecules undergo ceaseless random motions. Imagine that you’re taking a microscopic look at the membrane and the solutions just on either side, and you fix your eye on a particular glucose molecule to the left of the membrane (Figure 5.2b). This molecule, like all the others, will be moving constantly, sometimes colliding with and bouncing off other molecules in random directions. There is a chance that one of these random motions will carry the molecule through a pore in

FIGURE 5.2 Simple diffusion viewed macroscopically and microscopically (a) A beaker is divided in half by a porous artificial membrane that permits passage of glucose molecules, but nothing else. The solutions on either side of the membrane differ in glucose concentration (symbolized by different dot densities), and glucose diffuses through the membrane. (b) Looking at the same system microscopically reveals that random motions are more likely to carry glucose molecules from left to right than from right to left. A point to stress is that glucose pores of the sort in this example occur only in artificial membranes, not in living biological membranes.

the membrane to the right-hand side, as the figure shows. Over a period of time, more glucose molecules will move in this way from left to right than from right to left, merely because there are more glucose molecules per unit of volume on the left. Macroscopically, these individual molecular events will result in net glucose transport from left to right. Once the concentrations on the two sides have become equal, glucose molecules will continue to move at random from left to right and from right to left. The numbers of molecules going in the two directions will then be equal, however, because of the equal numbers of glucose molecules per unit of volume on the two sides. Thus, at a macroscopic level, the concentrations on the two sides will remain equal once they have become equal.

The mechanism of glucose transport that we have just described is **simple solute diffusion**. Such diffusion is *transport that arises from the molecular agitation that exists in all systems above absolute zero and from the simple statistical tendency for such agitation to carry more molecules out of regions of relatively high concentration than into such regions.* Note that simple solute diffusion could not possibly *increase* the difference

² We say much more about the second law of thermodynamics in Chapter 7.

³ Appendix J provides background on work and other physics concepts used in this chapter.

in glucose concentration between the two sides of a membrane. The equilibrium state for the beaker in Figure 5.2 is a state of equal glucose concentration on both sides, and simple solute diffusion can change the glucose concentrations only *toward* equilibrium. Thus simple solute diffusion is a *passive* transport mechanism.

Simple diffusion is not limited just to solutes in aqueous solutions. Because molecular agitation is universal, simple diffusion is universal: Gases diffuse in air; water diffuses; even heat diffuses. As we now discuss the quantitative principles of the simple diffusion of solutes in aqueous solutions, it is worth noting that all simple-diffusion phenomena follow similar principles. Thus, later when we discuss the quantitative laws of gas, water, and heat diffusion,⁴ you will notice close similarities to the principles we now address. Finally, note that simple diffusion is often called just *diffusion*.

Concentration gradients give rise to the most elementary form of simple solute diffusion

Solute molecules diffuse between any two regions of a solution, whether or not a membrane is present. To understand the quantitative laws of solute diffusion, we start with diffusion in an open solution, which is the most general case. Consider a still, open solution in which a solute, such as glucose, is at a relatively high concentration (C_1) in one region and at a relatively low concentration (C_2) in another. Imagine a representative 1-cm^2 cross-sectional area in the low-concentration region, facing toward the high-concentration region. As solute molecules diffuse into the low-concentration region from the high-concentration region, we can count the numbers of molecules passing through this representative cross-sectional area per second. Specifically, we can count the *net* numbers that diffuse into the low-concentration region per second (the numbers diffusing in, minus the numbers diffusing out). Let J be the net rate of diffusion into the low-concentration region; that is, J is the net number of solute molecules passing into the low-concentration region per second through each unit of cross-sectional area. Then

$$J = D \frac{C_1 - C_2}{X} \quad (5.1)$$

where X is the distance separating the region of high concentration (C_1) from the region of low concentration (C_2), and D is a proportionality factor termed the **diffusion coefficient**. This formulation is often called the **Fick diffusion equation**, after Adolf Fick (1829–1901), who devised it.

The terms on the right-hand side of the Fick equation reveal important aspects of diffusion. Note that the rate (J) at which solute molecules diffuse into the low-concentration region is directly proportional to the difference in concentration ($C_1 - C_2$). Note also that the rate increases as the distance separating the two concentrations (X) decreases: Diffusion is a notoriously slow process for transporting substances from one place to another in the macroscopic world, but when only a tiny distance separates regions of differing concentration, diffusion can transport substances very rapidly. **Table 5.1** illustrates this crucially important point. The table focuses on rates of diffusion when there is a concentration difference of a small solute between two regions of a water solution. The table

⁴Diffusion of gases is discussed in Chapter 22 (see page 572). Diffusion of liquid water is discussed later in this chapter, and that of water vapor in Chapter 27 (see page 705). Diffusion of heat (heat conduction) is covered in Chapter 10 (see page 230).

addresses the question: How much time is required for enough solute molecules to cross into the low-concentration region to reduce a concentration difference to half of its starting magnitude? The time required is *32 years* if the distance between regions is 1 meter (m), but it is only *100 nanoseconds* if the distance between regions is 10 nanometers (nm)—the approximate thickness of a cell membrane! The high rate of diffusion across minute distances helps explain why diffusion is a crucially important process in the lives of cells.

In the Fick equation, the ratio $(C_1 - C_2)/X$ is called the **concentration gradient**. It expresses how much the concentration changes per unit of distance. Note that J , the diffusion rate, is proportional to it. Sometimes the term *concentration gradient* is used in a looser sense to refer only to the difference of concentration ($C_1 - C_2$).

For analyzing complex solutions, an aspect of the concentration effects on diffusion that is worth emphasizing is this: The rate of diffusion of any particular solute is determined by the concentrations of *that* solute, not the concentrations of other solutes that might be present. *Each solute diffuses according to its own concentration gradient.*

What determines the diffusion coefficient D ? One important factor is the ease with which the solute of interest moves through the material separating the two concentrations; when diffusion is occurring through a cell membrane or an epithelium, this factor is termed the *permeability* of the membrane or epithelium to the solute (permeability is discussed later in this chapter). Another factor that determines D is temperature. As temperature rises, random molecular motions become more vigorous (see Chapter 10). Thus the rate of diffusion increases.

If a fluid current flows over the surfaces of an animal or cell, that flow can also affect the rate of diffusion. Suppose the concentration of a solute is 100 millimolar (mM) in the body fluids of an aquatic animal and 2 mM in the ambient water. The outward diffusion of the solute will then tend to create a *boundary layer* of elevated solute concentration next to the animal's body surface (**Figure 5.3**).

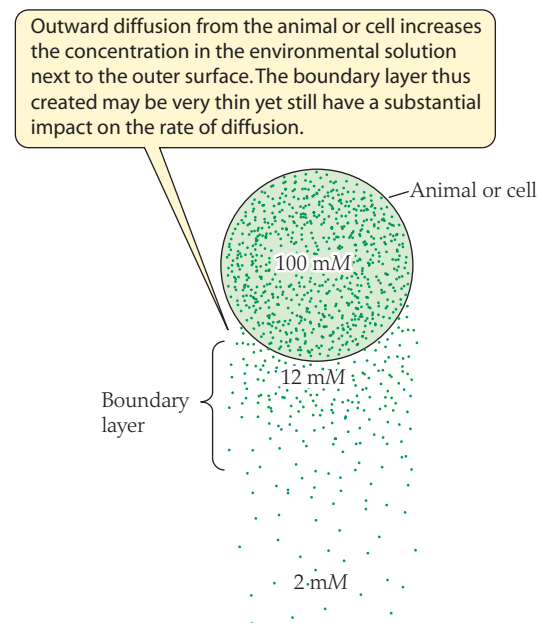

FIGURE 5.3 Diffusional concentration of a solute in a boundary layer next to an animal or cell In this example, the concentration of the solute is 100 mM inside the animal or cell and 2 mM in the open environmental solution.

TABLE 5.1 The time required for diffusion through water to halve a concentration difference

Values are calculated for small solutes such as O_2 or Na^+ . For each tabulated distance between solutions, the time listed is the time required for diffusion to transport half the solute molecules that must move to reach concentration equilibrium. It is assumed that no electrical effects exist, and thus only diffusion based on concentration effects is occurring.

A biological dimension that exemplifies the distance specified	Distance between solutions	Time required to halve a concentration difference by diffusion
Thickness of a cell membrane	10 nanometers	100 nanoseconds
Radius of a small mammalian cell	10 micrometers	100 milliseconds
Half-thickness of a frog sartorius muscle	1 millimeter	17 minutes
Half-thickness of a human eye lens	2 millimeters	1.1 hours
Thickness of the human heart muscle	2 centimeters	4.6 days
Length of a long human nerve cell	1 meter	32 years

Source: After Weiss 1996.

The presence of the boundary layer decreases the rate of diffusion. One way to understand this effect in terms of Equation 5.1 is to consider the effect of the boundary layer on X , which is the distance separating the two concentrations, 100 mM and 2 mM; without the boundary layer, these two concentrations would be separated just by the thickness of the outer epithelium of the animal, but with the boundary layer, the two concentrations are also separated by the thickness of the boundary layer itself, which increases X . Increasing the flow of water over an animal or cell tends to carry solute away from areas of accumulation at the animal or cell surface, thereby decreasing boundary-layer thickness. This decreases X and therefore increases the rate of diffusive solute loss from the animal or cell.

Electrical gradients often influence the diffusion of charged solutes at membranes

Many solutes of biological importance—such as Na^+ , Cl^- , and other inorganic ions—bear an electrical charge. The motion of charged solutes—in addition to being affected by concentration gradients—is influenced by forces of *electrical attraction or repulsion*, forces that do not affect the movement of uncharged solutes such as glucose. As individual ions or other charged solutes move ceaselessly because of atomic-molecular agitation, their paths of motion are affected by the attraction of positive charges toward negative ones, and by the tendency of like charges (e.g., two positive ones) to repel.

To understand *where* such electrostatic effects need to be considered in the analysis of diffusion, a key principle is that *solutions at large* are electrically neutral. In **bulk solution**—the solution that is away from contact with a membrane—the concentrations of positive and negative charges are always equal (Figure 5.4). The *net* charge in any region of bulk solution is therefore zero. Moreover, because all regions of bulk solution have zero net charge, regions do not differ in net charge. This means that in bulk solution, the charges on solutes do not affect their diffusion, and diffusion simply follows the *concentration*-based principles we have already discussed.

In contrast to what happens in bulk solution, electrical attraction and repulsion can play large roles in diffusion *along or across cell membranes or epithelia*. This is true because the lipid bilayers in cell membranes can maintain separation of oppositely charged ions—meaning that different regions of solution can differ in net electrical charge—by acting similarly to capacitors in electrical circuits.⁵ Within a few *nanometers* of a cell membrane or epithelium, the solution on one side may have a net positive charge because positive ions outnumber negative ones. Conversely, within a few nanometers of the membrane or epithelium, the solution on the other side may have a net negative charge because negative ions outnumber positive ones (see Figure 5.4). Under these circumstances the diffusion of electrically charged solutes may be greatly affected by electrical attraction and repulsion.

⁵Appendix J discusses capacitance and other physics concepts used in this chapter.

FIGURE 5.4 Ionic charge separation occurs only within nanometers of membranes

Thus only in the vicinity of membranes do conditions exist for the diffusion of charged solutes to be affected by electrical attraction and repulsion.

Biological aspects of diffusion across membranes: Some solutes dissolve in the membrane; others require channels

Principles we discussed at the start of Chapter 2 return to center stage when we consider the chemical mechanisms of the diffusion of solutes through cell membranes or epithelia. The interior of a cell membrane is hydrophobic because it consists principally of the hydrocarbon tails of phospholipid molecules composing the lipid bilayer (see Figure 2.1). The ease with which a solute can diffuse directly through the lipid interior of a cell membrane thus depends on the hydrophobic or hydrophilic nature of the solute.

Let's start by considering *lipid solutes*, such as steroid hormones and fatty acids, which are hydrophobic. Molecules of these solutes *dissolve* in the lipid interior of a cell membrane. In this dissolved state, they make their way from the side of the membrane where they are more concentrated to the side where they are less concentrated because of molecular agitation and the other principles of simple diffusion we have been discussing. *Molecular oxygen* (O_2), which is small and nonpolar, is also generally believed to make its way through cell membranes primarily or exclusively by simple diffusion through the lipid layers, without the need of channels or other proteins. Certain signaling molecules besides steroid hormones, such as *thyroid hormones* and *nitric oxide*, are also believed to cross cell membranes in this way.

Inorganic ions present a very different picture because they are hydrophilic and therefore have very low solubilities in membrane lipids. Studies using experimental *all-phospholipid* membranes demonstrate that the rates of simple diffusion of ions directly through membrane lipids are exceedingly low. However, ions of physiological importance—such as Na^+ , K^+ , Ca^{2+} (calcium), and Cl^- —can sometimes move passively through *actual* cell membranes at very rapid rates. They are able to do this because their passive transport through cell membranes is mediated by integral membrane proteins termed *ion channels*.

The defining characteristic of **ion channels** is that they permit the *passive* transport of inorganic ions by diffusion through a membrane. This means that the directions and eventual equilibrium states of the ion movements through channels are determined not by the channels themselves, but by the chemical-concentration and electrical-charge gradients that exist across a membrane. Another key characteristic of channels is that the ions that pass through them do not bind to the channel proteins. Structurally, an ion channel consists of one or more protein molecules that extend across the full thickness of a cell membrane or intracellular membrane and that encircle a lipid-free central passageway through the membrane (see Figures 2.4 and 13.16). From this fact and the fact that ions do not bind to channels, one might think that channels are simple holes through the membrane. Actually, they are intricate protein structures that are *selective* in determining which ions can pass readily through them.⁶ Some ion channels, for instance, are specific for Na^+ . They permit Na^+ to move through the cell membrane at a relatively high rate but do not permit rapid passage of other ions. Other channels are specific for K^+ . Still others allow Na^+ and K^+ to pass with equal ease. Some channels allow several sorts of ions to pass, but even the least selective channels discriminate between anions and cations.⁷

⁶The ion selectivity of channels is discussed in detail in Chapter 12.

⁷Anions are negatively charged ions; cations are positively charged ions.

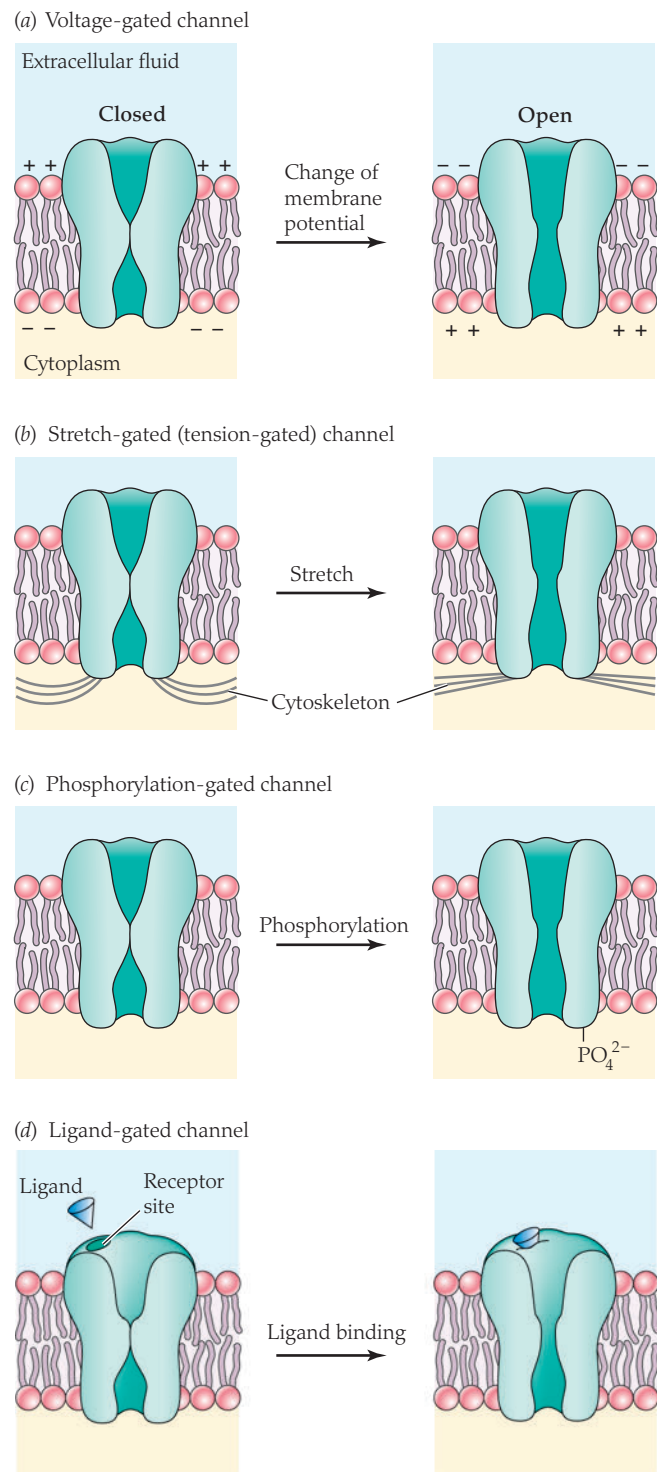

FIGURE 5.5 Gated ion channels Gated ion channels are classified into four functional categories based on which property must change for them to open and close: (a) transmembrane voltage, (b) stretch or tension, (c) phosphorylation, or (d) noncovalent binding with ligands at receptor sites.

Many ion channels are **gated channels**, meaning that they can “open” and “close” because the proteins of which they are composed are able to undergo conformational changes that cause their central passageways to increase or decrease the ease with which ions pass through (see Figure 12.20). Four categories of gated ion channels, distinguished by the mechanisms of gating, are recognized (**Figure 5.5**). **Voltage-gated channels** open and close in response to changes

in the voltage difference across a membrane; they are very important in the generation of nerve impulses. **Stretch-gated (tension-gated) channels** open or close in response to stretching or pulling forces that alter the physical tension on a membrane. **Phosphorylation-gated channels** open or close according to whether the channel proteins are phosphorylated; such channels are under the control of protein kinases (see page 50), which are often themselves controlled by second messengers (see pages 63–64). **Ligand-gated channels**, discussed in Chapter 2 (see page 58), act both as *receptors* of extracellular signals and as ion channels. They are closed to the passage of ions in the absence of a signal, but they open when their receptor sites bind to receptor-specific ligands (e.g., neurotransmitter molecules), thereby allowing the passage of selected ions.

The **permeability of a cell membrane to a solute** is defined to be the ease with which the solute can move through the membrane by diffusion. The concept of permeability applies both to solutes that dissolve in the membrane interior and to solutes that pass through channels. When Equation 5.1 is applied to solute diffusion through a membrane, the membrane permeability to the solute of interest helps determine D , the diffusion coefficient. For solutes, such as lipids and O_2 , that dissolve in the lipid bilayer to pass through a membrane, the permeability of a cell membrane depends on the factors that affect solute diffusion through lipid, such as the molecular size of the solute. For inorganic ions, the permeability of a cell membrane depends on the number of channels per unit of membrane area and on the proportion of the channels that are open. Permeability to an ion can be increased and decreased rapidly by the opening and closing of gated channels for the ion.

Cell membranes are often described as **selectively permeable** because they permit some solutes to pass through by diffusion with greater ease than others. One explanation for selective permeability is that different sorts of ion channels are often unequally present in a membrane. For example, if a membrane has a high density of Na^+ channels and a low density of Ca^{2+} channels, it is more permeable to Na^+ than to Ca^{2+} .

Diffusion of ions across cell membranes is determined by simultaneous concentration and electrical effects

The final aspect of the mechanism of simple diffusion that we need to consider is the manner in which concentration effects and electrical effects *interact* in affecting the diffusion of ions and other charged solutes. We have already seen that, in animal cells, there is a *concentration gradient* across the cell membrane for each major solute (see Figure 5.1*a*). The diffusion of each solute is affected by its own concentration gradient but not by the concentration gradients of other solutes. All cell membranes also exhibit charge separation. That is, there is always an **electrical gradient** across a cell membrane, defined to be the difference in voltage (electrical potential) between the two sides.⁸ The electrical gradient affects the diffusion of all charged solutes.

It is obvious that the diffusion of an ion or other charged solute must depend on *both* that solute's concentration gradient *and* the electrical gradient. A problem that soon arises in trying to *quantify* this dual effect is that concentration gradients and electrical gradients

are expressed in different units: molarity and volts, respectively. Walther Nernst (1864–1941), an early winner of the Nobel Prize, goes down in history for solving this problem. Using his *Nernst equation* (discussed in Chapter 12), investigators can directly compare concentration and electrical gradients to determine which is stronger, and thus predict the diffusion of an ion.

Here we take a more informal approach to understanding the dual effects of concentration and electrical gradients on an ion's diffusion across a cell membrane. We term the influence of the concentration gradient across the membrane on the ion's diffusion the **concentration effect** on the ion, and we term the influence of the electrical gradient on the ion's diffusion the **electrical effect** on the ion.

Sometimes the electrical charge difference across a membrane pulls an ion in the same direction as the ion is moving because of its concentration gradient. **Figure 5.6a** shows this situation in a model system. In such cases the electrical and concentration effects reinforce each other, and the presence of the electrical gradient *accelerates* diffusion compared with the rate at which it would proceed if only the concentration gradient were present.

On the other hand, the electrical charge difference and the concentration gradient sometimes act in opposite directions, as in **Figure 5.6b**. If the electrical effect on Na^+ diffusion in Figure 5.6*b* is weaker than the concentration effect, Na^+ ions diffuse, as shown, in net fashion from left to right—the direction favored by the concentration gradient—but *more slowly* than if the opposing electrical gradient were absent. If the electrical effect in Figure 5.6*b* is stronger than the concentration effect, Na^+ ions diffuse in net fashion from right to left—the direction favored by the electrical gradient—even though that direction of diffusion is opposite to what the concentration gradient alone would cause. A large voltage difference can cause an ion or other charged solute to diffuse in a direction that *increases* its concentration gradient!

A charged solute is *at equilibrium* across a membrane when the concentration effect on its diffusion and the electrical effect are equal but opposite. Under such conditions the solute will not move in net fashion in either direction. Such an equilibrium is called an **electrochemical equilibrium** to stress that both electrical and “chemical” (concentration) effects are involved. The concept of an electrochemical equilibrium is, in fact, an entirely general concept that can be applied whether a solute is charged or uncharged (if a solute is uncharged, no electrical effect exists, and therefore electrochemical equilibrium prevails when the concentration gradient is zero).

Diffusion often creates challenges for cells and animals

Because living creatures are inherently nonequilibrium systems and because simple diffusion moves solutes toward equilibrium, diffusion often creates challenges that must be met by energy expenditure. This point is illustrated by two of our focal examples, the individual animal cell and the freshwater fish (see Figure 5.1*a,b*).

Considering the cell first, let's examine the concentration and electrical effects on each of the three principal ions: Cl^- , Na^+ , and K^+ (**Figure 5.7**). A typical cell membrane is positively charged on the outside and negatively charged on the inside. The concentration and electrical effects on the diffusion of Cl^- across the cell membrane are therefore opposite to each other, because Cl^- is more

⁸A truly formal definition of the *electrical gradient* is that it is the difference in voltage divided by the distance between the high and low voltage levels. Less formally, the *electrical gradient* is simply the difference in voltage.

(a) Reinforcing concentration and electrical effects

(b) Opposing concentration and electrical effects

FIGURE 5.6 Ion diffusion depends on the dual effects of concentration and electrical gradients (a) Fast diffusion resulting from reinforcing concentration and electrical effects. (b) Slow diffusion resulting from opposing concentration and electrical effects. In both parts the different dot densities on the two sides of the membrane in the beaker symbolize the different Na^+ concentrations.

concentrated outside a cell than inside (favoring inward diffusion) but the inside of a cell membrane is negatively charged (repelling Cl^-). The magnitudes of the concentration and electrical effects on Cl^- are typically about equal, meaning that Cl^- is typically at or near electrochemical equilibrium across a cell membrane.

Na^+ presents an extremely different picture, however. The concentration and electrical effects on Na^+ diffusion are in the same direction; Na^+ is more concentrated on the outside of a cell than the inside, favoring inward diffusion, and the negative charges at the inside of the cell membrane also tend to draw Na^+ in by electrical attraction. Thus Na^+ is very far from electrochemical equilibrium across a cell membrane and has a great tendency to diffuse from the extracellular fluid into a cell. Of course, as stressed previously, Na^+ cannot cross the cell membrane unless open channels are present. However, there are sets of channels—called *resting channels*—that are open all or most of the time. These permit Na^+ to leak across the cell membrane. A cell therefore experiences a steady inward diffusion of Na^+ . This diffusion presents a challenge because it would do away with the Na^+ concentration gradient if it were unopposed. For a cell to maintain the normal Na^+ concentration gradient across its cell membrane, it must steadily get rid of Na^+ . That is, it must steadily use some of its energy resources to do work to oppose the effects of inward Na^+ diffusion.

The third major ion, K^+ , is not at electrochemical equilibrium across the cell membrane, but it is not as far from equilibrium as Na^+ . The concentration and electrical effects on K^+ tend to cancel rather than add (see Figure 5.7). The concentration effect on K^+ , however, exceeds the electrical effect. Animal cells therefore tend

steadily to lose K^+ by diffusion through resting channels. For cells to keep their inside K^+ concentration high, they must use energy to take in K^+ and counteract this diffusion. When we address active transport later in this chapter, we will discuss the mechanisms that cells use to move Na^+ out and K^+ in.

The major blood ions of a freshwater fish— Na^+ and Cl^- —are much more concentrated in the blood plasma of the fish than in surrounding freshwater—such as pond water—suggesting that the ions tend to diffuse outward across a fish's gills (see Figure 5.1b). At this point in our discussion, we recognize that electrical effects need to be taken into account, not just concentration effects. When investigators take both types of effects into consideration, however, they come to the same conclusion: For both Na^+ and Cl^- , the direction of simple diffusion is from the blood into the pond water. That is,

FIGURE 5.7 An electrochemical view of a typical animal cell. The size of the lettering symbolizes relative ion concentrations inside and outside the cell. A^- represents anionic proteins that cannot cross the cell membrane and thus are trapped inside the cell.

the ceaseless and unstoppable random motions of ions present a challenge to a freshwater fish by causing the fish to lose these important ions steadily from its blood. A fish could theoretically block the losses by making its whole body impermeable to the ions. However, fish need to breathe, and gills that are permeable to O_2 are inevitably also permeable to Na^+ and Cl^- . Freshwater fish lose Na^+ and Cl^- by diffusion, and they must replace what they lose. This task is accomplished by active transport, and it costs energy, as we will discuss soon.

Concentration gradients can create electrical gradients that alter concentration gradients

Thus far, we have discussed the diffusion of ions as if the process were purely the *consequence* of concentration and electrical gradients. Ion diffusion is actually more dynamic, however. Because cell membranes and epithelia are selectively permeable—excluding some solutes while allowing the passage of others—the concentration gradients of ions across cell membranes or epithelia can *create* electrical gradients that may then affect ion diffusion and ion concentration gradients.

To see how this process takes place, let's study an experiment in which the diffusion of K^+ along its concentration gradient produces a counteracting electrical gradient. For this purpose we will use the model system in **Figure 5.8**, in which a membrane that is *permeable only to K^+* separates two solutions. This membrane represents an example of selective permeability. At the start, shown in Figure 5.8a, the solutions on the two sides are equimolar, with one composed of K^+ and A_1^- (an anionic solute) and the other composed of Na^+ and A_2^- (another anionic solute). After the apparatus is set up in this way, K^+ will start to diffuse from left to right across the membrane because of its concentration gradient. This diffusion will *create* a voltage difference across the membrane because K^+ is charged; specifically, the diffusion of K^+ will cause more positive charges— K^+ ions—to accumulate along the right-hand surface of the membrane than along the left-hand surface. As the K^+ diffusion continues, this voltage difference will grow steadily larger, and it will keep growing larger until the electrical effect on K^+ diffusion (repelling K^+ from the right) fully counteracts the concentration effect (favoring diffusion to the right). At that point, illustrated by Figure 5.8b, K^+ will be at electrochemical equilibrium, and no further net diffusion of K^+ will occur.

Upon reviewing this experiment, you will see that when a membrane is selectively permeable and blocks some solutes from crossing, the diffusion of a permeating ion along its concentration gradient can *create* an electrical gradient. This sort of process produces the voltage difference, termed the *membrane potential*, that typically exists across the cell membrane of an animal cell (see Figure 5.7).⁹

When a membrane is permeable to more than one sort of ion, an electrical gradient produced by diffusion of any one ion will affect the diffusion of the others because of electrical attraction and repulsion. A complex type of electrochemical equilibrium involving diffusion of multiple ions (and osmosis of water) then tends to develop. The **Donnan**

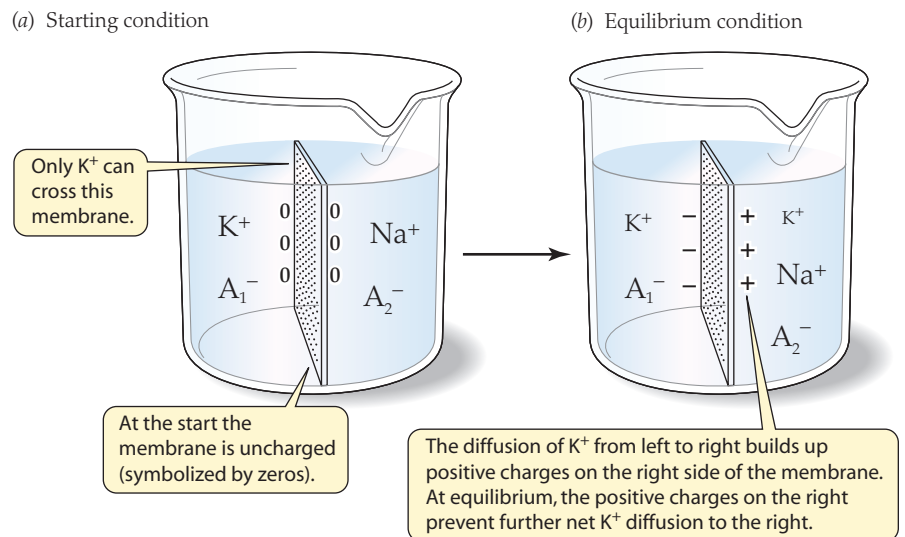

FIGURE 5.8 The development of an equilibrium in which a voltage difference generated by diffusion exactly opposes the remaining concentration gradient. Because K^+ is more concentrated on the left at the start (a), it diffuses to the right, causing accumulation of positive charges on the right side of the membrane. K^+ diffusion to the right continues—building up an ever greater voltage difference across the membrane—until eventually net K^+ diffusion stops (b) because the electrical effect on K^+ diffusion exactly opposes the remaining concentration effect. The size of the lettering symbolizes relative ion concentrations. A_1^- and A_2^- represent anionic solutes that cannot cross the membrane.

equilibrium, which you will see mentioned in advanced literature, is this type of equilibrium. Specifically, a Donnan equilibrium occurs across a membrane when a number of ions (anions and cations) can cross the membrane but there is a set of nonpermeating ions (ions that cannot cross the membrane) that are more abundant on one side of the membrane than the other. Animal cells tend toward Donnan equilibrium because, compared with the extracellular fluids bathing them, they have high concentrations of nonpermeating anionic materials (e.g., proteins and nucleic acids) within them.

SUMMARY Passive Solute Transport by Simple Diffusion

- A mechanism of solute transport is *passive* if it transports only *toward* electrochemical equilibrium. For an uncharged solute, the electrochemical equilibrium is the same as concentration equilibrium. For a charged solute, the electrochemical equilibrium is achieved when the voltage difference exactly counterbalances the solute's concentration gradient across a cell membrane or epithelium.
- Simple diffusion is the most straightforward type of passive solute transport. The fundamental mechanism of simple diffusion is exemplified most clearly by the diffusion of an uncharged solute in an aqueous solution. Molecular agitation tends by simple statistics to carry more molecules of such a solute out of regions of high concentration than into such regions, thereby tending to produce equality of concentration everywhere. If a solute is charged and diffusing where a voltage difference exists, forces of electrical attraction and repulsion affect the paths followed by molecules or ions during molecular agitation and thus contribute to diffusion.

⁹The generation of the *membrane potential* is discussed in detail in Chapter 12.

- Voltage differences can occur across cell membranes or epithelia because the lipid layers in cell membranes act as capacitors, permitting positive and negative charges to be unequally distributed on the two sides. Bulk solutions are electrically neutral, however, and voltage differences are therefore not a factor in simple diffusion within bulk solutions.
- When lipid solutes such as steroid hormones and fatty acids cross cell membranes by simple diffusion, they typically dissolve—because of their hydrophobic nature—in the lipid layers of the membranes. Ions, however, cannot cross membranes by this mechanism because of their poor solubility in lipids; thus their diffusion requires mediation by membrane proteins. Inorganic ions typically cross membranes by simple diffusion through ion channels. Channels are often gated—that is, opened and closed by factors such as ligand binding.
- The permeability of a membrane to a lipid solute depends on how readily the solute dissolves in and moves through the membrane lipid layer. The permeability of a membrane to an inorganic ion depends on the number of channels for the ion per unit of membrane area, and can be changed by the opening and closing of the channels.

Passive Solute Transport by Facilitated Diffusion

You may have noticed that when we discussed the passive movements of solutes across cell membranes in the last section, we did not mention *polar organic solutes*—such as glucose and amino acids. The reason we did not mention them is that when these solutes move passively across cell membranes, they typically do not do so by simple diffusion. Polar organic solutes cannot diffuse through the lipid interior of cell membranes because they are hydrophilic. Moreover, they cannot diffuse through channels because there are no channels for them. Passive transport of polar organic solutes across cell membranes occurs typically by the noncovalent and reversible *binding* of the solutes to solute-specific *transporter (carrier)* proteins¹⁰ in the membranes, a process called *facilitated diffusion*. As we discuss facilitated diffusion, it will be important to keep in mind that although polar organic solutes sometimes cross cell membranes by active transport, our focus now is exclusively on their *passive* transport.

Facilitated diffusion has three defining properties:

1. It always occurs in the direction of electrochemical equilibrium. This is why it is a form of passive transport and is called *diffusion*.
2. Solute transported by this mechanism move across membranes much faster than they could if they did not associate with transporter proteins. This is why the transport is called *facilitated*.
3. The mechanism requires solutes to bind reversibly with binding sites on the transporter proteins. This is why it is not a type of simple diffusion.

¹⁰Recall that Table 2.1 provides basic definitions of the functional categories of membrane proteins. Soon, in this chapter, we will provide an expanded definition of transporter proteins.

An important example of facilitated diffusion is the transport of glucose from the blood plasma into cells throughout an animal's body. Blood glucose typically crosses cell membranes to enter cells passively, aided by glucose transporters.¹¹ One of the most important effects of the hormone insulin in vertebrates is that it stimulates certain types of cells (notably muscle and adipose cells) to increase the numbers of transporter molecules in their cell membranes, thereby poising the cells to be able to take up glucose by facilitated diffusion at an accelerated rate (see page 436).

Active Transport

Animals are able to transport many solutes across their cell membranes and epithelia in directions away from electrochemical equilibrium by using ATP or some other input of energy from metabolism. Mechanisms capable of such transport are called **active-transport mechanisms** or **pumps**. Active-transport mechanisms do not *necessarily* move solutes away from electrochemical equilibrium, but they are *capable* of doing so. Historically, the secretion of stomach acid was the first case in which biologists realized that cellular mechanisms can generate nonequilibrium distributions of solutes. During the production of stomach acid by humans or dogs, cells with an internal pH of 7.1 to 7.2 (near neutrality) secrete dramatically acidic fluids with a pH as low as 0.8. The concentration of H⁺ in the secretions is more than 2 million times greater than the H⁺ concentration in the intracellular fluids! This huge difference in concentration is generated by active-transport pumps that draw the required energy (in this specific case) from ATP.

Active transport plays critical roles in all three of our focal examples. To see this, let's look first at the individual animal cell. We have seen that K⁺ is more concentrated inside a cell than in the extracellular fluids bathing the cell, and Na⁺ is less concentrated inside than out (see Figure 5.1a). We have also seen that diffusion tends to obliterate these concentration differences by carrying K⁺ outward and Na⁺ inward. Cells keep the inside K⁺ concentration high and the inside Na⁺ concentration low by using an active-transport mechanism that transports K⁺ in and Na⁺ out *at a cost*, using metabolic energy.

Active transport also plays critical roles in our other two focal examples—the freshwater fish and the vertebrate small intestine. In the case of the freshwater fish (see Figure 5.1b), Na⁺ and Cl⁻ are so much more concentrated in the fish's blood than in pond water that the two ions tend to diffuse out of the fish. A major mechanism by which a freshwater fish replaces lost ions is active transport of Na⁺ and Cl⁻ from the dilute pond water into its concentrated blood. By means of active-transport mechanisms in their gills, many fish can pump Cl⁻ from freshwater, where it is as dilute as 0.02 mM, into their blood plasma, where the concentration exceeds 100 mM. In the small intestines of vertebrates (see Figure 5.1c), active-transport mechanisms help transport sugars and amino acids from digested food into the blood. Active transport also plays countless other, vital roles in the lives of animals.

An instructive alternative name for *active transport* is **uphill transport**. For a rock on a hillside, the approach to equilibrium is to roll downhill. Uphill motion is away from equilibrium and

¹¹Because cells continuously use glucose, the concentration gradient for glucose is from the blood *into* the cells.

therefore requires an input of energy. Active-transport mechanisms are analogous to uphill motion in that they can make solutes move away from electrochemical equilibrium and require energy to do so.

Active transport and facilitated diffusion are types of carrier-mediated transport

For a solute to undergo active transport across a cell membrane, it must combine noncovalently and reversibly with a solute-specific *transporter* or *carrier* protein in the cell membrane. Active transport is therefore a form of **carrier-mediated transport**. Facilitated diffusion is also a form of carrier-mediated transport because, as we have noted already, it too requires binding of the transported solute to a transporter (carrier) protein. The two forms of carrier-mediated transport are distinguished by whether transport is driven by metabolic energy. In *facilitated diffusion*, no mechanism exists for metabolic energy to drive the process; thus transport is always toward electrochemical equilibrium. In *active transport*, metabolic energy is used to drive the process, so transport can be away from electrochemical equilibrium.

We have now reached a point where we can fully define **transporters (carriers)**, one of the five principal functional classes of membrane proteins (see Table 2.1). A transporter, or carrier, is a membrane protein that mediates *active* or *passive* transport across the membrane by binding noncovalently and reversibly with solute. *Carrier* is the older term and is the basis for the expression *carrier-mediated transport*. Physiologists originally called these proteins *carriers* because they believed the proteins linked up with solutes on one side of a cell membrane and then moved to the other side, carrying the solutes with them. By now it is clear that the proteins do not move through a cell membrane but instead stay in one place while they undergo *intramolecular conformational changes* that usher solutes through. The solutes that bind noncovalently and reversibly with a transporter protein are the **ligands** of the transporter.

An important attribute of carrier-mediated transport, whether active or passive, is that it exhibits saturation kinetics (see page 42). Saturation occurs because solute molecules must bind with transporter molecules. When the concentration of solute is so high that all transporter molecules are bonded with solute and engaged in transport at all times, the transport rate is maximal and cannot increase if more solute is made available.

Basic properties of active-transport mechanisms

Active-transport mechanisms in animal cells draw their energy directly or indirectly from ATP made by the catabolism of foodstuffs (see Chapter 8). Because of the requirement for ATP, active transport is sensitive to factors that affect a cell's ATP supply, such as poisons or O_2 deficiency. In some sorts of cells that are very involved with transport, such as certain kidney-tubule cells, active-transport mechanisms are the single biggest consumers of ATP, using as much as 40% of the ATP a cell makes.

A great diversity of active-transport mechanisms is known. Thus although any particular active-transport mechanism is specific for certain solutes, a great variety

of solutes can be actively transported in one situation or another, including inorganic ions, amino acids, and sugars.

However, active-transport mechanisms seem *not* to have evolved in animals for two of the most important chemical substances in physiology: H_2O and O_2 . Current evidence indicates that H_2O and O_2 *always move by passive transport in animals*.

An active-transport mechanism that transports ions is potentially able to create a voltage difference across a membrane because the mechanism moves charges. Active ion-transport mechanisms do not *necessarily* generate voltage differences, however, because they often simultaneously transport two ions, and the transport of two ions may be electrically neutral. For example, consider the pump—informally known as the **proton pump**—that in vertebrates is responsible for the extreme acidification of stomach contents. This active-transport mechanism (**Figure 5.9**) simultaneously transports H^+ (protons) into the stomach cavity and K^+ in the opposite direction *in a 1:1 ratio*. Mechanisms such as this, which do not generate an imbalance of electrical charge, are termed **electroneutral (nonelectrogenic)**. In contrast, an active-transport mechanism is **electrogenic** if the actions of the mechanism create a charge imbalance across a membrane.

Recognition of active transport completes our overview of a single animal cell

At this point we can complete our discussion of the first of our three focal examples, the single animal cell (see Figure 5.1a). We have seen that, in terms of its Na^+ and K^+ concentrations, a cell is not at equilibrium with its surroundings. This nonequilibrium state is maintained by a ubiquitous, exceedingly important pump, the **Na^+-K^+ pump**. During each cycle of pumping, this active-transport mechanism transports three Na^+ ions out of a cell and two K^+ ions in (**Figure 5.10a**). Among other things, the pump is therefore electrogenic: It helps create a charge difference across the cell mem-

FIGURE 5.9 Electroneutral active transport is responsible for secretion of stomach acid in the vertebrate stomach lining. This acid-secreting *parietal cell* is bounded by other types of cells in the epithelium lining the stomach.

FIGURE 5.10 Summary of active and passive ion transport in a typical animal cell (a) The action of the $\text{Na}^+\text{-K}^+$ pump in the cell membrane. (b) Active and passive ion transport processes, and related phenomena, in a cell. Again, the size of the lettering in the solutions symbolizes relative ion concentrations inside and outside the cell. The reason that Cl^- is approximately at electrochemical equilibrium is that its concentration gradient across the cell membrane is almost exactly opposed by the voltage difference across the membrane.

brane (outside positive) because it pumps more positive charges in one direction than the other.¹² The $\text{Na}^+\text{-K}^+$ pump is found in the basolateral membranes of all epithelial cells. It is found in all other sorts of animal cells as well.

Earlier (in discussing Figure 5.7) we concluded that a cell must transport Na^+ outward and K^+ inward, against electrochemical gradients, if it is to maintain observed differences of ion composition across the cell membrane (between the intracellular and extracellular fluids). The $\text{Na}^+\text{-K}^+$ pump carries out this transport using ATP-bond energy. Figure 5.10b summarizes the patterns of both active and passive ion transport between an animal cell and the extracellular fluids that bathe it.

Primary and secondary active transport differ in their cellular-molecular mechanisms

Active-transport mechanisms are classed as *primary* or *secondary* based on whether they use ATP directly or indirectly. We will discuss primary mechanisms first. Doing so will set the stage for drawing a rigorous distinction between the primary and secondary types.

One of the best-known transporter proteins engaged in active transport is **$\text{Na}^+\text{-K}^+\text{-ATPase}$** . This protein is the $\text{Na}^+\text{-K}^+$ pump discussed a moment ago. The molecule is called an **ATPase** because it is an *enzyme* that catalyzes the hydrolysis of ATP as well as a *transporter*. This hydrolysis provides the energy that the protein uses for active $\text{Na}^+\text{-K}^+$ transport. $\text{Na}^+\text{-K}^+\text{-ATPase}$ belongs to a category of ATPases called **P-type ATPases**. This name refers to

the fact that in these ATPases, the protein becomes phosphorylated and dephosphorylated during each pumping cycle.¹³

The mechanism by which ATP-bond energy is transduced into ion motive energy by $\text{Na}^+\text{-K}^+\text{-ATPase}$ —and by other P-type ATPases—has been dramatically clarified in the last 15 years and seems now to be largely understood. One key property is that these ATPases exhibit *strict coupling* between their molecular conformation and ATP hydrolysis: During each pumping cycle, the conformation of the transporter protein switches back and forth between two or more states, depending on whether the enzymatic hydrolysis of an ATP molecule has occurred. These conformation changes have two major effects on protein function. To understand these, we need to recognize that each molecule of a P-type ATPase has *cation-binding sites* deep within its molecular structure. Transported ions bind to these sites as they pass through the transporter protein on their way from one side of the cell membrane to the other side. One major effect of the conformation changes that occur during a pumping cycle is to *open passages between the cation-binding sites and the intra- and extracellular fluids*. However, unlike a channel protein, there is never an open passage all the way from the intracellular fluid to the extracellular fluid. Instead, as the molecular conformation undergoes change during a pumping cycle, at certain times a half-channel opens between the cation-binding sites and the *intracellular* fluid (while the sites remain closed off from the extracellular fluid); and conversely, at other times a half-channel opens between the cation-binding sites and the *extracellular* fluid (while the sites remain closed off from the intracellular fluid). The second major effect of the conformation changes that occur during a pumping cycle is that they *dramatically modify the affinity of the cation-binding sites for specific ions*. These affinity changes are synchronized with the opening and closing of the half-channels to control which ions are bound and which are expelled when each half-channel is open.

Let's look at the action of $\text{Na}^+\text{-K}^+\text{-ATPase}$ to clarify these points. Figure 5.11 presents a model of one pumping cycle. At step 1, the half-channel to the intracellular fluid is open, and the

¹²The $\text{Na}^+\text{-K}^+$ pump, being electrogenic, contributes a portion of the normal charge difference across the cell membrane (outside positive). However, much of the charge difference originates from ion *diffusion* processes of the type exemplified in Figure 5.8. The generation of the membrane potential is discussed in detail in Chapter 12.

¹³As discussed on page 50, phosphorylation is covalent bonding to an orthophosphate group, $-\text{PO}_4^{2-}$.

FIGURE 5.11 $\text{Na}^+\text{-K}^+\text{-ATPase}$ transduces ATP-bond energy into ion motive energy Shown here is a current model of the steps in a pumping cycle. Control of the cycle is intrinsic, in the sense that the molecular changes occurring at each step induce conformation changes that lead to the next step. Note that there is never an open channel all the way between the extra- and intracellular fluids; such a channel would permit ions to diffuse “backward” and reduce the gradients the pump is working to create. Instead, half-channels to the intra- and extracellular fluids open alternately (states 1 and 3), with occlusion periods in

between (states 2 and 4). The protein has two binding sites for ATP. ATP first binds to a regulatory site where it helps stimulate conformation changes, then moves into a catalytic site where it is hydrolyzed by the enzymatic activity of the protein. Because of the energy provided by ATP hydrolysis, ion movement can be against the electrochemical gradient. The protein is considered to have two major states, E1 and E2. In turn, each of those can be phosphorylated (E1-P and E2-P) or not. (After Bublitz et al. 2011.)

cation-binding sites have high affinity for Na^+ while having low affinity for K^+ . Accordingly, Na^+ is taken up from the intracellular fluid, and K^+ is expelled into it. A molecule of ATP is bound at the ATPase catalytic site. Enzymatic hydrolysis of the ATP energizes the protein molecule and helps induce a conformation change to state 2—in which three Na^+ ions are *occluded* (out of communication with both intra- and extracellular fluid) within the deep interior of the protein. The energized protein then changes conformation to state 3, in which the half-channel to the extracellular fluid opens and the cation-binding sites undergo a dramatic reduction in their affinity for Na^+ and an increase in their affinity for K^+ , thereby expelling Na^+ into the extracellular fluid and taking up K^+ . Also in state 3, an ATP molecule binds to the protein at an ATP regulatory site, where it is not poised for hydrolysis but instead exerts modulatory

effects. The state of the protein in 3 poises it to dephosphorylate, which leads to state 4, in which two K^+ ions are now occluded. The dephosphorylation then leads to a return to state 1. As this occurs, the ATP molecule moves from the ATP regulatory site to the catalytic site and thereby becomes poised to be hydrolyzed, energizing the protein once again.

The P-type ATPases include not only $\text{Na}^+\text{-K}^+\text{-ATPase}$ but also $\text{Ca}^{2+}\text{-ATPase}$, which is responsible for critical Ca^{2+} pumping in the sarcoplasmic reticulum of muscle (see Chapter 20), and $\text{H}^+\text{-K}^+\text{-ATPase}$, the proton pump that acidifies stomach contents (see Figure 5.9). All the P-type ATPases are thought at present to function in closely similar ways. Besides the P-type ATPases, there are three other principal categories of ATPases, known as F-type, V-type, and ABC-type ATPases.

Primary active transport is defined to be active transport that draws energy immediately from the hydrolysis of ATP. That is, the transporter protein in primary active transport is an ATPase. As you can see, the active transport of Na^+ and K^+ by Na^+-K^+ -ATPase is primary active transport. So also is the transport of Ca^{2+} by Ca^{2+} -ATPase, and that of protons by H^+-K^+ -ATPase.

Secondary active transport draws energy, in an immediate sense, not from ATP but from an electrochemical gradient of a solute. ATP is required for secondary active transport. However, ATP is not the immediate source of energy tapped by the transporter protein. Instead, ATP is employed to create an electrochemical gradient, which is employed by the transporter protein to drive transport.¹⁴

Glucose absorption in the small intestine of a hummingbird or other bird, or of a mammal, provides a classic example of secondary active transport. Thus, to explore the principles of secondary active transport and how energy is provided for it, we may now return to the focal example with which this chapter opened, the case of a hummingbird with abundant glucose in its intestinal lumen after feeding on nectar. Specifically, let's consider how glucose is transported into a single intestinal epithelial cell from the intestinal lumen across the apical membrane of the cell (Figure 5.12). Recall that Na^+-K^+ -ATPase (the Na^+-K^+ pump) is found in the basolateral membranes of all epithelial cells. This Na^+-K^+ -ATPase steadily transports Na^+ out of the intestinal epithelial cell using ATP-bond energy—thereby creating a Na^+ electrochemical gradient across the cell membrane, most notably the part of the cell membrane that faces into the gut lumen: the cell's apical membrane.¹⁵ Because of the action of Na^+-K^+ -ATPase, Na^+ is less concentrated on the inside of the apical membrane than on the outside, and in addition, the inside of the apical membrane is negative relative to the outside. As a result of *both* of these properties (see Figure 5.12a), a strong electrochemical gradient exists for Na^+ across the apical membrane.

From the perspective of energetics, the Na^+ electrochemical gradient across the apical membrane is an *energy store* that can be used to drive transport processes across the membrane. Box 5.1 explains this critically important concept. The hydrolysis of ATP by the Na^+-K^+ -ATPase adds energy to the cell system. This energy—instead of being used immediately for work—is partially stored as potential energy by the creation of the Na^+ electrochemical gradient. In the presence of this gradient, Na^+ tends to diffuse inward across the apical membrane. That is, the potential energy inherent in the electrochemical gradient tends to set Na^+ in motion across the apical membrane. This Na^+ movement can be used to do work. It can be used to pump glucose into the cell.

To understand the work performed, the properties of a remarkable, dual transporter protein must be considered. It facilitates the *obligatorily linked* transport of Na^+ and glucose. The transporter

(a) Na^+-K^+ -ATPase in the basolateral membrane and the Na^+ electrochemical gradient it generates across the apical membrane

(b) The Na^+ -glucose cotransporter in the apical membrane; glucose transport into the cell

FIGURE 5.12 The secondary active transport of glucose into an epithelial cell of the vertebrate small intestine Throughout this figure, the size of the lettering used for solutes in the intracellular and extracellular solutions symbolizes relative solute concentrations inside and outside the cell. Glu = glucose. (a) An intestinal epithelial cell emphasizing the actions of the Na^+-K^+ -ATPase. (b) The same cell, now also showing the Na^+ -glucose cotransporter protein in the apical membrane and glucose transport. After glucose is inside the cell, it crosses the basolateral membrane into the blood by mechanisms discussed in Chapter 6 (see Figure 6.22).

protein does not use ATP and is not an ATPase. The transporter, however, has the following essential attribute: For every two Na^+ ions it carries across the membrane, it *must*, because of its particular chemistry, carry a molecule of glucose in the same direction (see Figure 5.12b). As Na^+ diffuses into the cell from the intestinal lumen across the cell's apical membrane, glucose therefore enters with it. In fact, the transporter can move glucose into the cell *even when the concentration of glucose inside the cell exceeds the concentration in the intestinal lumen*.

In total, you can see, the transport of glucose into an intestinal epithelial cell from the intestinal lumen occurs by way of two energy-driven processes (see Box 5.1). First, Na^+ is transported out of the cell by the Na^+-K^+ pump using ATP-bond energy, a process that creates and maintains a Na^+ electrochemical gradient (representing potential energy) across the apical membrane. Second, glucose is transported into the cell across the apical membrane in linked fashion with Na^+ , driven by the energy stored in the Na^+ electrochemical gradient.

¹⁴Primary active transport is sometimes called *direct* active transport, and secondary active transport is sometimes called *indirect* active transport.

¹⁵The electrochemical gradient is created across all parts of the cell membrane, but we focus here on the apical part because it is where glucose is transported into the cell from the intestinal lumen.

BOX 5.1 ENERGY COUPLING VIA THE POTENTIAL ENERGY OF ELECTROCHEMICAL GRADIENTS

In 1961, Peter Mitchell revolutionized knowledge of energy metabolism in cells by proposing an entirely novel idea for a mechanism by which cells can couple energy sources to work-performing processes. He won the Nobel Prize for this idea, termed the *chemiosmotic hypothesis* in certain contexts. Mitchell proposed that *physical compartmentalization of cells by membranes* is critical. That is—contrary to the assumption prior to his research—chemistry alone is not sufficient for certain biochemical processes to take place. Instead, the chemistry occurs in a physical context—compartmentalization by membranes—that imparts *spatial directionality*, which is itself an essential functional constituent of the processes.

To see the underlying concept, consider a type of mechanism that engineers sometimes employ for energy coupling (e.g., in pumped-storage plants). At the left in Part 1 of the figure is a power plant; at the right is an apparatus that does work by use of energy. The

question to be addressed is how energy from the power plant can be coupled to the work-performing apparatus. The approach shown in Part 1 is to store energy from the power plant in the form of potential energy, then allow the work-performing apparatus to draw energy from the potential energy. Specifically, energy from the power plant is delivered to a pump that lifts water into an elevated tank (①). The water, by being moved to a higher elevation, acquires potential energy of position in Earth's gravitational field, thereby storing a fraction of the energy from the plant (②). Then, an apparatus is designed that can use energy from falling water to perform the type of work desired. When water from the elevated tank is allowed to fall back to its original elevation under force of gravity, a fraction of the potential energy present at ② acts to run the apparatus, and the work desired is accomplished (③).

Living organisms started to employ similar energy-coupling systems almost from the start of their evolution. These energy-coupling sys-

tems do not use the elevation of water to store potential energy. Instead, they store potential energy in the form of ionic electrochemical gradients between solutions separated by cell membranes or intracellular membranes. As seen in Part 2 of the figure, energy from an energy source—usually ATP or bonds of food molecules—is used to pump ions across a membrane (④), producing an electrochemical gradient that is far from equilibrium (⑤). The gradient, created by use of energy from the source, represents a store of that energy as potential energy, analogous to the store in Part 1. Ions tend to diffuse back across the membrane in the direction dictated by the electrochemical gradient. Membrane-spanning proteins have evolved that obligatorily couple ion diffusion to specific types of work performance. When ions diffuse across the membrane by passing through these proteins, work is performed (⑥). In this way, energy from the source—ATP or food molecules—is coupled to the performance of a specific type of work.

Two examples of energy coupling via an intermediate step in which energy is temporarily stored as potential energy Part 1 is an example from human engineering, whereas Part 2 shows a process that commonly occurs in cells. Both depend on an exacting energy-transducing mechanism that performs a specific type of work by use of the type of potential energy available. In Part 1, this

mechanism is a product of engineering (e.g., a turbine that turns an axle used to do work). In Part 2, the energy-transducing mechanism is a membrane protein that is a product of evolutionary natural selection. When energy is stored—① to ② in Part 1, ④ to ⑤ in Part 2—the process is less than 100% efficient. Similarly, when energy is used—③ in Part 1, ⑥ in Part 2—the process is also less than 100% efficient.

Most investigators today consider this type of transport of glucose to be a form of *active* transport because it meets three critical criteria: (1) The mechanism can move glucose away from glucose equilibrium, from a solution of low concentration into one of high concentration; (2) the glucose transport is carrier-mediated; and (3) the energy source for the uphill transport of glucose is metabolism. The active transport of glucose deserves, nonetheless, to be distinguished from forms of active transport that use ATP-bond energy directly. This is why *secondary active transport* (transport that draws energy from an electrochemical gradient of a solute) is distinguished from primary active transport (transport that draws energy from ATP).

Available evidence indicates that when *organic solutes* are *actively* transported by animal cells, secondary active transport is the usual mechanism. In the vertebrate intestine, for example, secondary-active-transport mechanisms are responsible for the active uptake not only of glucose but also of certain other sugars, amino acids, and water-soluble vitamins (see Chapter 6).¹⁶ A variety of apical-membrane transporter proteins are involved. All move two solutes simultaneously in an obligatorily linked fashion. When a transporter protein moves two solutes in linked fashion in *one* direction, the transport is called **cotransport**, and the protein is a **cotransporter**. When a transporter moves two solutes in obligatorily linked fashion in *opposite* directions, the transport is **countertransport**, and the protein is a **countertransporter**.¹⁷ In our focal example, the transporter for glucose is a cotransporter (see Figure 5.12b). All vertebrates have this cotransporter in the apical membranes of their intestinal epithelial cells. Hummingbirds are distinguished, however, by exhibiting extraordinarily high activity of this cotransporter, far higher than observed in most vertebrates (Figure 5.13). This exceptional glucose cotransporter activity in hummingbirds seems almost surely to be an adaptation to the exceptional glucose yield of their nectar diet.

Active transport across an epithelium does not imply a specific transport mechanism

Scientists who study *epithelia* often know that active transport occurs across a particular epithelium without knowing much, if anything, about the specific molecular mechanisms that carry out the transport. There are, in fact, two different perspectives in the study of active transport across epithelia. The simpler *whole-epithelium* perspective—exemplified by Figure 5.14a—regards the epithelium as a “black box”: The behavior of the epithelium itself is described without the underlying cell-membrane mechanisms being identified. The more-complex *cell-membrane* perspective—exemplified by the options in Figure 5.14b—seeks to identify the cell-membrane mechanisms of transport, including all the particular proteins that are involved (e.g., ATPases, cotransporters, and channels) in both the apical and basolateral membranes of the epithelial cells.

To make this clearer, suppose that a researcher carries out the following measurements on an epithelium: First the researcher measures the concentration of the solute of interest on the two sides of the epithelium, and if the solute is charged, the researcher

¹⁶ All intestinal uptake of organic solutes is not necessarily active, however. Recent research indicates, for example, that in several species of birds, following ingestion of glucose-rich meals, glucose is taken up both by secondary active transport and by paracellular diffusion (see Figure 2.9).

¹⁷ Cotransporters and countertransporters are sometimes called *symporters* and *antiporters*, respectively.

FIGURE 5.13 A species of hummingbird exhibited the highest capacity for intestinal glucose absorption of 42 vertebrate species measured. Glucose uptake by secondary active transport across the intestinal epithelium was measured. On the y axis, the measured glucose uptake is expressed as a ratio of proline uptake as a way of providing a common reference point for the glucose measures. Note that the data on the y axis are plotted on a log scale; the numerical values are more divergent than a quick visual impression might suggest. (After Karasov and Diamond 1988.)

measures the voltage difference across the epithelium. From these data, the electrochemical gradient across the epithelium is calculated. Next the researcher studies whether the epithelium can move the solute of interest from one side to the other in a way that *increases* the electrochemical gradient across the epithelium. If so, it is common practice to say that “the epithelium actively transports the solute.” By this standard, it is easy to show that the epithelium of the small intestine of a vertebrate actively transports glucose (see Figure 5.14a).

It is always the case, however, that many different cell-membrane mechanisms could permit an epithelium to function as it does. In the case of the intestinal epithelium, for example, *any* of the four mechanisms in Figure 5.14b (plus others not shown) would permit the epithelium to transport glucose as it does. Research at the level of cell membranes is required to identify the actual mechanism. As we have already seen, the actual mechanism in the intestinal epithelium is known; it is the one shown at the far right of Figure 5.14b. Often, however, physiologists have not fully resolved the molecular mechanisms of epithelial transport.

Two epithelial ion-pumping mechanisms help freshwater fish maintain their blood composition

Now we can complete our analysis of the movement of Na^+ and Cl^- across the gill epithelial membranes of freshwater fish (see Figure 5.1b), bringing to closure the third and final of our focal examples. We have seen that freshwater fish lose Na^+ and Cl^- from their blood into pond water by diffusion, and thus they face a constant threat of having their blood become too dilute. Food is one means by which they replace lost Na^+ and Cl^- . A more important means of ion replacement in most fish is that they actively take up Na^+ and Cl^- across their gill epithelial membranes. What are the mechanisms of this active transport?

(a) Whole-epithelium view of glucose transport

FIGURE 5.14 Two perspectives on epithelial active transport

(a) Whole-epithelium and (b) cell-membrane views of glucose transport across the epithelium of the vertebrate small intestine. Each diagram in (b) depicts a potential mechanism by which transporter proteins and channel proteins in the apical and basolateral membranes could endow the whole epithelium with the property shown in (a). In each diagram, proteins are labeled with the solutes they transport. Free-standing Glu symbols show relative glucose concentrations in the intracellular and extracellular fluids. Explanations of the four plausible cell-membrane mechanisms in (b): *Far left*: Glucose could cross the apical membrane by means of **primary active transport** mediated by an ATPase and powered with energy derived directly from ATP. The high glucose concentration thereby created within the cell would favor diffusion of glucose out of the cell, so transport across the basolateral membrane could occur by facilitated diffusion. *Middle left*: Glucose could enter

the cell across the apical membrane by **facilitated diffusion**. This could occur only if the cell concentration of glucose were low enough to be below the intestinal-lumen concentration, but the problem of then making glucose move out across the basolateral membrane could be solved by the presence of a glucose-transporting ATPase that uses ATP-bond energy to make glucose move against its concentration gradient. *Middle right*: Glucose could enter the cell across the apical membrane by **secondary active transport**, involving the $\text{Na}^+ - \text{K}^+$ -ATPase in the basolateral membrane and a Na^+ -glucose cotransporter in the apical membrane (see Figure 5.12b). Then glucose could cross the basolateral membrane by simple diffusion through a glucose channel. *Far right*: This is what actually happens. Glucose enters the epithelial cell across the apical membrane by **secondary active transport** and leaves across the basolateral membrane by facilitated diffusion mediated by a glucose-transporter protein (see Figure 6.22 for full detail).

Studies of whole gill epithelia demonstrate that the mechanisms of active Na^+ uptake and active Cl^- uptake are, for the most part, different and independent (Figure 5.15). Each active-transport mechanism is electroneutral (or approximately so) because each exchanges two ions of identical charge across the epithelium in opposite directions and in a 1:1 ratio. When the Na^+ -pumping mechanism actively transports Na^+ against its electrochemical gradient from dilute pond water into concentrated blood, it simultaneously secretes H^+ into the water in exchange for the Na^+ . The Cl^- -pumping mechanism secretes HCO_3^- (bicarbonate ion) into the water in exchange for Cl^- . The H^+ and HCO_3^- that are exchanged for Na^+ and Cl^- are, in essence, metabolic wastes because both are

FIGURE 5.15 A whole-epithelium view of active ion transport across the gill epithelium of a typical freshwater fish The Na^+ and Cl^- active-transport mechanisms are different and independent, for the most part. The pumping mechanisms exist within single epithelial cells. Some cells take up Na^+ principally or solely, whereas other cells take up Cl^- . Carbon dioxide (CO_2) from metabolism reacts with body water to form bicarbonate ions (HCO_3^-) and protons (H^+). These products are exchanged for Cl^- and Na^+ by the active-transport mechanisms.

BOX 5.2 CELLULAR MECHANISMS OF ION PUMPING IN FRESH-WATER FISH GILLS

What are the cell-membrane proteins and other cellular mechanisms that enable the gill epithelium of a freshwater fish to take up Na^+ and Cl^- ions from pond or stream water? This important question is still under active investigation. Nonetheless, some of the principal attributes of the ion-pumping mechanisms are well understood, as you will learn by reading **Box Extension 5.2** on the web.

Bluegill sunfish (*Lepomis macrochirus*)

derived from the CO_2 produced by metabolism. Thus freshwater fish employ waste ions to keep the active uptake mechanisms for Na^+ and Cl^- from generating large charge differences across the gill epithelium. You will recognize that our presentation of the active-transport mechanisms in Figure 5.15 is a whole-epithelium, black-box view. **Box 5.2** discusses the cell-membrane view.

SUMMARY Active Transport

- Active-transport mechanisms—also called uphill-transport mechanisms or pumps—are able to convert energy obtained from the catabolism of foodstuffs into solute motive energy and thus can transport solutes away from electrochemical equilibrium. Such mechanisms are known for many solutes but not for O_2 or H_2O .
- Solutes must bind noncovalently to a transporter protein for active transport to occur. Thus active transport is a type of carrier-mediated transport. A second type is facilitated diffusion, which differs in that it cannot tap metabolic energy and is therefore strictly toward equilibrium.
- Active transport is primary if the transporter protein is an ATPase and thus draws energy directly from ATP bonds. One of the best-known transporters of this sort is Na^+-K^+ -ATPase (a P-type ATPase), which is found in all animal cells, including the basolateral membranes of all epithelial cells. Primary-active-transport mechanisms pump ions. Active transport is secondary if the immediate source of energy for transport is a solute electrochemical gradient, rather than ATP. Secondary-active-transport mechanisms depend on transporter proteins—cotransporters or countertransporters—that obligatorily transport

two solutes simultaneously. Secondary-active-transport mechanisms pump organic solutes and ions.

- Active transport of ions is electrogenic if it produces a voltage difference but electroneutral if it does not.

Diversity and Modulation of Channels and Transporters

Like enzyme proteins, channel and transporter proteins exist in multiple molecular forms and can be modulated in numerous ways, providing many opportunities for the regulation of cell and tissue function. A detailed treatment of this topic would be at least as long and full of possibilities as our discussion of enzyme diversity and modulation in Chapter 2. Instead, the goal in this case will be simply to outline known phenomena.

- *Multiple molecular forms.* Multiple molecular forms of channel and transporter proteins are common. For example, just as the genome of an individual vertebrate animal codes for the synthesis of two or more LDH (lactate dehydrogenase) enzyme proteins, it codes for the synthesis of two or more Na^+-K^+ -ATPase proteins, and the various forms of Na^+-K^+ -ATPase are differentially expressed in different tissues. Multiple forms of Ca^{2+} -ATPase and H^+-K^+ -ATPase, expressed in different tissues, also occur. In addition, different species often have evolved different molecular forms of channels and transporters. Because different molecular forms can exhibit distinct transport, catalytic, and modulation characteristics, the presence of different forms in different tissues of a species or in different species provides opportunities for adaptation.
- *Modulation of gene expression.* Considering the molecular forms of channel and transporter proteins that are coded in an animal's genome, the forms and amounts that are synthesized by a particular cell are under control of gene expression. Thus, for example, differential gene expression produces different suites of channel and transporter proteins in the cells of different tissues during early development, helping establish the mechanistic basis for tissue specialization. All cells of a mammal, for example, have the gene that codes for the form of H^+-K^+ -ATPase responsible for stomach acidification, but only certain cells—notably the acid-secreting cells of the stomach—vigorously express the gene. Gene expression is also modulated during the life of an animal in response to an individual's circumstances, often under hormonal control. The adrenal hormone aldosterone, for instance, increases Na^+ reabsorption in the kidney tubules, thus increasing retention of Na^+ in the body. It exerts this effect in part by increasing expression of the gene that codes for Na^+-K^+ -ATPase in kidney-tubule cells (Na^+-K^+ -ATPase is just one component of the overall mechanism of Na^+ reabsorption).
- *Noncovalent and covalent modulation.* The channel and transporter proteins resident in a cell membrane often are subject to modulation. One form of modulation is analogous to the allosteric modulation of enzymes in that

it is mediated by noncovalent and reversible bonding with modulating agents. Ligand gating of channels provides an illustration (see Figure 5.5*d*). Covalent modulation (e.g., by phosphorylation) also occurs. Both noncovalent and covalent modulation provide for very rapid adjustment of a channel or transporter protein's function.

- Insertion-and-retrieval modulation.** Because channel and transporter proteins perform their functions only when in the cell membrane (or in a function-specific intracellular membrane), the *location* of the proteins in a cell provides a means of controlling their activity. Cells often have reserves of cell-membrane channel or transporter proteins held in locations other than the cell membrane. Protein molecules from these reserves can be **inserted** into the cell membrane—becoming functional—or molecules in the cell membrane can be **retrieved**. An excellent example is provided by H^+K^+ -ATPase in the acid-secreting cells of the stomach. Resting acid-secreting cells (see Figure 5.9) have relatively few molecules of H^+K^+ -ATPase in their apical cell membranes, but they have large reserves of ATPase molecules bound to intracellular membranes (where the molecules are nonfunctional). When a meal is ingested, the cells are hormonally stimulated to become active. This stimulation causes *insertion* of intracellular H^+K^+ -ATPase molecules into the apical membranes of the cells. The microvilli lining the canaliculi of the apical membranes (see Figure 5.9) grow dramatically, by a factor of six to ten, and the number of ATPase molecules positioned to function by secreting protons into the stomach cavity is vastly increased. After digestion, the ATPase molecules are *retrieved* from the apical membranes. Insertion mechanisms are much faster than gene-expression mechanisms because the time-requiring steps of transcription and translation are carried out prior to need for the channel or transporter proteins. The only step required to activate the proteins at a time of need is to insert them in the membranes where they are active, a process that can be completed in minutes.

Osmotic Pressure and Other Colligative Properties of Aqueous Solutions

Having discussed the mechanisms of *solute* transport, we now turn to the transport of the *solvent* in aqueous solutions: water. A logical starting point is to discuss the **colligative properties** of aqueous solutions, because osmosis of water, discussed in the next section, is fundamentally a colligative phenomenon. The colligative properties of aqueous solutions are the properties that depend simply on the *number* of dissolved entities per unit of volume rather than the *chemical nature* of the dissolved entities.

The three colligative properties of greatest significance for the study of animal physiology are the osmotic pressure, freezing point, and water vapor pressure of a solution.¹⁸ A useful way to define **osmotic pressure** is that it is the property of a solution that allows one to predict whether the solution will gain or lose water by osmosis when it undergoes exchange with another solution; in

other words, if you know the osmotic pressures of two solutions, you can *predict* the direction of osmosis between them. The **freezing point** of a solution is the highest temperature capable of inducing freezing. For a formal definition of **water vapor pressure**, we defer to Chapter 27 (see page 705), but here we can say that the water vapor pressure measures the tendency of a solution to evaporate.

The study of colligative properties requires a shift in view, compared with earlier sections of this chapter, because the colligative properties—unlike solute-transport mechanisms—do not depend on the particular chemical nature of solutes. In Figure 5.16, the two upper drawings are microscopic views of two complex solutions. The same two solutions are shown again in the two lower drawings, except that in the lower drawings, the chemical identity of each dissolved entity is not recognized; instead, each dissolved entity is represented just with a dot. For quantifying colligative properties, the view in the lower drawings is more straightforward because the colligative properties are independent (or approximately independent) of the chemical nature of dissolved entities. They depend instead on the simple matter of *how many dissolved entities (of any kind) are present per unit of volume of solution*. Whether a dissolved entity is a glucose molecule, a large protein molecule such as albumin, or a Na^+ ion, each makes an approximately equal contribution to the quantitative magnitudes of the colligative properties of a solution. Thus the two solutions in Figure 5.16 are identical or nearly identical in their osmotic pressures, freezing points, and water vapor pressures, even though they are very different in their chemical mixes of solutes.

All the colligative properties of a solution change in magnitude as the concentration of dissolved entities changes. Raising the concentration of dissolved entities in a solution increases the osmotic pressure of the solution. It also lowers the solution's freezing point and lowers its water vapor pressure. Speaking quantitatively, the osmotic pressure is approximately *proportional* to the concentration of dissolved entities; doubling the concentration approximately

FIGURE 5.16 Magnified views of two solutions that are similar in colligative properties. All the drawings depict identical volumes. The upper drawings of Solutions 1 and 2 show the chemical nature of each dissolved entity in the solutions. The lower drawings of the same two solutions show merely the numbers of dissolved entities within the volumes shown, disregarding chemical differences. Because the two solutions have identical numbers of dissolved entities per unit of volume, they are virtually the same in their osmotic pressures, freezing points, and other colligative properties. Alb = albumin; Glu = glucose.

¹⁸A fourth colligative property of occasional interest is the **boiling point**, the lowest temperature that will cause boiling.

doubles the osmotic pressure. The other colligative properties also exhibit simple proportionalities to concentration, but these proportionalities can be a little less obvious because of the way the properties are usually expressed. Consider the freezing point and water vapor pressure: When the concentration of dissolved entities in a solution is doubled, the factor that approximately doubles is the *difference* (sign ignored) between the actual freezing point or the actual water vapor pressure of the solution and the freezing point or the water vapor pressure of pure water. To see this more clearly, consider the **freezing-point depression**, defined to be the difference (sign ignored) between the actual freezing point of a solution and the freezing point of pure water. The freezing-point depression of a solution is approximately proportional to the concentration of dissolved entities. For example, if the freezing-point depression is 0.4°C before the concentration of dissolved entities is doubled, it is about 0.8°C after. This means that the freezing point itself is lowered from -0.4°C to -0.8°C . The **water-vapor-pressure depression** is the difference (sign ignored) between a solution's water vapor pressure and the water vapor pressure of pure water under the same conditions. It is approximately proportional to the concentration of dissolved entities.

A useful corollary of the points already made is that the osmotic pressure, the freezing-point depression, and the water-vapor-pressure depression of a solution *are all proportional to each other*. This means that if you have measured any one of these properties in a solution, you can calculate the others, a principle that we will see shortly has considerable practical significance.

Only dissolved materials affect the colligative properties of solutions. Suspended materials, such as clay particles in river water or red blood cells in blood plasma, do not affect the osmotic pressures or the other colligative properties of solutions because they are not dissolved.

Solutions of *nonelectrolytes* that are equal in their molar chemical concentrations typically are identical in their osmotic pressures and other colligative properties. This is easy to understand when you consider two principles: (1) a mole of solute always contains a fixed number of molecules (Avogadro's number, 6×10^{23}); and (2) when nonelectrolytes go into solution, each individual molecule remains intact in the solvent, meaning that each constitutes a single dissolved entity. These two principles dictate that if several solutions of nonelectrolytes have equal molarities, they are also equal in their numbers of dissolved entities per unit of volume. A $0.1\text{-}M$ solution of glucose, for example, has the same number of dissolved entities per unit of volume as a $0.1\text{-}M$ solution of urea. For the determination of colligative properties, it does not matter that the dissolved entities are glucose molecules in one solution and urea molecules in the other. Thus both solutions are virtually identical in their osmotic pressures and other colligative properties. Similarly, the colligative properties of a $0.1\text{-}M$ solution of a large, nondissociating protein such as serum albumin (molecular mass $\sim 66,000$ daltons [Da]) are essentially the same as those of the equimolar solutions of the lower-mass solutes: $0.1\text{-}M$ glucose (180 Da) and $0.1\text{-}M$ urea (60 Da).¹⁹

Solutions of *electrolytes* present additional complexities for predicting colligative properties because individual molecules of

electrolytes dissociate when placed in solution, giving rise to more than one dissolved entity. To take the simplest case, consider *strong electrolytes*, which dissociate fully when they are dissolved. When NaCl, a strong electrolyte, is dissolved, each molecule dissociates fully into two dissolved entities, a Na^+ ion and a Cl^- ion. This means that a $0.1\text{-}M$ solution of NaCl has twice as many dissolved entities per unit of volume as a $0.1\text{-}M$ glucose solution. Similarly, a $0.1\text{-}M$ solution of Na_2SO_4 (sodium sulfate) has three times as many dissolved entities as a $0.1\text{-}M$ glucose solution. The colligative properties of salt solutions exhibit nonideal behavior because such solutions do not behave exactly as if each dissociated ion is an independent dissolved entity. In most situations relevant to animal physiology, however, a relatively close approximation to ideal behavior is observed. From the viewpoint of ideal behavior, for example, we would expect a $0.1\text{-}M$ solution of NaCl to have an osmotic pressure and freezing-point depression that are 2 times higher than those of a $0.1\text{-}M$ glucose solution. The actual osmotic pressure and freezing-point depression are about 1.9 times higher in the NaCl solution.

Physiologists usually express osmotic pressure in osmolar units

The most commonly used system of units for osmotic pressure in biology today is the **osmolarity** system. A **1-osmolar (Osm)** solution is defined to be one that behaves osmotically as if it has 1 Avogadro's number of independent dissolved entities per liter. Saying the same thing in another way, a $1\text{-}Osm$ solution has the same osmotic pressure as is exhibited by a $1\text{-}M$ solution of ideal nonelectrolyte. Some solutions relevant to animal physiology, such as seawater and the bloods of most marine invertebrates, are concentrated enough to be about 1 Osm . Many solutions in animal physiology, however, are more dilute, and their osmotic pressures are typically expressed in units of **milliosmolarity**; a **1-milliosmolar (mOsm)** solution behaves osmotically as if it has 0.001 Avogadro's number of independent dissolved entities per liter.

Osmotic pressures can be measured in several ways

For day-to-day practical purposes in physiology and medicine today, people measure osmotic pressures by employing instruments that actually measure either the freezing-point depression or the water-vapor-pressure depression. These are called *freezing-point osmometers* and *vapor-pressure osmometers*. The instruments take advantage of the point, stressed earlier, that all the colligative properties of a solution are typically proportional to each other. Thus the osmotic pressure can be calculated after the freezing-point depression or the water-vapor-pressure depression has been measured.²⁰

Physical chemists have devised methods of measuring osmotic pressure itself, rather than calculating it from other colligative properties. These methods are the gold standard of osmotic-pressure measurement, but usually they are not employed for day-to-day practical work by biologists because they are cumbersome to carry out. **Figure 5.17** illustrates the basic approach to the direct measurement of the osmotic pressure of a solution. The solution is placed in a piston device as shown in **Figure 5.17a**. The end of the piston

¹⁹To be strictly accurate, solutions of various nonelectrolytes have the same ratio of dissolved entities to water molecules when they are of the same *molality*, not molarity. Thus it is solutions of identical molality that exhibit identical colligative properties. Biologists usually measure and discuss molarities, and for most purposes this habit does not introduce consequential errors.

²⁰Prior to about 1980, it was very common for biologists who measured freezing-point depression to leave their results in temperature units rather than converting them to osmolarity. Thus in the literature of that era you will find osmotic pressures expressed in degrees Celsius! The equivalency is that a freezing-point depression of 1.86°C corresponds to 1 Osm .

consists of a **semipermeable membrane**, defined to be a membrane permeable only to water. The reason for using such a membrane is that it ensures the solution will not be corrupted by losing some of its solute during the measurement process. A semipermeable membrane is a laboratory device; no animal or plant membranes are semipermeable. Note in Figure 5.17a that whereas the solution of interest is on one side of the semipermeable membrane, *pure water* is on the other side. If the piston is simply allowed to move freely, water molecules will travel by osmosis from the side filled with pure water to the side filled with the solution, and the changes in volume of the two fluid compartments will push the piston to the right (Figure 5.17b).

This piston movement can be prevented by exerting a force on the piston as shown in Figure 5.17c. The force will raise the hydrostatic pressure in the solution so it is higher than that in the pure water. The elevated hydrostatic pressure in the solution will then tend to force water molecules through pores of the membrane by pressure-driven, streaming bulk flow (termed **ultrafiltration**) from the solution into the pure water. For any given solution, there is a particular difference of hydrostatic pressure between the solution and pure water that will exactly prevent the piston from moving in either direction from its initial position, as in Figure 5.17c. When this difference of hydrostatic pressure prevails, water is forced out of the solution by the hydrostatic-pressure difference at the same rate that osmosis transports water into the solution. This difference of hydrostatic pressure therefore serves as a measure of the degree to which the solution tends to take on water by osmosis.

To a physical chemist, the specified difference of hydrostatic pressure *is* the osmotic pressure of

FIGURE 5.17 How to measure the osmotic pressure of a solution directly (a) A piston osmometer. (b) A later state of the system if the piston is free to move. Water moves into the solution by osmosis. (c) The stable state of the system if the solution is subjected to increased hydrostatic pressure by a force applied to the piston and the difference of hydrostatic pressure across the membrane is equal to the osmotic pressure of the solution. The open sidearm on the pure-water compartment in (c) permits the hydrostatic pressure in that compartment to remain constant as the hydrostatic pressure in the solution compartment is increased.

the solution. Stated succinctly, *the osmotic pressure of a solution is the difference of hydrostatic pressure that must be created between the solution and pure water to prevent exactly any net osmotic movement of water when the solution and the pure water are separated by a semipermeable membrane*. Historically, osmotic pressures came to be called *pressures* precisely because they can be measured as hydrostatic pressures; and to this day, in physical chemistry they are usually expressed in pressure units, such as pascals (Pa) or atmospheres (atm).²¹

To see the logic of the physical chemist's approach, suppose you place two solutions, called A and B, in the piston device at different times so that you can measure each solution's osmotic pressure, and suppose that the hydrostatic pressure required to negate osmosis into B is greater than that required to negate osmosis into A. From these results, you would know that when the solutions are studied in relation to pure water, B has a greater tendency than A to take on water by osmosis, as shown in the two images to the left in Figure 5.18. Knowing this, you could then accurately predict that if the two

²¹The equivalency to convert to osmolar units is that a 1-Osm solution has an osmotic pressure in pressure units of 22.4 atm (technically, at 0°C, because temperature matters to a small degree in the conversion).

FIGURE 5.18 Predicting the direction of osmosis between two solutions from measurements made independently on each The red arrows in the two diagrams on the left symbolize the tendency for water to move by osmosis into each of two solutions, A and B, when the solutions are separated by a semipermeable membrane from pure water. The thickness of each arrow is proportional to the hydrostatic pressure difference that is required between each solution and the pure water to block any net transfer of water by osmosis; thus the thicknesses of the red arrows are proportional to the osmotic pressures of the two solutions. In the right-hand diagram, the red arrows are repeated from the diagrams on the left, and the blue arrow shows the difference between them.

solutions, A and B, are placed on opposite sides of a water-permeable membrane, as at the right in Figure 5.18, the direction of water transport by osmosis will be from A into B. Recall that one way to define osmotic pressure is that it is the property of a solution that allows one to predict whether the solution will gain or lose water by osmosis when it undergoes osmotic exchange with another solution. The physical chemist's approach permits measurement of this property and is in fact the most fundamental of all ways to measure osmotic pressure (again, the gold standard). The measurements of osmotic pressure that biologists obtain using freezing-point osmometers or vapor-pressure osmometers typically provide the same information by different means.²²

SUMMARY Osmotic Pressure and Other Colligative Properties of Aqueous Solutions

- Colligative properties depend on the number of dissolved entities per unit of volume of solution rather than the chemical nature of the dissolved entities. The three colligative properties of greatest importance in biology are the osmotic pressure, freezing point, and water vapor pressure. Because the three are quantitatively related, any one can be calculated from the others.
- Osmotic pressures are generally expressed in osmolar units by biologists today. A 1-osmolar (*Osm*) solution behaves osmotically as if it has 1 Avogadro's number (6×10^{23}) of independent dissolved entities per liter.
- Physical chemists measure osmotic pressures by using hydrostatic pressure, explaining why osmotic pressures are called *pressures*.

Osmosis

Osmosis is the passive transport of water across a membrane, which can be a cell membrane, an epithelium, or an artificial membrane. Sometimes osmosis is referred to as “diffusion of water.” This is misleading as applied to biological membranes because strong evidence indicates that the rate of osmosis across some sorts of biological membranes is greater than can be explained by simple water diffusion. Because osmosis is a form of passive transport, it is strictly toward equilibrium, regardless of its rate or mechanistic details. Active water transport is not generally believed to occur.

When two solutions exchange water by osmosis, *water always moves from the one with the lower osmotic pressure into the one with the higher osmotic pressure*. This attribute of osmosis tends to be confusing at first because we are accustomed to thinking of things moving passively from high to low; heat moves from high temperature to low, glucose diffuses from high concentration to low, and so forth. Water undergoing osmosis, however, moves from low osmotic pressure to high. One way to remember this crucial point is to note that water itself is more abundant per unit of volume where dissolved matter is less abundant. Thus during osmosis water moves from where *it* is more abundant per unit of volume to where *it* is less abundant.

²²The physical chemist's approach is the *direct* method of measuring osmotic pressure. All other approaches are *indirect*. See Box 7.3 for a discussion of the fundamental distinctions between direct and indirect measurements.

Osmosis is important in the lives of animals in many ways. Striking examples are provided by the osmotic exchanges between freshwater animals and the environmental waters in which they live. Freshwater animals ceaselessly take on water by osmosis from the pond or stream waters they inhabit because their blood plasma and other body fluids have far higher concentrations of dissolved entities—higher osmotic pressures—than freshwater has (Figure 5.19). A 100-g goldfish (*Carassius auratus*) living in freshwater, for example, gains about 30 g of water per day by osmosis—a third of its body weight! Osmotic influxes like this tend to bloat freshwater fish and dilute their blood. The fish must continually expend energy to rid themselves of the excess water.

As you study transport, never forget that osmotic pressures have just one major claim to consideration: They govern the movements of *water* across membranes. It is easy to slip into a habit of thinking that osmotic pressures affect solute movements. They do not do so directly. When solutes diffuse, they are affected by gradients of their specific chemical concentrations. Only water follows the gradient of osmotic pressure.

Quantification and terminology

The *rate* at which water crosses a membrane by osmosis follows the equation

$$\text{Rate of osmotic water transport per unit of cross-sectional area} = K \frac{\Pi_1 - \Pi_2}{X} \quad (5.2)$$

where Π_1 and Π_2 are the osmotic pressures of the solutions on the two sides of the membrane, and X is the distance separating Π_1 and Π_2 . The ratio $(\Pi_1 - \Pi_2)/X$ is called the **osmotic-pressure gradient**

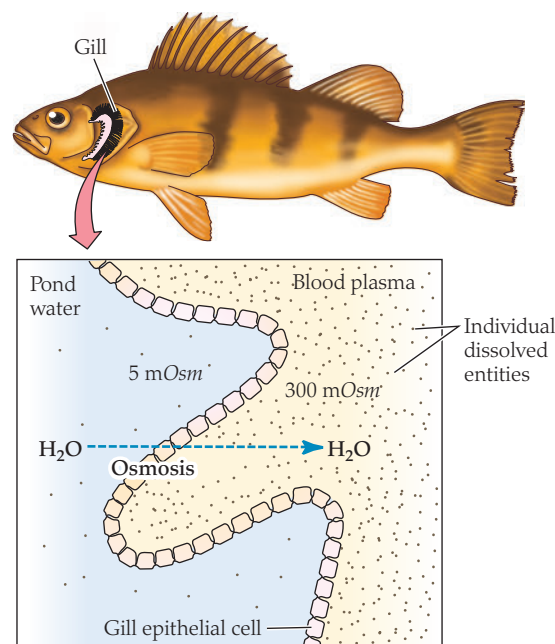

FIGURE 5.19 Osmotic uptake of water by a freshwater animal Because freshwater animals have osmotic pressures in their blood that greatly exceed the osmotic pressure of freshwater, they gain water by osmosis, especially across their gills or other highly permeable body surfaces. Each dot represents a single osmotically effective dissolved entity.

or **osmotic gradient**, although sometimes the term *osmotic gradient* is used less formally to refer to just the difference in osmotic pressure. The proportionality coefficient K depends in part on the temperature, and in part on the permeability of the membrane to osmotic water transport, termed the **osmotic permeability**.

If two solutions, A and B, have the same osmotic pressure, they are said to be **isosmotic**. If solution A has a lower osmotic pressure than solution B, A is said to be **hyposmotic** to B, and B is said to be **hyperosmotic** to A.²³ Note that the terms *isosmotic*, *hyposmotic*, and *hyperosmotic* are *relative*; the two solutions being compared must be specified for the terms to have meaning. In this system of terminology, the *direction* of net water movement by osmosis is from the hyposmotic solution into the hyperosmotic one. Osmotic equilibrium is reached when two solutions become isosmotic.

Hydrostatic pressures develop from osmotic pressures only when two or more solutions interact

For most people, the most confusing aspect of studying osmosis is that osmotic pressures are called *pressures*. To avoid confusion, it is important to be clear that *a solution by itself does not exert a hydrostatic pressure because of its osmotic pressure*. In pressure units, a 1-M glucose solution has an osmotic pressure of about 22 atm. Thus, this simple sugar solution would explode glass bottles if it exerted a hydrostatic pressure equal to its osmotic pressure! The glucose solution can be stored in exactly the same sorts of containers as pure water precisely because the osmotic pressure of an isolated solution is not a hydrostatic pressure. Osmotic pressures are named *pressures* because of a historical accident—namely, that the earliest scientists who studied them were physical chemists, who (as we have seen) used hydrostatic pressure as *a measurement device* to quantify osmotic pressures.

There are circumstances relevant to animal physiology when osmotic pressures generate hydrostatic pressures. These circumstances *always involve interaction between two or more solutions* across a membrane. If two solutions of differing osmotic pressure are separated by a water-permeable membrane and the solution of higher osmotic pressure is contained in some way that limits its freedom to expand, then osmosis will create an elevated hydrostatic pressure in that solution. The reason is simply that transport of water by osmosis adds matter (water molecules) to the solution with the higher osmotic pressure, and if that solution is prevented from freely expanding to accommodate the increased matter, it will be pressurized. This is why human red blood cells dropped into freshwater enlarge and burst. When a red blood cell first falls into freshwater, its cell membrane is intact and, like a rubber balloon, tends to resist expansion. Thus as osmosis carries water molecules into the cell from the surrounding freshwater, an elevated pressure develops inside the cell, as in a balloon being blown up. Eventually the pressure becomes so great that the cell bursts.

²³The *tonicity* system of nomenclature, often inappropriately used, is not equivalent to the *osmoticity* system mentioned here. The tonicity system refers to effects on cellular volume. An **isotonic** solution is one into which cells of a specified kind can be placed without the volumes of the cells being affected. If cells are placed in a **hypotonic** solution, they swell because of an osmotic influx of water. In a **hypertonic** solution, they shrink because of osmotic water loss. In many cases, solutions isosmotic to cells are not isotonic in the long run, emphasizing that the two systems of nomenclature are not equivalent.

Water may dissolve in membranes or pass through aquaporin water channels during osmosis

Experiments with artificial all-phospholipid membranes show that water molecules can dissolve in phospholipid bilayers and move through them by the random molecular motions of simple diffusion. This result seems odd at first because H_2O is a polar molecule. Evidently H_2O is small enough (0.3 nm in diameter) for the dissolve-and-diffuse mechanism to operate. Osmosis across many real cell membranes is thought to occur entirely by simple diffusion of water through the lipid bilayers.

On the other hand, in many sorts of cells, channel proteins called **water channels** provide avenues for water molecules to move by osmosis through the cell membrane without encountering the lipid bilayers. The most important of these are the *aquaporins*. The presence of aquaporins in a cell membrane greatly speeds osmosis across the membrane.

Aquaporins

The **aquaporins** (“water pores”) are a large family of water-channel proteins found in all groups of organisms. Although extremely important, they were discovered only in 1992. Prior to that date, mystery shrouded many of the processes and illnesses in which the aquaporins play roles.

The aquaporins are in general remarkably specific to H_2O . For example, although they allow H_2O to pass through, they do not allow hydronium ions (H_3O^+) to pass. Nor do they permit other materials to pass at consequential rates. However, a subgroup of the aquaporins—the *aquaglyceroporins*—is unusual in that they permit both H_2O and glycerol to pass. The study of aquaporins is an exploding area of research. Twelve molecular forms of aquaporins—identified as AQP-1, AQP-2, and so forth—are known in mammals, and hundreds are known among organisms taken as a whole. Some cells and tissues noted for having aquaporins in critical cell membranes are red blood cells, the brain, and certain kidney-tubule epithelia (see Chapter 29) in vertebrates in general, and the bladder and skin of amphibians. Aquaporins play essential roles in urine formation, production of the aqueous humor of the eyes, secretion of tears and sweat, and in the blood–brain barrier (they are involved in brain swelling after trauma). Cell membranes endowed with aquaporins are said to exhibit **channel-mediated water transport**.

Molecules of H_2O move through an aquaporin in single file (**Figure 5.20**). Each aquaporin molecule is a tetramer, and—very unlike the structure of ion channels—each of the four monomers has a pore through which H_2O moves. Electrochemical and conformation factors in the pores are responsible for H_2O selectivity.

Water transport through aquaporins is strictly passive. It does not employ metabolic energy, and it is always in the direction of equalizing osmotic pressure on the two sides. In a cell membrane without aquaporins, osmosis across the membrane occurs only by diffusion of H_2O molecules through the lipid bilayer. In a cell membrane with aquaporins, osmosis across the membrane occurs both by diffusion through the lipid bilayer and by channel-mediated H_2O transport through the aquaporin proteins. Membranes endowed with aquaporins exhibit high—sometimes very high— H_2O permeability. Osmosis occurs through them at rates that are typically 5–50 times higher than through membranes

FIGURE 5.20 Water molecules moving through a single aquaporin pore, one at a time Pictured is an aquaporin monomer within a cell membrane, modeled by means of computational biophysics. Blue represents H_2O molecules. The layers of H_2O molecules at the top and bottom represent the fluids outside and inside of a cell. The H_2O molecules actually passing through the aquaporin pore are represented at a larger size than the other H_2O molecules. The aquaporin monomer protein—represented by the gold, purple, and red cylinders, and by the other gold structures—permits H_2O molecules to move readily through the cell membrane by channel-mediated water transport. The finely divided red molecules at left and right represent the lipid matrix of the cell membrane. (Courtesy of Drs. Emad Tajkhorshid and Klaus Schulten, Theoretical and Computational Biophysics Group, University of Illinois at Urbana-Champaign; see also *Am. Sci.* 92: 554–555, 2004.)

lacking aquaporins. The mechanism by which aquaporins accelerate osmosis is not fully understood. Interestingly, a single aquaporin molecule has only a small effect on H_2O transport. Because of this, for a membrane to have high H_2O permeability it must be densely occupied by aquaporin molecules. Mammalian red blood cells, for example, are a classic example of cells with high H_2O permeability. Each red blood cell has about 200,000 copies of AQP-1 in its cell membrane!

Aquaporins are subject to modulation like other membrane proteins. Some aquaporins, for instance, have phosphorylation-modulation sites and are modulated covalently by protein kinases. Certain (but not all) aquaporins are controlled by *insertion* and *retrieval*. Insertion increases the number of aquaporin molecules in a membrane and thus increases membrane water permeability. Retrieval exerts opposite effects. Some kidney-tubule epithelia, for example, undergo rapid changes in water permeability by the insertion and retrieval of AQP-2 under control of the hormone vasopressin (antidiuretic hormone, ADH), as seen in Figure 29.17. Responses of this sort are important in the ability of people and other vertebrates to raise and lower their urine concentration (see Chapter 29).

Osmosis and solute physiology often interact

Because the osmotic pressures of solutions depend on solute concentrations, osmotic water movements are interrelated with solute physiology. The three concepts we now discuss demonstrate the often complex interrelations between water and solutes.

NONPERMEATING SOLUTES OFTEN CREATE PERSISTENT OSMOTIC-GRADIENT COMPONENTS ACROSS CELL MEMBRANES OR EPITHELIA

If a cell membrane or epithelium is impermeable to a solute and the solute is more concentrated on one side than the other, the solute creates a persistent difference of osmotic pressure across the cell membrane or epithelium. The osmotic-gradient component attributable to the nonpermeating solute is persistent because the solute

cannot diffuse to concentration equilibrium across the membrane or epithelium.

This principle is critically important for understanding water movement across the walls of blood capillaries, for example. Blood plasma typically contains relatively high concentrations of dissolved proteins that do not cross blood-capillary walls. These proteins create a persistent tendency for the blood inside the capillaries to take up water osmotically across the capillary walls from the tissue fluids surrounding the capillaries. On the other hand, the hydrostatic pressure of the blood (the *blood pressure*) tends to force water out of the capillaries. The net effect of these processes (see Figure 25.13) is for blood to lose water to the tissue fluids as it flows through the capillaries, but this loss would be vastly greater than it is, were it not for the osmotic effect of blood-plasma proteins trapped inside the capillaries. The portion of the blood-plasma osmotic pressure that is caused by nonpermeating dissolved proteins is termed the **colloid osmotic pressure** or **oncotic pressure** of the blood.

PASSIVE SOLUTE TRANSPORT AND OSMOSIS INTERACT When permeating solutes diffuse across a cell membrane or epithelium because they are not at electrochemical equilibrium, their movement tends to alter the osmotic-pressure gradient across the membrane by removing osmotically effective solute from one side and transferring it to the other. On the other hand, osmosis of water across a cell membrane or epithelium tends to alter the electrochemical gradients of solutes because solutes tend to become concentrated on the side losing water and diluted on the opposite side. In addition to these interactive effects of solute diffusion and osmosis on osmotic and electrochemical gradients, the rates of passive solute transport and passive water transport frequently interact by direct mechanical, chemical, or electrochemical coupling of solute and water movements. When water is crossing a membrane in one direction, for example, solute may tend to move physically with the water in the same direction by **solvent drag**, a

phenomenon roughly analogous to minute bubbles being carried along by a water current.

ACTIVE SOLUTE TRANSPORT PROVIDES A MEANS TO CONTROL PASSIVE WATER TRANSPORT Animals are generally believed to lack active water transport. However, active solute transport can create a gradient of osmotic pressure, thereby setting up conditions favorable for osmosis to occur in a particular direction. In this way, active solute transport provides a means by which animals can use metabolic energy to exert control over the direction of water transport. Suppose, for example, that it would be adaptive for an animal to force water to cross a membrane from left to right. The animal could employ an active solute pump to drive such water movement by concentrating a solute on the right side of the membrane, so that the solution on the right is hyperosmotic to that on the left. Then water would cross the membrane by osmosis in the adaptive direction. Indirectly, in this way, ATP-bond energy can be used to provide the motive force for water transport. This principle is believed to be used by animals in many situations; for example, many insects use the principle to concentrate their urine (see Chapter 29), and vertebrates are believed to use it to absorb water into their blood from the materials passing through their intestines.

SUMMARY Osmosis

- Osmosis is the passive transport of water across a membrane, such as a cell membrane or an epithelium. Osmosis always occurs from the solution of lower osmotic pressure (more abundant water) to the solution of higher osmotic pressure (less abundant water). Osmosis is always toward equilibrium, tending to bring the solutions on the two sides of a membrane to equal osmotic pressure.
- Two solutions are isosmotic if they have the same osmotic pressure. If two solutions have different osmotic pressures, they are described as being hyposmotic and hyperosmotic to each other, the one with the lower osmotic pressure being the hyposmotic one.
- A single solution exerts no increase in hydrostatic pressure because of its osmotic pressure. However, hydrostatic pressures can be generated by osmosis between two solutions interacting across a membrane.
- In some cell membranes, the only mechanism by which osmosis occurs is that H_2O molecules dissolve in the membrane and move through by molecular agitation (simple diffusion). Other cell membranes, such as the membranes of red blood cells and certain kidney tubules, however, have aquaporins, providing a second path for osmosis to occur and increasing the rate of osmosis 5- to 50-fold in comparison with membranes without aquaporins. Aquaporins permit highly specific, channel-mediated H_2O transport.

Study Questions

1. People often say things like “A city has reached equilibrium size” or “A person has reached equilibrium between needs and wants.” Discuss whether these uses of *equilibrium* are compatible with the word’s thermodynamic meaning.
2. What are the similarities and differences between the mathematical equation for the rate of simple solute diffusion and the equation for the rate of osmosis?
3. Consider three groups of solutes: (1) steroid hormones, fatty acids, and other lipids; (2) inorganic ions; and (3) polar organic solutes such as glucose and amino acids. What is the principal mechanism by which each group crosses cell membranes passively? Why do members of the first group cross in a fundamentally different way from solutes belonging to the other two groups?
4. (a) Life-threatening diarrhea is a shockingly common problem in the developing world. People with life-threatening diarrhea are often Na^+ -depleted, and to save their lives, replacing Na^+ is essential. However, “raw” Na^+ in the intestines is not absorbed. Drinking a solution of $NaCl$ does not, therefore, replenish body Na^+ . In fact, drinking such a solution can actually worsen a person’s situation by osmotically dehydrating the blood and other body fluids. Explain how the drinking of a $NaCl$ solution could have this effect. (b) One of the greatest physiological discoveries of the twentieth century was that drinking a solution of mixed glucose and $NaCl$ can promote restoration of the body’s Na^+ . With the glucose concentration high enough in the solution, glucose “drives” the glucose- Na^+ cotransporter in the apical membranes of intestinal epithelial cells, promoting Na^+ uptake in sick people. Explain the concept behind this manipulation of the cotransporter for therapeutic ends. The approach has saved millions of lives.
5. Explain why active transport of an ion shows saturation kinetics, whereas transport of an ion through an ion channel does not.
6. Whereas electrical currents are carried by electrons in copper wire, they are carried by ions in aqueous solutions. Explain how an active-transport mechanism can create an electrical *current* across a membrane.
7. One way to produce freshwater from seawater is “reverse osmosis,” in which high hydrostatic pressures are used to force water to move against its osmotic gradient, from seawater to freshwater, across a membrane. How would you calculate the minimal hydrostatic pressures required? Why might it be preferable to use salty water from a coastal bay diluted with river water rather than full-strength seawater as the water source?
8. Outline all the principal transport processes at work in the three focal examples shown in Figure 5.1.
9. When we discussed the microscopic mechanism of simple diffusion, we made the following point: After the concentrations of glucose on the two sides of a membrane have become equal, glucose molecules continue to move at random from left to right and from right to left; the numbers of glucose molecules going in the two directions are equal, however, explaining why the two concentrations stay equal once they have become equal. Taking advantage of the options provided by multiple isotopes of elements, how could you do an experiment, in an actual physical system, to determine whether the point we have made here is true?
10. The cell membranes of mammalian red blood cells are permeable to urea. If red blood cells are dropped into a solution of urea that is identical in osmotic pressure (isosmotic) to the cytoplasm of the cells, although the cells do not swell and burst as quickly as when they are dropped simply into pure water, they eventually swell and burst. Explain. Also discuss how you would design a solution into which red cells could be placed without ever swelling. (Hint: Think about whether urea will stay on the outside of the cells and the implications for osmotic pressures.)
11. Amphibian eggs laid in freshwater exhibit low water permeabilities and thus do not swell and burst osmotically. When investigators first believed they had identified an aquaporin, they manipulated

amphibian eggs so the eggs expressed the purported aquaporin protein. When the investigators observed those eggs swell and burst, they knew they had made a monumental discovery: They had found the first aquaporin. Recalling what we have discussed regarding red blood cells, explain why this experiment provided convincing evidence for channel-mediated water transport.

CHAPTER 11 ■ Food, Energy, and Temperature *at Work*: The Lives of Mammals in Frigid Places

Previous page: All growing animals require food as a source of matter for constructing their tissues. They require food also as a source of energy that enables them to mature into highly organized, functionally potent organisms despite the second law of thermodynamics. Adult mammals donate the essential resources of matter and energy to each new generation.

Nutrition, Feeding, and Digestion

The Maasai and other cattle-raising peoples of East Africa have long presented a mystery with respect to how they cope with milk as a major part of their diet in adulthood. Contrary to superficial impressions, most adult people on Earth—60–70% according to current estimates—are not able to digest lactose, the principal sugar in the milk of humans and many other mammals. Newborn babies and infants are able to digest the sugar. They do this by producing a digestive enzyme, lactase-phlorizin hydrolase—*lactase* for short—in their small intestine. This enzyme splits each lactose molecule into two smaller sugar molecules (glucose and galactose) that are readily absorbed into the bloodstream and distributed to cells throughout the body. In most species of mammals, however, individuals cease producing lactase after they stop nursing, and most human beings are no different. The norm for people, worldwide, is for individuals to cease production of lactase by the age of 3 or 4 years (an example of genetically controlled developmental programming, similar to Figures 4.5 and 4.7). People who follow this pattern can suffer from lactose intolerance disease in adulthood because lactose itself cannot be absorbed from the digestive tract and they are unable to break it down into simpler sugars that can be absorbed. If people lacking lactase ingest milk, the lactose in the milk simply passes the entire length of the digestive tract and is voided in the feces. Along the way, its presence can cause multiple problems.

Northern Europeans have long been known to be exceptions, as illustrated by the Dutch and Danes in Table 6.1. High proportions of people in northern Europe—and in populations descended from them around the world—continue to produce lactase throughout their lives, a condition known as **lactase persistence**. Because of their lactase persistence, they can digest lactose in adulthood. This explains why they can drink milk and eat dairy products in large quantities throughout their lives without ill effects.

Most black Africans, however, adhere to the worldwide norm, as exemplified by the Nigerian tribes in Table 6.1. Generally in Africa, adults do not produce lactase and are unable to digest lactose, thus the mystery mentioned in the first paragraph. In the cattle-raising African groups, how are adults able to consume lots of milk without suffering from lactose intolerance disease?

Cattle-raising began in East Africa only a few thousand years ago. Following the start of the practice, the Maasai and other cattle-raising peoples developed extremely close cultural associations with their herds. Many of these peoples were nomadic prior to the European colonization of Africa; they moved across the landscape to find suit-

The people of the cattle-raising tribes of Africa are distinctive in that in adulthood they continue to synthesize a key enzyme required for milk digestion Most African people can digest milk sugar (lactose) only when they are young children because they cease in childhood to produce the required digestive enzyme, lactase. Cattle-raising was adopted by certain cultural groups only a few thousand years ago. Recent research shows that, despite the short time since cattle-raising began, these cultural groups have evolved distinctive mutations that permit continued production of the digestive enzyme into adulthood. Thus substantial fractions of the people are able to digest milk sugar throughout their lives. This is a Maasai man with his herd.

TABLE 6.1 Percentages of people who synthesize lactase in adulthood

These data are based on clinical tests in which a person ingests a standardized test dose of lactose and investigators look for evidence of digestion of the sugar. Outside a clinical setting, the experience of “lactose intolerance disease” is partly subjective (depending, e.g., on a person’s sensitivity to gut distress). Thus, there is not necessarily a one-to-one relation between the proportion of a population that is clinically classified as failing to synthesize lactase and the proportion complaining of lactose intolerance disease.

Group	Percentage synthesizing lactase
Dutch	100
Danes	97
White Americans	76
Greeks	47
Mexican Americans	44
Indigenous people of Australia	33
Italians	29
African Americans	19
Members of the Ibo and Yoruba tribes (Nigeria)	11
Native Americans (Oklahoma)	5
Chinese	1
Asians in the United States	0

able grazing lands and watering places for their cattle, all the while depending on their animals for food and hides. Milk became a major food and a crucial source of liquid in times of drought.

Some years ago, studies of northern Europeans revealed that they differ from most people in the *control of expression* of the gene for lactase synthesis. A specific nucleotide mutation at a chromosome position near the gene for lactase synthesis acts on the lactase gene promoter to upregulate transcription of the lactase gene in adulthood, resulting in lactase persistence. This mutation is inherited as a dominant Mendelian trait and is so common in the gene pool of northern Europeans that almost all individuals inherit at least a single copy. The mutation is entirely absent, however, in East Africa.

Recent studies in East Africa have now not only clarified how the cattle-raising peoples gain food value from milk but also provided biologists with startling new insight into the *rate* at which evolution can proceed in human populations. The studies have revealed that large percentages (60–80%) of individuals in the populations of cattle-raising peoples exhibit lactase persistence—continuing to synthesize lactase as adults—and they evidently do so in the same fundamental way as northern Europeans, namely that they have mutations that affect control of the lactase gene, causing the gene to be expressed in adulthood. These mutations are entirely novel, however, and evidently arose in Africa in just the few thousand years since cattle-raising began there. One can reason in the abstract that mutations favoring lactase persistence would be of considerable advantage for cattle-raising peoples. Based on the actual evidence recently revealed, we now know that in fact such mutations are able to spread in human populations

so rapidly as to become common within a few thousand years! One especially common mutation in East African cattle-raising peoples is estimated to have first appeared only 5000 years ago.

A key general principle is implicit in the story of lactose: Eating a food substance is usually not sufficient for the substance to have nutritional value. To be of use, an ingested compound must be absorbed from the digestive tract, and absorption often depends on whether the compound can be broken down by digestion (or other processes) into molecules for which absorptive mechanisms exist.

Feeding, nutrition, digestion, and absorption, we see, are intimately interrelated. They evolve interactively in relation to the foods available in a population’s environment. **Figure 6.1** provides a map of the basic processes involved in meeting an animal’s nutritional needs through the ingestion of food. To meet its nutritional needs, an animal feeds on potentially useful food substances in its environment. The exact substances it ingests depend on the nature of its feeding apparatus, and also on its feeding behavior, which often is adjusted to match nutritional needs. After organic compounds are ingested, they are broken down by the action of digestive enzymes and other digestive mechanisms. These mechanisms, however, are not omnipotent and in fact are often highly specific. Thus, whereas some substances in a meal may be broken down rapidly and completely, others may not be digested at all. A key factor is the suite of digestive enzymes an animal synthesizes. Fermentation by symbiotic microbes may also be important in breaking down food. *Absorption* refers to the transfer of molecules from the open central cavity of an animal’s gastrointestinal tract into the living tissues of the animal. Absorption of many substances requires transporter proteins that are specific in the molecules they transport. Thus the successful use of ingested compounds often depends, in the end, on whether digestion can break up the compounds into molecules that can be transported by the specific absorption transporters an animal synthesizes. All the processes discussed here, taken together, determine which nutrient molecules are actually delivered to an animal’s tissues when the animal eats. Ideally, these molecules meet the animal’s nutrient needs.

A notable property of animals is that all must eat regularly throughout their lives. The frequency of eating varies: American people, for instance, eat three meals a day, whereas some pythons might eat three meals a *year*. Regardless of such differences in timing, all must eat repeatedly. Why is this so? We of course readily understand why growing animals need to eat over and over: They must accumulate all the diverse atomic building blocks required for their increasingly large bodies. But why do adults need to eat repeatedly for as long as they live? This question is especially compelling because feeding is often dangerous for animals in a state of nature; they must emerge from safe refuges to eat, for example—as when a squirrel leaves its nest cavity to search in the open for nuts. Why can’t a fully grown adult simply make do with the chemical building blocks and energy it already has? One of the principal reasons that animals must feed throughout their lives is the *dynamic state of body constituents* emphasized in Chapter 1 (see page 11). Individual cells and molecules in an animal’s body age or become damaged throughout the animal’s life, and they are discarded and replaced. During this turnover, some of the chemical building blocks of the old cells and molecules are lost from the body and must be replaced with new chemical building blocks from foods. New amino acids are needed to replace amino acids lost in the breakdown of old proteins, for example. Another key

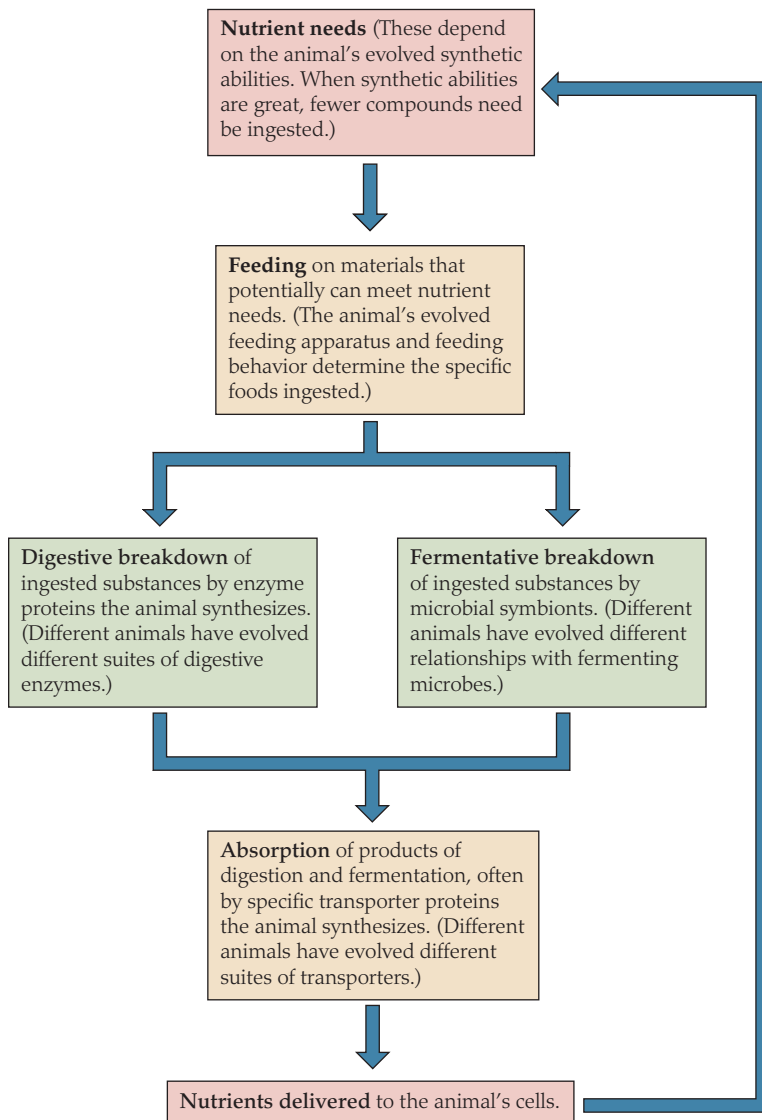

FIGURE 6.1 Relations of nutrition, feeding, digestion, and absorption in vertebrates and most types of invertebrates “Feeding” includes the processes of selecting, acquiring, and ingesting foods. Although evolved properties are emphasized in this presentation, phenotypic plasticity is also important. The particular digestive enzymes or absorption transporters expressed by a given animal at a given time may depend on the amounts and types of foods it has recently been eating. Fermentative breakdown by symbiotic microbes is of conspicuous quantitative importance in some animals (e.g., cows), although not in others (e.g., humans). Certain types of invertebrates have novel mechanisms of meeting nutrient needs not represented by this diagram; reef-building corals, for example, are photosynthetic because of algal symbionts.

Negative feedback: Ideally the processes of feeding, digestion, microbial fermentation, and absorption meet (or at least reduce) nutrient needs.

because of its importance in the skeleton, and phosphorus because it occurs not only in the skeleton but also in nucleic acids and the phospholipids of all cell membranes.

A useful way to understand animal nutrition is to consider the major components of the body—such as proteins or lipids—and ask several questions about each. Why is each sort of body component needed? How do animals acquire the chemical building blocks that are required to synthesize each sort? What peculiar challenges are likely to be faced for an animal to synthesize adequate amounts of each sort of body component? These are the questions that dominate this section.

Proteins are “foremost”

Among the major components of the body, proteins deserve to be discussed first because they occupy a position that is both uniquely important and uniquely tenuous in animal nutrition. The very word *protein* is derived from the Greek for “foremost,” referring to the preeminent position that proteins occupy in the structure and function of all animals. One way to see the impor-

consideration, stressed in Chapter 7, is that *the chemical-bond energy used in metabolism cannot be reused*. Instead, new chemical-bond energy must be acquired by food ingestion. Eating throughout life is a necessity despite the danger it entails because animals are physiologically dynamic systems, not static objects.

Nutrition

Nutrition is the study of the chemical compounds that compose the bodies of animals and how animals are able to synthesize the chemical components of their bodies from the chemical materials they collect from their environments. Nutrition also includes the study of the energy available from foods.

An instructive starting point for the study of nutrition is to look at the chemical composition of a familiar example, the human body (Figure 6.2). Excluding water, the human body is composed principally of proteins and lipids. Minerals are third in overall importance, followed by two additional categories of organic molecules: nucleic acids and carbohydrates. The most abundant types of atoms in the human body are carbon, hydrogen, and oxygen—the ubiquitous building blocks of organic compounds. Nitrogen, calcium, and phosphorus are additional, particularly abundant types of atoms—nitrogen because it appears in all proteins and nucleic acids, calcium

FIGURE 6.2 The composition of the adult human body The weights in kilograms of the five principal body components, other than water, in an average, slender adult weighing 70 kg. About 42 kg of the total body weight is water (not shown).

FIGURE 6.3 Amino acid chemistry

(a) Structures of five of the standard amino acids required for protein synthesis. All amino acids contain nitrogen even if lacking an α -amino group. Amino acids with α -amino groups may contain additional nitrogen, as exemplified by lysine. Box 2.1 discusses the relation between amino acids and protein structure. (b) The fate of amino acids that are ingested but that an animal either does not need or is unable to use for protein synthesis. The reaction shown here, although it can literally occur as drawn (catalyzed by an oxidase), is a conceptual version of what usually happens. Typically, the unneeded amino acid undergoes a transamination reaction (catalyzed by an aminotransferase) that removes the amino group from the unneeded amino acid and attaches it to another carbon chain, usually synthesizing another amino acid (only nonessential amino acids can be made in this way). A common product of this process is the amino acid glutamate, which then may be deaminated to produce NH_3 . Amino acids are typically not stored for future use. After a meal, all the amino acids from the meal that cannot be promptly used (including ones formed by transamination) are deaminated directly or indirectly.

(a) Five of the standard amino acids

The H_2N — group on the second carbon from the top in each molecule shown is an α -amino group. This type of amino group occurs in most, but not all, standard amino acids.

(b) The fate of unused amino acids

The unneeded amino acid (alanine in this example) is stripped of its amino group by an enzyme-catalyzed **deamination reaction**.

The result is a nitrogen-free carbon chain (pyruvic acid in this case), which can then be used in biosynthesis of nonnitrogenous compounds (e.g., glycogen) or catabolized for energy.

tance of proteins is to look at their abundance in the bodies of animals. About half the organic matter in a mammal is protein (see Figure 6.2), and proteins are similarly abundant in other types of animals. A second way to see the importance of proteins is to consider the many vital roles they play. Enzyme proteins *speed and regulate biochemical reactions*. Muscle proteins are responsible for *locomotion*, one of the most characteristic features of animals. Structural proteins, such as collagen in connective tissue and keratin in skin, *determine the structural properties of tissues*. Other proteins are so diverse in function as to defy simple classification. They include the receptor, channel, and transporter proteins in cell membranes; proteins dissolved in blood plasma (e.g., albumin); antibodies; proteins that function as hormones; oxygen-transport proteins such as hemoglobin; protein venoms; and the transparent crystallin proteins of eye lenses.

A set of 20–22 amino acids, called the **standard amino acids**, is required for the synthesis of proteins in all organisms. The structures of five amino acids are shown in Figure 6.3a, and all the standard amino acids are listed (along with their usual abbreviations) in Appendix I. In addition to the standard amino acids, more than 200 other amino acids are known in organisms and play diverse roles, although they are not involved in protein synthesis. As stressed in Box 2.1, protein structure is complex. However, from the simple perspective of *primary* structure (see Box 2.1), **proteins** are *defined* to be strings of amino acids composed of many amino acid units. Relatively short strings are often distinguished as **polypeptides**, although no strict dividing line exists between proteins and polypeptides, and for simplicity we will usually use the word *protein* to refer to both. **Dipeptides** consist of two amino acids; **tripeptides**, three. All amino

acids contain nitrogen. Proteins are about 16% nitrogen by weight, in contrast to carbohydrates and lipids, which do not contain nitrogen.

A fact that colors every aspect of the nutritional biology of proteins is that nitrogen is a limiting element in many ecosystems, including many terrestrial ecosystems and more than half of the oceans. Nitrogen limitation may at first seem strange because about 78% of the gas in the atmosphere is molecular nitrogen, N_2 . However, animals, plants, and most microbes cannot use N_2 as a source of nitrogen for building proteins or other nitrogen-containing body components. Instead, as their source of nitrogen they require the element in chemically combined, nongaseous (“fixed”) forms. Plants and algae most commonly use nitrate (NO_3^-), ammonium (NH_4^+), and other inorganic nitrogen-containing compounds as their nitrogen sources. The nitrogen available in these chemical forms in an ecosystem is often low enough that the growth and reproduction of plants or algae are held back by nitrogen insufficiency. Because herbivorous animals most commonly acquire nitrogen from proteins and other nitrogen-containing organic compounds in the tissues of the plants or algae they eat, nitrogen limitation can be relayed up food chains. If the production of plants and algae in an ecosystem is nitrogen-limited, growth and reproduction in herbivore populations may be nitrogen-limited, and fewer carnivores may be able to live there than if herbivores were more successful.

Of all the nutritional vulnerabilities of animals, one of the greatest is that they are biochemically unable to synthesize about ten of the standard amino acids at rates sufficient to meet their requirements (even if nitrogen is freely available). The amino acids that cannot be adequately synthesized are called **essential amino acids** because there is an “essential” requirement that they be

TABLE 6.2 Essential amino acids in the most thoroughly studied model, the growing laboratory rat, and in people

Essential amino acids in the growing rat	Ways that people are similar and different
Arginine	Arginine not essential in humans
Histidine	Histidine essential for children, probably not for healthy adults
Isoleucine	All essential in children and adults
Leucine

Sources: After Burton and Foster 1988; Morris 1991.

acquired *fully formed* from food or another *outside* source.¹ Experiments to determine the list of essential amino acids in a species are challenging. Thus ambiguity often exists about the list even for relatively well-studied species. The set of essential amino acids also varies a bit from one animal group to another. **Table 6.2** lists the ten amino acids that are essential for the best-studied animal model, the growing laboratory rat. As the table notes, eight of the ten are required in the diet of adult humans, and nine are essential in children. The ten essential amino acids of the growing rat are also essential in insects, fish, and birds. For some insects and birds, there are additional amino acids that are essential.

The inability of animals to synthesize certain amino acids might not be a problem if animals were to keep stores of amino acids or proteins in their bodies in the same way they store fat. If stores of “extra” amino acids were maintained, presumably there would always be some of each kind available. However, animals do not generally store amino acids for future use, either as free amino acids or as storage proteins. Instead, when an animal eats amino acids in excess of those it needs for the synthesis of functioning proteins at the time, it promptly strips the nitrogen-containing amino groups ($-\text{NH}_2$) from the carbon chains of the excess amino acids (**Figure 6.3b**). The stripped nitrogen is excreted, and the nitrogen-free carbon chains that are formed are used for biosynthesis or catabolized for energy. Consequently, the amino acids in an animal’s body at any one time are generally constituents of *functioning* protein molecules.

Another important fact about the amino acid physiology of animals concerns the source of nitrogen for synthesis of **nonessential amino acids**—that is, those amino acids that an animal is capable of synthesizing. A property of the biochemical pathways used by animals for such synthesis is that generally the nitrogen-containing amino groups are derived from other amino acids. Thus,

¹The word *essential* has a special meaning in the study of nutrients. A nutrient is essential to an animal if the animal—in and of itself—cannot synthesize it in amounts sufficient for its requirements and thus must get it from other organisms or from the nonliving environment. Vitamins, minerals, and certain fatty acids are essential in this sense, in addition to the essential amino acids. Essential amino acids are sometimes called *indispensable amino acids*.

for a nonessential amino acid to be synthesized, other amino acids must be available to serve as amino-group donors.

With these background points in mind, you will see that animals employ a “just in time” strategy for acquiring the raw materials they need for protein synthesis. In automobile-assembly plants, the standard practice throughout most of the twentieth century was to maintain large stores of all the necessary parts. The approach used nowadays in many assembly plants, however, is the “just in time” strategy. Large stores of parts for future use are not maintained. Instead, all parts are brought to the assembly plant just in time to be used. The “just in time” approach eliminates storage costs, but it makes car assembly more vulnerable to parts shortages; if shipments of *any* required parts are interrupted, assembly of cars must stop. Animals use a “just in time” strategy in building their proteins. The amino acid building blocks that an animal needs for protein synthesis must arrive in the body at the same time that the proteins are actually being synthesized. What is more, the essential amino acids must arrive fully formed. The nonessential amino acids either must arrive preformed or must be synthesized on the spot; synthesis requires the ingestion of alternative amino acids that can serve as nitrogen donors for making the amino acids that are synthesized.

To illustrate the weighty consequences of this strategy for protein synthesis, consider an animal that eats too little lysine in a particular week but for which lysine is an essential amino acid. The animal will be unable to synthesize lysine-containing proteins in the full amounts needed during the week in question. If too little lysine is obtained during the following week, the shortages of proteins will worsen. The animal’s health will deteriorate because the functions of the unmade proteins will not be carried out. Lysine deficiency, in fact, is a serious health problem for millions of people in impoverished parts of the world.

The failure of animals to store amino acids for future use leads to wastage of available essential amino acids when other essential amino acids are in too-short supply for protein synthesis. Returning to the animal we were just discussing, suppose, to illustrate, that a particular meal provides all the essential amino acids in abundance, except that lysine is in short supply. Needed proteins will go unmade because of the lysine shortage. In addition, as the meal is metabolized, the essential amino acids, besides lysine, *that are abundant in the meal and that could have been used to make needed proteins* will not be fully used and will be broken down, as discussed earlier. These other essential amino acids will therefore be wasted.

For the amino acids in a meal to be used optimally for protein synthesis, the meal typically must supply the full required amounts of all essential amino acids. Mixing foods is a mechanism to achieve this objective and thereby reduce or eliminate amino acid wastage. To illustrate, consider an animal for which both lysine and methionine are essential. If food A contains little lysine but much methionine and food B contains lots of lysine but little methionine, eating the two together will allow the animal to use the amino acids from the foods more fully than if either food were eaten alone. Foods must be eaten nearly simultaneously to complement each other in this way. In the human diet, combinations such as corn and beans, or milk and cereal, eaten approximately simultaneously, increase the use of amino acids for protein synthesis because the foods tend to make up for each other’s shortcomings in essential amino acids.

Where do essential amino acids originate in ecosystems? Plants and algae are able to synthesize from scratch all 20–22 of

the standard amino acids required for protein synthesis. For most animals, plants and algae are the principal ultimate sources of essential amino acids.² Herbivores eat the essential amino acids in their plant or algal foods, and then the molecules are relayed up food chains when carnivores eat the herbivores.

Lipids are required for all membranes and are the principal storage compounds of animals

Lipids are often about as abundant as proteins in the structure of animal bodies (see Figure 6.2). They are structurally very diverse and thus problematic to define. Lipids are usually defined as organic molecules composed principally of carbon and hydrogen that are predominantly nonpolar and therefore hydrophobic. The chemical components that most lipids have in common are **fatty acids**, which are hydrocarbons built on a backbone consisting of a chain of carbon atoms (Figure 6.4a). One important chemical category of lipids is the **triacylglycerols (triglycerides)**, also known as **fats** and **oils**; a triacylglycerol consists of three fatty acid molecules combined (esterified) with a molecule of glycerol (Figure 6.4b,c). Waxes, phospholipids (see Figure 2.2), and sterols (see Figure 16.2) are additional categories of lipids.

Fatty acids are chemically diverse; more than 50 different fatty acids are known in organisms. This diversity sets the stage for lipids to be very diverse in their chemical structures and other properties; many different triacylglycerols, for example, can be made by employing different fatty acids in the three fatty-acid positions (see Figure 6.4c). Most fatty acids in organisms have an even number of carbon atoms, between 8 and 24, in their carbon-chain backbone, and they are unbranched. Besides the number of carbon atoms, additional features that impart diversity to fatty acids—and help define their properties—are their degree of saturation and the positions of double bonds. A fatty acid is **saturated** if all the bonds between carbon atoms are single bonds, as exemplified by palmitic acid (see Figure 6.4a). A fatty acid is **unsaturated** if one or more of the bonds between carbon atoms are double. **Polyunsaturated** fatty acids are the subset of unsaturated fatty acids that contain multiple (two to six) double bonds, exemplified by linoleic acid (see Figure 6.4a).

A common system for symbolizing fatty acids specifies three integer numbers, as in the example “18.2ω6.” The first integer, preceding the decimal point, is the number of carbons in the fatty acid. The second, written between the decimal and the Greek letter omega (ω), is the number of double bonds. The third, which follows ω, is the position of the first double bond encountered when the molecule is scanned from its methyl (—CH₃) end. The example “18.2ω6” refers to linoleic acid (see Figure 6.4a), which has 18 carbons and 2 double bonds, with the first double bond at the sixth position from the methyl end. When people speak of “omega-3” or “omega-6” fatty acids, they are referring to unsaturated fatty acids with the first double bond in the third (ω3) or sixth (ω6) position.

Lipids play several functional roles. One role of lipids is that phospholipids and cholesterol (a lipid) are principal *components of cell and intracellular membranes* (see Chapter 2). Lipids are also *storage compounds* in both animals and plants. Lipids serve especially well as energy stores because they far exceed proteins and carbohydrates in their energy value per unit of weight (Table 6.3).

²Bacteria or other heterotrophic microbes may also act as ultimate sources, and some animals maintain symbioses of major nutritional importance with such microbes, as discussed later in this chapter.

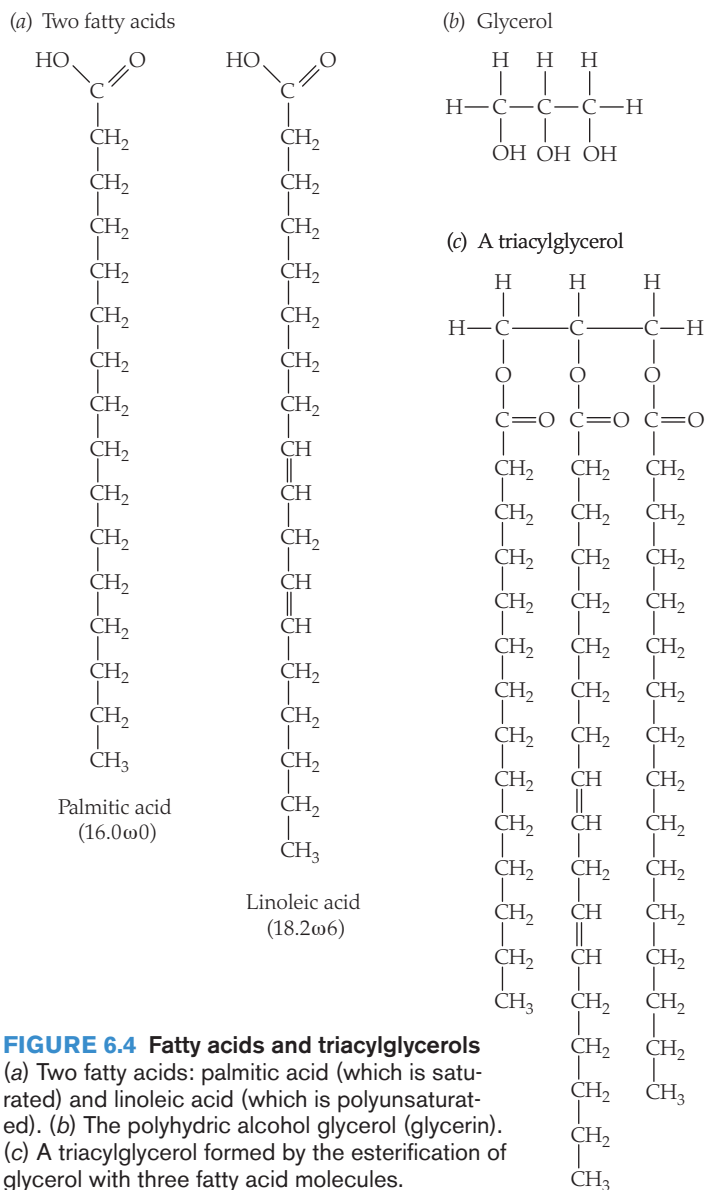

FIGURE 6.4 Fatty acids and triacylglycerols
 (a) Two fatty acids: palmitic acid (which is saturated) and linoleic acid (which is polyunsaturated). (b) The polyhydric alcohol glycerol (glycerin). (c) A triacylglycerol formed by the esterification of glycerol with three fatty acid molecules.

The high energy density of lipids means that the weight of material an animal must carry around to store a given amount of chemical-bond energy is far lower if lipids are the storage compounds than if other compounds are used. A third functional role played by lipids is that in fully terrestrial animals such as mammals and insects, lipids in or on the integument *greatly reduce the permeability of the integument to water*; by thus slowing the evaporative loss of body water, they permit the animals to live in the open air. Lipids play many other roles. Steroid lipids, for example, serve as hormones, and triacylglycerols are key components of the sound-focusing structures in echolocating dolphins.

Animals must synthesize a great variety of lipids to construct their cells and tissues and meet other requirements for lipids in their bodies. They are able to meet these biosynthetic requirements using a variety of organic carbon chains that they obtain in their diets. Indeed, carbon chains used to synthesize lipids may be derived from dietary carbohydrates and proteins, as well as dietary lipids (as is well known, we can add body fat by eating sugar). This biochemical flexibility is one reason that lipid nutrition is less likely than protein nutrition to be fraught with problems. Another reason is the fact that animals maintain stores of lipids; contrary to the

TABLE 6.3 The energy values of mixed lipids, carbohydrates, and proteins in aerobic catabolism^a

	Energy value in kilocalories (kcal) per gram	Energy value in kilojoules (kJ) per gram
Mixed lipids	9.3–9.5	39–40
Mixed carbohydrates	4.0–4.1	17
Hydrated glycogen	1.1	4.6
Mixed proteins	4.3–4.8	18–20

^aData are for mammals and were measured by bomb calorimetry (see Chapter 7). The values for proteins depend on the chemical form of nitrogen excreted; therefore, moderately different values apply to groups of animals that differ from mammals in their nitrogenous excretory compounds (e.g., protein that yields 4.77 kcal/g in urea-producing animals such as mammals yields more, about 4.85 kcal/g, in ammonia producers, but less, about 4.34 kcal/g, in uric acid producers). All values are for dry foodstuff material except those for hydrated glycogen; the glycogen values are for glycogen combined with its usual water of hydration.

case with proteins, lipids obtained in excess of needs at one time are often held over in the body for use in the future.

Problems can arise in lipid nutrition, however, because although animals have extensive capabilities to synthesize and structurally modify fatty acids, many types of animals—including mammals—lack the enzymes needed to create double bonds at the omega-3 and omega-6 positions. The omega-3 and omega-6 fatty acids therefore cannot be synthesized and must be obtained from foods or other *outside* sources, at least during critical life stages. The omega-3 and omega-6 fatty acids thus are **essential fatty acids**. Essential amino acids, you will recall, are specific compounds. The situation with essential fatty acids is usually a little different because when animals eat foods containing fatty acid carbon chains with double bonds in the ω_3 or ω_6 position, they often can modify those chains to obtain others that they need. For example, relatively long fatty acids with a double bond at the ω_3 or ω_6 position can meet the dietary requirement for shorter omega-3 or omega-6 fatty acids because the long fatty acids can be shortened. The simplest fatty acids that will meet omega-3 requirements and omega-6 requirements are α -linolenic acid and linoleic acid (see Figure 6.4a), respectively. Exceptions to this general picture occur. Cats and certain fish, for example, have dietary fatty acid requirements that are more chemically specific than the requirements of most vertebrates. These requirements must be taken into account in the design of foods for pets and aquaculture.

Carbohydrates are low in abundance in many animals but highly abundant when they play structural roles

The simplest carbohydrates are **monosaccharides** such as glucose and fructose (Figure 6.5a). Other types of carbohydrates are composed of two or more monosaccharides bonded together. Those consisting of two monosaccharides are called **disaccharides**; examples are sucrose (glucose + fructose) (Figure 6.5b), trehalose (glucose + glucose), and the sugar with which we started this chapter, lactose (glucose + galactose). **Polysaccharides** have more than ten monosaccharides per molecule and often consist of hundreds or thousands of polymerized monosaccharide units.

Carbohydrates play three principal functional roles in animals and plants. First, large polysaccharides often *provide structural support and shape* to cells and other parts of organisms. The most important structural carbohydrate in animals is the polysaccharide *chitin*,

which is the principal component of the exoskeletons of insects and many other arthropods. Often, more than half the dry weight of an arthropod consists of chitin. The structural polysaccharides of plants and algae, which include *cellulose* and *hemicelluloses*, are enormously abundant in ecosystems and thus are potentially major food sources for animals. Chitin and cellulose are the two most abundant organic compounds in the biosphere!

In their second principal role, carbohydrates function as *storage* compounds. Like the structural carbohydrates, the storage carbohydrates are polysaccharides. They are accumulated and broken down far more dynamically than structural polysaccharides, however. *Starch*, a form of polymerized glucose, is one of the principal storage carbohydrates in plants. *Glycogen*, also a form of polymerized glucose, is the principal storage carbohydrate in animals. In a simplistic sense, the “value” of stored glycogen is primarily that it is a source of energy. Glycogen, however, is far inferior to lipid as a general energy-storage compound for the following reason: Molecules of glycogen are highly hydrated in the tissues of living animals, and because of the added weight of their water of hydration, they yield a low amount of energy per unit of total weight (see Table 6.3). This attribute of glycogen probably explains why the amount of glycogen stored by animals is typically *far* less than the amount of lipid stored (see Figure 6.2). Glycogen serves mainly as a store of *glucose* that in turn serves as a *chemically specific energy source* for certain tissues and metabolic processes that require glucose as their energy source. The central nervous system in vertebrates requires glucose as its principal fuel; moreover, the fastest mechanism of ATP production in vertebrate skeletal muscles (anaerobic glycolysis) also requires glucose as its fuel. Stores of glycogen supply glucose energy to the brain and skeletal muscles in times of need.

The third principal functional role of carbohydrates is as *transport* compounds. The transport carbohydrates are small molecules—monosaccharides or disaccharides—found dissolved in the blood or other moving body fluids. When the body fluids travel from one place to another, the dissolved carbohydrates move with them—thereby, for example, transporting energy from place to place. Glucose is the principal blood transport carbohydrate (“blood sugar”) in vertebrates and most other groups of animals, although many insects employ the disaccharide trehalose in this role. Lactose is transported from mother to offspring in the milks of mammals.

FIGURE 6.5 Carbohydrate chemistry
Sucrose, a disaccharide, is composed of glucose and fructose units.

(a) Two monosaccharides

(b) A disaccharide

Animals typically have a great deal of latitude in the biochemical mechanisms by which they can synthesize the variety of carbohydrates they need to construct their cells and tissues. The carbon chains used to synthesize carbohydrates may be derived from dietary proteins or from the glycerol components of dietary lipids, as well as from dietary carbohydrates. Moreover, there are no essential carbohydrates; animals can synthesize all the carbohydrates they need. The one noteworthy “nutritional problem” that animals have with carbohydrates is that many animals are unable to digest cellulose, chitin, or some of the other structural polysaccharides. Such animals are potentially unable to use some of the most abundant organic materials on Earth. People, for example, cannot digest cellulose; consequently, cellulose in our food—for the most part—simply travels the entire length of our digestive tract and is eliminated in our feces. Cellulose may have been favored as a structural material in plant evolution precisely because it is indigestible and therefore potentially unusable by many animals.

Vitamins are essential organic compounds required in small amounts

Vitamins are organic compounds that animals must obtain in small quantities from food or another *outside* source because the compounds cannot be synthesized by the animals and yet are required in small amounts. Possibly this definition will seem strange because of its emphasis on small quantities. For historical reasons, however, compounds that must be ingested in relatively large amounts, such as essential amino acids, are not called vitamins. The existence of vitamins initially came to light when, in about 1880, scientists tried to maintain normal growth in mice by feeding them purified diets consisting only of carbohydrates, lipids, nutritionally complete proteins, and inorganic salts. The mice could not maintain normal growth. Decades of research then gradually revealed the need for small (often minute) amounts of additional organic compounds, which were called *vitamins*.

The need for vitamins in modern-day animals is often a consequence of “opportunism” during evolution. Vitamin A illustrates this point. The term *vitamin A* refers to *retinol* (Figure 6.6) and several closely related compounds. Animals cannot synthesize the retinol structure from small building blocks. Instead, they are dependent on plants or algae to make the structure. In plants and algae, the structure occurs as a subpart of photon-collecting *carotenoid pigments* such as β -carotene. An animal can obtain vitamin A by eating carotenoids and liberating the vitamin-A structure from these large molecules. The animal can alternatively obtain vitamin A by eating another animal that obtained the vitamin A from carotenoids. Either way, the source of the structure is plant or algal biosynthesis. In animals, the vitamin-A structure is incorporated into crucial visual pigments called *rhodopsins*. To synthesize a rhodopsin, an animal converts vitamin A to its aldehyde *retinal*, which then is conjugated with a protein (*opsin*) synthesized by the animal to form the rhodopsin.³ Remarkably, the light-absorbing portion of rhodopsin is the subpart of the molecule derived from vitamin A! In plants and algae, the carotenoids serve as photon-collecting molecules for photosynthesis. Evidently, as vision evolved, animals that ingested the plant or algal photon-absorbing molecules in their foods “opportunistically” used the vitamin-A structure from those molecules to serve as the photon-absorbing

FIGURE 6.6 Vitamin structures

portion of their visual pigments, rather than evolving an ability to synthesize their own photon-absorbing structure from scratch. This strategy means that animals need not be able to synthesize the photon-absorbing substructure of their rhodopsins. It also means, however, that animals are vulnerable to shortages if they are unable to get enough in their foods.

Because vitamins are consequences of opportunism during evolutionary history, it is not surprising to find that they are extremely diverse in their chemical structures (see Figure 6.6). They are also very diverse in their functions, meaning that there is no simple way to summarize what they do. The use made of most vitamins is that they are incorporated as *key molecular subsystems* into vital molecules, such as molecules that—binding to enzymes—are required for enzyme catalytic function.

Vitamins are usefully subdivided into a *water-soluble* set and *lipid-soluble* set. The water-soluble vitamins include the B vitamins and vitamin C (Table 6.4). Virtually all animals have a mandatory requirement for the B vitamins because the vitamins are required for biochemical reactions of universal importance. The lipid-soluble set of vitamins includes vitamins A, D, E, and K (Table 6.5). All four are required by vertebrates. Invertebrates, however, may or may not require them. The physiological uses of the lipid-soluble vitamins are more specialized than those of the B vitamins (see Tables 6.4 and 6.5), helping to explain why the need for them is not nearly so universal as that for B vitamins.

Elemental nutrition: Many minerals are essential nutrients

Many chemical elements—referred to as *minerals* in the study of nutrition—are required by animals, in addition to the carbon, hydrogen, oxygen, and nitrogen that predominate in organic molecules. One reason a wide diversity of elements is essential is that many enzymes and other proteins include in their structures trace amounts of atoms that otherwise are uncommon in protoplasm. About 40% of all proteins⁴ are in fact metal-containing *metalloproteins*; the metal atoms in the structures of such proteins include iron, copper, molybdenum, zinc, manganese, vanadium, selenium, and cobalt, among others. Humans and other mammals must obtain all of these metals in their diets for proper nutrition. They also require iodine for thyroid hormone synthesis. In addition, turning to some

³Rhodopsin is discussed further in Chapter 14 (see Figure 14.23).

⁴Including those of plants and microbes as well as animals.

TABLE 6.4 Water-soluble vitamins and their physiological roles

Of the vitamins listed, all except ascorbic acid (vitamin C) are classified as B vitamins, although some are not usually referred to using “B” symbols. The B vitamins are required for the reactions specified because they are incorporated into relatively small organic molecules that—binding to enzymes—are required for enzyme catalytic function.

Vitamin	Physiological role in animals
Thiamin (B ₁)	Required for oxidative decarboxylation reactions.
Riboflavin (B ₂)	Required for oxidation–reduction reactions (required for synthesis of FAD, flavin adenine dinucleotide).
Niacin	Required for oxidation–reduction reactions (required for synthesis of NAD, nicotinamide adenine dinucleotide).
Pyridoxine (B ₆)	Required for reactions of amino acid metabolism.
Pantothenate	Required for acetyl-transfer reactions (required for synthesis of coenzyme A).
Folate	Required for single-carbon-transfer reactions (as in nucleic acid synthesis).
Cobalamin (B ₁₂)	Required for single-carbon-transfer reactions (as in nucleic acid synthesis).
Biotin	Required for carboxylation reactions.
Ascorbic acid (C)	Protects cells against damage by reactive oxygen compounds (antioxidant; see Box 8.1). Plays many additional roles in reactions involving oxygen.

of the elements that are more abundant in the body, phosphorus is required for the synthesis of phospholipids, nucleic acids, and bone; and sodium, chlorine, and potassium are essential solutes in the body fluids. One striking way to see the elemental needs of humans is to look at a stoichiometrically correct chemical formula of the human body (published by Sterner and Elser in their book, which is listed in the References).

A person as a chemical formula:

Other kinds of animals have lists of elemental needs similar to those of humans and other mammals.

Mineral deficiencies are a potential problem for essentially all animals. Considering just terrestrial animals, for example, mineral deficiencies are common in a great many regions of the world because of mineral shortages in soils or because of soil-chemistry processes that render minerals unavailable. Sodium and phosphorus deficiencies are common threats to livestock worldwide; moreover, in much of tropical Africa, soil concentrations of calcium, magnesium, and copper are too low for plants to meet readily the needs of lactating mothers and the growing young of ungulate species. Iodine deficiencies provide another illustration; terrestrial regions so expansive that they are occupied by more than 1.5 billion people have soils that provide too little iodine for naturally growing foods to meet

TABLE 6.5 Lipid-soluble vitamins and their physiological roles

Unlike the water-soluble vitamins, lipid-soluble vitamins are usually referred to by their vitamin designations rather than by their chemical names. The reason is that multiple related compounds can often meet the vitamin requirement for lipid-soluble vitamins.

Vitamin	Physiological role in animals
Vitamin A	Light-activated component of visual pigments. Also needed for normal bone growth, reproductive function (e.g., sperm production), cell membrane integrity, and other functions, but exact biochemical mechanisms are not always known. Vitamin A is a regulator of gene transcription and can cause deranged development of a fetus if ingested in artificially large amounts by the mother during pregnancy.
Vitamin D	Activator of pathways of calcium and phosphorus metabolism; acts by binding, like a hormone, to specific receptors.
Vitamin E	Protects cells against damage by reactive oxygen compounds (antioxidant), preserving integrity of critical molecules, especially membrane phospholipids. See Box 8.1.
Vitamin K	Required for production of blood-clotting factors.

human iodine needs. Iodine deficiency is prevented in developed nations by the use of dietary iodine supplements, notably iodized salt. In impoverished regions, however, insufficient iodine ingestion is a major cause of mental retardation and abnormal neurological development in children. (Recent calculations indicate that average IQ could be raised in these regions by 10–15 points at a very low cost by alleviating iodine deficiency.)

The migration of wildebeests and zebras in the Serengeti ecosystem (Figure 6.7), justly called one of the wonders of the living world, may well be a quest for essential minerals. At the start of each rainy season, a herd of a million or more migrates 200 km (more than 100 miles) from the far north of the Serengeti—where rivers flow year-round—to the dry southeast. As the rains fall in the southeast, parched grasses spring to life, and dry streambeds fill with running water. The animals thrive there during the rains, giving birth to most of their young. When the rains end months later, however, the thin soils of the southeast dry out quickly, and the animals are forced by lack of water into a mass exodus that ultimately takes them back to their starting place in the north. Many die along the way. No one is certain why the wildebeests and zebras undertake their migration. Why don't they simply stay year-round in the north, where water is available in all seasons, rather than migrating a great distance into an area—the southeast—that cannot possibly be a permanent home because it is too dry for half the year?

The most compelling modern hypothesis is that the wildebeests and zebras migrate to the southeast to acquire minerals. In the Serengeti ecosystem, the soils of the southeast—because they are of relatively recent volcanic origin—are especially rich in needed minerals. For example, grasses in the southeast contain 1.5 times as much calcium per gram of tissue weight as grasses in the north because of higher soil concentrations in the southeast. Lactating mothers and their growing young require especially large amounts

FIGURE 6.7 The great Serengeti migration: A quest for minerals?

Wildebeests and zebras, in herds sometimes numbering a million or more, travel from the far north of the Serengeti ecosystem to the southeast at the start of the rainy season and return to the north for the dry season each year. According to one prominent hypothesis, the trek to the southeast is a quest for minerals. See Chapter 30 for more on the Serengeti migration.

of calcium. According to the mineral–nutrition hypothesis, the reason the fabled herds migrate to the southeast, and calve there, is that the migration ensures their young of adequate minerals for development.

SUMMARY Nutrition

- Essential organic nutrients are organic compounds that animals must obtain from other organisms because the animals are biochemically unable to synthesize them. About ten of the standard amino acids required for protein synthesis are essential in most sorts of animals. Omega-3 and omega-6 fatty acids are essential in many animals, and vitamins are essential.
- Proteins often present particular nutritional problems because nitrogen can be in short supply in ecosystems and essential amino acids may be unavailable in the amounts needed. Because animals employ a “just in time” strategy for protein synthesis (rather than storing amino acids for future use), the essential amino acids must be eaten together in the amounts they are needed if they are to be used. A shortage of any one essential amino acid can cause wastage of available supplies of others.
- Vitamins are very diverse in their chemical structures. What they have in common is not their chemical nature but the fact that they are organic compounds required in small (often minute) amounts. Most are used as substructures in molecules of critical importance for animal function. The water-soluble vitamins, notably the B vitamins, are essential for most or all animals. The lipid-soluble vitamins, such as vitamins A and K, are more specialized in their functions and not as universally required.
- Minerals are also essential nutrients. Metal atoms occur in approximately 40% of proteins. Minerals are also required as constituents of body fluids and skeletons. More than 20 chemical elements are required for the construction of animal bodies.
- Structural carbohydrates such as chitin, cellulose, and hemicelluloses are the most abundant organic compounds on Earth, but many animals lack enzymes required to digest them and thus are unable (on their own) to tap those carbohydrates for nutritional value.

Feeding

Feeding—by which we mean the process of obtaining and ingesting foods—needs to be targeted at food items that will meet an animal’s nutritional needs. One reason animals have evolved a diversity of feeding mechanisms is that they vary in the nutrients they must ingest. For instance, animals with especially extensive synthetic capacities can get along with a relatively narrow range of ingested foods because they are able to synthesize most of the compounds they need on their own.

Besides the structure of a feeding apparatus, behavioral modulation of its use is often important in determining what foods are ingested. For example, individuals with particular nutrient needs often behaviorally select foods that will meet those specific needs. Mountain gorillas, for example, are attracted to eating rotting wood because it is a particularly effective source of the sodium (Na^+) they require. A more intricate example comes from recent research on wolf spiders. The spiders are predatory, and they were provided with fruit flies to eat. Some of the flies—all of which were of one species and looked the same—had been manipulated to have a body composition high in protein, whereas others were high in lipid. As seen in [Figure 6.8](#), the spiders chose prey that helped balance their needs for protein and lipid. For example, if a spider had ingested lots of protein-rich flies during the 24 h before testing, its appetite for lipid-rich flies was heightened and its appetite for protein-rich flies was diminished.

The feeding mechanisms employed by animals are stunningly diverse. Consider, for example, three animals that live in the oceans: orcas, blue whales, and reef-building corals. Orcas (killer whales) feed in a way that is very familiar to us. They have large teeth and strong jaw muscles, and they feed by attacking other animals that are modestly smaller than they are, such as fish and seals ([Figure 6.9](#)). Blue whales (see [Figure 6.13](#)) lack teeth and do not attack individual prey. Instead, they are *suspension feeders*, meaning they ingest organisms suspended in the water that are minute by comparison with their own size. The whales capture their tiny prey by

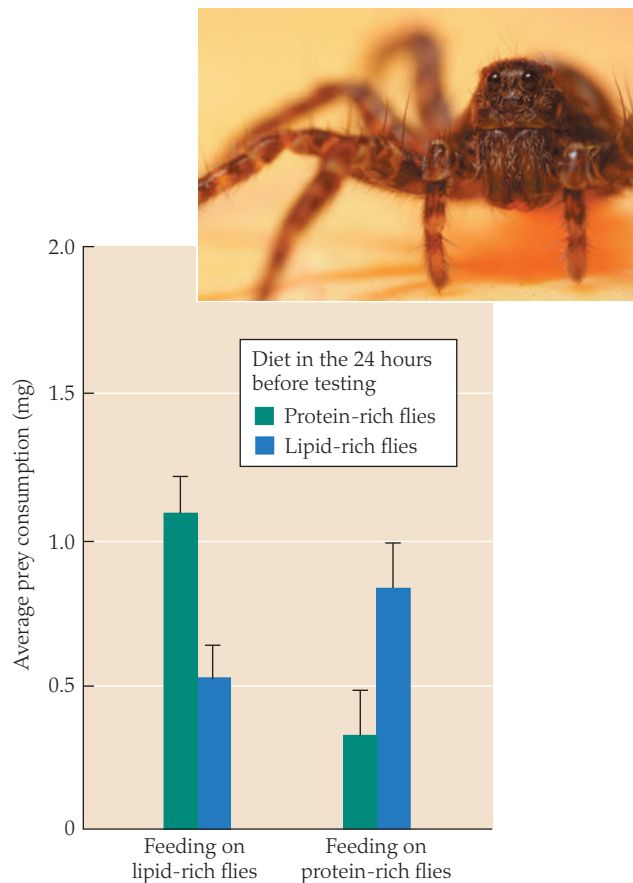

FIGURE 6.8 Behavioral food selection: Wolf spiders select the flies they eat in ways that balance their intake of protein and lipid Two groups of spiders (*Pardosa prativaga*; 22–24 spiders in each group) were, respectively, given only protein-rich or only lipid-rich fruit flies (*Drosophila melanogaster*) to eat for 24 h prior to testing. Then they were tested by being permitted to feed on lipid-rich (left) or protein-rich (right) flies for 72 h. As seen on the left, when the two groups of spiders were presented with lipid-rich flies to eat, the spiders that had been eating protein-rich flies before testing caught and ate far more than those that had been feeding on lipid-rich flies before testing. By contrast, as seen on the right, when the two groups were presented with protein-rich flies to eat, the spiders that had been eating lipid-rich flies ingested far more than those that had been feeding on protein-rich flies. The differences between groups are statistically significant. Error bars show the standard error. (After Mayntz et al. 2005. Photograph courtesy of David Mayntz.)

sieving them from the water. Reef-building corals (see Figure 6.15) are photosynthetic; they get much of their nutrition from algae with which they live in symbiotic associations. All three of the feeding modes exemplified by the orca, blue whale, and corals—attack of individual prey items, suspension feeding, and association with symbiotic microbes—are widespread in the animal kingdom.

Many animals feed on organisms that are individually attacked and ingested

Many animals, both terrestrial and aquatic, are like orcas in that their feeding is directed at individually targeted food items. This feeding mode requires that the individual food organisms be located, identified, subdued, and ingested. In contrast to the simplicity of these basic imperatives, the array of actual mechanisms employed is wonderful in its diversity. Carnivorous mammals that feed in this way grasp prey with teeth, and usually they use their teeth to reduce the prey to smaller pieces by tearing or chewing

before swallowing. Carnivorous fish grasp prey with teeth as well, but they usually swallow their prey whole. Some sea stars eat by enveloping prey in their evaginated stomachs. Fragile butterflies harvest the nectar of flowers with long proboscises. Peregrine falcons violently strike flying birds at high speed in midair, then circle back to grasp their victims as the latter—stunned—fall toward ground in the grip of gravity.

Related animals that share a particular mechanism of feeding usually exhibit specialized variations in the mechanism. Bird bills provide a familiar example. Virtually all birds collect food items using their bills. The bills, however, exhibit a wide range of specializations. Some bird species have long, strong, sharp bills that they use as chisels to reach prey within tree trunks (Figure 6.10a); other species have stout bills that help them crush seeds (Figure 6.10b); still others have slender bills that they insert, stiletto-like, deep into mud to collect burrowing prey (Figure 6.10c).

The food-collection devices of grazing mammals—their teeth and lips, plus their prioritization mechanisms—provide another vertebrate example of variations on a theme. Grazing can at first look as nonselective as lawn mowing. In fact, however, species of grazers that are ostensibly similar sometimes feed on very different sets of the plant species available. The teeth, jaws, and lips of zebras, for example, enable them to feed more readily on tall grasses than wildebeests can. Wildebeests, in contrast, are more effective at ingesting short grasses in large quantities, in part because they have an exceptionally blunt muzzle and a wide row of incisors. A third species that feeds with wildebeests and zebras on grasslands, Grant's gazelle, tends to choose herbs, sedges, and small woody plants more than the grasses themselves. Differences such as these are believed by most biologists to help account for the diversity of coexisting species.

FIGURE 6.9 Some species feed by targeting and subduing individual food items Orcas (*Orcinus orca*) eat fish, sea otters, and seals by attacking them with sharp teeth. Groups (pods) of orcas tend to be behavioral specialists in the prey they attack. Some groups, for example, eat mostly fish, whereas others eat mostly marine mammals.

FIGURE 6.10 Specialization of a vertebrate feeding apparatus
Bill specialization in a woodpecker, a cardinal, and a sandpiper (a type of shorebird).

Snails provide a dramatic invertebrate example of diversification in the use of a single basic feeding mechanism. The primitive feeding device of snails is a scraping organ, the **radular apparatus**. It consists of a ribbonlike band of connective tissue (the radular ribbon), studded with chitinous teeth and stretched over a cartilaginous rod (Figure 6.11a). Most snails use this apparatus to rasp organic matter

off objects, such as algae off rocks. The cartilaginous rod is pressed against a surface, and muscles at the two ends of the radular ribbon pull the ribbon back and forth over the rod to produce rasping action. The radular teeth, which are elaborate (Figure 6.11b), vary widely in shape from species to species. In some species, the teeth are hardened with iron or silica compounds, enabling the snails to rasp tissue from armored food sources.

The most exotic specializations of the radular feeding mechanism occur in species that attack and feed on living animals. One specialization for carnivory is the use of the radular apparatus as a *drill* to gain entry to shelled animal prey. Carnivorous snails with this specialization press their cartilaginous rod, with the tooth-studded radular ribbon at the end, against the shell of a clam or similar prey item. They then rasp a hole through the shell (Figure 6.11c) by turning the rod back and forth around its long axis. The most extreme specialization of the radular apparatus occurs in the carnivorous cone snails we discussed in Chapter 2. In these, the radular teeth have become detachable, elongated harpoons,

(a) The mouth cavity of a snail showing the radular apparatus

An herbivorous snail feeding by rasping algal growth off a rock.

(b) A radula ribbon viewed side-to-side, showing rows of teeth

(c) The shell of a clam that was killed by a carnivorous drill snail

Some carnivorous snails, called drills, have a specialized radular apparatus that cuts a neat hole through the shell of a clam, barnacle, or other armored prey item, permitting the snail to attack the living tissues inside. This clam was eaten by a drill.

(d) A harpoonlike radular tooth of a cone snail

In cone snails the radular teeth have evolved into the shape of barbed harpoons. A cone snail jabs a tooth into a prey animal, such as a fish, and injects a mix of potent conotoxins via the tooth to immobilize the prey animal.

FIGURE 6.11 Specialization of an invertebrate feeding apparatus The primitive form of the radular apparatus in snails is a scraping or rasping organ used to scrape algae off rocks, rasp flesh off dead animals, and so forth. The radular apparatus is greatly specialized in carnivorous snails that prey on living animals. (a) Longitudinal sections of the primitive radular apparatus in the mouth cavity of a snail. (b) A magnified drawing of a radular ribbon of the primitive sort seen in (a), viewed side-to-side and showing the intricate shapes and multiple rows of teeth; these details are species-specific. (c) The telltale sign of specialized radular feeding by a carnivorous snail called a drill. (d) A highly specialized radular tooth of a fish-eating cone snail, shown at great magnification. (b from Hyman 1967.)

complete with barbs (Figure 6.11d). Cone snails synthesize some of the most toxic venoms known (conotoxins), and they use their highly modified teeth to inject the venoms into fish or other prey (see Figure 2.28).

TOXIC COMPOUNDS Toxic compounds incorporated into venoms or employed in other ways are involved in the feeding biology of a wide diversity of animals that attack individual food items. Predators that employ poisons to attack prey include not just cone snails but also scorpions, spiders, many snakes, and many coelenterates, such as jellyfish. The poisons used by all these predators are proteins. The most common actions of the poisons, as we saw in Chapter 2, are to inflict structural damage on cell or basement membranes, or to interfere with nerve and muscle function by combining with receptor or channel proteins.

Another way that toxic compounds play roles in predation is that they are used as defenses by potential prey. Bees, wasps, and some skates, for instance, have defensive venoms (in which the active agents often include proteins or polypeptides). Far more common are toxic or repellent compounds *within the tissues* of sessile prey. Sessile organisms such as sponges or plants may seem at first to be easy meals—sitting in plain view, waiting to be eaten. Many, we now realize from advances in analytical chemistry, are far from defenseless, however, because they synthesize and deposit within their tissues chemicals that discourage attack. In addition to sponges and plants, other groups sharing this property include seaweeds, soft corals, and tunicates. The compounds *within the tissues* of these organisms that deter consumption are called **secondary compounds**, **secondary metabolites**, or **allelochemicals**. Some are merely distasteful; others disturb the digestion or metabolism of herbivores or predators. Chemically, the compounds are extremely diverse and include alkaloids, terpenes, polymerized phenolics (e.g., tannins), steroids, nonprotein amino acids, polyethers, and quinones.

Some herbivores and predators have become specialists at defeating defenses based on secondary compounds. They may, for instance, have a specialized biochemistry that detoxifies defensive chemicals, or they may be able to tolerate the chemicals or rapidly excrete them. Therefore, the battle to eat and avoid being eaten, on both sides, is often waged biochemically as well as mechanically.

Suspension feeding is common in aquatic animals

Suspension feeding, as noted earlier, is feeding on objects, suspended in water, that are very small by comparison with the feeding animal.⁵ Clams and oysters—which are often many *centimeters* long—typically feed on suspended particles that are 5 to 50 *micrometers* in size. They thus qualify as suspension feeders. Blue whales that are 20 to 30 *meters* long feed on shrimplike krill that are 2 to 3 *centimeters* long. Blue whales thus also qualify as suspension feeders. A requirement for suspension feeders is to collect large numbers of food items because each food item is so small. Although suspension feeders often display some evidence of selectivity, they typically do not single out and attack food items individually. Instead, they collect food items in numbers.

⁵Suspension feeding can in principle occur in air; in fact, some terrestrial animals, such as certain spiders, function as suspension feeders. However, little if any primary production occurs in the atmosphere, and potential food items for suspension feeders are sparse in air. Thus suspension feeding is far more common in aquatic animals than terrestrial ones.

In both freshwater and the ocean, suspension feeding is very common. A factor that helps explain this is that small, suspended food items are abundant in aquatic systems.

Besides food abundance, additional factors probably help explain why suspension feeding has evolved as often as it has in water. One of the most important factors is that suspension feeding permits animals to feed lower on food chains, where the food energy available per unit of time tends to be particularly great. Ecologists find that as food is passed through the steps of a food chain, only about 10% of the energy value of the food makes the transition through each step. Feeding lower on a food chain reduces the number of steps and thereby increases the energy available.

To see this more clearly, let's contrast two possible mechanisms by which a large whale can obtain food. One possibility is for the whale to eat fish just somewhat smaller than itself. Such fish might live by eating other fish only somewhat smaller than they are, and so forth. The entire food chain leading to the whale might thus look like that in Figure 6.12a. Note that there are four steps in this food

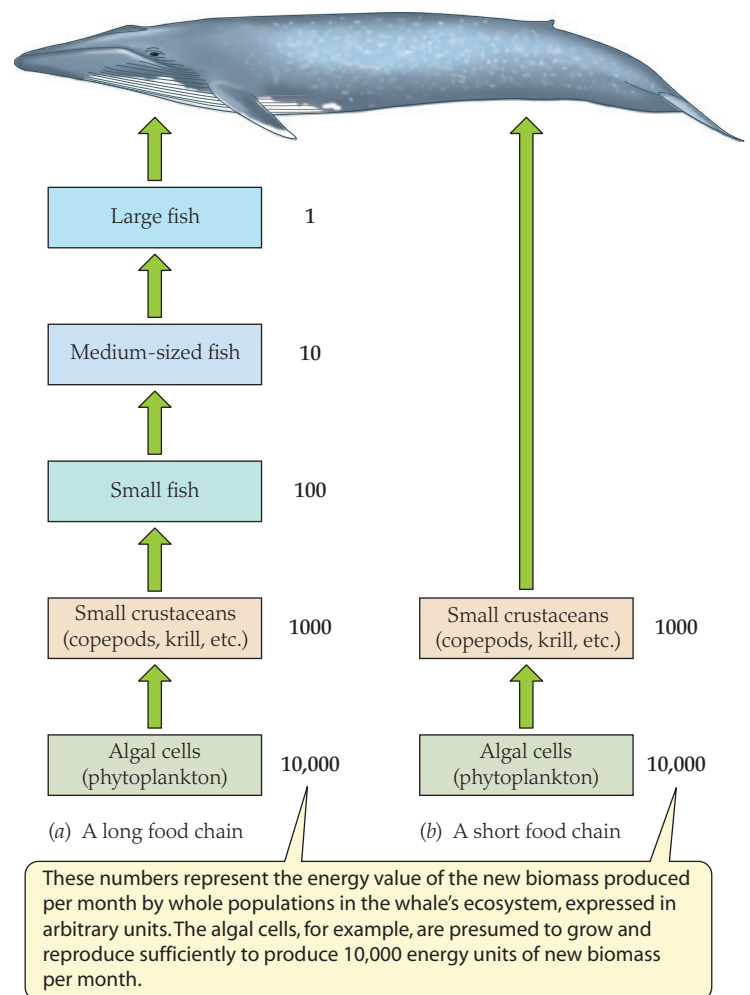

FIGURE 6.12 Short food chains deplete energy less than long food chains do In this thought exercise, we imagine a whale with two possible food chains. In (a), the whale eats fish just a bit smaller than itself, and the food chain leading to the whale's prey has four steps. In (b), the whale eats animals that are minute by comparison with its own size, and the food chain leading to the whale's prey has one step. The short food chain (b) depletes far less of the energy, prior to consumption by the whale, than the long food chain (a) does.

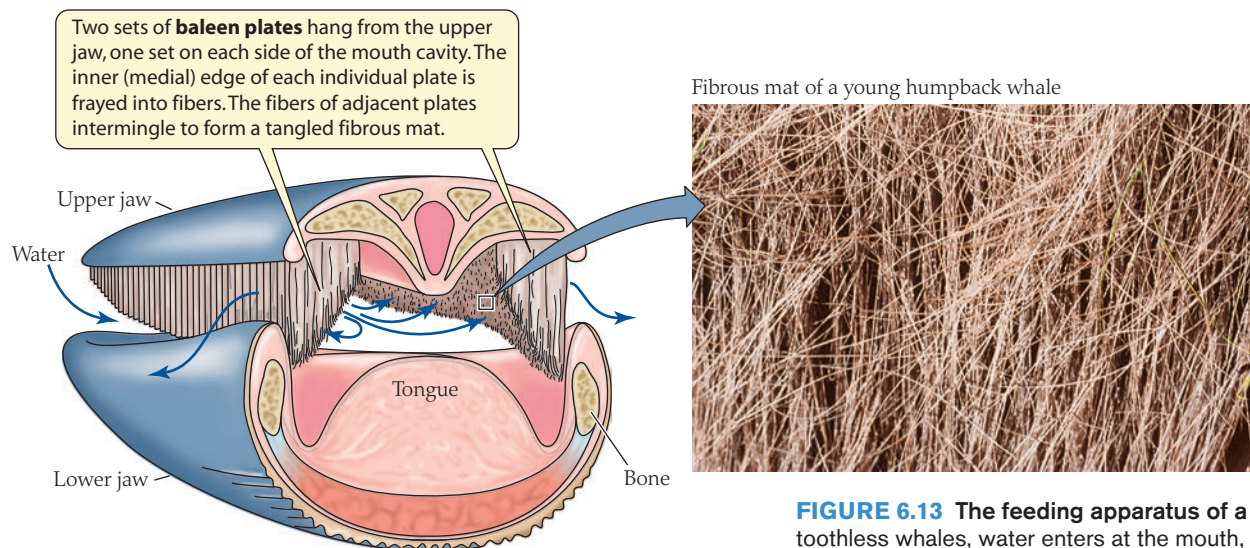

FIGURE 6.13 The feeding apparatus of a baleen whale In these toothless whales, water enters at the mouth, flows through an array of baleen plates on each side of the mouth cavity from the inside, and exits laterally. A thick fibrous mat on the inside face of each array of baleen plates forms a sieve. Small food items accumulate on the inside face of each fibrous mat because of sieving. To be swallowed, the food items are freed from the fibrous mats by some mix of backflushing, tongue licking, and vibrational movements that shake them free. (Drawing after Slijper 1979.)

chain between the photosynthetic organisms (the algal cells) and the prey of the whale (the large fish). Suppose that the population of algal cells grows and reproduces sufficiently over a period of a month to produce 10,000 units of food energy. Using the value 10%, we can then estimate that the population of small crustaceans will grow and reproduce enough to produce 1000 units of food energy during the month (10% of 10,000). Next, the food energy produced by the population of small fish during the month will be 100 units. That produced by the population of medium-sized fish will be 10 units, and finally, that produced by the population of large fish will be 1 unit. This 1 unit is the food available for a whale population at the top of the food chain. Thus a long food chain with many steps, as in Figure 6.12a, depletes most of the energy value of algal production before the energy reaches a form that the whales eat. In contrast, as presented in Figure 6.12b, a whale can function as a suspension feeder and eat organisms much smaller than it is, such as the small crustaceans. In this case, there is just one step between the photosynthetic algal cells and the prey of the whale. The energy available to the whale population in a month is thus 1000 units rather than 1. Shortening the food chain in this example increases the food available to the whales by a factor of 1000!

Many of the largest animals on Earth, and some of the most productive animal populations on Earth, are suspension feeders. The large individual size and high productivity observed in suspension feeders are believed to be consequences of, and evidence for, the energy advantages of suspension feeding. Blue whales, the suspension feeders we have already highlighted, are by far the largest animals that have ever lived. The two largest species of fish alive today are both suspension feeders: the whale shark (12 tons) and the basking shark (5 tons). About 30% of all the biomass of fish caught commercially in the world each year consists of herrings, sardines, menhadens, anchovies, and other species that belong to the clupeid group of fish—a group noted for suspension feeding. Crabeater seals, which are by far the most abundant and productive of all seals, are not actually “crab eaters” but use highly modified teeth to eat small crustaceans (notably krill) by suspension feeding.

For an animal to have a shortened food chain and reap the energy advantages of suspension feeding, the *mechanistic* challenge it must

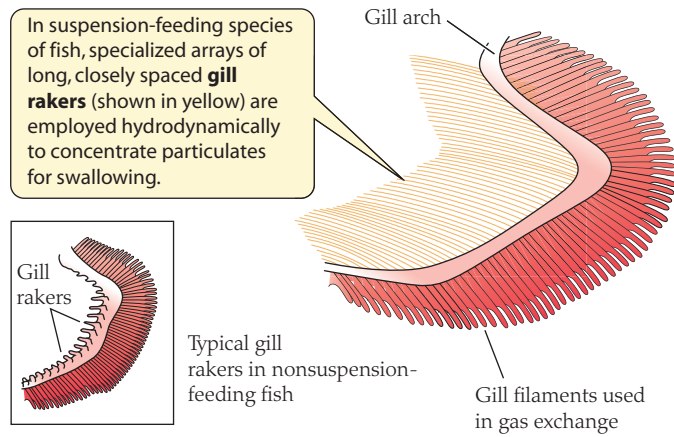

meet is that it must be able to gather food items far smaller than itself in great numbers. A blue whale feeding on krill, for example, must have a mechanism of collecting from the water great numbers of objects that are individually one-thousandth of its size. A rough analogy would be for a person to live by collecting objects the size of individual tomato seeds from the air.

The food-collection mechanism employed by suspension-feeding whales is based on sets of **baleen plates**, constructed mostly of keratin, that hang from the upper jaw on the two sides of the head, each plate oriented approximately perpendicular to the longitudinal axis of the whale’s body (Figure 6.13). In an adult blue whale, there are hundreds of these plates on each side of the mouth cavity; most are a meter or more long, and they hang like pages of a book from front to rear. The medial (inside) edge of each plate frays into strands of keratin, and the frayed strands of adjacent plates become tangled with each other. In this way, the entire inner face of the baleen array on each side of the whale’s mouth consists of a mat of tangled keratin fibers. A suspension-feeding whale typically feeds by taking a huge mass of water into its mouth cavity and forcing the water out laterally on each side through the baleen arrays. Krill, copepods, or tiny fish in the water cannot fit through the mats of fibers. Thus these small food items are sieved out in huge numbers and swallowed.

Although the baleen whales employ mechanical sieving (analogous to filtering) to collect food and therefore might be termed *filter-feeders*, most suspension feeders do not use simple mechanical sieving or filtering. Suspension-feeding devices sometimes employ hydrodynamic forces, electrostatic attractions, chemical attractions, targeted grasping by tiny appendages, and other processes to collect food items from the water.

In suspension-feeding fish, specialized gill rakers are used to collect food items (Figure 6.14a). People used to think water was rammed perpendicularly through the arrays of gill rakers, similarly to forcing water through a kitchen sieve. Actually, according to recent research

(a) Gill rakers employed by suspension-feeding fish

(b) Mechanism of separating suspended food particles from water in clupeid fish with specialized gill rakers

(c) Setae employed for suspension feeding by krill

FIGURE 6.14 Suspension-feeding mechanisms based on spines in vertebrates and invertebrates (a) A gill arch of a suspension-feeding clupeid fish. The gill rakers are extraordinarily long, numerous, and closely spaced compared with those of fish that do not suspension feed. Gill rakers are skeletal elements covered with ordinary epidermis and are not involved in gas exchange. (b) Based on research on several species of clupeid fish, water flows past (not through) the elaborate arrays of gill rakers in the buccal cavity, and the arrays are employed hydrodynamically to concentrate particulates in the stream of water prior to swallowing. Water flows in the mouth, and water not swallowed flows out through the gill slits (see Figure 23.10), driven by pumping motions or by pressure differences created when a fish swims forward with its mouth open. (c) A krill, *Meganyctiphanes norvegica*, showing arrays of feeding setae on the appendages. (b after Brainerd 2001.)

employing tiny cameras positioned to observe the process, water flows past, not through, the arrays of gill rakers toward the throat, and as it does so, pure water is bled off, as seen in [Figure 6.14b](#), concentrating food particles prior to swallowing. Some invertebrate suspension feeders, such as tunicates and some stream insects, use intricate nets woven of mucus to collect food items from the water. Other invertebrate suspension feeders, such as clams and oysters, use cilia. Still others, such as krill and barnacles, collect food using elaborate arrays of rigid spines (setae) formed as extensions of the exoskeleton ([Figure 6.14c](#)). For the most part, the exact ways that mucus nets, cilia, and spines are employed by invertebrates are not yet known.

Symbioses with microbes often play key roles in animal feeding and nutrition

Various types of animals maintain symbioses of nutritional importance with three different categories of microbes. One important distinction in categorizing the microbes is whether they are *heterotrophs* or *autotrophs*. Heterotrophic microbes require organic compounds of external origin as their sources of energy. Autotrophic microbes, in contrast, are able to synthesize organic molecules from inorganic precursors (e.g., CO_2 and NO_3^-) using nonorganic energy sources. Some autotrophs are *photosynthetic*; their source of energy for the synthesis of organic compounds is photon energy from the sun. Other autotrophs are *chemosynthetic* and obtain their energy from energy-releasing inorganic chemical reactions (oxidation reactions). In summary, therefore, the three categories of microbes with which animals maintain symbioses are **photosynthetic autotrophs**, **chemosynthetic autotrophs**, and **heterotrophs**.

SYMBIOSSES WITH PHOTOSYNTHETIC AUTOTROPHS (PHOTOAUTOTROPHS) Several sorts of aquatic animals obtain organic food molecules from internal populations of algae—photosynthetic autotrophs—with which they maintain symbiotic associations. After the algae synthesize organic molecules from inorganic precursors employing sunlight, they export some of the organic molecules to the tissues of their animal host, where the animal's cells use the organic molecules of algal origin as food molecules. All the animals characterized by these symbioses also have other modes of feeding. Nonetheless, the algal symbionts are in some cases so important that their photosynthetic products are able to meet 100% of their host's energy needs.

The reef-building corals are the most famous of the animals that feed by obtaining organic compounds from endogenous algal symbionts ([Figure 6.15](#)). More than 600 species of warm-water, reef-building corals are known, and all have algal symbionts. In addition to providing food energy to the coral animals, the algal symbionts metabolically facilitate formation of the calcareous skeleton that corals produce. A topic of great current importance in coral-reef biology is the *stability of the symbiotic association*. Stresses can destabilize the association so that algal symbionts leave the coral polyps, an unhealthy condition that can lead to polyp death and reef disintegration. Corals that have lost their symbionts are called *bleached* because they no longer have chlorophyll or other algal pigments.

Considering the entire animal kingdom, in most cases when there are symbiotic associations

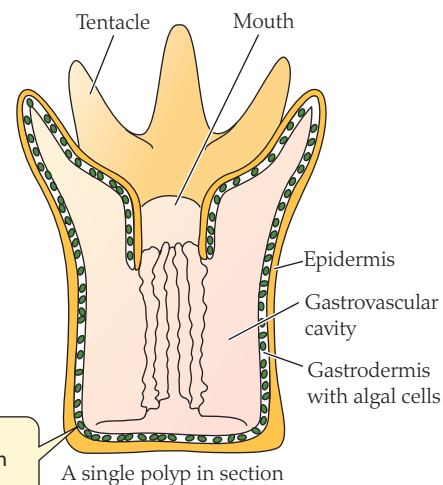

FIGURE 6.15 Reef-building corals require light because they are animal–algal symbioses The reef-building corals (a) are colonies of polyps (b) that secrete skeletal material. The polyps of warm-water species maintain a symbiosis with dinoflagellate algae (zooxanthellae). In addition to gaining nutrition from algal photosynthesis, the polyps have stinging cells with nematocysts and use them to capture small animals, which are taken into the gastrovascular cavity for absorption and digestion.

(a) A tropical coral-reef ecosystem

About a dozen living, coral polyps

Populations of symbiotic algae live in the **gastrodermis**. Photosynthetic products from the algae pass directly to the animal cells in each polyp.

A single polyp in section

between animals and algae, the algae belong to the taxonomic group known as *dinoflagellates* and are called **zooxanthellae** (pronounced as if the *x* were a *z*; singular *zooxanthella*).⁶ The reef-building corals have dinoflagellate zooxanthellae, as do the giant tridacnid clams (which live in coral-reef ecosystems) and certain marine sponges, jellyfish, anemones, and nudibranchs. In freshwater animals that have algal symbionts—such as some of the freshwater hydras, sponges, and flatworms—the algae belong to taxonomic groups other than the dinoflagellates.

All animals that depend on algal symbionts for nutrition must ensure that their symbionts receive adequate light for photosynthesis. This is a major reason why reef corals and giant clams occur only in clear or shallow waters. It also helps explain why any human activity that makes water turbid tends to destroy coral reefs; water turbidity can *starve* corals!

SYMBIOSES WITH CHEMOSYNTHETIC AUTOTROPHS (CHEMOAUTOTROPHS) Until the late 1970s, chemosynthetic autotrophs were not considered important as animal symbionts. That view changed abruptly with a now-famous expedition to the deep sea. The lightless bottom of the deep sea is generally an energy-poor habitat. With very little food available, the animals living there tend to be small and sparse. In 1977, however, a group of geologists exploring deep-sea tectonic spreading centers made the stunning discovery that crowded communities of large animals—including clams as big as quart bottles and worms as big as baseball bats—often live near the spreading centers. The communities are now named **hydrothermal-vent communities** because they occur at places where warm water rises out of underwater cracks (vents) in Earth's crust.

Chemoautotrophic **sulfur-oxidizing bacteria** are the key to the profusion of animal life in the hydrothermal-vent communities. These bacteria oxidize inorganic sulfide (S^{2-}) to obtain energy for the synthesis of organic molecules. The source of S^{2-} for hydrothermal-vent communities is in part *local* reduction of sulfate (SO_4^{2-}) by Earth's heat. Seawater is rich in SO_4^{2-} . At tectonic spreading centers, seawater seeps into deep cracks in Earth's crust, where it comes into contact with hot rock of Earth's core and is heated to temperatures as high as 400°C. Because of inorganic chemical reactions between the seawater and rock at the high temperatures and pressures that prevail, a portion of the sulfur in the heated water is chemically reduced from SO_4^{2-} to S^{2-} . In addition, S^{2-} is sometimes added by being dissolved out of the rock. Heated water has a reduced density because of its elevated temperature. Thus water heated in the cracks of Earth's crust rises back up into the open sea, carrying S^{2-} with it in the form of hydrogen sulfide (H_2S) (Figure 6.16). Chemoautotrophic bacteria in the vent communities take up the H_2S , oxidize the S^{2-} to chemical forms such as SO_4^{2-} , and use the energy released to synthesize organic molecules.

Sulfur, you will note, acts as an *energy shuttle* in these communities. As seawater passes down into cracks in the seafloor and contacts hot Earth, sulfur acquires energy by undergoing reduction. The sulfur later yields this energy when it is reoxidized by sulfur-oxidizing bacteria. In this way, the bacteria are able to draw on Earth's heat as an energy source for primary production.

Many animals in the hydrothermal-vent communities obtain organic nutrient molecules by maintaining symbiotic associations with sulfur-oxidizing bacteria. The most dramatic example is provided by the highly specialized annelid worm *Riftia* (see Figure 6.16), a large worm (up to 1.5 m long) named after the undersea rifts (cracks in Earth's crust) near which it lives. *Riftia* has no mouth, no gastrointestinal tract, and no anus. It cannot ingest food! However, about one-fifth of its body is filled with a tissue called the *trophosome*,

⁶The term *zooxanthellae* refers rather loosely to "golden-colored" algal symbionts. Most are dinoflagellates, but some belong to other taxa of algae, such as the diatoms or cryptophytes.

FIGURE 6.16 Hydrothermal-vent worms living in total darkness in the deep sea are symbiotic with chemoautotrophic bacteria. The hydrothermal-vent worm *Riftia pachyptila* has no mouth, gut, or anus. Its food comes from sulfur-oxidizing chemoautotrophic bacteria, living in its trophosome, that require H_2S . The worms must live near hydrothermal vents because the vents are their source of H_2S . SO_4^{2-} made in the trophosome is voided across the gills. (After Arp et al. 1985; photograph courtesy of Woods Hole Oceanographic Institution.)

where abundant populations of sulfur-oxidizing bacteria live. The blood hemoglobin of the worm transports not only O_2 but also H_2S . As the blood flows through the worm's gills, it picks up H_2S from the vent water. The symbiotic bacteria obtain H_2S from the blood, oxidize the S^{2-} , and use the energy released to synthesize organic compounds, some of which enter the worm's tissues and meet the worm's food needs. Clams and snails in the hydrothermal-vent communities also have sulfur-oxidizing bacterial symbionts in their tissues (e.g., gills), although they are also able to ingest and digest foods.

Animal symbioses with chemosynthetic autotrophs are now known to occur in many locations in the sea. They are common near oil seeps, for example, not just in hydrothermal-vent communities.

MICROBIAL POPULATIONS IN ANIMAL GUTS Humans—and probably all other animals—have populations of many species of microbes living in their *gut lumen*—the hollow central core of the gut. These populations are collectively known as the **gut microbiome**. When microbiologists have attempted to culture gut microbes, they have been unsuccessful in the great majority of cases; the microbes require specific, generally unknown conditions in the gut to survive. Inability to culture most of the microbes has long blocked the

acquisition of detailed knowledge about the species present in the gut microbiome and their functional abilities. The advent of genomics has changed all that and opened up a new field of research that is expanding spectacularly. With genomic methods, a nucleotide sequence can be acquired for an animal's entire microbiome—a type of *metagenome* (a mixed-species genome). Such a sequence is then searched for the signatures of particular microbial species to determine species composition. Moreover, when genes are identified, researchers can often make informed predictions about their functions by extrapolating from functional studies of homologous genes in culturable organisms. These genomic methods have been used mostly, thus far, in biomedical research.

A person or other mammal lacks gut microbes prior to birth. Colonization of the gut begins during the birth process, however (e.g., microbes are acquired from the mother's vagina), and thereafter colonization rapidly escalates as a youngster interacts with potential microbial sources such as other individuals or environmental surfaces. In some species of animals, including horses and certain lizards, juveniles consume the feces of adults. Conceivably, this behavior has evolved to establish a suitable gut microbiome in the youngsters. By the time the microbiome of a mammal reaches

a steady state in its size and species composition, the number of gut-microbe cells is about ten times the number of mammal cells in the mammal's body (a circumstance that is possible because microbial cells are far smaller than mammal cells). In humans, most of the species of gut microbes are bacteria; species of viruses, archaea, and microbial eukaryotes account for less than 10% of the total. According to current evidence, after the composition of the gut microbiome reaches steady state, it tends to be relatively stable within one individual. However, it can vary dramatically from one individual to another.

Evidence exists that the composition of the microbiome can potentially affect the physiology of the host. For the most part, however, the effects known at present relate to pathological states. For example, chronic changes in the gut microbiome can contribute to chronic diseases such as obesity, diabetes, and inflammatory diseases—sometimes acting by affecting immune function. In a recent study, gut microbes were transplanted from lab mice exhibiting a syndrome of metabolic disorders into germ-free lab mice, and the recipient mice thereafter exhibited the metabolic syndrome. By comparison with evidence for such effects in pathological states, little is known about the roles of the microbiome in the normal physiology of most animals.

In a recent study, investigators reported that most people in the human populations they studied fall into one of three types (termed *enterotypes*) in the composition of their gut microbiome. Although the composition is variable within each type, the three types are distinctly different. For understanding normal physiology, it is striking that the three types vary—based on the genes detected in them—in several important ways. For example, one type is especially effective at synthesizing biotin and riboflavin—two B vitamins (see Table 6.4)—whereas another type is especially effective at producing thiamin and folate—two other B vitamins. The types also differ in how effective they are in breaking down complex carbohydrates in the gut contents, potentially making breakdown products available to the host for use. Conceivably, individual people vary in their normal physiology in ways dependent on functions being performed by their respective gut microbial communities.

SPECIALIZED SYMBIOSES WITH HETEROTROPHIC MICROBES

Previously we have discussed symbioses between animals and *autotrophic* microbes. Although *heterotrophic* microbes, in dramatic contrast to autotrophs, are similar to animals in that the microbes require organic compounds from external sources, animals may nonetheless gain nutritional advantages from symbiotic association with heterotrophs because the microbes may provide metabolic capabilities that the animals lack. For example, heterotrophic microbes often can break down food materials that animals are unable to break down. In the last section we noted that humans and probably *all* other animals have large populations of gut microbes. Those microbes are heterotrophic, and conceivably—in the future—biologists will determine that symbioses with heterotrophic microbes are virtually universal. In studies of symbiosis with heterotrophic microbes up to now, however, biologists have focused on animals that exhibit *distinctive specializations for symbiosis*, and such animals will be our focus here.

In the animals that maintain specialized symbiotic relations with heterotrophic microbes, the microbes typically occur as *mixed communities* of multiple microbial types (e.g., bacteria, protists,

yeasts, and fungi) living in the gut lumen. The microbes are anaerobes, given that the gut lumen is typically anaerobic (devoid of O₂). They are often called **fermenting microbes** to emphasize that they carry out fermentation. **Fermentation** refers to several sorts of enzyme-catalyzed reactions that occur without O₂, such as reactions that break down organic compounds anaerobically to liberate energy substrates for metabolic use. Animals that maintain specialized symbiotic associations with fermenting microbes are often described as **fermenters**.

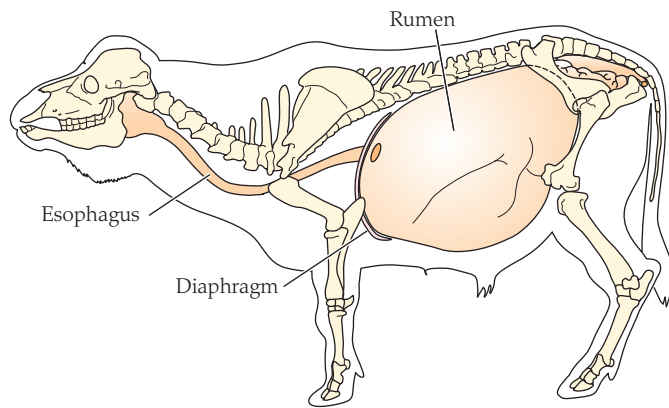

The groups of vertebrates that are particularly noted for having distinctive specializations for symbiosis with heterotrophic microbes have *specialized gut chambers* in which the microbes are housed. These chambers are enlarged or dilated, and the fluids in them are suitable for microbes to thrive (e.g., not strongly acidic). In many cases the specialized gut chambers of vertebrate fermenters are part of the foregut, which is the part of the gut composed of the esophagus and stomach. Those animals are called **foregut fermenters**. The most famous of them are the *ruminant mammals*. Other than the specialized fermentation chamber, the rest of the gut of a vertebrate foregut fermenter typically consists of a relatively ordinary, acid-secreting stomach chamber, and intestines.

Mathematical models used to understand gut function indicate that breakdown of foods by microbial fermentation is generally most effective when fresh, newly ingested food material is mixed with older material already colonized by the microbes. Conversely, enzymatic digestion of foods—carried out by enzymes the animal produces—is generally most effective when the enzymes are added to new material that is not mixed with material already subjected to enzymatic digestion. In foregut fermenters, these considerations are believed to explain (**Box 6.1**) why the specialized chambers for microbial fermentation are enlarged and vatlike, whereas the intestine remains tubular as in other mammals. Foods from successive meals mix in the vatlike part of the gut, creating optimal conditions for microbial fermentation. However, after material enters the tubular intestine, it does not mix with material that has already been in the intestine for a substantial time, an optimal condition for enzymatic digestion.

VERTEBRATE FOREGUT FERMENTERS Ruminant mammals—all of which are herbivores—provide the most famous example of foregut fermenters, as already noted. The stomach of a ruminant has a complex structure, consisting of several compartments (**Figure 6.17**). The first and largest compartment, to which the esophagus connects, is the **rumen**, where communities of fermenting microbes thrive in a nonacidified setting. When a ruminant swallows grasses, leaves, twigs, or other plant parts, the first step in processing is that the microbes colonize the materials and ferment them. Ruminants include sheep, antelopes, cattle, goats, camelids, moose, deer, giraffes, and buffaloes. Not all vertebrate foregut fermenters are ruminants. Others—all of which are herbivores like ruminants—include kangaroos, hippos, colobus monkeys, sloths, and a rain-forest bird called the hoatzin.

In ruminants and other foregut fermenters, three categories of function are carried out by the microbes in the mixed microbial community in the rumen. The first that we discuss here is the one already mentioned: The microbes carry out the *fermentative breakdown of compounds that the animal cannot digest*, notably cellulose and some of the other structural carbohydrates of plant cell walls,

(a) An African buffalo showing the size and position of the rumen

(b) The digestive tract of a domestic sheep

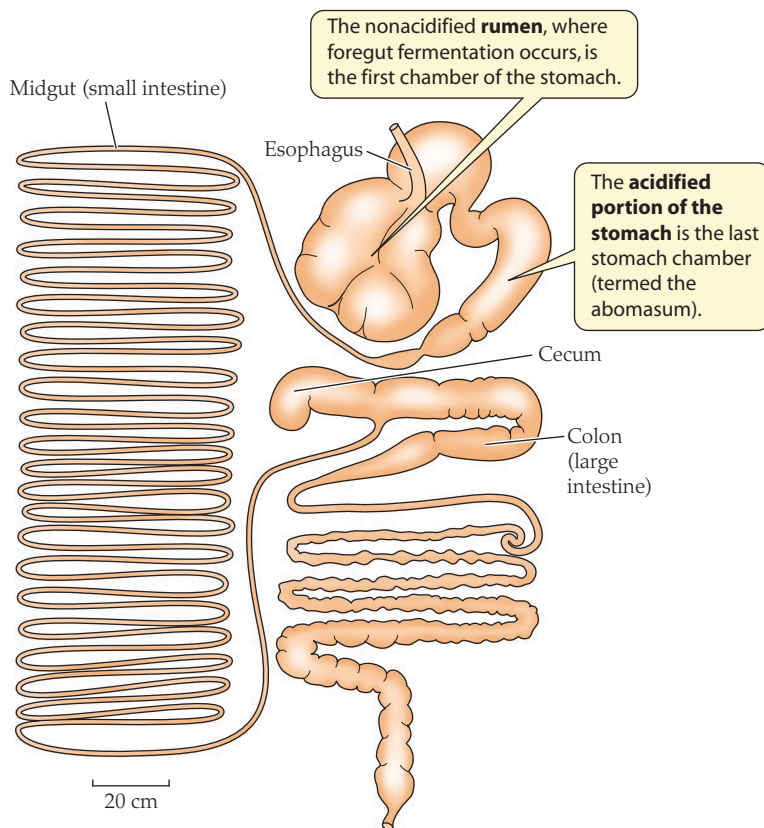

FIGURE 6.17 The digestive tract of ruminants (a) An African buffalo, showing the position and impressively great size of the rumen. (b) The digestive tract of a domestic sheep. To create this drawing, the digestive tract was removed in its entirety and laid out as shown. Ruminants periodically regurgitate fermenting material from the rumen into the mouth, break the material up by further grinding using their teeth, and reswallow it. In cows and sheep, the stomach chambers are, in order, the rumen, reticulum, omasum, and abomasum. The rumen and reticulum—the two largest chambers—are connected by a broad opening and function more or less together; the omasum, filled with leaflike folds, acts as a filter, allowing only liquids and fine particulates to move through to the abomasum; and the abomasum is the true stomach, secreting acid and digestive enzymes. There is an enormous range of variation in stomach morphology and function among other ruminant species. (a after Hofmann 1989; b after Stevens 1977.)

such as hemicelluloses. As noted earlier in this chapter, cellulose is one of the most abundant organic compounds in the biosphere and thus a major potential source of energy. Vertebrates, however, are unable to digest it on their own, and therefore—left to their own devices—allow it to pass into their feces. Some of the microbes in the rumen microbial community produce a complex of enzymes called **cellulase** that breaks down cellulose into compounds that their animal host can absorb and metabolize. **Short-chain fatty acids (SCFAs)**, sometimes called **volatile fatty acids**, are the principal useful products of the microbial breakdown of plant structural carbohydrates. SCFAs are fatty acids, structurally similar to those in Figure 6.4a, that consist of relatively few carbon atoms; they include acetic acid (two carbons), propionic acid (three), and butyric acid (four). SCFAs are readily absorbed and metabolized by animals. Other products of the fermentation of structural carbohydrates include CO_2 and methane (CH_4), which in foregut fermenters are voided to the atmosphere by retrograde passage up the esophagus. Methane is a potent greenhouse gas, and as absurd as it may seem, the collective burps of proliferating populations of cattle around the world are a factor in the worrisome global heat budget.

The second major function carried out by the microbes is *synthetic*. Rumen microbes are able to *synthesize B vitamins*, which vertebrate animals themselves cannot synthesize. The microbes of sheep and cattle, for instance, synthesize sufficient amounts of all the B vitamins to meet the animals' needs fully. The rumen microbes also *synthesize essential amino acids*. As the microbial cells grow and divide in an animal's rumen, they synthesize their own cellular proteins from nitrogenous and nonnitrogenous compounds in the animal's food. Some of the amino acids they synthesize to make their cellular proteins are essential amino acids for the animal. When the microbial cells later pass down the animal's digestive tract to the acid stomach and intestines, their protein constituents are digested by the animal's digestive enzymes, and the amino acid products of digestion are absorbed for use in the animal's metabolism. The essential amino acids obtained by the animal in this way reduce its requirement for essential amino acids in its ingested food.

The third noteworthy function of the microbial community is actually related to the second. The microbes *permit waste nitrogen from animal metabolism to be recycled into new animal protein rather than being excreted*. To see how this occurs, consider first that mammals incorporate nitrogen from their metabolic breakdown of proteins mostly into a waste compound called *urea* (see Figure 29.24). We ourselves and many other species excrete the urea in our urine. In ruminants, however, the urea can diffuse from the blood into the rumen, where certain of the microbes break down the urea to make ammonia (NH_3). Neighboring microbes are then able to use the NH_3 as a nitrogen source for the *synthesis of proteins*. When the microbial proteins are later enzymatically digested, the animal obtains amino acids, which it uses to synthesize animal proteins. In this way, nitrogen—which is potentially a very valuable asset—is saved from excretion and recycled into the animal's tissues.

VERTEBRATE HINDGUT AND MIDGUT FERMENTERS Some herbivorous vertebrates, called **hindgut fermenters**, have specialized gut chambers to support communities of mixed, fermenting microbes in their hindgut, the part of the gut corresponding to the mammalian large intestine and cecum. Many species of mammals, for example, are hindgut fermenters. They have an enlarged cecum or enlarged

BOX 6.1 TYPES OF MEAL PROCESSING SYSTEMS

Physiologists have looked to industrial models to gain insight into the types of meal processing systems that are possible and their properties. When chemical or microbial processes are used to make commercial products in industry, the apparatus used to carry out a process is termed a **reactor**. Three types of reactors are recognized,

as shown in the figure. You will immediately recognize parallels in the meal processing systems of animals. Our intestines, for example, function like the type of reactor shown in Part 2 of the figure, and the rumen of a cow functions like the type of reactor in Part 3 of the figure. **Box Extension 6.1** discusses these reactor types in greater depth. It

focuses on the type of meal processing that occurs in ruminants, which takes place in two very different stages: a first stage in which self-replicating microbes act on the meal, and a second stage in which non-self-replicating digestive enzymes produced by the animal act on it.

Reactor models applied to meal processing in animals Three meals (coded red, blue, and yellow) are ingested at three successive times.

(1) Batch reactor:

Each meal is processed before the next meal enters.

(2) Continuous-flow reactor without mixing: Meals line up in a tubular reaction vessel so they do not mix, but each can be processed for far longer than in a batch reactor.

(3) Continuous-flow reactor with mixing: New meals mix with meals that have already undergone some processing.

colon—or both—where thriving microbial communities reside (**Figure 6.18**). The mammalian hindgut fermenters include rabbits, horses, zebras, rhinos, apes, elephants, koalas, and some rodents. Hindgut fermentation in the cecum or colon—or both—occurs also in many ground-dwelling herbivorous birds—ostriches, geese, grouses, and chickens—and some herbivorous lizards and turtles. Many herbivorous fish are classed as **midgut fermenters** because part of the midgut (the gut between the foregut and hindgut) serves as the principal fermentation chamber. These fish include tilapias, carps, and catfishes—all noted for their usefulness in aquaculture.

The functions of microbial communities in hindgut fermenters differ from those in foregut fermenters because the hindgut is posterior to the acid stomach and the small intestine, meaning (among other things) that microbes from hindgut communities are not automatically digested. One function occurs in hindgut fermenters in much the same way as in foregut fermenters—namely, the microbial breakdown of cellulose and other structural carbohydrates to form short-chain fatty acids (SCFAs) used in animal metabolism. SCFAs readily diffuse across the gut wall to enter an animal's blood wherever they are produced in the gut (see page 155). Thus the SCFAs produced by hindgut or midgut fermentation of structural carbohydrates are readily available to the animal.

However, the roles of microbes in supplying B vitamins and essential amino acids, and recycling nitrogen, are not fulfilled in

the same way in hindgut fermenters as in foregut fermenters—if they occur at all. Let's first consider the B vitamins. To be absorbed, they require specialized absorption mechanisms (e.g., transporter proteins), present mainly in the small intestine. The B vitamins synthesized by hindgut microbes do not pass through the small intestine and thus tend mostly to be lost in an animal's feces. Similarly, for an animal to gain from microbial synthesis of essential amino acids (or nitrogen recycling), the cellular proteins of the microbes must be digested; yet when microbial growth occurs in the cecum or colon, the microbes are eliminated in the feces, undigested. As odd as it may seem at first, a *common* solution to the problems just described is for hindgut fermenters to eat defecated material. Some eat ordinary feces; others (such as rabbits) eat special soft feces derived from the contents of the cecum. In either case, the animals ingest microbes and microbial products in defecated material just like other foods and thus can digest and absorb them.

INVERTEBRATE SYMBIOSES WITH HETEROTROPHIC MICROBES

A variety of invertebrate animals also maintain critical symbiotic associations with heterotrophic microbes in their digestive tracts. The “lower” termites (consisting of four of the six termite families) are the most famous example. Because termites are wood eaters, much of the nutritional value of their food lies in cellulose. Some invertebrates, unlike vertebrates, synthesize cellulose-digesting

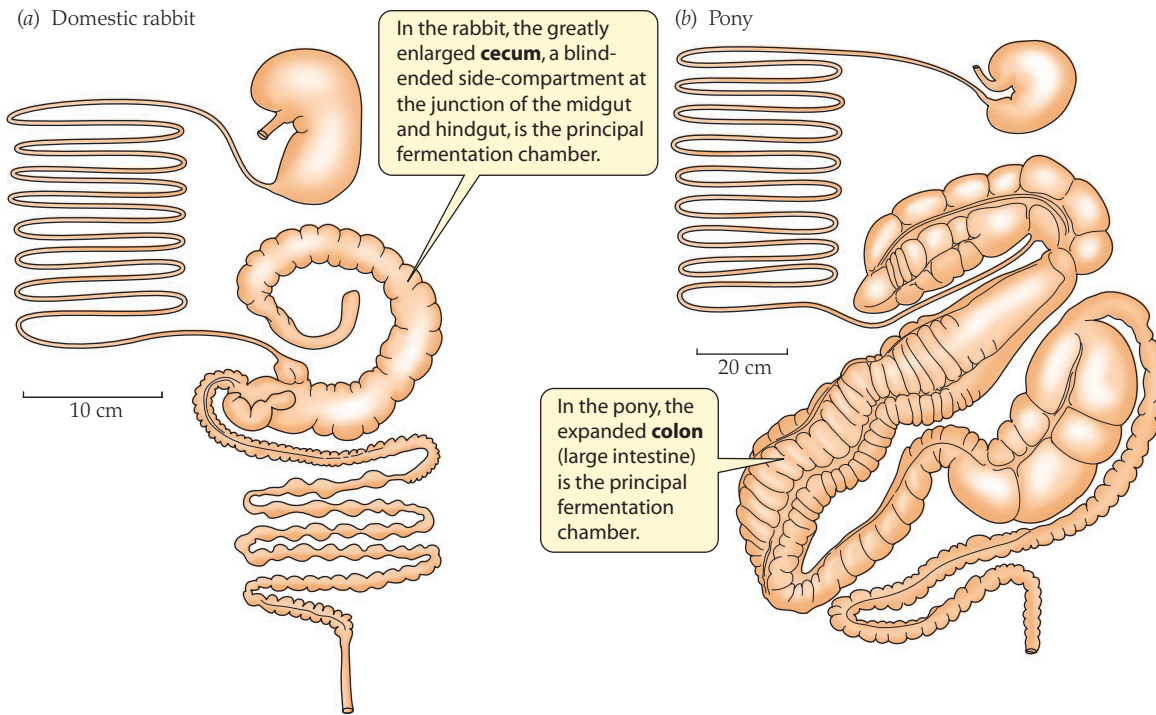

FIGURE 6.18 The digestive tracts of two hindgut fermenters

(a) A rabbit. (b) A pony. Both species have simple, one-chambered stomachs. Their fermentation chambers are parts of the hindgut. See Figure 6.17 for labeling of other parts of the digestive tract and for information on the format of the drawings. Rabbits produce hard and soft feces. The hard feces are the familiar “rabbit pellets.” The soft feces, which are less familiar, consist of material from the cecum that is enclosed in a mucous membrane and that passes through the full length of the colon without being altered. Soft feces are eaten as they emerge from the anus. (After Stevens 1977.)

enzymes; certain insects, for example, are entirely self-sufficient in their capacity to digest and metabolize cellulose. More commonly, however, both insects and other invertebrates rely on microbial symbionts to aid cellulose breakdown. In their hindguts, the lower termites maintain communities of anaerobic flagellated protists and bacteria, which ferment cellulose to acetic acid the termites use. Similarly, scarab beetles—which are sometimes of immense ecological importance—depend on gut bacteria to ferment cellulose to SCFAs. Microbial symbionts of invertebrates may also provide B vitamins, essential amino acids, and nitrogen recycling.

Some roles of microbial symbionts in invertebrates are novel by comparison with their roles in vertebrates. A spectacular recent study has shown that intracellular bacterial symbionts of shipworms (wood eaters) carry out nitrogen fixation and supply the shipworms with nitrogenous compounds made from atmospheric N_2 ! Sterol synthesis in insects provides another impressive example. Unlike most animals, insects cannot synthesize required precursors for making sterols. Microbial symbionts commonly supply these precursors. A third distinctive role for symbionts in invertebrates occurs in those that feed on vertebrate blood—such as leeches, tsetse flies, ticks, and sucking lice. Bloodsucking animals seem to have a universal requirement for symbiotic bacteria; the symbionts help them digest blood and may produce antibiotics that prevent the decay of blood during processing.⁷

⁷Similar symbionts are also required by vampire bats.

SUMMARY Feeding

- One mode of feeding is for animals to target and ingest individual food items, such as when orcas or cone snails catch fish. Toxic compounds, such as venoms and secondary compounds, often play roles as weapons or defenses in feeding of this sort.
- Suspension feeding is a second major mode of feeding. In this mode, an animal feeds on living or nonliving food items, suspended in water, that are individually tiny in comparison with the animal and that typically are collected in numbers rather than being individually targeted. Suspension feeding permits animals to feed lower on food chains and thus gain access to higher food productivity. Many of the largest and most productive animals on Earth are suspension feeders.
- Symbiotic associations with microbes are a third major mode of feeding in animals. Some animals maintain symbiotic associations with algae; warm-water reef corals, which are symbiotically associated with dinoflagellate zooxanthellae, are prominent examples. Other animals, notably species in hydrothermal-vent communities, are symbiotically associated with chemosynthetic autotrophs. Many herbivorous animals, both vertebrate (e.g., ruminants) and invertebrate (e.g., lower termites), maintain specialized symbiotic associations with heterotrophic, anaerobic fermenting microbes.
- Fermenting microbes most commonly provide three sorts of nutritional advantages to their animal hosts. They synthesize vitamins and essential amino acids. They break down structural polysaccharides such as cellulose so that the host can gain food value from them. They permit waste nitrogen to be recycled for use in animal protein synthesis.
- Apart from specialized symbioses with heterotrophic microbes, biologists now recognize that large assemblages of bacteria—termed the gut microbiome—are found in the guts of all mammals and probably most other animals. The functions of these assemblages are only starting to be understood.

Digestion and Absorption

Of all the topics in physiology, digestion and absorption are often the first to be studied in detail. Many students learn about the parts of the digestive tract and the major digestive enzymes on several occasions before studying physiology at the university level. These early treatments rightfully emphasize humans and other vertebrates. A problem can arise in the *comparative* study of animal digestion and absorption, however, because vertebrate anatomy and physiology do not provide effective models for understanding the anatomy and physiology of many other animal groups. The comparative study of digestion and absorption therefore calls for a particular effort to be open-minded.

Digestion is defined as the breakdown of food molecules by enzyme action (or other animal-mediated processes) into smaller chemical components that an animal is capable of distributing to the tissues of its body. In the case of food proteins, for example, digestion splits up the proteins—which typically cannot be absorbed and distributed throughout the body—into amino acids that can be taken up from the digestive tract and distributed. **Extracellular digestion** is digestion in an extracellular body cavity, such as the lumen of the stomach or intestines. It is the principal mode of digestion in vertebrates, arthropods, and many other animals. In **intracellular digestion**, food particles are taken into specialized cells prior to digestion, and digestion occurs within the cells. Digestion is principally intracellular in sponges, coelenterates, flatworms, and some molluscs.

In human physiology, *absorption* is defined to be the transfer of products of digestion from the lumen of the gastrointestinal tract to the blood or lymph. Because digestion is almost entirely extracellular in humans, digestion and absorption occur in sequence: digestion first, absorption second. These organizing concepts, however, are inadequate for the animal kingdom as a whole. When digestion is predominantly intracellular, *absorption* is defined to be the transfer of food particles from the gut lumen into the cells that digest the particles intracellularly, and only later are digestive products passed to the blood. *Absorption* of small organic molecules (e.g., amino acids and B vitamins) even occurs directly from seawater solution into the bloods of some marine animals, without being preceded by ingestion or digestion. Defined generally, **absorption**—also called **assimilation**—is the entry of molecules into the living tissues of an animal from outside those tissues.⁸

To understand digestion and absorption more thoroughly, our first step will be to examine the major features of the digestive–absorptive systems in some of the principal groups of animals. Terminology will continue to be a problem. The reason is that biologists have often tried to apply a single set of human anatomical terms to digestive systems throughout the animal kingdom—meaning that many, very diverse digestive systems are described as consisting of the parts we ourselves have: esophagus, stomach, small intestine, pancreas, and so forth. This use of human terms can be extremely misleading because the *functional* properties of organs in invertebrates sometimes differ dramatically from those of the like-named organs in humans. Therefore, one must be cautious about drawing any conclusions about function from names alone.

⁸The lumen of an animal's gut is continuous with the ambient air or water. Thus the gut lumen is outside the animal, and materials pass into the animal's living tissues when they leave the lumen.

Vertebrates, arthropods, and molluscs represent three important digestive–absorptive plans

Modern morphologists recognize four sequential segments of the tubular digestive tract in vertebrate animals: **headgut**, **foregut**, **midgut**, and **hindgut** (see Figures 6.17 and 6.18). The *headgut* of a vertebrate consists of the parts of the digestive tract in the head and neck, such as the lips, buccal cavity, tongue, and pharynx. The principal functions of the headgut are to capture and engulf food and to prepare the food for digestion. The preparation of food by the headgut is minimal in some vertebrates, such as many predatory fish, which swallow food quickly and whole. In other cases, preparation is extensive and involves chewing or grinding, the addition of lubricating agents, and the addition of digestive enzymes.

The *foregut* of a vertebrate consists of the parts of the digestive tract between the headgut and the intestines. Therefore, the foregut consists of the esophagus and stomach, and sometimes a crop (storage chamber) or gizzard (grinding chamber). The function of the esophagus is to move food from the headgut to the stomach. The functions of the stomach are to store ingested food, initiate protein digestion, and break up food by a combination of muscular, acid, and digestive-enzyme effects.⁹ With few exceptions, the stomach of a vertebrate secretes acid (HCl)—often at very high chemical activity, such as pH 0.8 in humans and dogs (see page 108). It also secretes pepsins, a set of protein-digesting enzymes.

The *midgut* and *hindgut* are the first and second segments of the intestines. In humans, they are distinguished by diameter: The midgut is of smaller diameter and thus termed the *small intestine*, whereas the hindgut is called the *large intestine*. The distinction between “small” and “large” does not apply in many vertebrates because the two parts are of similar diameter. The midgut of a vertebrate is the principal site of digestion of proteins, carbohydrates, and lipids. It is also typically the principal site of absorption of the products of digestion of all three categories of foodstuffs, as well as vitamins, minerals, and water. The main functions of the hindgut are to store wastes between defecations and complete the absorption of needed water and minerals from the gut contents prior to elimination. The removal of water and minerals by the hindgut may sound like a humble function, but it is vitally important. In humans, for example, about 7 L of a watery solution containing Na⁺, Cl⁻, and other ions is secreted from the blood into the gut per day to facilitate processing of food. Reabsorption of this water and electrolytes is a life-and-death matter. If reabsorption is impaired for several days, as happens in cholera and dysenteries, death can result.

In addition to the headgut, foregut, midgut, and hindgut, the vertebrate digestive system includes two additional components that secrete important materials into the midgut: the **pancreas** and the **biliary system**. The pancreas secretes many digestive enzymes into the midgut. The biliary system, which is a part of the liver, secretes bile, which plays a crucial emulsifying role in the digestion of lipids.

Muscular action is the principal mechanism by which food and other materials are moved along as they pass through the digestive systems of vertebrates. The muscles of the gut wall, which are composed mostly of smooth muscle cells (see page 542), are arrayed in two primary layers: an outer layer of *longitudinal* muscles that

⁹In this general overview, we cannot address the full range of vertebrate variation. Thus, for example, the special stomach features of ruminants—discussed already—are not repeated here. Nor are the special hindgut features of hindgut fermenters.

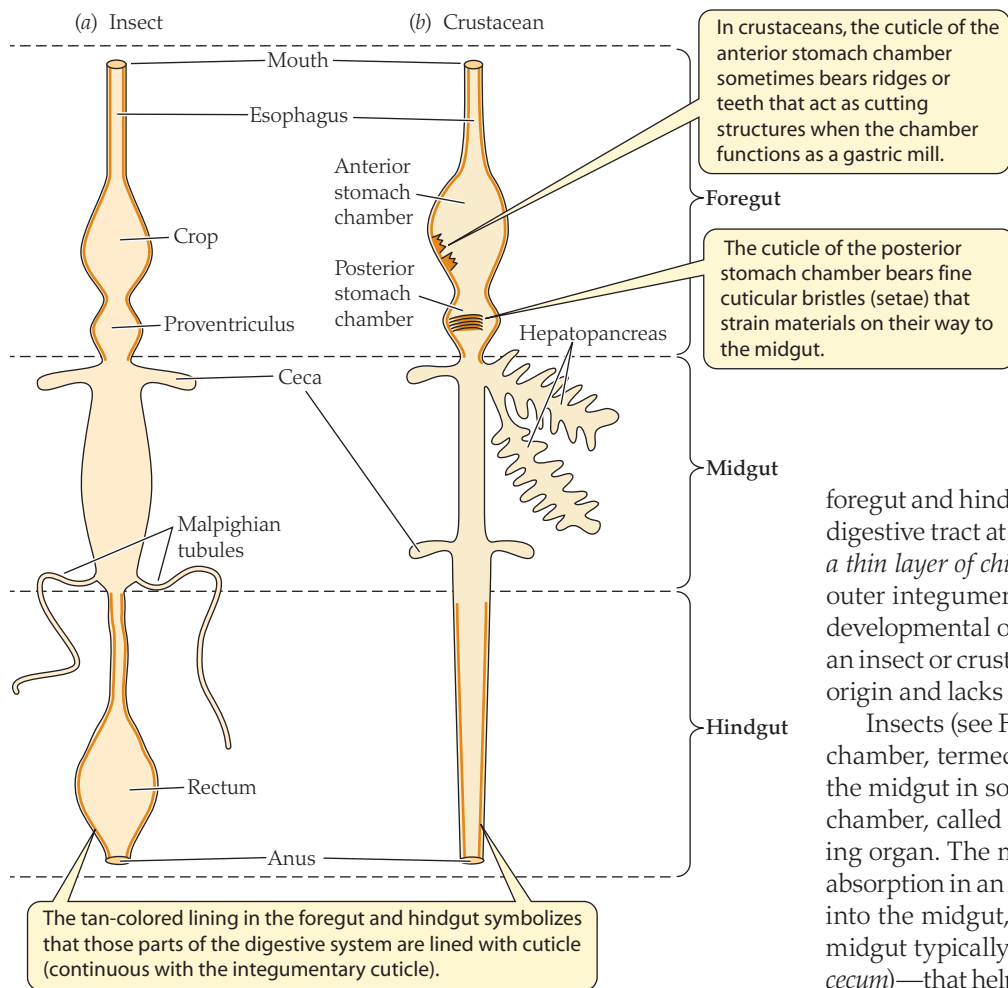

FIGURE 6.19 The digestive systems of two types of arthropods: insects and crustaceans (a) An insect. (b) A crustacean. Although the excretory system of crustaceans is separate from the digestive system, in insects the Malpighian tubules—which constitute the initial part of the excretory system—connect to the digestive system at the junction of the midgut and hindgut; therefore, the insect hindgut is actually part of both the digestive system and the excretory system.

foregut and hindgut, in this case, are defined to be the parts of the digestive tract at the anterior and posterior ends that are lined with a thin layer of chitinous exoskeleton material, called *cuticle*. Like the outer integument, the foregut and hindgut have an ectodermal developmental origin and synthesize exoskeleton. The midgut of an insect or crustacean is of different (endodermal) developmental origin and lacks a lining of cuticle.

Insects (see Figure 6.19a) commonly have an enlarged storage chamber, termed a *crop*, in the foregut. Where the foregut meets the midgut in some species, the foregut also includes a muscular chamber, called a *proventriculus* or *gizzard*, which acts as a grinding organ. The midgut is the principal site of both digestion and absorption in an insect. Numerous digestive enzymes are secreted into the midgut, which is maintained at a near-neutral pH. The midgut typically bears anterior diverticula—called *ceca* (singular *cecum*)—that help with absorption and sometimes house microbial symbionts. The urine-producing tubules of insects, called *Malpighian tubules*, empty into the gut at the junction of the midgut and hindgut. Thus urine joins other gut material at that point and travels through the hindgut. Because the hindgut plays a crucial role in adjusting the final composition and quantity of the urine, it is part of the excretory system as well as the digestive system of an insect. Some nutrient absorption occurs in the hindgut.

The foregut of crustaceans (see Figure 6.19b) consists of a tubular esophagus followed by a saclike structure called the *stomach* (*proventriculus*). Acidic conditions are created in the stomach during digestion, but not nearly as acidic as those in the human stomach.¹⁰ The stomach is often divided into two chambers. The anterior (“cardiac”) chamber is particularly muscular, and often part of it is specialized as a *gastric mill*. The cuticular lining of the mill is thrown into ridges with cutting edges, and the mill grinds food, frequently with the aid of digestive enzymes that arrive in the anterior stomach chamber by retrograde movement from the midgut. The second stomach chamber of a crustacean—the posterior (“pyloric”) chamber—is smaller than the first. Its cuticular lining often bears bristlelike *setae* (singular *seta*), which act collectively as a sieve, keeping food particles from leaving the foregut until the gastric mill has reduced them to a small size.

The midgut of crustaceans varies in complexity from being a fairly simple tube in some species to bearing elaborate arrays of

shorten the gut when they contract, and an inner layer of *circular* muscles that *constrict* the gut when they contract. **Peristalsis** is one of the gut’s principal modes of muscular activity. It is a highly coordinated pattern of contraction in which constriction of the gut at one point on its length initiates constriction at a neighboring point farther along, producing a “wave” of constriction that moves progressively along the gut, propelling food material before it. **Segmentation** is a second important mode of muscular activity, in which constrictions of circular muscles appear and disappear in patterns that push the gut contents *back and forth*. The control of peristalsis and segmentation depends principally on the *enteric nervous system* (see page 409), a network of nerve cells within the gut walls. **Gut motility** is a general term that refers to peristalsis, segmentation, or other muscular activity by the gut in vertebrates or invertebrates.

THE DIGESTIVE SYSTEM OF ARTHROPODS The insects and crustaceans (e.g., crayfish, crabs, and shrimp) nicely illustrate the digestive system of arthropods (Figure 6.19). In them, digestion is principally extracellular. Another similarity to vertebrates is that food is moved through the insect or crustacean digestive tract by muscular contraction.

Morphologists describe the digestive tract of an insect or crustacean as consisting of a **foregut**, **midgut**, and **hindgut**. The

¹⁰The pH is 4 or higher in crustaceans but can be lower than 1 in humans and other mammals.

FIGURE 6.20 Food processing in the stomach of a clam In bivalve molluscs such as clams, the stomach and associated digestive diverticula are the most critical parts of the digestive system. Materials are mostly moved about by ciliary action. Turning of the crystalline style draws a mucus strand containing food particles into the stomach and, by abrasion against the gastric shield, releases digestive enzymes from the style material. In many species, digestion occurs primarily within the epithelial cells of the digestive diverticula, as depicted here. The digestive tract inside the clam is presented diagrammatically, not realistically.

anterior and posterior diverticula (ceca) in others. The **hepatopancreas**, an organ of enormous importance in crustacean digestion, connects to the anterior midgut via ducts. The hepatopancreas is poorly named because its name greatly exaggerates any similarity it bears to the vertebrate liver and pancreas. The hepatopancreas consists of a branching array of blind-ended tubules lined with epithelium. One of its several functions is to secrete digestive enzymes that flow by way of its ducts into the midgut and then retrograde to the stomach. Food particles from the midgut also *enter* the hepatopancreas, and much extracellular digestion and absorption occur *within* the hepatopancreas. In addition, the cells of the hepatopancreas play important storage and sequestration roles; lipids and glycogen are stored in the hepatopancreas, and toxins may be sequestered in hepatopancreas cells. Current evidence indicates that the hepatopancreas is both the principal source of digestive enzymes in crustaceans and the principal site of nutrient absorption.

THE DIGESTIVE SYSTEM OF BIVALVE MOLLUSCS The bivalve molluscs—clams, mussels, oysters, and their relatives—are ecologically important animals that provide an outstanding example of how very different from vertebrates some animals can be in their

digestive and absorptive processes. The gross morphology of the digestive tract in bivalves is not particularly remarkable. Bivalves are said to have an **esophagus, stomach, intestine, rectum**, and so forth. Striking differences from the vertebrates and arthropods come to light when details are examined, however. First, bivalve molluscs *depend strongly on ciliary action, rather than muscular contraction, to move food through their digestive tracts*. This is important in part because ciliary action is capable of *sorting* particles according to size and other features. A second major difference is that in many bivalves, *digestion is primarily intracellular*.

The key to understanding bivalve digestion is to understand the complex array of processes that take place in the stomach (**Figure 6.20**). One striking feature of the stomach is the presence of a long, slender gelatinous rod called the **crystalline style**. Many an oyster lover has been startled to stumble upon this dramatic structure—as perfectly clear and colorless as ice—while preparing fresh oysters for eating. It is synthesized by the *style sac*. Because the protruding end of the style disintegrates during food processing, as we will see, new style material must be added regularly by the style sac. One end of the style remains sheathed by the style sac, and cilia within the sac turn the style on its long axis.

The style has several functions. One is to help pull strands of mucus, containing collected food particles, into the stomach from the mouth. It does this by winding the strands onto itself. The end of the style that protrudes from the style sac pushes against a chitinous plate, the *gastric shield*, on part of the stomach wall. The turning of the style against the gastric shield helps break up food particles by mechanical action. In addition, the material substance of the style contains digestive enzymes, particularly amylases (starch-digesting enzymes), which are released into the stomach cavity as the turning of the style against the gastric shield causes style material to disintegrate. Once released, the enzymes carry out extracellular digestion.

The wall of a bivalve's stomach is lined with complex ciliary fields, which *sort* food particles and *direct them along intricate*

paths. Of particular importance, ciliary action carries materials into and out of **digestive diverticula** connected to the stomach. These diverticula (often misleadingly called the *digestive gland*) are composed of branching, blind-ended tubules and represent particularly critical components of the bivalve digestive–absorptive system (as well as being major storage sites for lipids). The digestive diverticula, in fact, are the principal sites of digestion and absorption in many species of bivalves. Food particles are carried into the diverticula by certain ciliary tracts. The food particles are then taken into cells lining the diverticula by phagocytosis and pinocytosis. The cells possess intracellular digestive enzymes, and much of digestion occurs intracellularly. The nutrient products of digestion are believed then to be passed into the blood bathing the diverticula.

In some types of bivalves, the tubular midgut is also implicated in digestion and absorption. A bizarre and poorly understood aspect of the bivalve digestive tract is that the hindgut passes directly through the ventricle of the heart on its way to the anus!

Digestion is carried out by specific enzymes operating in three spatial contexts

In all animals, digestion is carried out for the most part by **hydrolytic enzymes**, which catalyze the breakup of large molecules into smaller parts by bond-splitting reactions with H_2O , termed *hydrolytic reactions*. The dynamics of the interaction between food molecules and digestive enzymes depend in part on the gross morphology of the part of the gut where digestion occurs, plus patterns of filling and emptying, as discussed in Box 6.1. Here our principal focus will be on the digestive enzymes themselves: their chemistry and the fine-scale spatial contexts in which they operate.

Each digestive enzyme is specific (more or less) in the type of chemical bond it can break. Because of the specificity of digestive enzymes, a species can digest only those ingested molecules for which it has enzymes that hydrolyze the specific types of bonds in the molecules. The enzyme *chitinase*, for example, is required for a species to digest chitin;¹¹ the enzyme initiates chitin breakdown by attacking key bonds in the large chitin polysaccharide to divide it into disaccharide (chitobiose) subunits. Whereas many species of rodents and bats synthesize chitinase, humans and rabbits do not. Thus humans and rabbits cannot digest chitin even though other mammals can. We are reminded by this example of the crucial point stressed at the start of this chapter (see Figure 6.1): The nutritional value of a food depends in part on the digestive enzymes an animal possesses, not just the chemical composition of the food.

Digestive enzymes, like other enzymes, typically occur in multiple molecular forms (see Chapter 2). When two species both have a particular enzyme, they often synthesize different molecular forms of the enzyme. If a digestive enzyme is synthesized by two tissues in one species, the molecular forms are often different in the tissues.

Digestive enzymes act in *three spatial contexts* in animals. An enzyme that acts in one context in one group of animals may act in another context in a different group. Thus the three spatial categories of enzyme action, which we now list and discuss, do not bear a one-to-one correspondence with the chemical categories of enzymes.

1. Intraluminal enzymes. Sometimes digestive enzymes are secreted into the lumen of a body cavity, such as the lumen of the stomach or the midgut, where the enzyme molecules mix freely with food materials and catalyze digestive reactions. When digestive enzymes operate in this spatial context, their action is termed *intraluminal*, meaning “in the lumen.” Intraluminal digestion is a type of extracellular digestion because it occurs outside cells.

2. Membrane-associated enzymes. Sometimes digestive enzymes are cell-membrane proteins that are synthesized by epithelial cells lining the gut and that remain associated with the epithelial cells while digesting food molecules in the gut lumen. Such *membrane-associated enzymes* are located in the apical membranes of the epithelial cells and positioned so that their catalytic sites are exposed to the gut lumen. Food molecules must contact the epithelial cells to be digested by the membrane-associated enzymes. Digestion by these enzymes is extracellular because the food molecules affected are in the lumen, not inside cells.

3. Intracellular enzymes. Digestive enzymes may also be positioned inside cells, where they carry out intracellular digestion. For food particles or molecules to be affected by these enzymes, the particles or molecules must be taken into the cells.

Individual animals commonly have digestive enzymes functioning in all three spatial contexts. However, the emphasis on the three varies from one group of animals to another, as we have already seen. In some clams, for example, the great majority of digestive reactions are carried out by intracellular enzymes. In vertebrates, by contrast, the majority of digestive reactions are extracellular, catalyzed by intraluminal or membrane-associated enzymes; only some of the final reactions of protein digestion occur intracellularly.

CARBOHYDRATE DIGESTION Disaccharides are sometimes ingested as foods, as when hummingbirds feed on sucrose-rich flower nectars, infant mammals ingest lactose in their mother’s milk, or people eat candies rich in sucrose. Disaccharides are also produced in the digestive tract by the digestion of more-complex ingested carbohydrates. Enzymes that hydrolyze disaccharides into their component monosaccharides are called **disaccharidases**. They include *sucrase*—which breaks sucrose into two monosaccharides—*lactase*, *trehalase*, and others. In vertebrate animals, the disaccharidases are membrane-associated enzymes found in the apical membranes of the midgut epithelium.

When a polysaccharide is digested, it is typical for two enzymes to carry out the process, acting in sequence. The first enzyme splits the polysaccharide into disaccharides or oligosaccharides (short chains of three or more monosaccharides). Then the second enzyme splits the products of the first into monosaccharides.

As stressed earlier, the enzymes that carry out the initial breakup of *structural* polysaccharides are far from universally distributed in the animal kingdom. *Cellulase*, required for the initial breakup of cellulose, is not synthesized by any vertebrates, for example, meaning that vertebrates cannot tap cellulose for its food value unless they have symbiotic associations with microbes that ferment cellulose. *Chitinase*, required for the initial breakup of chitin, is synthesized by some species of vertebrates and invertebrates, but not others;

¹¹ Chitin (see page 133) is a structural polysaccharide of great importance in the exoskeletons of insects and other arthropods.

therefore, only some animals can obtain food value from the exoskeletons of insects and other arthropods.

Although the ability to digest cellulose or chitin is spotty, most animals are able to digest starch and glycogen, two of the principal *storage* polysaccharides. The first enzyme to act on starch or glycogen is **amylase**. It hydrolyzes the molecules to yield the disaccharides maltose and isomaltose, plus oligosaccharides such as maltotriose. In a mammal, molecular forms of amylase are present in both the saliva and the pancreatic juices. The disaccharides and oligosaccharides produced by amylase digestion are hydrolyzed to yield free glucose by *maltase*, a disaccharidase, and by other enzymes.

PROTEIN DIGESTION Protein digestion involves a much larger array of enzymes than carbohydrate (or lipid) digestion. This is true because proteins include, by far, the greatest diversity of types of chemical bonds that must be hydrolyzed for digestion to occur. Three or more enzymes are often required for the complete breakdown of a protein. The enzymes that digest proteins and polypeptides are categorized as *endopeptidases* and *exopeptidases*. Both types break bonds between amino acids (i.e., peptide bonds). **Endopeptidases** create breaks *within* chains of amino acids, whereas **exopeptidases** split off terminal amino acids from amino acid chains.

An interesting problem associated with protein digestion is that digestive enzymes targeted at proteins have the potential to attack an animal's own body substance! When protein-digesting enzymes function intraluminally, they are typically synthesized in inactive forms called **proenzymes** or **zymogens**. The enzymes are activated only after they have arrived at the location where they are to act in food digestion.

Protein digestion in vertebrates usually begins in the stomach with the action of a set of intraluminal endopeptidases named *pepsins*, which require acid conditions to be enzymatically effective. Pepsins are secreted by stomach cells—and in some vertebrates by esophageal cells—as proenzymes called *pepsinogens*. Exposure to acid in the stomach lumen activates the pepsins by cleaving the pepsinogens.

When proteins and protein fragments arrive in the midgut of a vertebrate, they are subjected to further intraluminal digestion by enzymes synthesized by the pancreas. The midgut intraluminal enzymes are secreted by the pancreas as proenzymes, which are carried in the pancreatic juice to the midgut; the proenzymes are activated in the midgut by enzyme-catalyzed cleavage reactions that release the active peptidases. Some of the pancreatic enzymes are endopeptidases, including *trypsin*, *chymotrypsin*, *elastase*, and *collagenase* (not all are found in all species). The pancreatic enzymes also include exopeptidases, notably *carboxypeptidases A and B*. **Figure 6.21** shows how these enzymes act together to break up a protein.

After the intraluminal protein-digesting enzymes of the vertebrate stomach and midgut have had their effect, the resulting product is a mix of both free amino acids and short amino acid chains called *oligopeptides*. The next step in protein digestion is for the oligopeptides to be further hydrolyzed. They are digested by a great diversity of membrane-associated endo- and exopeptidases (about 20 in humans) located in the apical membranes of the midgut epithelium. The amino acids from the original proteins are then in the form of free amino acids, dipeptides, and tripeptides. These products are transported into the digestive-absorptive cells of the midgut epithelium (see Figure 2.5). There, protein digestion is completed by intracellular peptidases, which hydrolyze the di- and tripeptides. In the end, therefore, the products passed to the blood are mostly free amino acids.

LIPID DIGESTION Lipid digestion is both simpler and more complex than protein digestion. It is simpler because fewer types of chemical bonds need to be hydrolyzed, and thus fewer enzymes are required. It is more complex because although digestive enzymes are in the aqueous phase, lipids are insoluble in water. Successful lipid digestion depends not just on enzymes but also on nonenzymatic, emulsifying processes that break up lipids into small droplets having lots of surface area relative to their lipid content. The principal digestive enzymes of lipids are **lipases**. They act at lipid-water interfaces, and therefore their effectiveness depends on the surface area produced by emulsifying processes. Emulsification can be brought about by mechanical agitation or chemical action.

The midgut is the principal site of lipid digestion in vertebrates. One reason for the vigor of lipid digestion in the midgut is the presence there of intraluminal *pancreatic lipases*, secreted by the pancreas as active enzymes. A second important factor promoting effective lipid digestion in the midgut is that chemical emulsifying agents—namely, **bile salts** and other bile constituents—are secreted into the midgut by the biliary system of the liver. Bile salts are amphipathic molecules (see page 33) that act as detergents, dispersing lipids into droplets having a large collective surface area at which lipases can act. Interestingly, bile salts are not destroyed in the gut. Instead, they are reabsorbed downstream by active transport in terminal portions of the midgut and returned to the liver biliary system, which again secretes them upstream. Any given bile-salt molecule may be recycled in this way several times during the digestion of a single meal!

The products of the digestion of fats and oils (triacylglycerols) by lipases are free fatty acids, glycerol, and 2-monoacylglycerols (glycerol esterified at the middle position with a single fatty acid) (see Figure 6.4). Lipids such as phospholipids and cholesterol esters

FIGURE 6.21 The digestion of a short protein by three pancreatic peptidases, each specific for particular types of peptide bonds Arg = arginine; Gly = glycine; Leu = leucine; Pro = proline; Tyr = tyrosine.

(containing ring structures) require other enzymes in addition to lipases for digestion (e.g., *phospholipases* and *esterases*).

Absorption occurs by different mechanisms for hydrophilic and hydrophobic molecules

Absorption can mean different things in different sorts of animals, as stressed earlier. Here we discuss just the type of absorption that occurs in vertebrates, arthropods, and other groups in which digestion is principally extracellular. Absorption in these animals consists primarily of the transport of chemically simple compounds—such

as monosaccharides, free amino acids, and free fatty acids—across the epithelial cells lining the digestive tract, from the gut lumen into blood or lymph.

Surface area is important for absorption. Often the lining of the gut is configured in ways that greatly increase the surface area of the epithelium across which absorption occurs. (This expansion of surface area also aids digestion.) The inset drawings in **Figure 6.22** show how the surface area of the midgut digestive–absorptive epithelium is expanded by the presence of folds and minute fingerlike projections in humans and many other vertebrates.

FIGURE 6.22 The structure of the vertebrate midgut and the mechanism of absorption of monosaccharides (glucose, fructose, and galactose)

The insets show how the surface area of the midgut epithelium—composed principally of digestive–absorptive epithelial cells—is enlarged by the presence of folds and projections. The drawings are of the human midgut. There are huge numbers of minute fingerlike structures (less than 1 mm long), called intestinal *villi* (singular *villus*). Collectively they greatly increase the total surface area of the epithelium and thus the numbers of digestive–absorptive epithelial cells. Four membrane transporter proteins of those cells—SGLT1, Na⁺–K⁺-ATPase, GLUT2, and GLUT5—play key roles in the absorption of monosaccharides, as shown. GLUT2, shown here only in the basolateral membrane, sometimes also is present in the apical membrane. Cells turn over rapidly in the midgut epithelium; for example, the average life span of an epithelial cell in humans is about 3 to 4 days. This rate of cell turnover means equally rapid turnover of the transporter proteins involved in absorption. See Figure 2.5 for more cytological detail and Figure 5.12 for a more rigorous treatment of secondary active transport by transporters like SGLT1.

Three mechanisms of transport are involved in absorption: simple diffusion, facilitated diffusion, and active transport.¹² Active transport is always of the secondary type in this context, meaning that the transporter proteins are cotransporters or countertransporters that are able to transport nutrient molecules uphill by use of energy from metabolically generated electrochemical gradients of inorganic ions such as Na⁺ (see Box 5.1 and Figure 5.12).

Monosaccharides, amino acids, and water-soluble vitamins are aptly considered together in the study of absorption because all three are hydrophilic and thus do not pass readily by simple diffusion through cell membranes (see page 108). Transporter proteins in cell membranes are required for these compounds to be absorbed. Because of the necessity of transporters, these compounds are absorbed only in the parts of the gut where the epithelial cells of the gut lining synthesize the transporters, notably the midgut in vertebrates.

The absorption of glucose in the vertebrate midgut is the best understood of all transporter-mediated absorptive systems. For glucose to be absorbed into the bloodstream across a midgut digestive-absorptive epithelial cell, the glucose must first enter the cell from the gut lumen across the apical, brush-border cell membrane, and then it must exit the cell into the blood across the basolateral cell membrane. The transport of glucose across both cell membranes is transporter-mediated (carrier-mediated). The best-known transporter in the apical membrane is a cotransporter, *sodium-glucose transporter 1 (SGLT1)*, that mediates the secondary active transport of glucose using energy from the Na⁺ electrochemical gradient across the apical membrane (see Box 5.1). Figure 6.22 shows this transporter, and Figure 5.12 explains in detail how a transporter of this type mediates the active transport of glucose into an epithelial cell. After glucose has entered a midgut epithelial cell by *active* transport, it leaves the cell to enter the blood across the cell's basolateral membrane by transporter-mediated *passive* transport—that is, by facilitated diffusion. The best-known transporter protein that mediates this facilitated diffusion is GLUT2 (see Figure 6.22).

The absorption of monosaccharides other than glucose by vertebrates exhibits similarities and differences relative to glucose absorption. Galactose—a monosaccharide released by the digestion of lactose—is transported into vertebrate midgut epithelial cells actively by SGLT1. But fructose—a monosaccharide product of sucrose digestion—enters the cells principally by facilitated diffusion mediated by an apical-membrane transporter, GLUT5 (see Figure 6.22). GLUT2 transports fructose and galactose, as well as glucose, out of the cells.

In the last few years, evidence has developed that GLUT2 can occur in the apical membrane as well as in the basolateral membrane. When monosaccharides are more concentrated in the gut lumen than they are within the midgut epithelial cells, GLUT2 in the apical membrane facilitates inward diffusion. Under some conditions, more glucose enters this way than via SGLT1, a discovery that may well be pertinent to understanding diseases affecting sugar absorption.

Amino acid absorption in the vertebrate midgut is complicated (partly because of the diversity of amino acids) and not thoroughly understood. As many as seven distinct transporter proteins for amino acids are found in the apical, brush-border membranes of digestive-absorptive epithelial cells. Each transporter is specialized

to transport a distinct *set* of amino acids (e.g., the set of cationic amino acids) into the epithelial cells. Most of the amino-acid transporters carry out secondary active transport using energy drawn from electrochemical gradients of Na⁺ or other ions. Additional transporters are involved in moving dipeptides into epithelial cells and in moving amino acids out of the cells into the blood across the basolateral membranes.

Transporters are also known in the apical membranes of vertebrate midgut epithelial cells for many of the water-soluble vitamins. Active transporters driven by the Na⁺ electrochemical gradient are known for some of the B vitamins, for example. Many primates (including humans), and some other vertebrates, also possess a Na⁺-driven active transporter for vitamin C.¹³

The principles that govern the absorption of the products of *lipid* digestion typically are different from those that govern the absorption of hydrophilic molecules. Fatty acids and monoacylglycerols (mono-glycerides) produced by lipid digestion, because they are hydrophobic, are able to dissolve in the lipid-rich interior of cell membranes. Thus they can move through cell membranes readily by simple diffusion (see page 104). In fact, simple diffusion—unmediated by transporter proteins—often seems to account for much or all of the transport of fatty acids and monoacylglycerols into gut epithelial cells. However, transporters for these compounds—some active—are known.

To fully understand the absorption of fatty acids and monoacylglycerols, one must take into account that most are poorly soluble in the aqueous solutions inside and outside epithelial cells. Vertebrates have mechanisms to emulsify or solubilize the lipids in both solutions. In the midgut lumen, as fatty acids and monoacylglycerols are produced by lipid digestion, they are dramatically solubilized by combining with bile salts to produce minute disc- or sphere-shaped molecular aggregates called *micelles*; a micelle is smaller than 10 nanometers (nm) and maintains its lipid constituents in solution by means of the emulsifying effects of the amphipathic bile salts. Lipid-soluble vitamins participate in micelle formation as well. The solubilization of fatty acids, monoacylglycerols, and lipid-soluble vitamins by micelle formation greatly aids the absorption of the molecules. Micelles themselves are not absorbed, however. Instead, the fatty acids and other molecules dissociate from micelles next to the apical membranes of gut epithelial cells, and then move through the membranes by simple diffusion.

After the products of lipid digestion are inside gut epithelial cells (Figure 6.23), enzyme-catalyzed metabolic pathways synthesize intracellular triacylglycerols, phospholipids, and cholesterol esters from them. These complex lipids are then combined inside the cells with proteins to form **lipoprotein molecular aggregates**, especially ones called **chylomicrons**. The formation of chylomicrons sets the stage for the lipids to be carried throughout the body by way of the lymphatic and circulatory systems, because the protein constituents of the chylomicrons are amphipathic and emulsify the lipids in the aqueous solution of the lymph or blood. The chylomicrons produced inside a midgut epithelial cell are assembled into secretory vesicles by the cell's Golgi apparatus. The vesicles then fuse with the cell's basolateral membrane to release the chylomicrons into

¹² See Chapter 5 for a detailed discussion of these transport mechanisms. A fourth mechanism that may be important in certain situations is *solvent drag*, in which solutes are carried along by osmotic water movement.

¹³ The acquisition mechanisms for some vitamins are particularly complex. Looking at vitamin B₁₂ in mammals, for example, at least five animal-synthesized proteins are involved in protecting the vitamin from destruction during digestion and absorbing it. Knowledge of such systems is clinically important, in part because defects at any step along the way can lead to vitamin deficiency.

FIGURE 6.23 Major steps in fatty acid absorption across a midgut epithelial cell Figure 6.22 shows the location of such cells. Chylomicrons are packaged into vesicles by the Golgi apparatus. The vesicles then move to the basolateral membrane and, fusing with the membrane, release their contents to the lymphatic circulation in the villus interior.

the midgut lymphatic circulation, which carries the chylomicrons into the bloodstream.

The absorption of *short-chain fatty acids* (SCFAs) produced by microbial fermentation is a special case because these particular fatty acids (e.g., acetic acid) are both water-soluble and lipid-soluble. The SCFAs do not require emulsification, because of their water solubility. Moreover, they tend to be absorbed wherever they are produced in the gut. The least-complicated model for their absorption is that they simply diffuse through cell membranes and cell interiors by being lipid- and water-soluble. Detailed studies show, however, that their absorption is sometimes transporter-mediated in ways that remain poorly understood.

SUMMARY Digestion and Absorption

- Digestion is the process of splitting food molecules into smaller parts that an animal can take into its living tissues and distribute throughout its body. Absorption (assimilation) is the process of taking organic compounds into the living tissues of an animal from the gut lumen or from other places outside those tissues. In vertebrates, arthropods, and some other groups, digestion precedes absorption. However, absorption precedes digestion in certain other animals, such as certain bivalve molluscs.
- Digestion is carried out mostly by hydrolytic enzymes, each of which catalyzes the splitting of specific types of chemical bonds. The enzymes may be intraluminal, membrane-associated, or intracellular. Extracellular digestion is carried out by intraluminal and membrane-associated enzymes, whereas intracellular digestion is carried out by intracellular enzymes.
- The absorption of relatively simple hydrophilic compounds—such as monosaccharides, amino acids, and water-soluble vitamins—usually requires transporter proteins in the cell membranes involved, and it occurs by either facilitated diffusion or secondary active transport. The absorption of the hydrophobic fatty acids and monoacylglycerols produced by lipid digestion can occur to a large extent by simple diffusion across cell membranes. However, complexities arise in the absorption of these compounds because (being hydrophobic) they need to be emulsified in the aqueous solutions outside and inside cells while being absorbed. SCFAs are a special case because they are water- and lipid-soluble.

- In vertebrates, the midgut is typically the most important site of digestion and absorption. This is true because (1) the apical membranes of midgut epithelial cells are richly populated by membrane-associated digestive enzyme proteins and by transporter proteins, and (2) pancreatic and biliary secretions enter the midgut.
- An animal's digestive and absorptive capabilities are major determinants of the nutritional value of foods because ingested organic compounds can be used only to the extent that they can be digested and absorbed.

Responses to Eating

When you eat a meal, your gastrointestinal system responds to the arrival of food in intricate ways that enable the system to carry out its function of making the constituents of the food available to your body. These responses belong to the category of *acute responses* defined in Chapter 1 (see Table 1.2). Cellular activities that are modified to process a meal include the secretion of digestive enzymes, the secretion of acid, and the contraction of muscles. Nerve, endocrine, and paracrine cells control and coordinate the responses.¹⁴

After chewing and secretion of saliva, the first step to consider is the transit of food from the mouth to the stomach. Each mouthful of food that we force by *voluntary* swallowing to the pharynx in the back of our mouth initiates an *involuntary* wave of peristaltic muscular contraction that passes from the pharynx along the length of the esophagus. Complexities arise because of the presence of sphincters at the two ends of the esophagus. A **sphincter** is a circular muscle that can contract tightly and steadily (tonically) for long periods, thereby preventing exchange between one segment of the gut and another. When a peristaltic wave initiated by the presence of food in the pharynx reaches the upper esophagus, the upper esophageal sphincter transiently relaxes, allowing the food to pass. The food is then propelled by peristalsis down the esophagus, and when it reaches the lower esophageal sphincter, the latter opens transiently to permit entry to the stomach. The sphincters are normally kept closed except when food is passing.

In the human stomach, the upper (initial) part serves as a storage region for food; it is the principal place where food is housed while awaiting processing. When food arrives from the esophagus, the muscles in the walls of this part of the stomach relax in response to autonomic commands from the parasympathetic nervous system (see page 407). The lumen then expands to accommodate the food, a mechanism that allows large quantities of food to be swallowed in a brief period of time.

The presence of food in the stomach exerts mechanical and chemical effects on endocrine cells, called *G cells*, located in the mucosal lining of the lower (final) part of the stomach. The G cells are stimulated to secrete into the blood a polypeptide hormone called **gastrin**. As depicted by the blue lines in **Figure 6.24**, when gastrin reaches other stomach cells by way of blood circulation, it stimulates both the acid-secreting cells (see Figure 5.9) and the pepsinogen-secreting cells to undergo secretory activity, and it

¹⁴As discussed in Chapter 16 (see Figure 16.1), *endocrine cells* secrete hormones into the blood, which carries them to often-distant target cells where they exert their effects. *Paracrine cells* secrete communicatory chemicals into the fluids between cells, where the chemicals affect other neighboring cells.

FIGURE 6.24 Gastrointestinal function after a meal is coordinated in part by hormones secreted by endocrine cells in the gut epithelium. The arrows represent hormones traveling by way of blood transport from endocrine cells to target cells. Red and blue arrows marked with plus (+) signs symbolize stimulatory effects on target cells. Black arrows marked with minus (-) signs symbolize inhibitory effects. The controls shown here are only a small fraction of the total set of nerve, endocrine, and paracrine controls that coordinate the processes activated by eating.

of the gut, and the types of endocrine cells differ from one region of the gut to another, meaning that each region can send out distinctive hormonal messages. An illustration is provided by three classes of endocrine cells that occur in the epithelium of the upper midgut. These three classes of cells secrete three polypeptide hormones: **secretin**,¹⁵ **cholecystokinin (CCK)**, and **gastric inhibitory polypeptide (GIP)**.

The endocrine cells in the upper midgut are stimulated to secrete their respective hormones by acidity and by exposure to nutrient molecules. Thus, when acidified and partly digested food is metered into the upper midgut from the stomach, it causes release of the three hormones we have mentioned into the blood. As shown by the red lines in Figure 6.24, CCK and secretin synergistically stimulate the pancreas and the biliary system of the liver to secrete into the midgut the array of critical digestive agents we have already discussed, notably pancreatic digestive enzymes and bile. An additional critical function stimulated by secretin is the secretion by the pancreas of bicarbonate (HCO_3^-), which neutralizes acid from the stomach. The midgut hormones also affect the stomach. As shown by the black lines in

Figure 6.24, all three inhibit gastric-acid secretion, gastric emptying, and muscle contraction in the storage part of the stomach, for example; in this way the hormones promote retention of food in the stomach when acidity and nutrient concentrations in the midgut are high, signifying that the midgut—for the moment—already has adequate input from the stomach. Stomach function is also affected by neuron-mediated reflexes from the midgut; excessive acidity or accumulation of unabsorbed digestive products in the midgut, for instance, can inhibit stomach motility by this means.

Motility of the midgut is under control of a complex array of hormonal and neuronal influences, both stimulatory and inhibitory. Segmentation is the principal type of midgut motility. It pushes the midgut contents back and forth. This action mixes food products with intraluminal digestive enzymes and bile, and it ensures contact of all digesting material with the walls of the midgut, where the membrane-associated digestive enzymes and absorption transporters are found. In addition to segmentation, the midgut exhibits progressive, peristaltic contractions that move material toward the hindgut.

Just as humans exhibit responses to the arrival of food, so also do all other animals. In oysters, mussels, and clams, for example, the principal cells lining the digestive diverticula (the cells responsible for intracellular digestion; see Figure 6.20) *grow dramatically* as they take in food particles. They rapidly synthesize new cell membrane

stimulates the muscle layers of the nonstorage part of the stomach to begin and sustain peristaltic contractions. This motility of the stomach physically mixes and breaks up food at the same time that acid and pepsins initiate digestion of the meal. Additional controls are involved in modulating stomach function. For example, in addition to having gastrin receptors and being stimulated by gastrin, the acid-secreting cells have receptors for acetylcholine—released by the parasympathetic nervous system—and for histamine. The smell and taste of food cause stimulatory signals to be passed from the brain to the acid-secreting cells by way of the parasympathetic system. Histamine—which acts as a paracrine agent—is released by cells neighboring the acid-secreting cells (partly in response to gastrin and parasympathetic stimulation) and stimulates the acid-secreting cells.

The midgut (small intestine) can accommodate only a relatively small amount of material at a time. A sphincter between the stomach and midgut, the *pyloric sphincter* (see Figure 6.24), meters material into the midgut by opening only enough to let an appropriate amount of the most liquefied stomach contents through. At the end of each peristaltic wave passing along the stomach toward the sphincter, most of the material being processed in the stomach is refluxed back toward the main body of the stomach. Only a metered amount passes into the midgut. The midgut, as we have already seen, is the principal site of both digestion and absorption in the human gastrointestinal tract.

One of the most important principles of gut coordination is that *endocrine cells of many sorts are found in the epithelium lining much*

¹⁵Secretin, discovered in about 1900, was the first hormone known to science.

at this time to meet the membrane requirements of phagocytosis and pinocytosis. Some cells grow flagella when food is present, permitting them to circulate fluid and food particles within the diverticula by flagellar action. All these changes reverse after food has been processed.

Nutritional Physiology in Additional Time Frames

A fascinating subject that deserves far more attention than it has received is the fact that surprising numbers of animals undergo periods of *natural fasting* that last days, weeks or months, as discussed in **Box 6.2**. These animals undergo dramatic shifts in their nutritional physiology, from periods in which they have abundant inputs of nutrients to periods in which they have no inputs at all.

Speaking of animals more generally, a dramatic revelation of research in the last 20 years is that their nutritional physiology is commonly adjusted—often in adaptive ways—in *all five time frames* stressed in Chapter 1 (see Table 1.2). In the preceding section we looked at *acute* responses displayed shortly after eating. Here we look at the other four time frames and some related issues.

Nutritional physiology is responsive to the environment

Individual animals and populations commonly undergo changes in their nutritional physiology in response to their environments.

Three aspects of this theme deserve emphasis: responses of the nutritional physiology of individuals to long-term (chronic) environmental changes, alterations of gene expression in individuals in response to diet, and evolutionary responses of populations to changed nutritional conditions.

INDIVIDUALS RESTRUCTURE THEIR DIGESTIVE–ABSORPTIVE SYSTEMS WHEN THEY EXPERIENCE NEW SETS OF ENVIRONMENTAL CONDITIONS FOR EXTENDED PERIODS Often, when individual animals chronically alter their diet—so that they eat new types of foods compared with what they were previously eating—they upregulate digestive enzymes and absorption transporters targeted at the new foods. These changes, which require a few days to a few weeks to be completed, quite literally *increase the nutritional value* of the new foods because, as earlier stressed (see Figure 6.1), the nutritional value of a food depends in part on how readily an animal is able to digest and absorb it.

The sugar-transporter proteins in the midgut epithelial cells of a person (see Figure 6.22) provide an excellent example. The numbers of molecules of SGLT1, GLUT2, and GLUT5 *per cell* are not static in an adult human. Instead, the numbers of these molecules per cell become relatively low if an individual eats little carbohydrate for many days. Then, if the person changes his or her diet so that a lot of carbohydrate is ingested for several days, the numbers of transporter molecules per cell increase. Therefore, the capacity for carbohydrate absorption changes chronically, depending on

BOX 6.2 LONG-TERM NATURAL FASTING, EMPHASIZING PYTHONS

For people, it is strange to contemplate animals that, while remaining relatively active, undergo long fasts as parts of their ordinary life history. We eat every day if we can. However, many animals have evolved life histories that include weeks or months of fasting while they are still active (quite apart from hibernation or other resting states). Pacific salmon do not eat as they migrate up rivers to their spawning grounds, nor do European eels eat while migrating to the Sargasso Sea near Bermuda to breed. Polar bears, because of having evolved a hunting strategy dependent on ice platforms, fast for up to 4 months in some regions each year during the Arctic summer. Male emperor penguins fast for 4 months each year while incubating eggs away from the seacoast. Many species of seals undergo long fasts when they are nursing, molting, or carrying out other functions on land—given that they feed only at sea. Male northern elephant seals, for example, fast for up to 3 months while competing on land for territories, necessary for mating. Although *long-term natural fasting* is far from fully understood, physiologists have generally concluded that it needs to be distinguished from *starvation*. A state of physiological well-being is better maintained

during fasting (a normal part of life history) than during starvation (a state forced on the animal by external circumstances).

Alternation between feasting and long-term fasting is an intrinsic aspect of the life history of some predators because of the unpredictability of capturing prey. For example, small owls (e.g., *Aegolius funereus* in Europe) may routinely go for many days between prey captures under some circumstances. Pythons probably represent the extreme. The snakes obtain food by waiting for suitable prey animals to wander near. With this strategy, many weeks sometimes pass between meals. One adaptation of the pythons to their feast-and-fast type of life is that they are equipped to ingest large animals if the opportunity arises. Fully grown snakes can weigh more than a person and can easily eat animals that weigh 70% as much as they do. Thus stories of goats, antelopes, and teenagers being consumed are true.

Unlike humans and many other animals—which maintain their digestive systems in a state of readiness between meals—pythons deconstruct their gastrointestinal systems between meals! Burmese pythons (*Python molurus*), for example, undergo extensive deconstruction of their digestive apparatus if they are deprived of food for a month. Then, when they

obtain food, they rapidly reconstruct the apparatus. In the first 24 h after feeding, these pythons *double* the mass of their midgut, largely by the growth of new gut epithelium (critical for both digestion and absorption). Simultaneously, they undergo massive synthesis of midgut transporter proteins; the total numbers of molecules of both glucose transporters and amino acid transporters may increase 20-fold or more. In extreme cases, the metabolic rates of pythons increase 40-fold after eating. Part of the reason for the pythons' steep increase in energy use after eating is that they need to expend energy to rebuild their digestive systems to process the food. Pythons also increase the size of their heart muscle by 40% within 48–72 h after eating a large meal, as discussed in Chapter 21 (see Figure 21.9).

the amount of carbohydrate in the diet. Similarly, acclimation of midgut sugar transporters has been observed in experiments on many other vertebrates, from fish to mammals. Midgut amino acid transporters are also often upregulated or downregulated when dietary protein is chronically increased or decreased.

Sustained changes in diet commonly also bring about chronic adjustments in the quantities of digestive enzymes produced. The intraluminal digestive enzymes secreted by the pancreas in vertebrates provide dramatic examples. In a variety of species, a sustained increase in the amount of carbohydrate in the diet results in chronically increased pancreatic secretion of amylase. Similarly, sustained increases in the amounts of dietary proteins or lipids lead to chronically heightened secretion of pancreatic peptidases or lipases. Laboratory rats provide the best-studied model of these responses. In a rat, changes in pancreatic enzyme secretion start within 24 h after a change in diet and require about a week to be fully expressed. At that point a rat may exhibit a fivefold or greater increase in pancreatic secretion of digestive enzymes targeted at the new foods.

The size of the gastrointestinal tract is also subject to chronic adjustments. When a mouse or a small bird is placed chronically at subfreezing air temperatures, its intestines grow. House wrens, for example, gradually increase their intestinal length by 20% when placed at -9°C after living at $+24^{\circ}\text{C}$. For small birds or mammals to stay warm in cold environments, they must metabolize more food energy per day than when they are living in warm environments. Growth of the midgut in cold environments helps them increase their rates of food digestion and absorption. Similarly, female mice increase their midgut length when they are nursing young. Pythons provide the most stunning known display of chronic changes in gut size (see Box 6.2).

DIETARY CONSTITUENTS SOMETIMES ALTER GENE TRANSCRIPTION One of the cutting-edge stories in nutritional physiology today is the increasing realization from genomic research that food constituents or their immediate metabolic products sometimes induce upregulation or downregulation of genes. That is, some genes are *diet-regulated*. The exact implications of this discovery will probably not be fully understood for many years. Perhaps, for example, we will find that the effects discussed in the last section are mediated by relatively straightforward effects of food constituents on the control of genes that code for enzyme or transporter proteins. Already, researchers have found that dietary fatty acids often bind with receptor molecules, in the nuclei of cells, that control genes that are pivotal in fatty acid metabolism! Thus, when a person alters the lipids—the suites of fatty acids—he or she eats, that change can alter the manner in which the person metabolizes lipids. This phenomenon is one way in which changes in diet can affect long-term health for better or for worse.

IN POPULATIONS, NUTRITIONAL PHYSIOLOGY UNDERGOES EVOLUTIONARY CHANGE IN RESPONSE TO THE NUTRITIONAL ENVIRONMENT A good starting point to discuss this theme is to recall the intriguing recent studies of lactase persistence (adult lactase expression) in human populations discussed at the start of this chapter. When populations of people alter their nutritional environment over the course of many generations by adding milk and milk products to their adult diet, it seems clear that—at least sometimes—mutations that permit lactose digestion in adulthood are favored by natural

selection and come to be shared by large proportions of individuals. This phenomenon has long been recognized in northern European populations (e.g., the Dutch and Danes in Table 6.1). Similar evolutionary outcomes are now being discovered in various cattle-raising peoples in East Africa. Studies of such peoples emphasize that different populations of a single species can differ in nutritional physiology, and when selective pressures are great, evolutionary change can take place in human populations in only a few thousand years.

When groups of related species are compared, they are often found to differ in their digestive physiology in ways that are well correlated with the types of foods they eat, providing interspecific comparative evidence that digestive physiology evolves in parallel with diet. The distributions of disaccharidases in relation to disaccharides in the diet provide well-documented illustrations. For example, sucrase tends to be synthesized in abundance just by species that consume sucrose-rich foods. Although sucrose is common in our kitchens in the form of “table sugar,” it is actually not a common sugar in nature; flower nectars that are rich in sucrose are relatively distinctive foods. Species of birds, bats, and insects that specialize in feeding on sucrose-rich nectars synthesize abundant sucrase. However, related birds, bats, and insects that do not eat such nectars usually do not synthesize sucrase in particular abundance. The distributions of trehalase and dietary trehalose parallel each other in an equally striking way. The disaccharide trehalose has a very limited distribution in the biosphere. One of the few places it is found in abundance is in the blood of insects. Mammal species that do not eat insects typically synthesize little or no trehalase. By contrast, insectivorous mammals, such as insectivorous bats, exhibit high trehalase activity.

The midgut glucose transporters of vertebrates provide another example. Starches from plants yield glucose when digested. Vertebrate species that are principally plant eaters (herbivores), from fish to mammals, tend to show higher activities of midgut glucose transporters than related carnivorous vertebrates, which get less glucose in their diets. Some direct evidence exists (from studies of herbivores and carnivores subsisting on similar foods) that these differences are at least partly genetic, not merely consequences of acclimation to different diets.

The nutritional physiology of individuals is often endogenously programmed to change over time

Nutritional physiology often undergoes *developmentally programmed changes* as individuals mature from birth to adulthood. One example is lactase in mammals, as already discussed; individuals usually stop synthesizing lactase when they become old enough to have stopped taking in milk by nursing. Other developmentally programmed changes sometimes occur simultaneously. In some mammal species, for example, disaccharidases other than lactase, such as sucrase and maltase, increase as nursing comes to an end. The substrates of these alternative disaccharidases appear in the diet only as young mammals start to eat solid foods.

Programmed developmental change is particularly dramatic in amphibians. Whereas the tadpoles of frogs and toads are herbivores or omnivores, the adults are carnivores. The gut of a frog or toad is rapidly shortened and restructured during metamorphosis.

In addition to developmental changes, animals also often exhibit *periodically repeating programmed changes in nutritional physiology under the control of biological clocks*. The disaccharidases in the

Study Questions

1. Malnutrition of children is a profound global problem, and protein deficiencies are the most common form of childhood malnutrition. Why are people so vulnerable to protein deficiencies?
2. Explain how and why the absorption of hydrophobic and hydrophilic organic molecules differs.
3. List three major roles played by each class of foodstuffs: proteins, carbohydrates, and lipids.
4. Many of the most important vertebrate species in agriculture and aquaculture are foregut, midgut, or hindgut fermenters. Name an example of each, and discuss why species of this sort have advantages in agriculture and aquaculture.
5. Explain why wastage of essential amino acids can occur and how eating two foods simultaneously can prevent wastage.
6. Many species of hindgut fermenters, including horses, eat their feces to a greater extent when they have protein insufficiency than when they have plenty of protein. How might increased fecal consumption help?
7. It can be difficult or impossible to find a single diet that will serve the needs of both an herbivore and a carnivore. If you were trying to determine if two related species, one an herbivore and the other a carnivore, differ *genetically* in their digestive enzymes or absorption transporters, why would it be important to try to find a common diet for your test subjects of both species?
8. On the basis of our discussion of food-chain energetics, explain how the global human population's need for food could be met more readily if meat consumption were reduced and people lived more on plant foods.
9. Discuss hypotheses for why pythons deconstruct their digestive systems between meals (see Box 6.2). Similarly, discuss hypotheses for why small birds and mammals, having lengthened their intestines during cold seasons, permit their intestines to shorten during warm seasons. In other words, why might natural selection favor plastic, rather than static, gastrointestinal morphology?
10. Most people tend to think that if the sun ever stopped emitting light, all animal life on Earth would soon end. Populations of hydrothermal-vent animals might continue to exist for thousands of years, however. Explain.

Each of the two ground squirrels studied in a *constant* environment fattened and lost weight in an internally timed cycle over a period of years.

FIGURE 6.25 Endogenously timed annual rhythms in nutritional physiology Two golden-mantled ground squirrels (*Callospermophilus lateralis*) were kept under *constant* environmental conditions in a laboratory for more than 3 years, during which they received no information about the seasons or the time of year. The plotted lines show how their body weights changed; each ground squirrel lost a great deal of weight when it hibernated and gained weight by fattening between periods of hibernation. The bars near the bottom mark the time periods when each animal hibernated (bars are color coded to match the plots of body weight). The changes in eating behavior, fat storage, and hibernation were under the control of endogenous timekeeping mechanisms that are called *circannual clocks*. The reason for the name “circannual” is that when animals receive no exogenous information about the time of year, these clocks maintain *approximately* 365-day rhythms, not *exactly* 365-day rhythms (*circa* means “about”; thus *circannual* means “about a year”). Some other species of ground squirrels have now been shown to maintain circannual rhythms in nutritional physiology for a *decade* under constant laboratory conditions. (After Pongelley and Asmundson 1969.)

midgut of laboratory rats illustrate this phenomenon. In the apical membranes of epithelial cells, these enzymes are upregulated at night and downregulated during the day under the control of an endogenous biological clock. This rhythm ensures greatest digestive capability at the time that the rats—being nocturnal—are most likely to ingest food.

On another time scale, the annual fattening cycles of some mammals and birds are among the most dramatic of the clock-controlled cycles in nutritional physiology. Some species of hibernating ground squirrels, to illustrate, increase their ingestion and absorption of food energy—and fatten dramatically—in the autumn of each year even when kept under constant environmental conditions in a laboratory (Figure 6.25). *Circannual* (“approximately annual”) *biological clocks* control these changes in nutritional physiology. Circannual clocks in fact were originally discovered by research on annual cycles of fat storage in ground squirrels.

Energy Metabolism

In 1986 explorers set out to reach the North Pole by dogsled from Ellesmere Island at latitude 83° north. Their objective was to make the journey without resupply along the way and thus to reenact the famous expedition by Admiral Robert Peary in 1909. Each of the modern explorers' sleds was huge—16 feet (5 m) long, and loaded with 1400 pounds (630 kg) of material. Of the two-thirds of a ton on each sled, most was food for people and dogs. Most of the weight of the food, moreover, was required to meet energy needs; if the only food materials that had needed to be hauled were vitamins, minerals, amino acids, and other sources of chemical building blocks for biosynthesis, the pile of food on each sled would have been much smaller. Two people's needs for energy were to be met by the supplies on each sled. The sleds needed to be pulled and pushed over numerous ice ridges 20–60 feet high on the way to the pole. Even during progress over level ice fields, the way for the sleds' runners had to be cleared by the explorers often. A team of sled dogs had to be maintained and fed to do most of the hauling. A trek to the North Pole by dogsled would be immeasurably easier if there were no need for food energy for people and dogs. The need for energy is equally consequential in the natural world. Animals regularly risk their lives to obtain energy, or die because they did not obtain enough.

Why do animals need energy? Even if the answer to that question seems obvious, why do animals need new inputs of energy on a regular basis? Why do people typically need new food energy every day, for instance? Why not take in an adequate amount of energy early in life and simply reuse it, over and over, for the rest of life? These are some of the key questions addressed in this chapter.

Other questions to be discussed are more practical. The food on the sleds of the North Pole explorers was rich in fats and oils; the meat they carried, for instance, was a 50:50 mix of ground beef and lard (pure fat). Why did they emphasize lipids? If you yourself were planning an Arctic expedition, how would you use physiological principles to predict your energy needs and calculate the amount of food to pack on your sleds?

Energy metabolism, the subject of this chapter, is the sum of the processes by which animals acquire energy, channel energy into useful functions, and dissipate energy from their bodies. Energy metabolism consists of two subsets of processes mentioned in Chapter 2: *catabolic processes* that break down organic molecules to release energy, and *anabolic processes* that use energy to construct molecules.

Why Animals Need Energy: The Second Law of Thermodynamics

Animals are *organized* or *ordered* systems. As we saw in discussing the dynamic state of body constituents in Chapter 1, the atoms composing an animal's body are routinely exchanged with atoms in the environment. The *organization* of atoms in the body persists, however, even as particular atoms come and go. As this observation suggests, organization is a far more fundamental feature of animals than their material construction is (see page 11).

The **second law of thermodynamics**, one of the greatest achievements of intellectual history, provides fundamental

The burden of food A trek to the North Pole from the nearest land requires that hundreds of pounds of food be hauled per explorer, to supply energy for the explorers and their dogs.

insight into the nature of organized systems. The law applies to **isolated systems**. An isolated system is a part of the material universe that exchanges nothing—neither matter nor energy—with its surroundings. Animals, you will recognize, are not isolated systems. In fact, true isolated systems are difficult to create even in the highly controlled setting of a physics laboratory. Thus the concept of an isolated system is largely an abstraction. Nonetheless, we can gain insight into animal energetics by analyzing isolated systems. The second law of thermodynamics states that *if an isolated system undergoes internal change, the direction of the change is always toward greater disorder*.

A corollary of the second law is that order can be maintained or increased within a system only if the system is *not* isolated. If “energy” is permitted to enter a system from the outside, order may be maintained or increased within the system. **Energy** is defined in the field of mechanics to be the capacity to do mechanical work, measured as the product of force and distance. A broader definition that is often more useful for biologists is that *energy is the capacity to increase order*.

To illustrate the second law of thermodynamics, let’s examine an isolated system that consists of a closed loop of copper pipe filled with water, with the water initially flowing around and around in the loop. We need not know how the water started moving; it is enough to know that the loop of pipe has water flowing in it and that the loop, being isolated, exchanges no energy or matter with its surroundings. Let’s focus on the motions of atoms and molecules *on an atomic-molecular scale*. Initially, the distribution of atomic-molecular motions in this system is highly nonrandom, because each water molecule is moving in an ordered way in its direction of travel around the loop of pipe (**Figure 7.1a**). In addition, all of the water molecules—and all of the copper atoms in the walls of the pipe—are also undergoing ceaseless random motions on an atomic-molecular scale.¹

As time passes in this system, the energy of *directional* motion of the water molecules is gradually transformed into energy of *random* motion (**Figure 7.1b**). This transformation occurs because each time water molecules collide with copper atoms or other water molecules, some of their energy of directional motion is transferred in such a way as to increase the intensity of random motions of the atoms and molecules with which they collide. Over time, the rate of flow of water around the loop of pipe gradually decreases as energy of directional motion is lost in this way. Simultaneously, a gradual increase occurs in the energy of random molecular agitation (heat), and the temperature of the system rises. Eventually, all the energy of directional motion is lost, and the flow of water comes to a halt. At that point the water molecules and copper atoms in the system display only random motions, and the original order in the system (the directional motion of water molecules) is entirely degraded to disorder. *This inevitable outcome represents the second law of thermodynamics in action.*

The only way to keep the water flowing—and thus maintain the original order in the water-filled loop of pipe—would be to convert the system into an **open system**, a system that is *not* isolated. If there were a pump in the loop of pipe, and if electricity were provided to the pump from outside, the initial nonrandom state could be sustained indefinitely. That is, an energy input to the system could

FIGURE 7.1 The second law of thermodynamics in action

Energy of directional motion is converted to energy of random motion in this isolated system. This transformation of energy increases the intensity of random motions of both the water molecules and the copper atoms, causing the system temperature to rise.

create order in the system as rapidly as processes within the system tend to diminish order.

In terms of their thermodynamics, animals must function as open systems. Without an energy input, the blood coursing through an animal’s circulatory system will slow to a halt, just as the water in a loop of pipe does when there is no energy supplied from outside. Without an energy input, vital molecules in an animal’s tissues will become more disorganized, as by spontaneously breaking down; eventually, therefore, many molecules will lose their critical structural and functional properties. Without an energy input, positive and negative ions will distribute themselves randomly across an animal’s cell membranes; this randomization of electrical charges, among other things, will make nerve impulses impossible. The second law of thermodynamics dictates that if an animal were required

¹Random atomic-molecular motions are a universal property of matter that is at a temperature above absolute zero. In fact, the *temperature* of an object is a measure of the intensity of these motions within the material substance of the object.

to function as an isolated system, all forms of order within its body would decay. This loss of order would eventually kill the animal because order is essential for life. *Animals require energy from the outside because energy is necessary to create and maintain their essential internal organization.*

Fundamentals of Animal Energetics

To understand animal energetics more thoroughly, the first step is to recognize that energy exists in different *forms*, and the various forms differ in their significance for animals. We will focus here on four forms of energy of particular importance: chemical energy, electrical energy, mechanical energy, and heat. **Chemical energy (chemical-bond energy)** is energy liberated or required when atoms are rearranged into new configurations. Animals obtain the energy they need to stay alive by reconfiguring atoms in food molecules, thereby liberating chemical energy. **Electrical energy** is energy that a system possesses by virtue of separation of positive and negative electrical charges. All cell membranes possess electrical energy because there is charge separation across them (see Figure 5.10). There are two forms of energy of motion (kinetic energy) that are important for animals. One, **mechanical energy**, is energy of *organized* motion in which many molecules move simultaneously in the same direction. The motion of a moving arm, or that of circulating blood, provides an example. **Heat**, often called **molecular kinetic energy**, is the energy of *random atomic-molecular* motion. Heat is the energy that matter possesses by virtue of the ceaseless, random motions of all the atoms and molecules of which it is composed.²

The forms of energy vary in their capacity for physiological work

Although, by definition, all forms of energy are capable of doing work in one context or another, all forms of energy are *not equally* capable of doing physiological work in animals. **Physiological work** is any process carried out by an animal that increases order. For example, an animal does physiological work when it synthesizes macromolecules such as proteins, generates electrical or chemical gradients by actively transporting solutes across cell membranes, or contracts its muscles to move materials inside or outside its body (or set its whole body in motion).

How do the forms of energy that we have mentioned—chemical energy, electrical energy, mechanical energy, and heat—differ in their ability to do physiological work? Animals can use chemical energy (directly or indirectly) to do *all* forms of physiological work; hence, for animals, chemical energy is *totipotent* (*toti*, “all”; *potent*, “powerful”). Animals use electrical and mechanical energy to accomplish some forms of physiological work, but neither form of energy is totipotent. For example, animals use electrical energy to set ions in motion and mechanical energy to pump blood, but they cannot use either form of energy to synthesize proteins. Finally, *animals cannot use heat to do any form of physiological work.*

This last point is important. According to thermodynamics, a system can convert heat to work only if there is a temperature difference between one part of the system and another. Temperature is a measure of the intensity of random atomic-molecular motions. If the

intensity of random motions differs from one place to another within a system, this difference represents a form of order (nonrandomness), and the system can be used as a machine to convert heat to work; the high temperatures in the cylinders of an internal combustion engine, for example, permit heat from the burning of fuel to be converted into mechanical energy that propels a car. Consider, however, a physical system that has a uniform temperature. The purely random molecular motions that exist throughout such a system cannot do work. Within cells—the relevant functional systems of organisms—temperature differences from place to place are very small and transient, when they exist at all. Hence, cells cannot in theory use heat to do physiological work, and biological experiments confirm that they cannot. Heat is hardly unimportant to animals; as discussed later in this chapter and in Chapter 10, inputs of heat influence animal metabolic rates and affect the abilities of macromolecules such as proteins to carry out their functions. However, heat has no importance as a source of energy for physiological *work* because heat cannot do work in organisms.

The forms of energy are placed into two categories based on their ability to do physiological work. **High-grade energy** can do physiological work; chemical, electrical, and mechanical energy are included in this category. **Low-grade energy**—heat—cannot do physiological work. When we say that animals **degrade** energy, we mean that they transform it from a high-grade form to heat.

Transformations of high-grade energy are always inefficient

When organisms transform energy from one high-grade form to another high-grade form, the transformation is always incomplete, and some energy is degraded to heat. The **efficiency of energy transformation** is defined as follows:

$$\text{Efficiency of energy transformation} = \frac{\text{output of high-grade energy}}{\text{input of high-grade energy}} \quad (7.1)$$

The efficiency of energy transformation is typically much less than 1. For example, when a cell converts chemical-bond energy of glucose into chemical-bond energy of adenosine triphosphate (ATP), at most only about 70% of the energy released from glucose is incorporated into bonds of ATP; the other 30%—which started as high-grade energy—becomes low-grade energy: heat. When, in turn, a muscle cell uses the chemical-bond energy of ATP to contract, typically a maximum of only 25%–30% of the energy liberated from the ATP appears as energy of muscular motion; again, the remainder is lost as heat. The contraction efficiency of muscles in fact depends on the type of work they are doing. If you plant one of your feet on a wall and use your leg muscles to push your foot steadily against the wall (a type of isometric exercise), no motion occurs, and the muscles’ efficiency in producing motion is zero. If you ride an exercise bike, however, the efficiency of your leg muscles in producing external motion might be as high as 25%–30%. Even then, 70%–75% of the energy liberated from ATP in the process would become heat inside your body, rather than producing external motion.

You may be familiar with the Hollywood image of a jungle explorer caught in quicksand. The victim sinks deeper every time he moves. In certain ways an animal’s use of food energy is analogous to this image. To make use of the chemical energy from a meal, an animal *must* transform the energy, usually in multiple steps. Each step, however, robs the energy of part of its value because energy transformations are always inefficient and degrade energy to heat.

²The study of forms of energy is part of thermodynamics. Some specialists in thermodynamics emphasize energy transfer. For them, heat and mechanical work are not forms of energy, but rather *heating* and *working* are processes that *transfer* energy.

Thus, with each step an animal takes to use the high-grade energy in its food, the resource shrinks, just as each move of the hapless jungle explorer lowers his body farther into the quicksand.

Animals use energy to perform three major functions

It can be helpful to visualize the energy used for physiological work as a resource that “flows” through an animal during its lifetime (Figure 7.2). From the viewpoint of energetics, each time an animal eats, it gains chemical energy from its external environment. Chemical energy, therefore, enters an animal repeatedly throughout life. This energy, the energy in the chemical bonds of food, is known as the animal’s **ingested chemical energy** or **ingested energy**. Forms of energy derived from the ingested energy later pass back into the external environment.

If we follow ingested energy after it is first taken into an animal’s body, we find that although some of the ingested energy is absorbed, some is not. This distinction parallels the principle—emphasized in Chapter 6—that some chemical compounds in foods can be successfully digested (or fermented) and absorbed into the bloodstream, whereas others cannot. Ingested compounds that an animal is unable to absorb are egested in the feces. The chemical-bond energy in these compounds is known as the animal’s **fecal chemical energy** or **fecal energy** (see Figure 7.2). By contrast, the chemical-bond energy of the organic compounds that are absorbed (or assimilated) is known as the animal’s **absorbed chemical energy** or **absorbed energy** (or **assimilated chemical energy**).³ The absorbed energy from ingested food is the energy that is distributed to the animal’s living tissues and that therefore is made available to the animal’s cells for use in physiological work.

An animal uses its absorbed chemical energy to carry out three major types of physiological work. As we discuss these, note that Figure 7.2 diagrams many of the points made.

1. **Biosynthesis.** An animal synthesizes its body constituents, such as its proteins and lipids, by use of absorbed energy. As this process—called **biosynthesis**—takes place, some of the absorbed energy that is used *remains in chemical form* because the products of biosynthesis are organic molecules with significant chemical-energy content. During *growth*, chemical energy accumulates in the body in the form of biosynthesized products that are used to assemble new cells and tissues. Some of the chemical energy accumulated in body tissues through growth (e.g., the chemical energy of fat) may be used by an animal as food energy during times of fasting or starvation; ultimately, all of the chemical energy accumulated in body tissues becomes food for predators or decay organisms when the animal dies. In addition to contributing to tissues during growth, biosynthesis also produces *organic compounds that are exported from the body during an animal’s life*, taking chemical-bond energy with

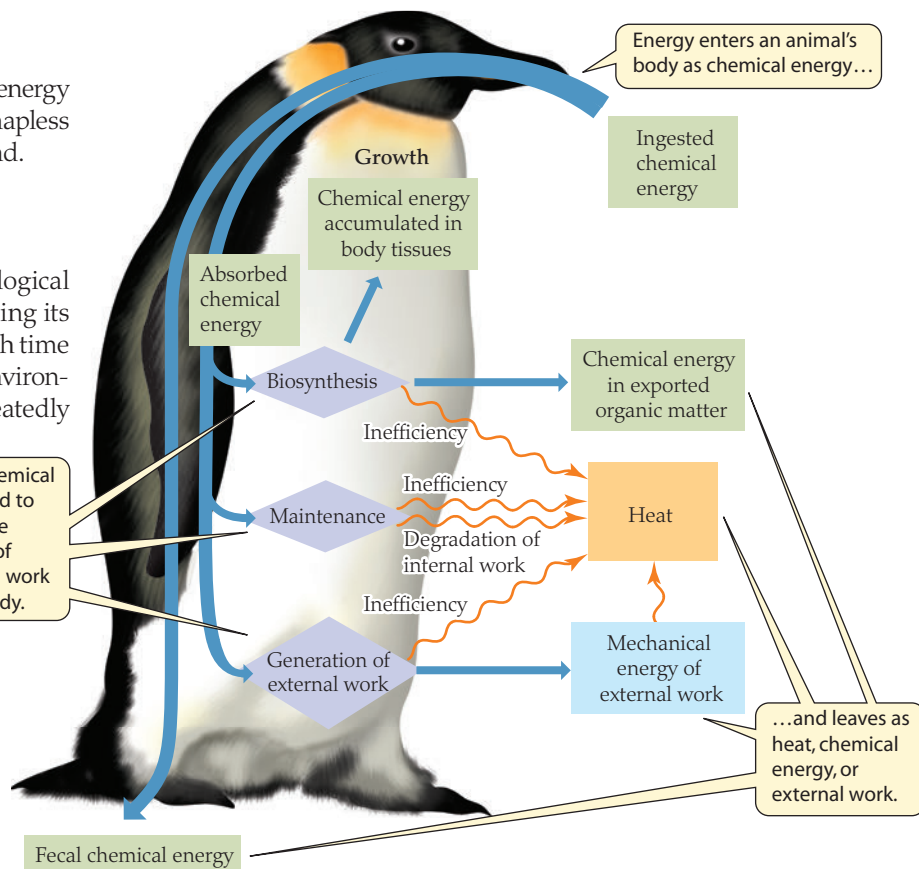

FIGURE 7.2 The uses of energy by an animal At death, chemical energy in body tissues becomes ingested energy for other organisms.

them. Gametes, milk, externally secreted mucus, sloughed skin or hair, and shed exoskeletons are just a few of the organic products that animals synthesize and lose to the environment during their lives. Whether biosynthesis yields growth or exported organic products, this form of physiological work typically involves elaborate biochemical pathways requiring many steps. Each step is inevitably inefficient. Biosynthesis therefore produces heat, as well as organic products, because of inefficiency.

2. **Maintenance.** An animal’s **maintenance** functions are all the processes that *maintain the integrity* of its body; examples include circulation, respiration, nervous coordination, gut motility, and tissue repair. With only trivial exceptions, *the energy used for maintenance is degraded entirely to heat within the body*. To see why, consider the circulation of the blood as an example. First, the chemical-bond energy of the absorbed food molecules that are used as fuel must be converted into chemical-bond energy of ATP, and energy is lost as heat in the process because of the inefficiency of ATP synthesis discussed previously. Additional energy is then lost as heat when the energy of ATP is used to drive contraction of the heart muscle. Finally, a small fraction of the chemical-bond energy originally obtained from food molecules appears as mechanical energy in the motion of the blood ejected from the heart. Even that mechanical energy is degraded to heat within the body, however, in overcoming the viscous resistances that oppose the motion of the blood through the blood vessels. Mechanical work

³The term *digestible energy* is widely used as a synonym, but it is not used in this book because the absorbed chemical energy depends on not only digestive but also absorptive processes.

that takes place *inside an animal's body* is termed **internal work**. Several maintenance functions, such as the circulation of the blood and gut motility, are types of internal work. The energy of internal work is degraded to heat within the body.

3. *Generation of external work.* Animals perform **external work** when they apply mechanical forces to objects outside their bodies. A mouse running across a field and a bicyclist ascending a hill, for example, are performing external work using their leg muscles. Much of the absorbed chemical energy used to fuel external work is degraded to heat within the body (e.g., in using ATP to drive muscle contraction). However, when external work is performed, some energy leaves the body as mechanical energy transmitted to the environment. The fate of that energy depends on whether it is stored. *Energy of external work is stored if it is converted into increased potential energy of position.* When a bicyclist ascends to the top of a hill, as in **Figure 7.3**, part of his energy of external work is stored as increased potential energy of position because his body and bike move to a higher position in Earth's gravitational field. (When the bicyclist later descends, this potential energy of position is converted into mechanical energy [motion downhill] and then to heat.) By contrast, consider horizontal motion. If a mouse scurries a *horizontal* distance across a field—or a person bicycles along a *horizontal* road—no energy is stored in repositioning the body relative to gravity, and the mechanical energy transmitted to the environment is entirely, and quickly, degraded to heat in overcoming resistances to motion.

Reviewing the flow of energy through an animal's body (see Figure 7.2), we see that *all uses of energy by animals generate heat*. All living animals, therefore, produce heat. Because frogs, fish, clams, and other poikilotherms are often cool to the touch, one can get the erroneous impression that they do not produce heat.

FIGURE 7.3 In this type of external work, some of the energy driving locomotion is converted to potential energy of position. As this bicyclist goes uphill, although much of his mechanical energy of external work becomes heat, a fraction is stored as potential energy because he is propelling the mass of his body and bicycle higher in Earth's gravitational field.

However, such animals are cool not because they fail to produce heat, but because their rates of heat production are so low and their bodies are so slightly insulated that they are not warmed by the heat they produce (see page 256). Animal heat, which is universal, has been studied for centuries—far longer than most physiological phenomena—and these studies have led to fundamental discoveries about the nature of life (**Box 7.1**).

BOX 7.1 VIEWS ON ANIMAL HEAT PRODUCTION

Heat is an inevitable by-product of the use of high-grade, chemical-bond energy to create and maintain the vital organization of living organisms. Interestingly, from the time of Aristotle until the nineteenth century, the significance of heat was generally viewed in a completely opposite way. Far from being a by-product, heat was usually seen as a primary source of life, a vital force that endowed many parts of organisms with their living attributes. This “vital heat” was thought to differ from the heat of a fire. It was believed to originate exclusively in the heart, lungs, or blood and to suffuse the rest of the body. When William Harvey first described the circulation of the blood in the early seventeenth century, one of the principal roles attributed to the newfound circulation was transport of “vital heat” from tissues where it was produced to other tissues, which it animated.

The old view of animal heat began to change at about the time of the American Revolution, when Antoine Lavoisier, in France, showed that the ratio of heat production to CO_2 production was about the same for a guinea pig as for burning charcoal. From this and other evidence, Lavoisier and the Englishman Adair Crawford argued that animal respiration is a slow form of combustion, and that animal heat is the same as the heat produced by fire. Still, for several more decades, all animal heat was believed to originate in the lungs, and the lungs were thought to be the exclusive site of O_2 use. Not until 1837 did Heinrich Gustav Magnus show that the blood takes O_2 from the lungs to the rest of the body and returns CO_2 . Evidence for the all-important concept that tissues throughout the body make heat came a decade later when Hermann von Helmholtz demonstrated that

muscular contraction liberates heat. In 1872, Eduard Pflüger presented evidence that all tissues consume O_2 .

The discovery that all tissues use O_2 and produce heat was one of several lines of thought and investigation that came together in the nineteenth century to give birth to our modern understanding of animal energetics. Other important developments were the flowering of the science of thermodynamics (sparked by the Industrial Revolution) and profound changes in the understanding of energy. In the 1840s, Julius Robert von Mayer in Germany and James Joule in England developed the seminal concept that heat, motion, electricity, and so on are all forms of one thing: energy. Mayer, a physician, was probably the first person to conceptualize the true nature of animal energy transformations, as described in this chapter.

Another point to stress as we conclude our discussion of energy flow through animals is that *the conversion of chemical-bond energy to heat is one-way*: No animal or other living creature is able to convert heat back to chemical-bond energy or to any other form of high-grade energy. Thus *energy is not recycled* within individual animals or within the biosphere as a whole. This principle provides the answer to a key question we asked at the start of this chapter—namely, why do animals need to obtain food energy regularly throughout their lives? When an animal ingests and uses totipotent chemical-bond energy, it converts much of the energy in a one-way, irreversible fashion to heat, which is useless for physiological work. Accordingly, as the animal uses the chemical-bond energy from a meal, it inevitably develops a need to eat again to acquire new chemical-bond energy. The biosphere as a whole requires a continuing input of high-grade photon energy from the sun for much the same reason. The photon energy captured in bonds of organic compounds by photosynthesis is converted progressively to heat by plants as well as animals, meaning that new photon energy is required if organic compounds are to continue to be available. The heat that all organisms collectively make is radiated from Earth into outer space.

SUMMARY Fundamentals of Animal Energetics

- Forms of energy vary in their capacity to do physiological work. Chemical-bond energy is totipotent for animals. Electrical and mechanical energy can do certain types of physiological work but are not totipotent. Heat cannot perform physiological work of any kind.

- Animals use their absorbed chemical energy for three major functions: biosynthesis, maintenance, and generation of external work. Biosynthesis, which preserves some of the absorbed energy in the form of chemical energy, includes both growth and the synthesis of organic materials that are exported from the body during an individual's life.
- Some energy is degraded to heat (low-grade energy) whenever one high-grade form of energy is transformed to another. Energy transformations are always inefficient.
- Animals take in chemical-bond energy and put out heat, chemical-bond energy, and external work.

Metabolic Rate: Meaning and Measurement

We have seen that an animal takes in chemical energy in its food, and in the process of living it releases chemical energy, heat, and external work to its environment (see Figure 7.2). The energy that an animal converts to heat and external work is defined by physiologists to be **consumed** because that energy is “spent” or “exhausted”: The heat cannot be used at all to do physiological work, and the energy of external work—far from being totipotent—(1) can be used for only a narrowly defined function (the specific external work performed) and (2) soon will itself become heat in most cases.

The *rate* at which an animal consumes energy is its **metabolic rate**. That is, an animal's metabolic rate is the rate at which it converts chemical energy to heat and external work. *Heat is always the dominant component of the metabolic rate*. Accordingly, for simplicity we will sometimes speak of metabolic rates as rates of heat production. Energy is measured in *calories* or *joules*. Metabolic rates, therefore, are expressed in *calories per unit of time* or *watts* (Box 7.2).

BOX 7.2 UNITS OF MEASURE FOR ENERGY AND METABOLIC RATES

The traditional unit of measure for energy is the **calorie (cal)**, which is the amount of heat needed to raise the temperature of 1 g of water by 1°C. Although the calorie is defined as a quantity of heat, it can be used as a unit of measure for all other forms of energy, because the forms of energy bear strict equivalencies to each other. A **kilocalorie (kcal)** is 1000 cal. Sometimes the kilocalorie is written *Calorie*, with a capital C, an unfortunate system often producing confusion. In the United States, the “calories” listed in formal nutrition labels for foods (see the figure) are kilocalories. To illustrate the sorts of confusion that arise, note in the figure that “calorie” is capitalized at the top of the label but not at the bottom, which would be correct only if the meaning at the top were a unit 1000 times greater than at the bottom. Popular books and periodicals sometimes write “calorie” with a lowercase c when they mean kilocalorie, a

practice that creates three orders of magnitude of ambiguity. If energy is expressed in calories or kilocalories, then *rates* of energy exchange or transformation—such as metabolic rates—are expressed in calories or kilocalories *per unit of time*.

The fundamental unit of measure for energy in the SI system of units is the **joule (J)**, named in honor of James Joule. Appendix A discusses the derivation of the joule from the SI base units. A **watt (W)**, which is equivalent to 1 joule/second (J/s), is the fundamental SI unit for rates of energy exchange or transformation.

One calorie is equivalent to 4.186 J, a relation that permits the interconversion of units in the calorie and SI systems. For example, as you sit quietly reading this page, your body is likely producing heat at a rate near 23 cal/s, equivalent to $23 \times 4.186 = 96$ J/s, or 96 W. That is, you are producing heat about as rapidly as a 100-W incandescent light bulb.

A nutrition label for frozen macaroni and cheese sold in the United States In most parts of the world, energy values are given in unambiguous SI units.

At the start of this chapter, we raised the question of how one could predict the food needs of people and sled dogs during a polar expedition. The *metabolic rates* of the people and dogs are the basis for making this prediction. Knowing the average metabolic rates of the people and dogs, one can calculate how much chemical energy they will need per day and then calculate the total food energy they will require for all the days of their trek.

Speaking broadly, metabolic rates are significant for three principal reasons:

1. An animal's metabolic rate is one of the most important determinants of *how much food it needs*. For an adult, food needs depend almost entirely on metabolic rate.
2. Because every energy-using process that takes place in an animal produces heat, an animal's metabolic rate—its *total rate of heat production*—provides a *quantitative measure of the total activity of all its physiological mechanisms*. An animal's metabolic rate, roughly speaking, represents the animal's *intensity* of living.
3. Ecologically, an animal's metabolic rate measures the *drain the animal places on the physiologically useful energy supplies of its ecosystem*, because the metabolic rate is the pace at which the animal degrades the chemical energy of organic compounds in its ecosystem.

Direct calorimetry: The metabolic rate of an animal can be measured directly

Physiologists sometimes measure metabolic rates directly using a **direct calorimeter**, a device that measures the rate at which heat leaves an animal's body (Box 7.3). Although modern direct calorimeters are technically complex instruments, the basic operation of a direct calorimeter is illustrated nicely by the device that Antoine Lavoisier used in the very first measurements of animal heat production (Figure 7.4). The heat produced by the test animal melted ice in an ice-filled jacket surrounding the animal, and Lavoisier collected the melt water over measured periods of time. By knowing the amount of heat required to melt each gram of ice, he was able to calculate the animal's rate of heat output, and thus its metabolic rate.

For measures of metabolic rate by direct calorimetry to be fully accurate, external work—not just heat—sometimes must be considered. If the animal under study is at rest, it is not performing external work; a measurement of heat production alone is then fully sufficient for measuring the animal's metabolic rate. If the animal *is* performing external work, the energy of the external work is often rapidly degraded to heat; this is true, for example, if the animal merely moves around horizontally. In such cases, a measure of heat production includes the energy of external work; again, therefore, a measurement of heat production alone is fully sufficient for measuring the metabolic rate. However, if the test animal is performing external work and some of the energy of its external work fails to be converted to heat because it is stored, that energy must be measured independently and added to heat production to quantify the animal's metabolic rate accurately by direct calorimetry.

Indirect calorimetry: Animal metabolic rates are usually measured indirectly

Indirect calorimetry measures an animal's metabolic rate by means other than quantifying heat and work (see Box 7.3). Biologists today

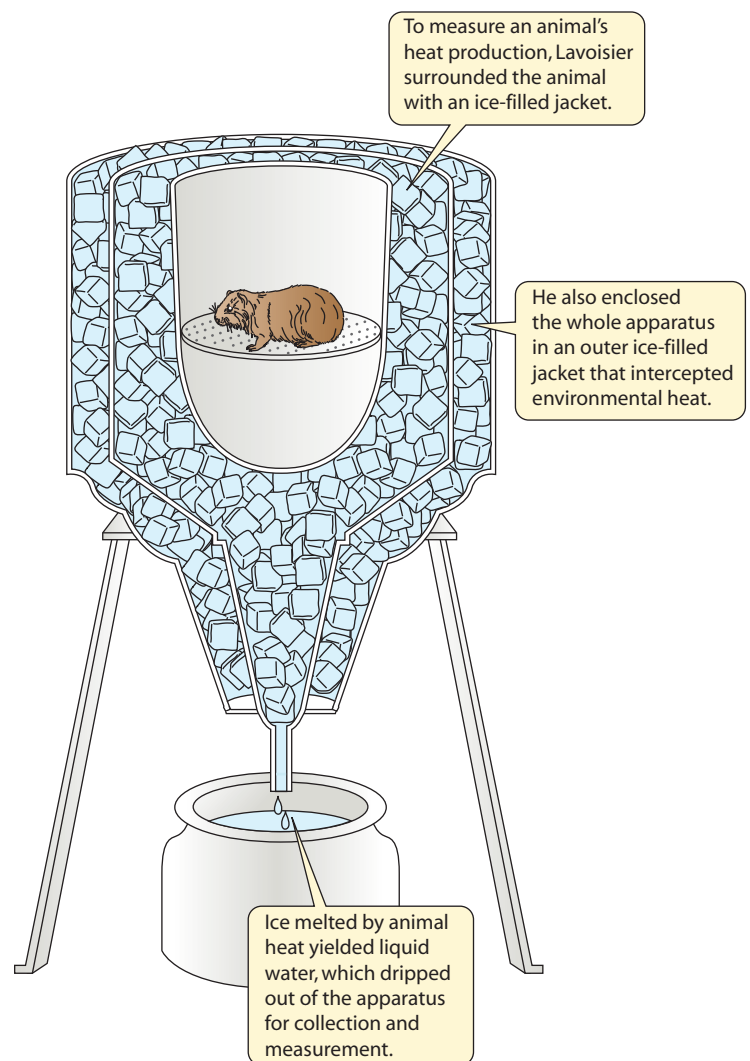

FIGURE 7.4 Lavoisier's direct calorimeter Heat from the general environment must be excluded from measurement of animal heat. In Lavoisier's device, heat entering from the air surrounding the calorimeter was intercepted by an outer ice-filled jacket, which prevented the environmental heat from melting the same ice as the animal heat. Modern direct calorimeters, although they measure heat in a different way and more precisely, still reflect the fundamental design considerations that Lavoisier introduced. (After Lavoisier 1862.)

usually measure metabolic rates indirectly because the methods of indirect calorimetry are cheaper and easier than those of modern, sophisticated direct calorimetry. Here we consider two methods of indirect calorimetry: (1) measuring an animal's rate of respiratory gas exchange with its environment (termed *respirometry*) and (2) measuring the chemical-energy content of the organic matter that enters and leaves an animal's body (the *material-balance method*).⁴

INDIRECT CALORIMETRY BASED ON RESPIRATORY GAS EXCHANGE An animal's rate of oxygen (O_2) consumption provides a convenient and readily measured estimate of its metabolic rate. To understand the use of O_2 consumption for this purpose, consider first an oxidation reaction occurring in a test tube. If a mole

⁴Additional methods of indirect calorimetry that are used for active or free-living animals are discussed in Chapter 9.

BOX 7.3 DIRECT MEASUREMENT VERSUS INDIRECT MEASUREMENT

The distinction between *direct* and *indirect* methods of measurement is one of the most fundamental and important concepts in the science of measurement. Direct and indirect methods give results that can be expressed in the same units; a metabolic rate, for example, can be written down in watts whether it is measured directly or indirectly. The distinction between direct and indirect methods is in the property that is *actually measured*.

Rigorously speaking, any physiological trait is *defined* by specific properties. A **direct method of measurement** actually measures the *very properties that are specified by the definition of a trait*. An animal's metabolic rate, for example, is defined to be its rate of production of heat and external work. Thus a direct method of measuring metabolic rate actually measures heat and external work. Direct methods are the *gold standards* of measurement because their results relate unambiguously to the trait being studied.

By contrast, an **indirect method of measurement** actually measures *properties that are different from those specified by the definition of a trait*. The properties that are actually measured by an indirect method serve as “stand-ins” or “proxies” for the properties that define the trait. For instance, some indirect methods for measuring metabolic rate record O₂ consumption. Researchers use such methods because O₂ consumption is relatively easy to measure and often closely reflects an animal's rate of production of heat and external work. After measuring the amount of O₂ consumed per unit of time, researchers often convert the amount of O₂ to calories or joules, units of energy. It is crucial to understand that *the act of converting the measurement results does not change the nature of the measurement method*. A measure of metabolic rate obtained by recording O₂ consumption is indirect regardless of the units in which it is ultimately expressed.

Why is the distinction between direct and indirect methods important? A direct method, if carried out carefully with suitable instruments, *must provide information of the sort desired* because it measures exactly what the definition specifies. An indirect method, however, may introduce errors regardless of how carefully it is carried out, because it measures something different from what is stated by the definition. The accuracy of an indirect method is assessed by determining how well its results agree with a direct method. Whereas indirect methods often have *practical advantages*, they are usually less accurate than direct ones, at least under certain circumstances. Thus the choice of method involves a compromise. In the measurement of metabolic rate, the indirect methods commonly introduce uncertainties of ±1–5% in the results, but they might reduce costs of time and money by tenfold, making them attractive.

of glucose (C₆H₁₂O₆) is burned completely, chemical stoichiometry dictates that 6 moles of O₂ will be used, and 6 moles of CO₂ will be produced. The reaction will also release heat, known as *heat of combustion*. For glucose, the heat of combustion during complete oxidation is about 2820 kilojoules per mole (kJ/mol), or 673,000 calories per mole (cal/mol). The following equation therefore applies:

Note that when glucose is oxidized, a fixed proportional relation exists between the amount of heat produced and the amount of O₂ used: 2820 kJ of heat per 6 mol of O₂. Similarly, a fixed proportional relation exists between heat production and CO₂ production: 2820 kJ per 6 mol of CO₂. Knowing these relations, if you oxidize an *unknown* quantity of glucose in a test tube and you measure only the amount of O₂ used, or only the amount of CO₂ produced, you can *calculate* the exact amount of heat produced.

When an animal metabolically oxidizes glucose (or any other chemical substance), if the chemical end products are the same in the animal as in a test tube, then the stoichiometric relations that prevail in the animal are the same as those in the test tube. This important principle, established by Max Rubner and Wilbur Atwater in the 1890s, is true even though the *intermediate* steps of the metabolic oxidation reactions in an animal differ from the intermediate steps of test-tube oxidation. Because of this principle, if an animal oxidizes glucose to CO₂ and H₂O, the stoichiometry in Equation 7.2 applies to the animal. Accordingly, if you measure either the animal's O₂ consumption or its CO₂ production, you can calculate the animal's heat production. This is the rationale for estimating animal metabolic rates from rates of respiratory exchange of O₂ and CO₂.

Table 7.1 lists conversion factors for calculating the amount of heat generated when a milliliter of O₂ is consumed or a milliliter

of CO₂ is produced.⁵ To understand how to use the table, imagine that an animal consumes O₂ at a rate of 10 mL/minute (min), and suppose you know that the animal's cells are oxidizing only glucose (a carbohydrate). The animal's metabolic rate would then be 10 mL O₂/min × 21.1 J/mL O₂ = 211 J/min.

As you can see from Table 7.1, problems can arise in the use of respiratory gas exchange to measure metabolic rates because the correct conversion factor for calculating heat production from O₂

⁵According to universal convention, gas volumes in metabolic studies are expressed at Standard Conditions of Temperature and Pressure (STP). That is the way they are expressed in this chapter and throughout this book. For more information, see Appendix C.

TABLE 7.1 Ratios of heat production to O₂ consumption, and heat production to CO₂ production, during the aerobic catabolism of carbohydrates, lipids, and proteins

Values given are for representative mixtures of each of the three foodstuffs. Gas volumes are at Standard Conditions of Temperature and Pressure, STP (see Appendix C).

Foodstuff	Heat produced per unit of O ₂ consumed (J/mL O ₂)	Heat produced per unit of CO ₂ produced (J/mL CO ₂)
Carbohydrates	21.1	21.1
Lipids	19.8	27.9
Proteins ^a	18.7	23.3

Source: After Brown and Brengelmann 1965.

^aFor proteins, values depend on the metabolic disposition of nitrogen; the values tabulated here apply to mammals and other animals in which urea is the dominant nitrogenous end product.

consumption (or from CO₂ production) is not a simple, fixed number. Instead, the conversion factor for calculating heat production varies depending on the foodstuffs being oxidized. If animals were to oxidize only glucose, calculating their metabolic rates by measuring their rates of O₂ consumption would be unambiguous, as we have already seen. However, animals oxidize a *variety* of foodstuffs, which yield *different* quantities of heat per unit of volume of O₂ consumed (or CO₂ produced; see Table 7.1). This consideration introduces the possibility of ambiguity or inaccuracy. Returning to our previous example, we saw that if an animal consumes O₂ at a rate of 10 mL O₂/min, its metabolic rate is 211 J/min (10 mL/min × 21.1 J/mL) if its cells are oxidizing carbohydrates. Its metabolic rate is only 198 J/min, however, if its cells are oxidizing lipids (10 mL/min × 19.8 J/mL). Hence an investigator cannot calculate metabolic rate (the rate of heat production) exactly from measurements of O₂ consumption (or CO₂ production) unless the investigator knows the exact mixture of foodstuffs that the study animal's cells are oxidizing.

An animal's recent diet often does not provide accurate insight into the foodstuffs its cells are oxidizing, because animals store and interconvert foodstuffs. We can determine the foodstuffs that *cells* are oxidizing only by looking at indices of *cellular function*. One useful index of this sort is obtained by simultaneously measuring both CO₂ production and O₂ consumption and taking their ratio:

$$\frac{\text{moles of CO}_2 \text{ produced per unit time}}{\text{moles of O}_2 \text{ consumed per unit time}}$$

This ratio is called the **respiratory exchange ratio (*R*)** when measured at the respiratory organs (e.g., lungs); it is called the **respiratory quotient (*RQ*)** when measured at the level of the cells. Under many circumstances, *R* and *RQ* are equal, and we limit our discussion here to that straightforward situation.

The value of *R* (and *RQ*) is, in essence, a metabolic signature that reveals the particular sorts of foodstuffs being oxidized by an animal's cells (Table 7.2). If an animal exhibits a value of *R* near 1.0, for example, its cells are likely oxidizing mostly carbohydrates. However, if the animal's *R* value is near 0.7, its cells are likely catabolizing mostly lipids. An *R* or *RQ* value near 1.0 or 0.7 strongly suggests which conversion factor from Table 7.1 should be used to calculate an animal's metabolic rate from its O₂ consumption. Specifically, an *R* value near 1.0 suggests use of the carbohydrate factor, 21.1 J/mL O₂, whereas an *R* value near 0.7 suggests use of the lipid factor, 19.8 J/mL O₂.

TABLE 7.2 Respiratory exchange ratios (*R* values) during the aerobic catabolism of carbohydrates, lipids, and proteins

Respiratory quotients (*RQ* values) are equal in steady state.

Foodstuff	Respiratory exchange ratio
Carbohydrates	1.0
Lipids	0.71
Proteins	0.83 ^a

Source: After Kleiber 1975.

^aThe value listed for proteins is for animals such as mammals in which urea is the dominant nitrogenous end product. Different values apply to animals that produce ammonia or uric acid as their principal nitrogenous end product.

Unfortunately, *R* values that are not close to 1.0 or 0.7 are often difficult to interpret. For example, if an animal has an *R* value of 0.8, a researcher cannot simply conclude that its cells are catabolizing proteins, because the catabolism of a mixture of carbohydrates and lipids (or of all three foodstuffs) could also produce an *R* value of 0.8. The potential for ambiguity stems from the fact that although three unknowns exist (the proportions of the three foodstuffs being oxidized), the *R* or *RQ* value encompasses only two knowns (O₂ consumption and CO₂ production). The ambiguity can be resolved, but only by measuring additional indices of cellular function besides O₂ consumption and CO₂ production.

Investigators often sidestep the uncertainty concerning foodstuffs by using a “representative” conversion factor of about 20.2 J/mL O₂ (4.8 cal/mL O₂) to calculate an animal's metabolic rate from its O₂ consumption. This conversion factor approximates the heat produced by an animal that is assumed to be catabolizing a representative mixture of carbohydrates, lipids, and proteins. Using the representative conversion factor to calculate metabolic rate does not do away with the uncertainty we have been discussing. To illustrate, suppose that an investigator uses the conversion factor of 20.2 J/mL O₂ but the animal is actually oxidizing only carbohydrates. Because the true conversion factor (for carbohydrates) is 21.1 J/mL O₂, the investigator will underestimate the metabolic rate by 4.5% by using the approximate factor of 20.2 J/mL O₂. If the animal is oxidizing only proteins, the true conversion factor (see Table 7.1) is 18.7 J/mL O₂; thus the investigator will overestimate the metabolic rate by 8% by using the approximate factor. The use of the representative conversion factor is a “good news, bad news” situation. The bad news is that the metabolic rate can be misestimated by ±5–8% if one ignores the foodstuff question and simply multiplies the O₂ consumption by the representative conversion factor to calculate metabolic rate. The good news is that the use of this conversion factor is convenient, and for many purposes an error of ±5–8% may not be much of a worry.⁶

Among all the methods available to measure metabolic rate, by far the most common approach used today for routine studies is to measure the rate of O₂ consumption—nothing more—and “live with” the relatively small potential errors that are inherent in the method. Metabolic rates, in fact, are often expressed simply as rates of O₂ consumption. The O₂ consumption method has four notable advantages: Two of these, already mentioned, are its technical ease of accomplishment (Box 7.4) and its relatively small inherent uncertainty under many conditions. A third advantage is that external work does not, in most cases, have to be measured independently when the O₂ consumption method is used. Because the O₂ consumption of an animal is proportional to the ultimate yield of heat from the foodstuffs it aerobically catabolizes, the heat equivalent of any aerobic external work performed by the animal is included in the metabolic rate calculated from its O₂ consumption. The fourth advantage of the O₂ consumption method is that it excludes the metabolism of microbes in the gut (the gut microbiome) because those microbes are anaerobic and do not consume O₂.

⁶If one measures only CO₂ production and calculates metabolic rate with a representative conversion factor, the potential error is much greater: ±15–20%. You can see the principal reason in Table 7.1; namely, the relationship between CO₂ production and heat production depends very strongly on foodstuff. Because of the large potential error, CO₂ production—measured by itself—is hardly ever used as an indirect measure of metabolic rate in laboratory studies.

BOX 7.4 Respirometry

Respirometry is the process of measuring an animal's gas exchange with its environment. The devices used are called *respirometers*. For studies of metabolic rate, the most common type of respirometry is the measurement of an animal's rate of O₂ consumption. In **Box Extension 7.4**, you will find illustrations and explanations of the two basic types of respirometry configurations that are used to measure O₂ consumption: (1) *closed* configurations, in which an animal is housed in a fully sealed chamber with a relative fixed volume of nonmoving air and (2) *open* configurations, in which the animal draws its O₂ from an air stream flowing by during measurement.

Regardless of how large and metabolically active the gut microbial populations may be, the method measures just the metabolic rate of the animal tissues.

Related to the points just made, a limitation of the O₂ consumption method—and a vital point to keep in mind—is that an animal's metabolic rate will not be measured accurately if some or all of the animal's tissues are employing anaerobic mechanisms of catabolism to release energy. As discussed in Chapter 8, for example, anaerobic ATP production is used often by skeletal muscles during sudden, highly intense exercise in people and many other sorts of animals. To measure an animal's metabolic rate during anaerobically fueled exercise, one must turn to more-elaborate methods than just measuring O₂ consumption.

INDIRECT CALORIMETRY BASED ON MATERIAL BALANCE In addition to methods based on respiratory gas exchange, the second most commonly used approach for measuring animal metabolic rates today is a type of indirect calorimetry in which one measures the chemical-energy content of *organic materials* entering and leaving an animal's body. This approach, which is widely used in agricultural production research, is described as the study of **material balance**. To apply the method, one measures the chemical-energy content of all the food an animal eats over a period of time, as well as the chemical-energy content of the feces and urine eliminated over the same period.⁷ Subtracting the energy content of the excreta from that of the food then gives an estimate of the animal's metabolic rate. The logic of the method is straightforward: Any energy that an animal ingests as chemical energy, but does not void as chemical energy, must be consumed.

Complications arise if the animal under study is increasing or decreasing its biomass. If, for example, an animal is growing and thus increasing the chemical-energy content of its body, some of the chemical energy ingested but not voided is nonetheless not consumed; an estimate of this quantity must enter the calculation of metabolic rate. Another type of complication is that chemical energy may enter or leave an animal's body in ways other than in food, feces, and urine. For instance, an animal could lose chemical energy by shedding feathers or secreting mucus. For the material-balance method to be applied, the chemical-energy content of *all* significant inputs and outputs of organic material must be measured.

⁷An instrument known as a *bomb calorimeter* is used to measure the energy values of organic materials. It does this by burning them explosively in pressurized, pure O₂ and measuring the heat evolved.

To use the material-balance method, measurements of ingestion, egestion, and other relevant processes must extend over a substantial period—typically 24 h or more—so that average, steady-state rates of input and output of chemical energy are quantified. The metabolic rate calculated from the method is the animal's average rate over the entire study period. Thus the material-balance method is suited only for *long-term measurements of average metabolic rates*. To measure minute-by-minute variations in metabolic rate, the methods of choice are those based on respiratory gas exchange or direct calorimetry.

SUMMARY Metabolic Rate: Meaning and Measurement

- An animal's metabolic rate is the rate at which it converts chemical energy into heat and external work.
- Metabolic rate is important because it helps determine the amount of food an animal needs, and therefore the food energy that the animal removes from its ecosystem. An animal's metabolic rate also provides a quantitative measure of the total activity of all its physiological mechanisms.
- An animal's rate of O₂ consumption is the most common measure of metabolic rate. Metabolic rates can also be measured by direct calorimetry or studies of material balance.

Factors That Affect Metabolic Rates

Now that we have discussed how metabolic rates are defined and measured, we can turn our attention to the experiences of animals and the processes within them that influence their metabolic rates. The two factors that typically exert the greatest effects on an animal's metabolic rate are the intensity of its physical activity (e.g., speed of running) and the temperature of its environment. Other factors that commonly influence animal metabolic rates include the ingestion of food, age, gender, time of day, body size, reproductive condition, hormonal state, psychological stress, and for aquatic animals, the salinity of the ambient water. **Table 7.3** provides an overview of many of these factors and identifies where they are discussed in this book.

Ingestion of food causes metabolic rate to rise

Among the factors that affect metabolic rate, the ingestion of food deserves some extended consideration—even though it is not the most influential factor quantitatively—because it must be taken into account in almost all metabolic studies. Under many circumstances, if an animal has not eaten for a while and then consumes food, its metabolic rate temporarily increases following the meal *even though all other conditions are kept constant*. This increase in metabolic rate caused by food ingestion is known as **specific dynamic action (SDA)**, the **calorigenic effect of ingested food**, or the **heat increment of feeding** (**Figure 7.5**). Although we ourselves may often not notice this process in our day-to-day lives, it is very apparent at certain times. Think back, for example, to a festive holiday dinner when everyone ate lots of high-protein food such as turkey or other meat. After such a meal, people may feel so warm that they remove sweaters and loosen neckties or scarves. The reason for the sense of excessive warmth is the SDA of the ingested protein. The occurrence of SDA means that

(a) The concept of SDA

(b) SDA in flatfish

a certain portion of the energy available from a meal is degraded to heat in processing the meal; only the remaining portion of the energy is available for subsequent physiological uses.

The *magnitude* of the SDA following a meal is the *total excess* metabolic heat production induced by the meal, integrated from the time metabolism first rises to the time that it falls back to the

FIGURE 7.5 Specific dynamic action (SDA) (a) Following a meal, the SDA begins after a delay, which may be up to 1 h. The solid line shows the animal's actual metabolic rate. The dashed line depicts what the rate would have been, had the meal not been eaten. The area shaded blue is the *magnitude* of the SDA. The timing of the process varies enormously; the SDA might be over in a few hours in a mouse, in 12 h in a cow, and in 1–3 days in a fish. "Fasting" in such studies means the animal has not eaten for long enough that the SDA of the last meal is over. (b) Actual data for predatory flatfish (*Pleuronectes*) fed two different-sized meals of fish meat. The apparent absence of a delay in the beginning of the SDA is an artifact of the sampling schedule: Data were not gathered in the immediate aftermath of feeding, when the delay would have been evident. (b after Jobling 1993.)

background level. Thus the blue area in Figure 7.5a, showing the integrated difference between the actual metabolic rate after a meal and the metabolic rate that would have prevailed without eating, represents the magnitude of the SDA. The magnitude of the SDA that occurs after a meal of a particular type of food tends to be roughly proportional to the amount of food eaten, for given animals under given conditions (see Figure 7.5b): Doubling the amount of food eaten tends approximately to double the SDA. Protein foods exhibit much higher SDAs, in proportion to the amount eaten, than do lipids or carbohydrates. Traditionally the SDA of a protein meal has been considered to be equivalent to 25%–30% of the total energy value of the meal. Recent research indicates, however, that the percentage (while virtually always high) can vary considerably with prevailing conditions.

TABLE 7.3 Some factors that affect the metabolic rates of individual animals

Factor	Response of metabolic rate	Chapter(s) where discussed in this book
Factors that exert particularly large effects		
Physical activity level (e.g., running speed)	↑ with rising activity level	8, 9
Environmental temperature	<i>Mammals and other homeotherms:</i> Lowest in thermoneutral zone ↑ below thermoneutral zone ↑ above thermoneutral zone <i>Fish and other poikilotherms:</i> ↑ with increasing temperature ↓ with decreasing temperature	10
Factors that exert smaller effects		
Ingestion of a meal (particularly protein-rich)	↑ for several hours to many hours following ingestion	7
Body size	Weight-specific rate ↑ as size ↓	7
Age	Variable; in humans, weight-specific rate ↑ to puberty, then ↓	—
Gender	Variable; in humans, ↑ in male	—
Environmental O ₂ level	Often ↓ as O ₂ ↓ below a threshold; not affected above threshold	8, 23
Hormonal status	Variable; example: ↑ by excessive thyroid secretions in mammals	16
Time of day	Variable; in humans, ↑ in daytime	15
Salinity of water (aquatic animals)	Variable; in osmoregulating marine crabs, ↑ in dilute water	28

The mechanism of SDA remains uncertain. Although digestive processes make a contribution, strong evidence exists that the SDA in most animals arises principally *after the absorption* of digestive products from the gastrointestinal tract, as a consequence of cellular processing of the absorbed organic compounds. An important cause of the SDA associated with protein meals, for example, is believed to be the energy expenditure required to synthesize nitrogenous waste products (e.g., urea in mammals) to dispose of nitrogen from excess amino acids.

In the last 20 years, after a long quiet spell in SDA research, the SDA has been “back in the news” of animal physiology. In some cases, new programs of research have focused on specializations of SDA physiology to particular challenges that animals face. For example, investigators have recently reported evidence that gray seals (*Halichoerus grypus*) dramatically postpone the SDA, compared with terrestrial mammals, when they are engaged in extended bouts of underwater hunting and feeding. In this way, it is argued, the seals prevent the SDA of their protein-rich food (mostly fish) from shortening their dive times by raising their metabolic requirements *during* dives. The postponed SDA occurs after a bout of hunting and feeding has ended. Another striking discovery is the exceptionally great rise in metabolic rate that occurs after feeding in snakes, notably pythons, that undergo long-term fasting, for weeks, from one meal to the next (see Box 6.2).⁸

The SDA is a relatively short-term phenomenon, but sometimes an animal’s diet induces a *semipermanent*, or *chronic*, change in its metabolic rate. Experiments have revealed that if laboratory rats are enticed to eat unusually large amounts of food day after day (as by adding sweets to their food), some individuals do not fatten, because their metabolic rates chronically rise, turning the excess food energy into heat. The long-term increase in metabolic rate induced by persistent overeating is dubbed **diet-induced thermogenesis (DIT)**. Research on DIT has been intense ever since its discovery because DIT is an anti-obesity process of potential human importance. The relation between DIT and SDA is confused at present. We say more about DIT in Chapters 8 and 10.

Basal Metabolic Rate and Standard Metabolic Rate

Physiologists, ecologists, and other biologists often wish to compare metabolic rates. A physician, for example, might want to know how the metabolic rate of a particular patient compares with the average metabolic rate of all people of similar age, because some diseases are distinguished by abnormal rates of energy consumption. An ecologist might want to compare the metabolic rates of two species in an attempt to learn which species is more likely to place high demands for food on an ecosystem.

In making comparisons, it is often important to standardize factors that could confound results. For example, physicians typically standardize food ingestion during diagnostic metabolic studies by having patients fast for at least 12 h prior to measurements of

their metabolic rates; otherwise, some patients would have their measured metabolic rates elevated by SDA, whereas others would not, creating confounding variation. Similarly, biologists who want to know if species have inherently different metabolic rates typically standardize physical activity, so that results are not confounded by having the individuals of one species walking around while those of the other rest during measurement. Several standardized measures of metabolic rate have been defined to facilitate valid comparisons. The two most commonly used standardized measures are the *basal metabolic rate* and the *standard metabolic rate*.

The **basal metabolic rate (BMR)** is a standardized measure of metabolic rate that applies to *homeotherms*, animals that physiologically regulate their body temperatures, such as mammals and birds. For each homeothermic species, there is a range of environmental temperatures within which the metabolic rate is minimal. This range, called the *thermoneutral zone*, is illustrated in Figure 10.28. The basal metabolic rate of a homeotherm is the animal’s metabolic rate while it is (1) in its thermoneutral zone, (2) fasting, and (3) resting. The term *fasting* here has a different meaning than in some other contexts. In studies of metabolic rate, **fasting** (or **postabsorptive**) means that a subject’s last meal took place sufficiently long ago for the SDA of the meal to be over.

The concept of **standard metabolic rate (SMR)** applies to *poikilotherms* (*ectotherms*), animals that allow their body temperatures to fluctuate freely with variations in environmental temperature, such as amphibians, molluscs, and most fish. The standard metabolic rate is the metabolic rate of a poikilothermic animal while it is (1) fasting and (2) resting. Again, *fasting* signifies that the SDA of the last meal is over. An animal’s standard metabolic rate is specific for its prevailing body temperature; thus, for a given animal there are as many SMRs as there are different body temperatures.

Besides specifying a fasting state, both of the standardized measures of metabolic rate mentioned here call for subjects to be resting. The term *resting* can have somewhat different meanings in different studies because inducing animals to rest is often not simple. Specific levels of rest are formally recognized in some subdisciplines of physiology. Fish physiologists, for instance, often use the term **routine metabolic rate** to refer to metabolic rates of reasonably quiet fish exhibiting only small, spontaneous movements; when they speak of *standard metabolic rate*, they refer to fish that have been coaxed to truly minimal levels of activity. In human medicine, *resting* means lying down but awake.

Metabolic Scaling: The Relation between Metabolic Rate and Body Size

How does metabolic rate vary with body size within a set of phylogenetically related species? This simple question turns out to have a profoundly important, intricate answer. The study of the relation between metabolic rate and body size is known as the study of **metabolic scaling** or the **metabolism–size relation**.

A comparison between meadow voles and white rhinos provides a revealing starting point for understanding metabolic scaling (Figure 7.6). Both of these species are mammals, and both eat similar foods, being “pure grazers” that eat little else besides grassland plants. They are very different in body size, however. An interesting way to gain insight into the effect of their different body sizes on their metabolic rates is to compare how much food they must eat to meet

⁸Although the dramatic post-feeding rise in metabolic rate in pythons and other snakes is considered to be a form of SDA in the literature, its causation may prove not to be entirely typical of SDA as seen in animals in general. When the snakes do not eat for a long time, they deconstruct their digestive apparatus (see Box 6.2). Costs of reconstructing the digestive apparatus are believed to be included in the post-feeding rise in metabolic rate.

FIGURE 7.6 The effect of body size on weekly food requirements Both species—(a) the 30-g meadow vole (*Microtus pennsylvanicus*) and (b) the 1900-kg white rhino (*Ceratotherium simum*)—are grazers. (Calculated from Golley 1960 and Owen-Smith 1988, assuming 70% moisture content in the forage.)

their metabolic needs. If we pile up all the grass that a vole and a rhino must eat in a week under similar measurement conditions, we find, not surprisingly, that the rhino requires more food than the vole. However, a week's pile of food for the vole is far larger than the vole itself, whereas the pile for the rhino is much smaller than the rhino. This disparity reveals that *the energy needs of the species are not proportional to their respective body sizes.*

Resting metabolic rate is an allometric function of body weight in related species

To fully understand the relation between metabolic rate and body size, it is important to compare large numbers of related species, not just two. The BMRs of more than 600 species of placental mammals have been measured. When all of these BMRs are plotted against the body weights of the species, statistics can be used to draw the best-fitted line through the data.⁹ From this sort of analysis, physiologists have discovered that the pattern we have observed in comparing voles and rhinos is in fact a general pattern that applies across the full range of mammalian body sizes. Although the total BMR of species of placental mammals increases with body weight, it does not increase in proportion to weight. Instead, the total BMR increases less than proportionally with body weight (Figure 7.7). Consider, for example, that an average 10-g species of placental mammal exhibits a total BMR of about 400 J/hour. If BMR increased in proportion to body size, a 100-g species

⁹As discussed in Chapter 1 (see page 17), the most common statistical approach for analyzing these sorts of data is to apply ordinary least squares regression (see Appendix D) to all the available data. A case can be made, however, that methods based on phylogenetically independent contrasts (see Appendix G) should often be used. In the literature today, investigators often analyze data by both approaches, recognizing that a consensus does not exist. The fitted equations in this book are from ordinary least squares regression.

would have a total BMR of 4000 J/hour. In actuality, the average total BMR of a 100-g species is much less, about 2200 J/hour. This quantitative trend persists throughout the entire range of mammalian weights. For instance, the average BMR of a 400-g species of placental mammal is only about 2.7 times higher than that of a 100-g species, not 4 times higher.

An alternative way to examine the relation between metabolic rate and body weight is to calculate the metabolic rate *per unit of body weight*, termed the **weight-specific metabolic rate**, and plot it as a function of body weight. Figure 7.8 presents the data points and curve from Figure 7.7 in this new way. This representation illustrates that the weight-specific BMR of mammals decreases as weight increases. Under basal conditions, a 670-g desert cottontail rabbit produces only about 40% as much metabolic heat per gram as a 21-g white-footed mouse. These differences become even more dramatic if we examine mammals still larger than those represented in Figure 7.8. A 70-kg human produces about 10% as much heat per gram as the mouse, and a 4000-kg elephant produces about 5% as much. The rate of basal energy expenditure of a gram of mammalian tissue is far lower if it is a gram of elephant than a gram of mouse!

Suppose that instead of focusing on mammals, we expand our investigation of metabolic scaling by looking at many species of fish of different body weights—or many species of crustaceans of different sizes. Do poikilothermic animals (ones having variable body temperatures) exhibit the same sorts of relations between metabolic rate and body size as mammals do? Yes, they do. Within a set of phylogenetically related poikilothermic species of different body sizes, the SMR at a particular body temperature usually varies with body size in the same basic pattern as seen in mammals. The total SMR increases with body weight, but it increases less than

FIGURE 7.7 BMR as a function of body weight in various species of placental mammals The solid curve—showing the actual relation—is statistically fitted to data for all sizes of mammals, although this plot includes body weights up to only 700 g. The points are data for seven North American species (see Figure 7.8 for identifications), illustrating that although the statistical line runs through the data, individual species do not necessarily fall right on the line. (After Hayssen and Lacy 1985.)

FIGURE 7.8 Weight-specific BMR as a function of body weight in various species of placental mammals Although the x axis (body weight) and animals are the same as in Figure 7.7, here the BMRs (y axis) are expressed per gram of body weight. (After Hayssen and Lacy 1985.)

proportionally. Thus the weight-specific SMR decreases as body weight increases.

Metabolic scaling is investigated in detail by use of equations. With total (whole-animal) metabolic rate symbolized M and body weight symbolized W , the equation that has been applied for more than half a century is

$$M = aW^b \quad (7.3)$$

where a and b are constants. This type of equation describes the relation between M and W for species of various body sizes within a defined set of related species, such as the bony fish or, alternatively, the placental mammals. The constants in the equation are determined—that is, fitted—statistically. To determine a and b for placental mammals, for example, researchers begin by tabulating M and W for as many species as possible. The raw information used for the process, in other words, is a series of points on M , W coordinates, such as those plotted on the graph in Figure 7.7. The researchers then use a statistical algorithm to fit an equation of the form $M = aW^b$ as closely as possible to the data points. Such a statistical procedure calculates the values of a and b that make the equation match the data points as closely as possible.¹⁰

Note that the values of a and b depend on the *particular data used* as well as the animal group being studied. This is important. If two researchers independently investigate a *single* group of animals but use data for different sets of species, they will obtain somewhat different values of a and b .

In the past decade, several teams of researchers have presented strong evidence that Equation 7.3—despite its long history—is sometimes too simple. Sometimes a more complex equation, with more terms and fitted constants, is required to describe a metabolism–weight relation in the full detail required for advanced scaling

research. We will return to this consideration later. For an introduction to animal physiology, however, Equation 7.3 is appropriate for three reasons:

1. It provides a good approximation to the metabolism–weight relation in great numbers of animal groups
2. It has obvious conceptual meaning, unlike more-complex equations that may be little more than mathematical expressions to everyone except specialists.
3. Because of its long history, thousands of published scaling relations are expressed in this form.

If b were to equal 1.0, Equation 7.3 would become $M = aW$, a proportional relation. However, in studies of metabolic scaling, b is almost always less than 1.0. When b is not 1.0, Equation 7.3 is nonproportional and is known as an **allometric equation**.¹¹ Often, therefore, the metabolic rates of animals are said to be *allometric functions of body size*.

Let's now continue with our discussion of the ways in which *basal* metabolic rate (BMR) and *standard* metabolic rate (SMR) vary with body weight. In other words, let's assume for the moment that, in Equation 7.3, M is the total *resting* metabolic rate—the total BMR or SMR—of the animals under discussion.

Biologists have discovered that the exponent b in the allometric relation between total resting metabolic rate, M , and W exhibits an impressive consistency in its value from one phylogenetic group to another.¹² *The value of b for the resting metabolic rates of diverse groups of animals tends to be about 0.7.* This is true of mammals, fish, decapod crustaceans, snails, echinoderms, and most other animal groups. Most commonly, b is 0.6–0.8; it is nearly always between 0.5 and 0.9. Universal biological principles seem to be at work in determining b .

Unlike the value of b , the value of a in studies of resting metabolic rate is not at all consistent from one phylogenetic group to another. From Equation 7.3, you can see that $M = a$ when $W = 1$. Thus a is the metabolic rate of a 1-gram animal (real or theoretical) in the phylogenetic group under consideration. Some phylogenetic groups (e.g., mammals) have metabolic rates that are intrinsically far higher than those of other groups (e.g., fish) and thus also have much higher values of a . A high value of a means high metabolic intensity.

What is the mathematical relation between *weight-specific* resting metabolic rate and body weight? This relation is easily derived if both sides of Equation 7.3 are divided by W , yielding

$$M/W = aW^{(b-1)} \quad (7.4)$$

The expression M/W is the weight-specific BMR or SMR, and you can see that it is an allometric function of W . The value of a is the

¹¹An allometric equation is defined to be an equation of form $Y = aX^b$ with $b \neq 1$. Allometric equations are discussed in Appendix F.

¹²The exponent b is dimensionless and thus has no units of measure.

¹⁰The considerations discussed in footnote 9 are again relevant.

FIGURE 7.9 Weight-specific metabolic rate as a function of body weight in four groups of vertebrates The lines for birds and mammals show BMRs. The line for lizards shows the SMR when the lizards are at the same body temperature as placental mammals, 37°C. The line for amphibians shows the SMR in temperate-zone anurans and salamanders at a body temperature of 25°C. (Sources for equations: birds, McKechnie and Wolf 2004; mammals, Hayssen and Lacy 1985; lizards, Templeton 1970; amphibians, Whitford 1973.)

same as in Equation 7.3, but the exponent in Equation 7.4 is $(b - 1)$. Because b is usually about 0.7, the exponent here is usually about -0.3 . The negative value of $(b - 1)$ in Equation 7.4 signifies what we have already said; namely, weight-specific resting metabolic rate *decreases* with increasing body weight (see Figure 7.8). **Figure 7.9** presents four examples of Equation 7.4, fitted to four different groups of vertebrates. Note the similarity of the exponents but the differences in a , signifying different metabolic intensities in the four types of animals.

A useful property of Equations 7.3 and 7.4 is that they are *linear* equations when plotted on log–log coordinates (see Appendix F). For example, if we take the logarithm of both sides of Equation 7.3, we get

$$\log M = \log a + b \log W \quad (7.5)$$

Note that the dependent variable in Equation 7.5 ($\log M$) equals a constant ($\log a$) plus the independent variable ($\log W$) multiplied by another constant (b). This means that Equation 7.5 describes a straight line. Accordingly, a plot of $\log M$ as a function of $\log W$ is linear, and

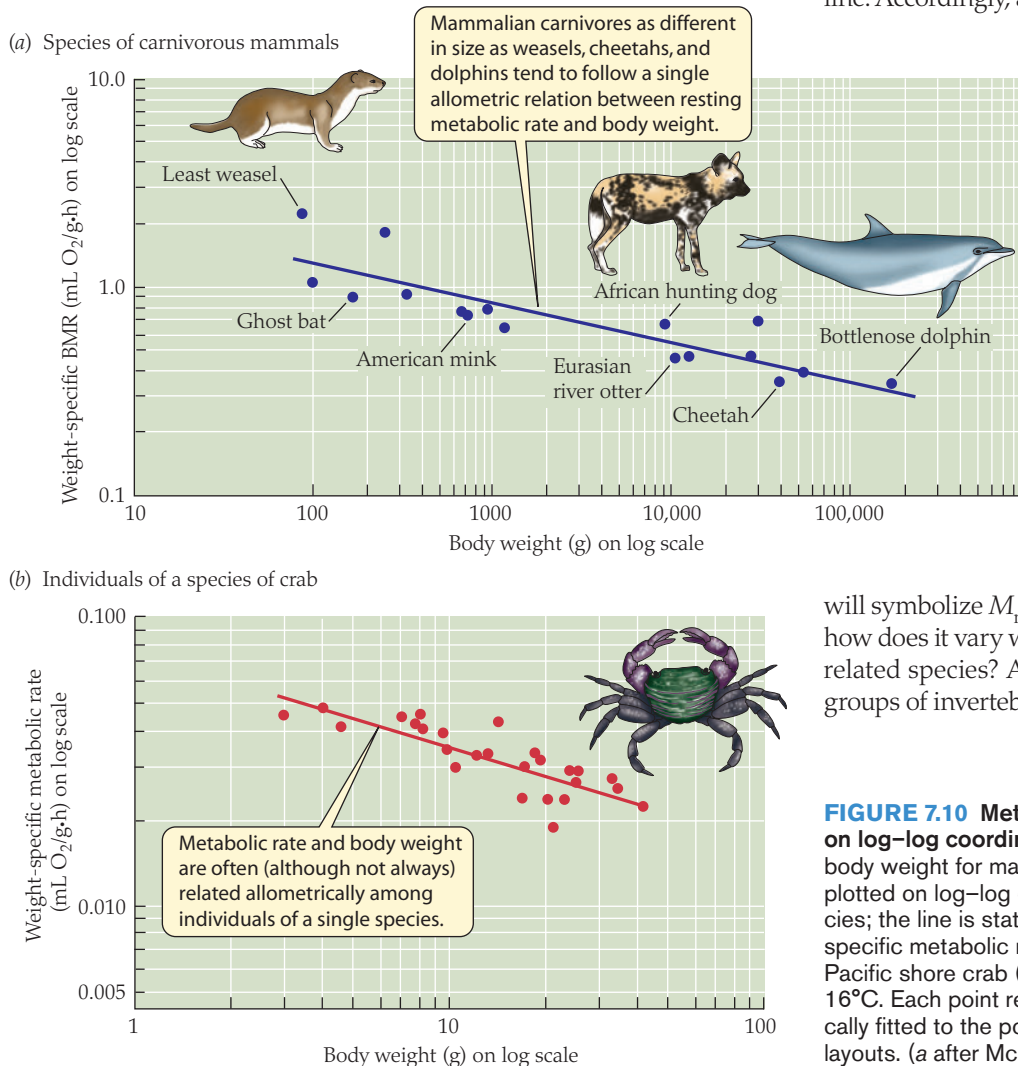

similarly, a plot of $\log M/W$ against $\log W$ is linear. Data relating metabolic rate to weight are nearly always graphed on a log–log plot, as exemplified by **Figure 7.10**. An advantage of logarithmic axes is that they can accommodate very wide ranges of values. The log–log format of **Figure 7.10a**, for instance, permits species of mammals ranging in weight from 80 g to almost 200,000 g to be analyzed together on one graph.

The metabolic rate of active animals is often also an allometric function of body weight

Sustained vigorous physical activity causes an animal's rate of aerobic metabolism to reach a maximum. How does the maximal rate of aerobic metabolism, which we

will symbolize M_{\max} , compare with the resting metabolic rate, and how does it vary with body weight within a set of phylogenetically related species? A useful rule of thumb in vertebrates and some groups of invertebrates is that the exercise-induced maximal aero-

FIGURE 7.10 Metabolic rate and body weight are related linearly on log–log coordinates (a) Weight-specific BMR as a function of body weight for mammalian species that eat primarily vertebrate flesh, plotted on log–log coordinates. The points represent individual species; the line is statistically fitted to them. (b) A log–log plot of weight-specific metabolic rate as a function of body weight in a common Pacific shore crab (*Pachygrapsus crassipes*) at a body temperature of 16°C. Each point represents a particular individual. The line is statistically fitted to the points. See Appendix E for information on the axis layouts. (a after McNab 1986; b after Roberts 1957.)

bic metabolic rate tends to be about ten times higher than the resting metabolic rate (BMR or SMR). Usually M_{\max} is an allometric function of body weight: $M_{\max} = a'W^{b'}$, where a' and b' are the constants that apply in the case of the maximal metabolic rate. The value of a' tends to be roughly ten times the value of a , which applies to the resting metabolic rate (corresponding to the tenfold difference we noted). The exponent b' for M_{\max} is usually similar to b , the exponent for resting metabolic rate. However, b' and b clearly differ a bit in mammals, flying insects, and some other groups that can be analyzed in close detail using available data; in placental mammals, for example, whereas the exponent for resting metabolic rate is about 0.7, that for M_{\max} is about 0.85. This difference is noteworthy because it has theoretical significance, as we will soon discuss.

What about the *average* metabolic rates of animals *living in nature*—a state in which they are active at some times but resting at other times? Recognizing that both M_{\max} and resting metabolic rate are typically allometric functions of body weight, we might expect that *average daily* metabolic rate is also an allometric function of weight within sets of phylogenetically related animals. It is.¹³

The metabolism–size relation has important physiological and ecological implications

The allometric relation between metabolic rate and body weight (a relation seen during both rest and activity) suggests that different-sized, but related, species are likely to differ in how well their cells and tissues are endowed with mitochondria and other components of the aerobic catabolic apparatus. Cellular properties indeed often vary allometrically with body size. In animals as diverse as mammals and fish, for example, the skeletal muscles of small species have more mitochondria per unit of tissue than those of related, large species. The density of mitochondria varies allometrically with body weight, paralleling the relation between weight-specific metabolic rate and weight.

Because the breathing and circulatory systems are responsible for delivering the O_2 consumed by an animal's tissues, you might predict that key features of respiratory and circulatory physiology are also allometrically related to body size within a set of related species. If such predictions made millionaires, you would be one!

The resting heart rate in placental mammals, to cite one example, varies with body weight in almost exactly the same functional relation as weight-specific BMR: Small species have far higher heart rates than do large ones (Table 7.4). This pattern makes sense in view of the fact that, statistically, all mammals have about the same size of heart in relation to their body size (Figure 7.11; see Table 7.4). Small mammals require more O_2 per gram of body weight than large ones, but their hearts are no bigger relative to body size than are the hearts of large mammals. Thus the hearts of small mammals must beat faster than those of large mammals for O_2 to be delivered at a greater rate per unit of body weight. How is the function of the mammalian heart scaled to permit different rates of contraction and recovery in small and large species? Investigators

TABLE 7.4 Resting heart rate, and heart size relative to body weight, in seven species of mammals

Species and average body weight	Resting heart rate (beats/min) ^a	Heart weight per unit of body weight (g/kg) ^b
African elephant (4100 kg)	40	5.5
Horse (420 kg)	47	7.5
Human (69 kg)	70	5.2
Domestic dog (19 kg)	105	9.2
Domestic cat (3 kg)	179	4.1
Roof rat (0.34 kg)	340	2.9
Lab mouse (0.03 kg)	580	4.0

Source: After Seymour and Blaylock 2000.

^aAccording to the source of these data, the statistical relation between resting heart rate (RHR) and body weight (W) in mammals is $RHR \text{ (beats/min)} = 227W^{-0.23}$, where W is in kilograms.

^bAlthough heart weight per unit of body weight varies, it shows little or no consistent relation to body size.

are just now exploring the answers to this fascinating question (Box 7.5). Similar to the case with the heart, various species of mammals also have lungs of about the same size in relation to body size. Thus, by much the same logic as we have just outlined for the heart, small mammals must take breaths at higher rates than large mammals. Whereas humans, for example, breathe about 12 times per minute when resting, mice breathe about 100 times per minute. The metabolism–weight relation pervades almost every aspect of an animal's physiology.

Numerous ecological and practical implications also arise from the allometric relation between metabolic rate and body weight.

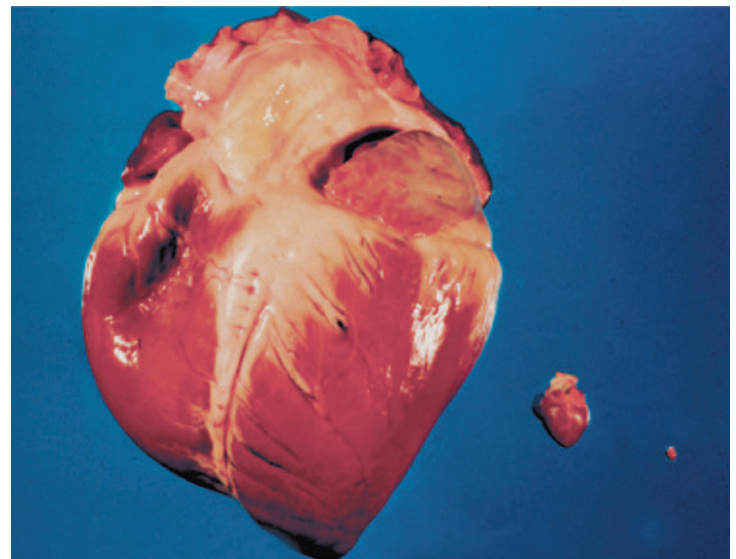

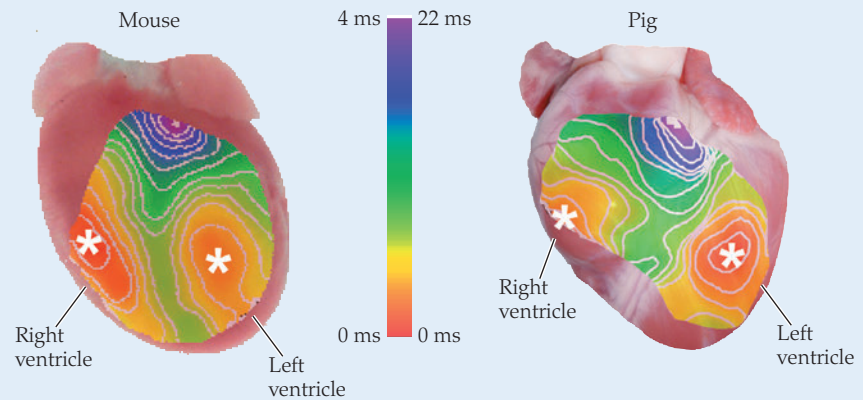

FIGURE 7.11 Hearts of a horse, cat, and mouse: Heart size in mammals is roughly proportional to body size As a corollary, the relatively high weight-specific O_2 demands of small species are *not* met by pumping more blood, relative to body size, *per heartbeat*. Instead, the number of heartbeats per minute must be far greater in small species than in large ones. (From Noujaim et al. 2004; photograph courtesy of Sami Noujaim and José Jalife.)

¹³Chapter 9 discusses the methods that are used to measure the average daily metabolic rates of free-living animals, and it discusses the results in greater detail.

BOX 7.5 SCALING OF HEART FUNCTION

Each contraction of the heart muscle entails a complex sequence of coordinated electrical and mechanical events (see Chapter 25). In outline, at the time of each heartbeat, the heart's pacemaker initiates a wave of electrical activity that sweeps through the heart muscle. This electrical wave first causes the atrial chambers to contract, then pauses as it passes from the atrial to the ventricular chambers, and finally causes the ventricular chambers to contract. For the hearts of two species to contract at different rates, adjustments are required in all of these individual processes. The sweep of electrical activity in two hearts of very different size is shown in the figure and discussed in **Box Extension 7.5**.

Views of the ventricles of a mouse heart and pig heart showing the sweep of activation of the superficial muscle layer during a single heartbeat The wave of electrical activity responsible for activating contraction first appears in the superficial muscle layer at the points marked by the white asterisks. It then sweeps through the superficial muscle layer in the color-coded order shown in the center, taking a total of 4 ms in the mouse heart but 22 ms in the pig heart. (From Noujaim et al. 2007; images courtesy of Sami Noujaim and José Jalife.)

We have already seen in our initial comparison of voles and rhinos, for example, that within a set of phylogenetically related animals, small-bodied species typically require food at a greater rate per unit of body weight than large-bodied species (see Figure 7.6). Ecologically, the uninitiated might expect that—in terms of basal food requirements—3500 mice, each weighing 20 g (total weight 70,000 g), would place about the same demand on a woodland ecosystem as a single 70,000-g deer would. Because the weight-specific BMR of a 20-g mouse is about eight times greater than that of a deer, however, the total basal food requirement of only about 440 mice is equivalent to that of a deer.

When entire ecosystems are analyzed, ecologists sometimes observe that the allometric relation between metabolic rate and body weight has a significant structuring effect. Consider, for example, the savannas and woodlands of eastern and southern Africa. These ecosystems are among the marvels of life on Earth, in part because they support an extreme diversity of coexisting antelopes and other medium-sized to large mammalian herbivores (Figure 7.12). From aerial surveys of major national parks in Africa, we know the average numbers of many herbivore species per square kilometer. Multiplying numbers by body weights, we can calculate the average population biomass per square kilometer of each species. Population biomass per square kilometer turns out to be a regular function of body size; for example, whereas all the warthogs (a relatively small species) living per square kilometer together weigh about 95 kg, the zebras in a square kilometer collectively weigh 460 kg, and the elephants weigh 1250 kg (Table 7.5). Metabolic allometry, while emphatically not the only factor at work, helps explain this trend, because each kilogram of a large-bodied species requires less food than each kilogram of a small-bodied species.

The allometric relation between metabolic rate and body size also means that related small- and large-bodied species

often process foreign chemicals differently. Because small-bodied species eat food and breathe air at greater rates per unit of body weight than their larger counterparts, they tend to receive greater weight-specific doses of food-borne and airborne toxins such as pesticides; this consideration, in itself, creates a tendency for toxins to accumulate more readily to high concentrations in the tissues of the small-bodied species. However—correlated with (not necessarily caused by) their high weight-specific metabolic rates—small-bodied animals tend to catabolize or excrete some substances faster per unit

FIGURE 7.12 Herbivores of different body sizes coexisting on an African grassland When extensive landscapes are analyzed statistically, species are found to vary in population biomass in a way that depends in part on body size and metabolic allometry.

TABLE 7.5 Biomasses of populations of selected herbivores living in mixed communities in African national parks

Species are listed in order of increasing individual size. These species were chosen for listing because they are statistically about average in population biomass for their body sizes.

Species	Average biomass of entire population per square kilometer (kg/km ²)	Average individual body weight (kg)
Oribi (<i>Ourebia ourebi</i>)	44	13
Gray duiker (<i>Sylvicapra grimmia</i>)	62	16
Gray rhebok (<i>Pelea capreolus</i>)	105	25
Warthog (<i>Phacochoerus aethiopicus</i>)	95	69
Waterbuck (<i>Kobus ellipsiprymnus</i>)	155	210
Greater kudu (<i>Tragelaphus strepsiceros</i>)	200	215
Plains zebra (<i>Equus burchelli</i>)	460	275
White rhino (<i>Ceratotherium simum</i>)	2400	1900
African elephant (<i>Loxodonta africana</i>)	1250	3900

of weight than do related larger animals; a practical consequence is that small-bodied species may require relatively high doses of a veterinary drug per unit of weight to achieve and sustain the drug's intended effect. Overall, the dynamics of accumulation and dissipation of foreign chemicals often differ between related large- and small-bodied species.

The explanation for allometric metabolism–size relations remains unknown

The fact that b , the allometric exponent, tends to be near 0.7 in widely diverse groups of animals is profoundly intriguing. For a century, some of the greatest minds in biology have grappled with the questions of *why* metabolic rate and body size are related allometrically and *why* the allometric exponent is sometimes impressively consistent. Great minds have been drawn to these questions because of a conviction that the allometries are manifestations of fundamental organizing principles of life. As yet, however, no consensus exists about how to explain the allometries.

Ninety years ago, the problem seemed solved! Physiologists thought then that they understood the reasons for not only the allometric metabolism–size relation, but also the particular value of b . The theory offered at that time has been reinvented by every generation of biologists because it seems so “obvious.” Thus an understanding of the theory's flaws remains important even today. At the time the theory first appeared in the early twentieth century, all the data on metabolism–size relations were data gathered on mammals, and mammals therefore dominated thinking about the subject. During that period, Max Rubner articulated an explanatory theory that is still known as *Rubner's surface “law.”*

Euclidean geometry provides the starting point for understanding this “law” that is not a law. Recall from your study of geometry that the surface area s of a sphere is proportional to the square of r , the sphere's radius: $s \propto r^2$. The volume v of a sphere, however, is proportional to the cube of the radius: $v \propto r^3$. From the rules of

exponents, we can write $r^2 = (r^3)^{2/3}$. Thus $s \propto (r^3)^{2/3}$; and substituting v for r^3 , we get

$$s \propto v^{2/3} \quad (7.6)$$

In words, as spheres increase in size, their surface area increases only as the two-thirds power of their volume. Big spheres, therefore, have less surface area per unit of volume (or of weight) than little spheres. Similar relationships hold true for all sets of geometrically similar objects. Whether you consider cubes, cylinders, hearts, or whole animals, as the objects within a geometrically similar set become larger, the area of the outside surface is expected to increase approximately as the two-thirds power of volume, and the ratio of outside-surface area to volume declines.

Rubner's surface “law” stated that the BMR of a mammal is proportional to its body-surface area¹⁴ and that the allometric relation between BMR and body weight is a corollary of this proportionality. Rubner's explanation of the allometric relation rested on four logical steps:

1. Placental mammals maintain high, relatively constant body temperatures (near 37°C) and thus tend to lose heat to the environment when studied at thermoneutral environmental temperatures.
2. Because heat is lost across an animal's outer body surfaces, the rate of heat loss from a mammal is approximately proportional to the animal's body-surface area.¹⁵
3. Small mammals have more surface area per unit of weight than do large mammals and thus lose heat more rapidly per unit of weight.
4. Heat lost must be replaced metabolically for a mammal to stay warm. Accordingly, small mammals must produce heat at a greater rate per unit of weight than large ones.

The surface “law” as just outlined can hardly be faulted as a thought exercise. Why, then, do most physiologists today believe that it is not the correct mechanistic explanation of the allometric relation between BMR and body weight? The answer is that data contradict the “law” in two respects. First, although the surface “law” predicts an exponent b equal to about 0.67 (2/3), most physiologists who have estimated values of b for mammals have concluded that b is statistically higher than 0.67 to a significant degree. Second, by now we realize, as emphasized already, that poikilothermic animals—such as fish, frogs, and crabs—display allometric metabolism–size relations (see Figures 7.9 and 7.10). Rubner's “law” cannot possibly explain these relations in

¹⁴A modern holdover of the early emphasis on body-surface area is that surface areas are employed to calculate certain sorts of critical variables in the contemporary practice of medicine. In breast cancer chemotherapy, for example, the doses of chemotherapeutic agents administered to a woman are calculated from her body-surface area.

¹⁵During the era when Rubner's surface law was accepted, this concept seemed too obvious to be questioned. In fact, it is not exactly true because of details in the physics of heat transfer.

poikilotherms because the reasoning behind the “law” applies only to animals that warm their bodies to elevated, regulated temperatures using metabolic heat production. The consistency of the metabolism–size relation across many animal groups suggests a single mechanistic explanation. Because Rubner’s “law” is irrelevant for most types of animals (most are poikilotherms), it cannot be that explanation.

Since the time in the mid-twentieth century when the surface “law” started to be rejected by most physiologists, several alternative hypotheses have been put forward to explain allometric metabolism–size relations. Physiologists, however, have not reached a consensus in supporting any of the hypotheses. Until recently, debate tended to center on whether the true value of b is $2/3$ or $3/4$. Physiologists assumed that a single universal exponent existed and that, if it could be nailed down, the underlying mechanistic basis for allometry would be revealed. Why did difficulty exist in nailing down the exponent? For a long time, the amount of relevant data was not great, and everyone could assume, therefore, that when abundant data became available, the correct value for b would become obvious. What has actually happened is quite different. Now that great quantities of carefully scrutinized data are available, many specialists have concluded that in fact there is no universal exponent. With lots of high-quality data available, if researchers calculate two different values of b for two different animal groups, the difference cannot readily be dismissed as being merely a product of inadequate information.

Several research reports published in the past decade have concluded that although the exponent b generally tends to be *similar* in many animal groups, it is not *identical*. *The exponent b is not a constant*, according to these reports. Among placental mammals, for example, several meticulous efforts have concluded that b is different in some mammalian orders than in others. Also, as already noted, b is greater when mammals are exercising than when they are at rest. Moreover, b is higher when only large-bodied species are analyzed than when only small-bodied species are.¹⁶

As physiologists have searched for the mechanistic basis of metabolism–size relations, a key question has been, what attributes of animals are so *common* and so *fundamental* that they

¹⁶Accordingly, the log–log plot of metabolism–size data exhibits a bit of curvature and requires a more complex equation than Equation 7.3 to be described in detail.

FIGURE 7.13 As the circulatory system is scaled up and down in size and extent, constraints predicated on fractal geometry may help give rise to allometric metabolic scaling. A mammal’s metabolism is dependent on distribution of required resources to tissues throughout the body. When Andreas Vesalius first described the circulatory system (a), its function was a mystery. Oxygen had not yet been discovered, and the fact that the circulatory system delivers O_2 to all tissues was inconceivable. In the years since, as many old questions were answered, new questions came to the fore. One modern question is this: Given that mammals all have a circulatory system built on similar principles—and yet the dimensions of that system have had to be scaled dramatically up and down as big and small species have evolved—what geometric and functional constraints might have been encountered? A fractal geometric approach to this question had to await Benoit Mandelbrot’s invention of fractal mathematics around 1980. Fractal systems, as seen in (b), are “self-similar” at multiple scales, meaning that the patterns of branching of fine elements are miniatures of the patterns of branching of large elements. (a from *De Humani Corporis Fabrica*, produced by Andreas Vesalius in 1543, as reproduced in Saunders and O’Malley 1950; b after Mandelbrot 1983.)

could explain the way in which metabolism varies with size? One attribute in particular has attracted a great deal of attention: internal transport. For metabolism to occur, internal transport of metabolic resources—notably O_2 and metabolic fuels—is critical. In mammals and many other types of animals, this transport is carried out by the circulatory system. Physiologists therefore realized that they had to understand how the circulatory system—first accurately described by Andreas Vesalius (1514–1564) in 1543 (Figure 7.13a)—changes in its inherent capabilities for transport

(a) Vesalius 1543: One of the first anatomically accurate images of the human circulatory system

(b) Mandelbrot 1983: A fractal model of a branching system such as the circulatory system

as animals evolve to be bigger or smaller. The new mathematics of *fractal geometry*—invented more than 400 years later to describe the properties of branching systems (Figure 7.13b)—was marshaled to analyze this question. From this fractal research, a hypothesis was propounded, that allometric metabolism—size relations occur in part because of geometrically imposed constraints. This hypothesis stresses that in fractally structured transport systems, *rates* of transport—and thus rates of supply of resources required for metabolism—are geometrically constrained in distinctive ways as body size is scaled up or scaled down over the course of evolution. Computer models have been used to examine how the constraints of fractal geometry interact with evolutionary selection pressures to maintain optimized transport capabilities as animals evolve different body sizes. These models initially predicted a universal allometric exponent of $3/4$ —a discovery followed by an almost giddy application of that exponent to new branches of biology even though it is a product of theory and often not supported by empirical data. Now most physiologists acknowledge that b probably does not exhibit a single fixed value. Nonetheless, one of the major themes in ongoing research is to revisit the analysis of circulatory systems and other transport systems responsible for distributing metabolic resources in the body. Those systems may well play roles in constraining how metabolic rate can vary with body size. Several other fascinating hypotheses are also being investigated at present.

SUMMARY Metabolic Scaling: The Relation between Metabolic Rate and Body Size

- BMR, SMR, and other measures of resting metabolic rate are allometric functions of body weight within phylogenetically related groups of animals ($M = aW^b$, where b is usually in the vicinity of 0.7). Small-bodied species tend to have higher weight-specific metabolic rates than do related large-bodied species, an effect so great that the weight-specific BMR is 20 times higher in mice than in elephants.
- Maximal aerobic metabolic rate also tends to be an allometric function of body weight in sets of related species. In many cases studied thus far, the allometric exponent for maximal metabolic rate differs from that for resting metabolic rate.
- The allometric relation between metabolic rate and weight exerts important effects on the organization and structure of both individual animals and ecosystems. Heart rates, breathing rates, mitochondrial densities, and dozens of other features of individual animals are allometric functions of body weight within sets of phylogenetically related species. In ecosystems, population biomasses and other features of community organization may vary allometrically with individual body size.
- Physiologists are not agreed on the explanation for the allometric relations between metabolic rate and body weight. Rubner's surface "law," based on heat loss from homeothermic animals, does not provide a satisfactory explanation. Many of the newest hypotheses recognize that the allometric exponent varies in systematic ways and seek to explain that variation, as by examining evolutionary constraints in resource distribution systems such as the circulatory system.

Energetics of Food and Growth

Food and growth are important topics in animal energetics, aptly discussed together because one animal's growth is another's food. A consequential attribute of foods as energy sources is that lipids are at least twice as high in energy density—energy value per unit of weight (see Table 6.3)—as proteins and carbohydrates are. We asked at the start of this chapter why polar explorers carry lipid-rich foods, such as meat mixed with pure lard. If they are going to pull, push, and lift their food for many miles before they eat it, the explorers should choose food that provides a lot of energy per kilogram transported. Similarly, migrating animals often capitalize on the high energy density of lipids by carrying their fuel as body fat.

A key question about any food in relation to an animal's physiology is how efficiently the animal can digest (or ferment) the food and absorb the products of digestion. The **energy absorption efficiency** is defined to be the fraction of ingested energy that is absorbed for use:¹⁷

$$\text{Energy absorption efficiency} = \frac{\text{absorbed energy}}{\text{ingested energy}} \quad (7.7)$$

This efficiency matters because the absorbed energy is the energy actually available to an animal for use in its metabolism. To illustrate the importance of absorption efficiency, consider the processing of ingested cellulose by humans and ruminants. Because people cannot digest cellulose, they cannot absorb it, and their absorption efficiency for cellulose is essentially 0%; if they eat only cellulose, they starve. Ruminants such as cows, in contrast, commonly achieve about 50% absorption efficiency for cellulose because their rumen microbes ferment cellulose into compounds that the animals can absorb; thus ruminants are able to use about half of the energy available from cellulose in their metabolism. This example illustrates how the physiology of digestion and absorption, discussed in Chapter 6, bears on the physiology of energy.

Growing animals accumulate chemical-bond energy in their bodies by adding tissue consisting of organic molecules. An important question in many contexts is how efficiently they are able to use their available food energy to build tissue. Two types of growth efficiency, termed **gross growth efficiency** and **net growth efficiency**, are defined on the basis of whether the food energy is expressed as the ingested energy or the absorbed energy.¹⁸

$$\text{Gross growth efficiency} = \frac{\text{chemical-bond energy of tissue added in net fashion by growth}}{\text{ingested energy}} \quad (7.8)$$

$$\text{Net growth efficiency} = \frac{\text{chemical-bond energy of tissue added in net fashion by growth}}{\text{absorbed energy}} \quad (7.9)$$

¹⁷See Figure 7.2. Recall that the energetic efficiency of a process is the output of high-grade energy expressed as a ratio of input (see Equation 7.1). When digestion, fermentation, and absorption are the functions of interest, the output of high-grade energy is the absorbed energy, whereas the input is the ingested energy.

¹⁸Referring to Equation 7.1, when growth is the energy input–output process of interest, the output of high-grade energy is the chemical-bond energy of added tissue, whereas the input is food energy.

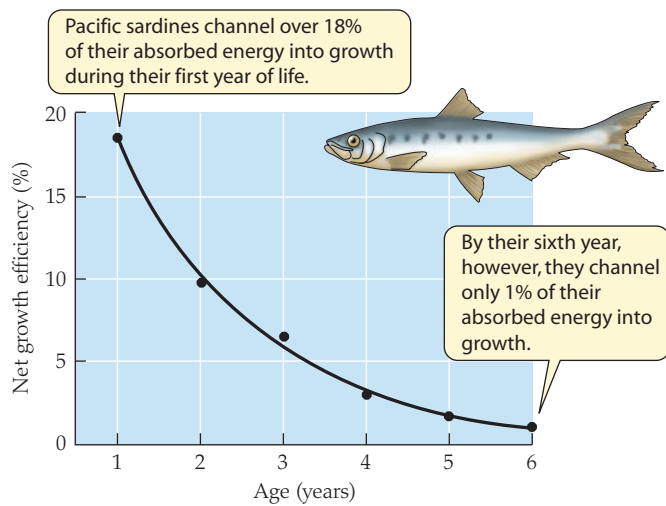

FIGURE 7.14 Net growth efficiency during each year of life in Pacific sardines (*Sardinops sagax*) When their populations are thriving, these fish are a major food source for seals, predatory fish, birds, and humans. (After Lasker 1970.)

The growth efficiency of animals (gross and net) typically declines with age (Figure 7.14). This pattern is important in the analysis of energy flow in ecological communities. It is also important in agriculture and aquaculture; because growth efficiency declines as animals age, a decline occurs in the amount of product (e.g., meat) that is obtained in return for a farmer's or aquaculturalist's investment in feed. In the production of broiler chickens, for example, the birds are slaughtered at just 2–3 months of age because at that point they are large enough to be meaty but their growth efficiency—their growth in return for feed provided—is declining.¹⁹

Conclusion: Energy as the Common Currency of Life

Energy features in virtually every biological process and in many inanimate processes as well. It is a factor in animal growth, body maintenance, migration, photosynthesis, automobile operation, building construction, ecosystem degradation, and war.

When scientists attempt to analyze complex systems—from individual animals to entire ecosystems or even the entire planet—they inevitably come up with long lists of processes that they must take into account. Although the isolated study of individual processes may be straightforward, the *integration* of multiple processes is usually not. One of the greatest challenges for the integrated study of complex systems is to find a common set of units of measure—a “common currency”—in which all the operative processes can be expressed so that they can be compared, added, or multiplied.

Energy is probably the single most promising common currency. In the study of an individual animal, for example, processes as diverse as growth, running, nerve conduction, blood circulation, tissue repair, and thermoregulation can all be expressed in units of energy. The costs of all these processes can therefore be summed to estimate the individual's total cost of life, and the cost of life of an entire population can be calculated by multiplying the cost

per individual by the number of individuals present. Few, if any, other properties come close to *energy* in their potential to serve as common currencies in this way.

POSTSCRIPT: The Energy Cost of Mental Effort

Not the least of the energy costs of analyzing complex systems is the cost of operating our brain. This cost has some fascinating and unexpected properties. From studies of tissue metabolic rates, we know that in adult humans, the brain accounts for about 20% of resting metabolic rate (although it accounts for a much higher percentage in young children; see page 87); loosely put, in adulthood, one-fifth of our food is for our brain when we are at rest. This cost resembles an “idling” cost; the energy is expended whether we subjectively feel we are doing hard mental labor or not. Decades ago, the prominent physiologist Francis Benedict (1870–1957) wanted to estimate how much the brain's energy needs increase with mental “effort.” So, of course, he recruited a group of college students to find out. He told the students on one occasion to sit for tens of minutes keeping their minds as blank as possible. Then he had them spend an equal amount of time working mental arithmetic problems at a fevered pace. Measures of their metabolic rates under the two conditions indicated that the increase in energy consumption caused by an hour of hard mental effort is slight, equivalent to the energy of half a peanut! Benedict's methods were crude by today's standards. Nonetheless, recent calculations from modern neuroimaging methods confirm his conclusions. Thus the brain's high costs are largely steady costs, and thinking hard is not a way to stay slim.

Study Questions

- Assuming that ten people plan to trek 500 miles to the North Pole, outline the steps you would take to calculate the amount of food they should pack, taking into account the number of sled dogs needed and the food needed for the dogs.
- Suppose you use a tire pump to inflate a tire on a bicycle. The elevated pressure created in the tire represents a form of potential energy because the release of the pressure can do mechanical work (such as making a pinwheel turn). The potential energy in the tire is derived from chemical-bond energy in your food. Trace the energy from the time it enters your mouth at a meal until it ends up in the tire, identifying losses of energy as heat along the way.
- Define *absorbed energy* (*assimilated energy*). Then list the major categories of use of absorbed energy, and specify the fate of energy used in each category. Explain rigorously why heat is always made, regardless of the way energy is used.
- Small animals tend to expire sooner than related large ones if forced to live on stored supplies. For instance, suppose you have a mouse and a dog that both start with body stores of fat equal to 20% of body weight. Explain why the mouse would be likely to die sooner if these animals could not find any food and thus had to live on their fat reserves. Which one would die sooner if they were trapped underwater and had only their stores of O_2 to live on while trying to escape?
- Suppose that over a period of 4 h a dog was observed to consume 20 L of O_2 and produce 14 L of CO_2 . Using Tables 7.1 and 7.2, estimate the dog's total heat production over the 4 h. Explain why Table 7.2 is essential for your calculation.

¹⁹Feed accounts for 60–75% of a farmer's costs.

6. Poultry scientists are doing research on the design of diets that are nutritionally complete for chickens but minimize the SDA. These scientists believe that such diets would be particularly helpful to the poultry industry in southern states during the heat of summer. Why might this be true?
7. Before Mayer and Joule came along (see Box 7.1), people were well aware that if a person cranked a drill, heat appeared. For instance, the drilling of the bores of cannons was legendary for the heat produced. However, heat per se was believed to be neither created nor destroyed, and thus no one thought that the motion associated with drilling *turned into* heat. Mayer and Joule go down in history in part because they demonstrated the real relation between motion and heat. Imagine that you were alive in the early nineteenth century, and like Mayer and Joule, you hypothesized that animal motion could turn into heat. Design an experiment that would provide a rigorous test of your hypothesis.
8. Suppose you are measuring the metabolic rate of a young, growing cow by using the material-balance method. What procedures could you use to take account of the cow's growth, so that you measure a correct metabolic rate?
9. Suppose you have measured the average rate of O₂ consumption of two groups of laboratory rats that are identical, except that one group was injected with a hormone that is being tested to see if it affects metabolic rate. If the hormone-treated group has a rate of O₂ consumption 5% higher than the other, there are physiological reasons why you cannot conclude that the hormone has changed the metabolic rate. Explain, referring to Table 7.1. According to the table, what might the hormone have done to change the rate of O₂ consumption without changing the metabolic rate?
10. Only nine species of existing land mammals grow to adult body weights over 1000 kg (1 megagram). All are herbivores that employ fermentative digestion. These "megaherbivores" are the two species of elephants, the five species of rhinos, the hippo, and the giraffe. What are the metabolic pros and cons of such large size? Can you suggest why no terrestrial carnivores achieve such large size?
11. If there are many species of herbivores in a grassland ecosystem, and if the species as populations are equally competitive in acquiring food, predict *b* in the following allometric equation: population biomass per square kilometer = aW^b , where *W* is individual body weight. Do the data in Table 7.5 follow your equation? What hypotheses are suggested by the comparison?

Aerobic and Anaerobic Forms of Metabolism

A startled crayfish swims backward at jetlike speed by flipping its tail in a series of powerful contractions. In this way, a crayfish discovered under a rock in a stream can move to another rock and disappear almost before its presence is appreciated. The tail muscles, which account for 25% of a crayfish's weight in some species, are a powerful tool for escape and survival. To contract, however, the crayfish's muscles—like all other muscles—require adenosine triphosphate (ATP) as their immediate source of energy for contraction. When a crayfish is startled, its first tail flip occurs instantly and is followed in short order by multiple additional flips. Each of these massive contractions requires a substantial amount of ATP. How is the ATP made available so promptly? The same question can be asked about the ATP that a human sprinter requires to run 100 meters (m) in 10 seconds (s).

Burst exercise is a general term that refers to sudden, intense exercise. Besides escaping crayfish and sprinting people, burst exercise is illustrated by salmon leaping waterfalls during their upstream journey, cheetahs racing toward antelopes, and scallops jetting away from danger by clapping their shells. In most animals, burst exercise cannot be continued for long periods. Crayfish escaping by flipping their tails become exhausted after 15–30 flips, just as human sprinters are exhausted or nearly exhausted at the ends of their races.

A second general form of physical activity is **sustained exercise**, defined to be exercise that can be continued at a steady rate for a long period. Jogging by humans, migratory flight by birds, and steady cruising by fish or crayfish are examples. During sustained exercise, the locomotory muscles must be supplied with ATP minute after minute for long, uninterrupted periods. What are the mechanisms that supply ATP in this way?

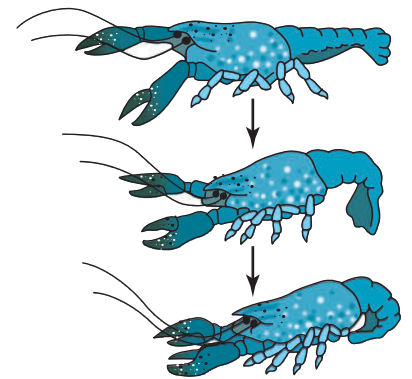

Comparing sustained exercise and burst exercise, do the mechanisms that supply ATP during sustained exercise differ from the higher-intensity, shorter-duration mechanisms used during burst exercise? Do different types of animals differ in their ATP-producing mechanisms? Is exercise ever forced to stop because of limitations in ATP-generating mechanisms? These are some of the questions we discuss in this chapter.

ATP is not transported from one cell to another. *Each cell, therefore, must make its own ATP.* This is one of the most critically important properties of ATP physiology. Another key property is that *ATP is not stored by cells to any substantial extent.* Because of these two properties, the *rate* at which a cell can do muscular work (or carry out other forms of ATP-requiring physiological work) at any given moment depends strictly on the rate at which that *very cell* is able to produce ATP at the moment.

The following two complementary reactions, taken together, serve as a crucial *energy shuttle* and *energy transduction* mechanism in cells:

The biochemistry of survival Crayfish can escape rapidly from danger by tail flipping, provided that the cells in their tail muscles can generate adenosine triphosphate (ATP) at high enough rates. The contractile apparatus in each muscle cell requires ATP at a high rate to have energy for rapid, powerful contractions.

A cell uses energy from carbohydrates, lipids, or other foodstuff molecules to drive Equation 8.1, causing ATP to be formed from adenosine diphosphate (ADP) and inorganic phosphate ions (HPO_4^{2-}), symbolized P_i . In this way, the energy from the bonds of the foodstuff molecules is moved into bonds of ATP and becomes poised for use in physiological work. Energy-demanding processes—such as muscle contraction or ion pumping—then split the ATP, as shown in Equation 8.2, thereby releasing the energy they need. Cellular energy-demanding processes are not able to draw energy directly from the bonds of foodstuff molecules. The energy-demanding processes, therefore, (1) are utterly dependent on the cellular mechanisms that drive Equation 8.1 and (2) can take place only as fast as those mechanisms supply ATP.

Mechanisms of ATP Production and Their Implications

There are two major categories of catabolic, biochemical pathways by which animal cells release energy from foodstuff molecules to synthesize ATP and thus make energy available for the performance of physiological work. Some pathways, termed **aerobic**, require O_2 ; others, termed **anaerobic**, can function without O_2 . In this section we examine the mechanistic features of the aerobic and anaerobic catabolic pathways. In later sections of this chapter we will look at the interplay between the aerobic and anaerobic modes of energy release when animals engage in burst or sustained exercise, or when they face environmental stresses such as O_2 deficiency. There is a compelling reason to start with study of the mechanistic features of the pathways of ATP production: The overall performance of animals during exercise and in other situations often depends on the mechanistic peculiarities of the particular biochemical pathways by which energy is extracted for use from foodstuff molecules.

Aerobic catabolism consists of four major sets of reactions

Each cell in most animals possesses **aerobic catabolic pathways**: pathways that, by use of O_2 , completely oxidize foodstuff molecules to CO_2 and H_2O and capture in ATP bonds much of the chemical energy thereby released. These aerobic pathways typically can oxidize *all* the major classes of foodstuffs. Here, for simplicity, we emphasize just the catabolism of carbohydrates. Moreover, our aim is to provide an overview, not to duplicate detailed treatments available in texts of cellular physiology or biochemistry. The principal aerobic catabolic pathway can be subdivided into four major sets of reactions: (1) *glycolysis*, (2) the *Krebs cycle (citric acid cycle)*, (3) the *electron-transport chain*, and (4) *oxidative phosphorylation*.

GLYCOLYSIS Glycolysis is the series of enzymatically catalyzed reactions shown in Figure 8.1, in which glucose (or glycogen) is converted to pyruvic acid. The enzymes and reactions of glycolysis occur in the cytosol. The first step in glycolysis is that glucose is phosphorylated at the *cost* of an ATP molecule to form glucose-6-phosphate. Glucose-6-phosphate is then converted to fructose-6-phosphate, and the latter is phosphorylated—also at the *cost* of an ATP molecule—to form fructose-1,6-diphosphate. The latter is cleaved to form two three-carbon molecules: dihydroxyacetone phosphate and glyceraldehyde-3-phosphate. These compounds are interconvertible, and when glucose is being catabolized for release of energy, the former is

FIGURE 8.1 The major reactions of glycolysis Each reaction requires catalysis by an enzyme protein. Three-dimensional structures are shown for six of the enzyme proteins. Subunits of an enzyme are shown in different colors. The expression for reduction of NAD, $\text{NAD} \rightarrow \text{NADH}_2$, is shorthand; the actual reaction is $\text{NAD}^+ + 2 \text{H} \rightarrow \text{NADH} + \text{H}^+$. P_i = inorganic phosphate. (Protein structures from Erlandsen et al. 2000.)

converted to the latter, yielding two molecules of glyceraldehyde-3-phosphate. The reactions subsequent to glyceraldehyde-3-phosphate in Figure 8.1 are all multiplied by 2 to emphasize that two molecules follow these pathways for each glucose molecule catabolized.

The reaction that uses glyceraldehyde-3-phosphate is the *only oxidation reaction* in glycolysis and is particularly significant for understanding not only aerobic but also anaerobic catabolism. Each molecule of glyceraldehyde-3-phosphate is oxidized, with the addition of inorganic phosphate (P_i), to a three-carbon diphosphate: 1,3-diphosphoglyceric acid. Although this reaction is an oxidation reaction, it does not itself require O_2 . Instead, it occurs by the simultaneous reduction of one molecule of nicotinamide adenine dinucleotide (NAD) per molecule of glyceraldehyde-3-phosphate. NAD—which a cell synthesizes from the vitamin niacin—is a relatively small, nonprotein molecule that undergoes reversible oxidation and reduction. When a molecule of glyceraldehyde-3-phosphate is oxidized, two hydrogen atoms are removed from it and transferred to NAD, reducing the NAD to form $NADH_2$.¹ The two hydrogens remain bound to $NADH_2$ only temporarily and are later passed to another compound, regenerating NAD.

An alternative way to think about an oxidation–reduction reaction—such as the oxidation of glyceraldehyde-3-phosphate—is that electrons are transferred. In the reaction under discussion, NAD serves as the *immediate electron acceptor* because it combines with electrons (hydrogens) removed from glyceraldehyde-3-phosphate.

The 1,3-diphosphoglyceric acid formed from the oxidation of glyceraldehyde-3-phosphate is next converted to a monophosphate, 3-phosphoglyceric acid, with the formation of one ATP per molecule. The 3-phosphoglyceric acid is then converted in two steps to phosphoenolpyruvic acid, and the latter reacts to form pyruvic acid, again with the formation of one ATP per molecule.

Three important consequences of glycolysis deserve note:

- Each molecule of glucose is converted into two molecules of pyruvic acid.
- Two molecules of NAD are reduced to $NADH_2$ per molecule of glucose catabolized.
- Two molecules of ATP are used and four are formed for each glucose processed, providing a *net yield of two ATP molecules per glucose molecule*.

THE KREBS CYCLE (CITRIC ACID CYCLE) During aerobic catabolism, the pyruvic acid formed by glycolysis is oxidized in the mitochondria by a cyclic series of enzymatically catalyzed reactions called the **Krebs cycle (citric acid cycle)**. This set of reactions, named after Hans Krebs, who in 1937 was the first to envision its features, is diagrammed in Figure 8.2. For simplicity the reactions involved in the oxidation of just one molecule of pyruvic acid are shown, although two molecules are in fact processed for each molecule of glucose.

Pyruvic acid enters the Krebs cycle by participating in a complex set of reactions in which it is oxidatively decarboxylated, forming CO_2 and a two-carbon acetyl group that is combined with coenzyme A in the form of acetyl coenzyme A.² In the process, a molecule of NAD

FIGURE 8.2 The major reactions of the Krebs cycle (citric acid cycle) A molecule of H_2O enters the reactions at each asterisk (*). The expression for reduction of NAD, $NAD \rightarrow NADH_2$, is shorthand; the actual reaction is $NAD^+ + 2 H \rightarrow NADH + H^+$.

is reduced. Acetyl coenzyme A then reacts with oxaloacetate, with the end result that coenzyme A is released and the acetyl group is condensed with oxaloacetate (four-carbon) to form citrate (six-carbon). In the ensuing series of reactions, oxaloacetate is ultimately regenerated and then again can combine with acetyl coenzyme A. For our purposes, there is no need to review the reactions stepwise. It is more important to emphasize the overall outcomes of the reactions:

- The six carbons of each glucose molecule catabolized emerge in the form of six molecules of CO_2 as the pyruvic acid molecules produced by glycolysis are processed by the Krebs cycle. The CO_2 is formed by decarboxylation reactions. Such reactions occur at two points in the Krebs cycle: in the conversion of isocitrate to α -ketoglutarate and in the conversion of α -ketoglutarate to succinyl coenzyme A. These two decarboxylations, plus the one in the reaction of pyruvic acid to form acetyl coenzyme A, account for the formation of three molecules of CO_2 for every molecule of pyruvic acid processed (thus six molecules of CO_2 formed per glucose molecule).
- For each glucose molecule catabolized, the Krebs cycle produces eight molecules of $NADH_2$ and two molecules of $FADH_2$. Oxidation reactions occur at four points in the Krebs cycle. At three of these, NAD is reduced, forming $NADH_2$. At one (the oxidation of succinate to fumarate), another small, nonprotein molecule that undergoes reversible oxidation and reduction—flavin adenine dinucleotide (FAD)—is reduced, forming $FADH_2$.³ Recall also that one $NADH_2$ is formed in the reaction of pyruvic acid to form acetyl

¹The reduction of NAD is symbolized " $NAD + 2 H \rightarrow NADH_2$ " or " $NAD \rightarrow NADH_2$ " in this book because these simplified expressions compactly emphasize the features of relevance for us. The true reaction is $NAD^+ + 2 H \rightarrow NADH + H^+$.

²Coenzyme A, an essential compound for aerobic metabolism, is synthesized from pantothenic acid, a B vitamin.

³Flavin adenine dinucleotide is synthesized from riboflavin (vitamin B_2).

coenzyme A. Considering all the oxidation reactions, the processing of each pyruvic acid molecule results in four NADH_2 and one FADH_2 (thus eight NADH_2 and two FADH_2 per glucose molecule).

- *Two molecules of ATP are produced in the Krebs cycle for each molecule of glucose catabolized.* Guanosine triphosphate (GTP) is formed from guanosine diphosphate (GDP) when succinyl coenzyme A reacts to form succinate in the Krebs cycle. GTP donates its terminal phosphate group to ADP, resulting in GDP and ATP. Thus one molecule of ATP is generated for each molecule of pyruvic acid processed (two ATPs per glucose).

ELECTRON TRANSPORT, OXIDATIVE PHOSPHORYLATION, AND THE ROLE OF O_2 The final two of the four sets of reactions in the aerobic catabolic pathway are the *electron-transport chain* and *oxidative phosphorylation*. We discuss them together because they are often tightly linked.

A paradox you may have noticed is that thus far, in discussing *aerobic* catabolism, we have not mentioned the involvement of O_2 . The reason is that O_2 is in fact not a participant in any of the reactions of glycolysis or the Krebs cycle; in a very narrow sense, all those reactions can proceed without O_2 . Nonetheless, O_2 is essential. The reason it is essential lies in the disposition of the reduced NADH_2 and FADH_2 molecules.

NADH_2 and FADH_2 cannot serve as final resting places for electrons because NAD and FAD are present in only limited quantities in a cell. Whenever one of the mainstream molecules in glycolysis or the Krebs cycle is oxidized, the electrons (or hydrogens) removed are transferred to NAD or FAD. As stressed earlier, therefore, NAD and FAD are the *immediate* electron acceptors. However, if the NADH_2 and the FADH_2 thereby formed were simply allowed to accumulate, a cell would soon run out of NAD and FAD. Running out of NAD and FAD would bring glycolysis and the Krebs cycle to a halt because NAD and FAD are required. Thus NAD and FAD cannot serve as *final* electron acceptors. The electron-transport chain regenerates NAD and FAD by removing electrons (hydrogens) from NADH_2 and FADH_2 . For the ordinary operation of the electron-transport chain, O_2 is required. In that way O_2 is necessary for glycolysis and the Krebs cycle to function as they do during aerobic catabolism.

Let's now focus on the **electron-transport chain** itself. It consists of a series of four major protein complexes (I–IV), plus other compounds, located in the inner membranes of mitochondria (**Figure 8.3**). A key property of the constituents of the electron-transport chain is that each is capable of undergoing reversible reduction and oxidation. The compounds function in a discrete order—a chain. The chain takes electrons from NADH_2 and FADH_2 and passes them in sequence from one compound to the next in a series of reductions and oxidations (see Figure 8.3). Finally, the last compound in the electron-transport chain, known as *complex IV* or *cytochrome oxidase*, passes the electrons—along with “accompanying” protons (H^+ ions)—to oxygen, reducing the O_2 to water.⁴ In this way, O_2 acts as the *final electron acceptor*. The net effect of the operation of the electron-transport chain is to take electrons from NADH_2 and FADH_2 (thereby regenerating NAD and FAD) and pass the electrons to O_2 .

The special role played by O_2 is important. The constituents of the electron-transport chain (e.g., cytochrome *b-c*₁ and cytochrome oxidase), just like NAD and FAD, are present in limited quantities in a cell and therefore cannot act as terminal electron acceptors. In contrast, O_2 is continuously supplied to a cell, and the product of its reduction, water, can be voided into the environment, *thereby carrying electrons out of the cell*. An adult person produces about 0.8 L of water per day in the process of voiding electrons from cells!

The electron-transport chain, in addition to reoxidizing NADH_2 and FADH_2 , is also pivotally involved in the *transfer of energy* from the bonds of foodstuff molecules to ATP. Molecular O_2 has a much higher affinity for electrons than NAD and FAD. Accordingly, there is a large decline in free energy as the electrons originally taken from foodstuff molecules are passed through the electron-transport chain. A considerable portion of this energy is captured in bonds of ATP. The process of forming ATP from ADP by use of energy released in the transport of electrons through the electron-transport chain is called **oxidative phosphorylation**.

How is the energy released in electron transport used by oxidative phosphorylation? How, in other words, are the two processes coupled? According to the **chemiosmotic hypothesis** currently favored by most biochemists, the coupling is achieved indirectly by a two-step process of the sort discussed in Box 5.1.⁵ As energy is released in electron transport, it is used to pump protons across the inner mitochondrial membrane, creating—across that membrane—a proton electrochemical gradient that is far from equilibrium. This gradient represents an energy store. Driven by the electrochemical gradient, protons diffuse back across the membrane toward equilibrium by way of molecules of a membrane-spanning, ATP-synthesizing protein. In this process, energy from the proton electrochemical gradient becomes energy of proton movement, and the ATP-synthesizing protein uses the proton motive energy to synthesize ATP from ADP.

Let's now look at further details of electron transport and oxidative phosphorylation. Of the four protein complexes in the electron-transport chain, three (complexes I, III, and IV) use energy released from electron transport to pump protons across the inner mitochondrial membrane, as shown in Figure 8.3*b*. As already indicated, this proton pumping is away from equilibrium and *builds* an electrochemical gradient, seen in **Figure 8.4a**. Collectively, according to current estimates, the three complexes pump 10 protons into the intermembrane space for each pair of electrons (or hydrogens) that flow the full length of the electron-transport chain from NADH_2 to oxygen. Although protons in the intermembrane space (see Figure 8.4*a*) have a strong tendency to diffuse back across the inner mitochondrial membrane, they are largely unable to pass through the membrane itself. Their back-diffusion therefore occurs, as shown in **Figure 8.4b**, via molecules of a membrane-spanning protein—**ATP synthase**—that is permeable to protons and that couples the motive energy of the diffusing protons to the synthesis of ATP from ADP.⁶

A common mode of expressing the efficiency of ATP production by oxidative phosphorylation is as a **P/O ratio** (P = phosphate, O = oxygen), defined to be the number of ATP molecules formed per

⁴Two electrons and two protons combine with one oxygen atom. A molecule of oxygen (O_2), therefore, can react with four electrons and four protons.

⁵The term *chemiosmotic hypothesis* refers to the entire process outlined in this paragraph. Box 5.1 is essential reading for fully understanding the hypothesis.

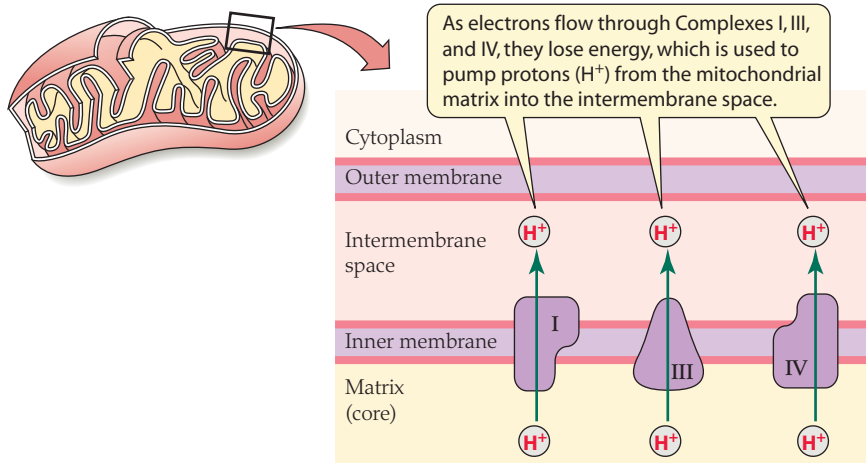

⁶Spectacular simulations of the operation of this “splendid molecular machine” are available on the web.

(a) Electron flow in the mitochondrial inner membrane

(b) Pumping of protons into the mitochondrial intermembrane space

FIGURE 8.3 The electron-transport chain As shown in (a), the electron-transport chain consists of four enzyme protein complexes, called complexes I through IV, embedded in the inner mitochondrial membrane, plus ubiquinone and cytochrome c . The three purple complexes (I, III, and IV) capture energy from the flux of electrons to pump protons into the intermembrane space from the matrix across the inner membrane, as shown in (b), storing energy for synthesis of ATP. Ubiquinone, also called coenzyme Q, is a lipid-soluble compound that is mobile in the lipid core of the membrane. As also shown in (a), ubiquinone that is reduced by receiving hydrogens from complex I or FADH_2 becomes reoxidized by passing electrons to complex III, also called cytochrome $b-c_1$. Complex III then passes the electrons to cytochrome c (a water-soluble compound), which in turn passes them to complex IV (also called cytochrome oxidase, cytochrome $a-a_3$, COX, or cytochrome c oxidase). e^- = electron, H^+ = proton. (After Saraste 1999.)

atom of oxygen reduced to water. According to current estimates, in mammalian mitochondria, ATP synthase makes one ATP for every 4.3 protons that cross through it. As earlier noted, electron transport pumps 10 protons for each pair of electrons (or hydrogens) that pass through the electron-transport chain. Inasmuch as a pair of electrons (or hydrogens) combines with one atom of oxygen at the end of the chain, that's 10 protons per O atom reduced. Those 10 protons, when they pass through ATP synthase, result in production of 2.3 ATP molecules (1 ATP per 4.3 protons). Thus the P/O ratio is 2.3. This value, $P/O = 2.3$, is currently considered to be the maximum P/O ratio for electrons that pass the entire length of the electron-transport chain from NADH_2 to oxygen.

Linkage of electron transport with oxidative phosphorylation is called **coupling**. An important aspect of coupling is that it is capable of being **graded** in its completeness. Because of this graded nature, the P/O ratio can be lower than the maximum possible. In fact, a P/O ratio of 0 (zero) is observed at times in some types of

cells, meaning that the P/O ratio can be as high as 2.3 or as low as 0. Electron transport and oxidative phosphorylation are said to be **fully** ("tightly") **coupled** when the P/O ratio is high and **completely uncoupled** when $P/O = 0$. Intermediate states of coupling are possible. Usually, coupling is relatively tight.

The mitochondria of *some* (specialized) cells express in their inner membrane—in addition to ATP synthase—a second type of membrane-spanning protein, **uncoupling protein 1 (UCP1)**. This protein forms the basis for the most thoroughly understood mechanism of uncoupling. As shown in **Figure 8.4c**, UCP1 provides a path for protons to diffuse from the intermembrane space across the inner membrane to the mitochondrial matrix without ATP synthesis.⁷ Uncoupling opposes ATP production: In the fully uncoupled state ($P/O = 0$), even though electron transport continues

⁷There are at least four different hypotheses regarding how exactly UCP1 functions to achieve this outcome. The concept that UCP1 provides a straightforward back-diffusion path for protons is the simplest of the models.

FIGURE 8.4 Principles of oxidative phosphorylation and uncoupling (a) Electron transport produces a proton electrochemical gradient, as shown in Figure 8.3, by pumping protons from the matrix into the intermembrane space. In (b) and (c), protons diffuse back to the matrix, driven by the proton electrochemical gradient, which is present in (b) and (c)—just as in (a)—but not shown for simplicity. Ordinarily, as seen in (b), protons diffuse back to the matrix through ATP synthase, which produces ATP by oxidative phosphorylation. In cells with uncoupling protein 1 (UCP1), as seen in (c), protons can also diffuse back to the matrix through UCP1, which produces no ATP and results in all the proton motive energy being dissipated as heat.

This value for leakage is so high that it suggests there may be advantages achieved by allowing leakage to occur.

An important incidental effect of the processing of O_2 by mitochondria is that reactive forms of oxygen-containing compounds are produced as the processes we have described take place. These highly reactive entities—known as *reactive oxygen species (ROS)*—can react with and damage mitochondrial constituents. Some can exit the mitochondria, creating the possibility that they will react with and damage extramitochondrial cell constituents (**Box 8.1**).

THE YIELD OF ATP FROM AEROBIC CATABOLISM

Now let's look at the total yield of ATP from the aerobic catabolism of glucose

to convert $NADH_2$ and $FADH_2$ to NAD and FAD —thereby permitting continued oxidation of foodstuff molecules by glycolysis and the Krebs cycle—none of the energy released by electron transport is captured as ATP. The energy instead is immediately converted to heat. Uncoupling by UCP1 therefore is a specialized biochemical state that is ordinarily employed only when there is an advantage to converting food energy to heat rather than ATP. Uncoupling of oxidative phosphorylation is a major mechanism of increasing metabolic heat production in many mammals in cold seasons (see Chapter 10). It also sometimes serves as a mechanism of body-weight regulation by “burning off” the energy of excess food molecules.⁸ In a tissue with UCP1, the degree of coupling is controlled by modulation of the extent to which protons back-diffuse by way of the two possible paths: ATP synthase and uncoupling protein (see Figure 8.4c). This control is mediated by a variety of agents, including fatty acids, hormones, and Ca^{2+} ions.

Uncoupling by UCP1 is not the only mechanism that causes the P/O ratio to be less than maximal. A mechanism that is observed in a wider diversity of cells than those with UCP1 is *leakage* of protons across the inner mitochondrial membrane. In this case, protons diffuse across the membrane, from the intermembrane space to the matrix, by way of largely unknown, nonspecific pathways. Leakage reduces the amount of ATP synthesized (it reduces the P/O ratio) because protons that leak do not pass through ATP synthase. In some tissues, 20% or more of the proton electrochemical gradient is dissipated by leakage, according to the evidence now available.

⁸Recall, for example, the rats mentioned in Chapter 7 that remain slim despite chronic overeating by undergoing diet-induced thermogenesis (DIT). Uncoupling is the principal mechanism of DIT in those animals.

when coupling is tight. For each molecule of glucose that is catabolized, 10 molecules of $NADH_2$ and 2 molecules of $FADH_2$ are formed in glycolysis and the Krebs cycle. When these molecules are processed via the electron-transport chain, the maximum yield of ATP by oxidative phosphorylation is 25 ATP molecules per glucose.⁹ Even in tightly coupled mitochondria, this theoretical yield is probably not fully achieved in reality because of leakage. Nonetheless, for simplicity, we will use this value in this book without further qualification.

Besides the ATP molecules made by oxidative phosphorylation, additional ATP molecules are generated by phosphorylation reactions associated with several steps in glycolysis and the Krebs cycle: the reaction of 1,3-diphosphoglyceric acid to form 3-phosphoglyceric acid (see Figure 8.1), that of phosphoenolpyruvic acid to form pyruvic acid (see Figure 8.1), and that of succinyl coenzyme A to form succinate (see Figure 8.2). These phosphorylations, in contrast to oxidative phosphorylations, are known collectively as **substrate-level phosphorylations** because they occur immediately in the reactions of substrates of glycolysis and the Krebs cycle. Altogether, 6 ATP molecules are formed by substrate-level phosphorylation per molecule of glucose under aerobic conditions. In total, therefore, 31 molecules of ATP are generated for each glucose

⁹This value is calculated using the latest estimates of P/O ratios: P/O = 2.3 for most $NADH_2$ oxidation, P/O = 1.4 for $FADH_2$ oxidation. The paper by Martin Brand in the References provides a full, accessible explanation. By way of background, note that although both $NADH_2$ and $FADH_2$ are oxidized by the electron-transport chain, their electrons enter the chain at different points, giving the compounds different P/O ratios; also, a factor discussed in biochemistry texts is that $NADH_2$ produced in glycolysis has a lower effective P/O ratio than most $NADH_2$, because the former is produced outside the mitochondria and its electrons must be shuttled in. The P/O ratios used here are lower than those traditionally used (P/O = 3 for most $NADH_2$ oxidation, P/O = 2 for $FADH_2$ oxidation) because of modern revisions in the estimates.

BOX 8.1 REACTIVE OXYGEN SPECIES (ROS)

The ordinary metabolism of aerobic cells produces molecules—chemical species—that because of the status of their oxygen atoms have a high potential to react with (e.g., oxidize) cell lipids, proteins, and nucleic acids. These are called **reactive oxygen species (ROS)**. ROS can have benign functions; they play signaling roles, for example. ROS are more famous, however, for their ability to damage macromolecules on which health and life depend. ROS, in fact, are believed by some biologists to be the primary causative agents of aging. According to this hypothesis, we age because of incessant damage done to vital macromolecules by metabolically produced ROS; this damage is repaired, but not entirely, so defects accumulate over time. ROS are also implicated in muscle fatigue and many other phenomena.

The superoxide anion—an O_2 molecule with an extra electron—is often the initial ROS produced by metabolism (see figure). Mitochondria routinely generate superoxide as a byproduct of electron transport, and in turn, superoxide and its ROS products can injure mitochondria by reacting in destructive ways with mitochondrial macromolecules. Superoxide is produced also by several

extra-mitochondrial reactions. Superoxide is converted to three other ROS: hydrogen peroxide, hydroxyl radicals, and peroxynitrite (see figure). All ROS are short-lived—sometimes exceedingly so. Hydroxyl radicals, for example, exist for less than one-billionth of a second after they are formed, precisely because they are extraordinarily reactive.

Cells possess **antioxidant mechanisms**—enzymatic and non-enzymatic mechanisms of detoxifying ROS. Enzyme antioxidants catalyze the transformation of ROS to less-reactive chemical forms. *Superoxide dismutase*, for example, converts superoxide to hydrogen peroxide, and *catalase* converts hydrogen peroxide to water and O_2 (see figure). Non-enzymatic antioxidants often function in a sacrificial way: By reacting with ROS, they prevent the ROS from reacting with other, more critical molecules.

Oxidative stress (oxidant stress) refers to damage inflicted by ROS on cellular integrity. It occurs when the rate of ROS production exceeds the rate at which antioxidant mechanisms can dispose of ROS. **Box Extension 8.1** discusses antioxidants and the roles of ROS in more detail.

An outline of the chemical relationships of O_2 and four reactive oxygen species (ROS)

The ROS are shown in boxes. A rough estimate of the average lifespan of each ROS is shown below the name of the ROS; for example, superoxide radicals typically react—and therefore cease to be superoxide radicals—within 1 millionth of a second (10^{-6} s) after they are formed. Superoxide dismutase (SOD) and catalase are enzymes. A superscript dot next to a compound symbolizes an unpaired electron. The reactions are shown in outline only, not as fully balanced reactions. (After Allen et al. 2008.)

molecule catabolized. However, 2 ATP molecules are consumed at the start of glycolysis (see Figure 8.1).

Thus the *net* yield of ATP by aerobic catabolism is 29 molecules of ATP per glucose. The *energetic efficiency* of this ATP production—defined by Equation 7.1—is not altogether certain and can vary even in a tightly coupled cell, depending on metabolite concentrations and other conditions.¹⁰ In glucose catabolism, assuming tight coupling, the efficiency is usually considered to be 60–70%. That is, 60–70% of the chemical energy released by oxidizing glucose to CO_2 and H_2O is captured as chemical-bond energy of ATP.

O_2 deficiency poses two biochemical challenges: Impaired ATP synthesis and potential redox imbalance

What are the biochemical implications if cells are denied O_2 or supplied with O_2 at an inadequate rate? To explore this question, let's for simplicity consider cells deprived entirely of O_2 , even though for many animals this would be an unrealistically extreme state.

Without O_2 , electrons entering the electron-transport chain cannot be discharged at the end by the reduction of O_2 . Thus the electron-transport chain becomes a *dead end* for electrons. The consequences for most animals are easily summarized. Soon after the supply of O_2 is cut off, all the cytochromes and other constituents of the electron-transport chain become fully reduced because electrons

entering the chain accumulate. The electron-transport chain then can no longer accept further electrons, and two major consequences follow. First, oxidative phosphorylation cannot take place, eliminating a cell's ability to produce 25 of the 29 ATP molecules that can be produced in net fashion by the aerobic catabolism of glucose. Second, the electron-transport chain can no longer serve as a mechanism for reoxidizing the reduced molecules of $NADH_2$ and $FADH_2$ that are produced by glycolysis and the Krebs cycle. The cell's supply of NAD and FAD is thus threatened. A complete failure to regenerate NAD and FAD would mean that a cell could produce no ATP at all, because NAD is needed for glycolysis, and both NAD and FAD are required for operation of the Krebs cycle.

The inability of the electron-transport chain to regenerate NAD and FAD from $NADH_2$ and $FADH_2$ in the absence of O_2 can be described as a problem of *redox balance*, meaning *reduction–oxidation balance*. **Redox balance** is a key concept in the study of all cellular compounds that undergo alternating reduction and oxidation. By definition, a cell is in redox balance for such a compound if the cell possesses the means to remove electrons from the compound as fast as electrons are added to it.

Applying the concept specifically to NAD, a cell is in redox balance for NAD if it can convert $NADH_2$ back to NAD (a process that removes electrons) as fast as NAD is being converted to $NADH_2$ (a process that adds electrons). During aerobic catabolism, O_2 and the electron-transport chain together provide the means for maintaining redox balance for NAD and FAD, thereby ensuring that NAD and FAD are steadily available to perform their essential

¹⁰For example, ATP does not have a fixed energy value, as often implied by introductory biology texts. Instead, the “energy content” of ATP depends on how close, or far away, the ATP–ADP interconversion reaction is to chemical equilibrium, which in turn depends on relative concentrations of the reactants in a particular cell.

roles in glycolysis and the Krebs cycle. To make ATP without O_2 , a cell must possess alternative mechanisms that will permit redox balance to be maintained while at least some ATP-generating reactions continue to take place.

Certain tissues possess anaerobic catabolic pathways that synthesize ATP

Only some tissues have evolved an ability to make ATP at significant rates without O_2 . The mammalian brain is a prime example of a tissue that lacks this ability. The brain succumbs rapidly when denied O_2 (as during cardiac arrest) because when O_2 is unavailable, the brain is unable to synthesize ATP at the rate it needs it. Many other vertebrate tissues possess an anaerobic catabolic pathway that can produce ATP at a substantial rate without O_2 . These other tissues are therefore less rigidly dependent on an O_2 supply than the mammalian brain is.

Anaerobic glycolysis is the principal anaerobic catabolic pathway of vertebrates

Vertebrate skeletal muscle and many other vertebrate tissues are able to use the substrate-level phosphorylations of glycolysis to transfer energy from the bonds of glucose to ATP at substantial rates in the absence of O_2 . For a tissue to have this ability, it must have a way of maintaining redox balance for NAD without O_2 . Glycolysis requires NAD to serve as the immediate electron acceptor for the oxidation of glyceraldehyde-3-phosphate, and in using NAD in this way, it converts the NAD to $NADH_2$ (see Figure 8.1). Under anaerobic conditions in skeletal muscles and other such tissues, the $NADH_2$ molecules are reoxidized to NAD by passing their electrons (hydrogens) to pyruvic acid, reducing the latter to lactic acid (Figure 8.5). Pyruvic acid, in essence, is used as the final electron acceptor by the anaerobic cell. The entire sequence of reactions that converts glucose to lactic acid is called **anaerobic glycolysis**.

The principal determinant of whether a cell can carry out anaerobic glycolysis at a substantial rate is its expression of the enzyme lactate dehydrogenase (LDH), the enzyme that reduces pyruvic acid. LDH occurs in multiple molecular forms, as discussed in detail in Chapter 2 (see page 46). For a cell to carry out anaerobic glycolysis, it must synthesize significant amounts of one or more LDH forms that are catalytically effective in converting pyruvic acid to lactic acid under the intracellular conditions that prevail during O_2 deprivation. In cells that meet these criteria, a true redox balance exists during anaerobic glycolysis. As a study of Figure 8.5 reveals, one molecule of pyruvic acid is produced for each molecule of NAD that is reduced to $NADH_2$. Thus the supply of pyruvic acid keeps exact pace with the need for it as an electron acceptor. A cell with appropriate amounts and types of LDH is thus able to convert every $NADH_2$ that it forms back to NAD without O_2 . This means that from a strictly biochemical perspective, the cell can maintain a steady production of ATP without O_2 .

What fuels can anaerobic glycolysis use, and how much ATP can it make? Glucose and glycogen are the only foodstuff molecules that can serve as fuels for anaerobic glycolysis under most conditions. The amount of ATP synthesized in net fashion by anaerobic glycolysis is two molecules of ATP per glucose molecule catabolized (see Figure 8.5). This yield of ATP is vastly lower than that from the aerobic catabolism of glucose. However, as we will see, the anaerobic pathway can nonetheless be an impressively important source of ATP. The major

FIGURE 8.5 Anaerobic glycolysis The reduction of pyruvic acid is catalyzed by the enzyme lactate dehydrogenase (LDH) and permits redox balance to be maintained without O_2 . The net yield of ATP is two ATP molecules per glucose molecule if the initial fuel is glucose itself, as shown here. If glycogen is used as fuel, there is a net yield of three ATPs per glucose unit catabolized.

reason for the comparatively low yield of ATP per glucose molecule during anaerobic glycolysis is that only a small fraction (about 7%) of the free energy available from glucose is released by the conversion of glucose to lactic acid. Lactic acid is itself an energy-rich molecule.

Anaerobic glycolysis is not the only mechanism of anaerobic catabolism in animals. However, we will take up other anaerobic pathways later and now address the important matter of the disposition of end products.

What happens to catabolic end products?

For an animal to make use of any ATP-producing pathway, it must possess satisfactory means of disposing of the chemical end products generated. The principal products of aerobic catabolism, CO_2 and H_2O , are fully oxidized and not capable of being tapped for further energy. Animals typically dispose of CO_2 and H_2O by voiding them into the environment, as when we exhale CO_2 by breathing.¹¹

The end products of anaerobic catabolic pathways, in contrast to CO_2 and H_2O , are always organic compounds that are far from fully oxidized and possess considerable further potential to yield energy. The high energy value of these products places a premium on retaining them in the body for future use as energy sources; excreting lactic acid, for instance, would be equivalent to voiding more than 90% of the energy value of catabolized carbohydrates. However, unlimited retention of the organic end products of anaerobic catabolism is usually not possible, because the end products typically exert harmful effects if allowed to accumulate to high concentrations. These two competing considerations seem to have been major operative factors in the evolution of animal strategies for disposing of anaerobic end products. A third factor of importance is time. An animal that makes only short-term use of anaerobic catabolic pathways is more likely to be able to retain all

¹¹ In the study of water balance, the H_2O produced by aerobic catabolism is known as *metabolic water* or *oxidation water*. This water is sometimes an important part of the water budget (see Chapter 27).

FIGURE 8.6 Major paths by which lactic acid is metabolized when O₂ is available Some carbon from lactic acid may also be incorporated into amino acids and proteins by way of Krebs-cycle intermediates.

the end-product molecules without adverse effects than an animal that uses anaerobic catabolism for days or weeks on end.

THE DISPOSITION OF LACTIC ACID IN VERTEBRATES When vertebrates use anaerobic glycolysis, they universally retain the lactic acid they produce in their bodies, and they ultimately get rid of the lactic acid *metabolically*. The metabolism of lactic acid requires O₂ and thus can take place only when and where O₂ becomes available. Lactic acid itself is a metabolic cul-de-sac (Figure 8.6). Thus, for lactic acid to be metabolized, it must first be converted back to pyruvic acid by a reversal of the very reaction that formed it. The conversion of lactic acid to pyruvic acid is an oxidation reaction, with NAD acting as the immediate electron acceptor. After conversion to pyruvic acid, the carbon chains of lactic acid are metabolized by one of two major paths, both of which require O₂ (see Figure 8.6):

1. One path is for the carbon chains to be used to form glucose or glycogen, thereby replenishing a cell's carbohydrate stores. The conversion of lactic acid or pyruvic acid to glucose or glycogen is a form of **gluconeogenesis** ("new formation of glucose"). The process *uses ATP* (six ATP molecules per glucose molecule formed). It requires O₂ because the ATP must be made aerobically.
2. The second path is for the carbon chains to be fully oxidized by way of the Krebs cycle and electron-transport chain. This process *makes ATP* (27 ATP molecules per pair of lactic acid molecules). It requires O₂ because the electron-transport chain must be functional.

To determine the relative importance of the two paths followed by lactic acid, investigators inject animals with lactic acid containing the unusual carbon isotope ¹⁴C. They then monitor the fractions of the ¹⁴C that show up in CO₂ and carbohydrate. These fractions vary, even within single species, in ways that are still poorly understood. As a gross generalization, the poikilothermic groups of vertebrates—fish, amphibians, and the reptiles other than birds—use carbon chains of lactic acid principally for

gluconeogenesis, whereas mammals either emphasize oxidation of the carbon chains in the Krebs cycle or employ both oxidation and gluconeogenesis about equally.

Lactic acid may be metabolized by the same tissues that produce it, or it may be carried by the blood to other tissues that metabolize it. Quite often, tissues that are well supplied with O₂ metabolize lactic acid made by other tissues that are deprived of O₂; this can occur even while lactic acid production continues.

The functional roles of ATP-producing mechanisms depend on whether they operate in steady state or nonsteady state

One of the most consequential properties of any ATP-producing mechanism is whether or not it can operate in **steady state**. Ideally, a mechanism is in steady state if (1) it produces ATP as fast as ATP is used, (2) it uses raw materials (e.g., foodstuff molecules) no faster than they are replenished, (3) its chemical by-products (besides ATP) are voided (or metabolically destroyed) as fast as they are made, and (4) it does not cause other changes in cell function that progress to the point of disrupting cell function. When a cell uses a **steady-state mechanism** of ATP production, even as ATP is made and used in the cell, the cell remains essentially constant in its levels of ATP and of the precursors and by-products of ATP production, and it also remains essentially homeostatic in other ways as well. At least in principle, therefore, *a steady-state mechanism can go on and on indefinitely, free of intrinsic limitations*.

In contrast, a **nonsteady-state mechanism** of ATP production depletes supplies, accumulates products, or otherwise alters the conditions of its own operation at rates fast enough that the mechanism is *self-limiting* or *self-terminating*. For this reason, a nonsteady-state mechanism cannot persist for long by comparison with steady-state ones.

The concepts of steady-state and nonsteady-state mechanisms are relative rather than absolute. Nonetheless, they provide useful organizing principles in the study of ATP synthesis. In vertebrates and many invertebrates, aerobic ATP production is usually a steady-state process, whereas anaerobic ATP production is usually a nonsteady-state process.

EXAMPLES FROM HUMAN BIOLOGY To understand the practical meaning of steady-state and nonsteady-state mechanisms better, let's examine some examples in our own lives. Routine daily living provides a good illustration of a circumstance in which ATP is produced by aerobic catabolism functioning in steady state. Consider what you are doing now, for instance. As you read this page, unless you have bizarre reading habits, you are in an aerobic steady state. You are making all your ATP by aerobic catabolism; your needs for ATP are fully met; you are taking in O₂ at the rate you use it; you are voiding CO₂ and H₂O approximately as you produce them; and your cells are not undergoing any progressive alterations that might disrupt their function. The one way in which you may not be in steady state is in regard to the foodstuff molecules you are using as fuels. If a person is not eating while reading, fuel levels are obviously falling. However, the rate of decline during reading is very low relative to fuel stores, and intakes of fuels probably closely match uses when averaged over a day (including meals). Thus, even with respect to fuels, the departure from steady state is merely technical.

- Anaerobic glycolysis is a redox-balanced process by which ATP can be made without O_2 in certain tissues. Whether a tissue can employ anaerobic glycolysis depends on the amount and type of its lactate dehydrogenase (LDH). Anaerobic glycolysis typically can use only carbohydrate fuel. It releases only about 7% of the energy of glucose. Thus it produces just 2 ATP molecules per glucose molecule, and the lactic acid produced is itself an energy-rich compound.
- Vertebrates retain the lactic acid that they produce. The metabolism of lactic acid requires O_2 , either to oxidize the lactic acid via the Krebs cycle—thereby producing ATP—or to convert lactic acid to glycogen or glucose (gluconeogenesis)—a process that uses ATP.
- Phosphagens in muscle cells serve as temporary stores of high-energy phosphate bonds, which they can transfer to ADP to make ATP anaerobically.

Comparative Properties of Mechanisms of ATP Production

We have now identified four mechanisms of ATP production: (1) aerobic catabolism by use of O_2 acquired simultaneously from the environment, (2) anaerobic catabolism, (3) anaerobic ATP production by use of phosphagen, and (4) aerobic ATP production by use of internal O_2 stores. To compare the functional properties of these four, we now discuss several key questions. See [Table 8.1](#) for a summary of this discussion.

Question 1: What is each mechanism's total possible ATP yield per episode of use?

If an animal uses a particular mechanism to make ATP and continues using it until no more ATP can be made, what is the total amount of ATP that can be produced? Because aerobic catabolism using environmental O_2 operates in steady state, it is capable of supplying an indefinite amount of ATP (a lifetime's amount). In contrast, the three mechanisms that operate in nonsteady state are limited in the amount of ATP they can produce during any one episode of use because of their mechanistic self-limitations. For example, the amount of ATP that can be made from phosphagen is limited by the quantity of phosphagen available; after the phosphagen originally present has been used, no more ATP can be made until (at some later time) the phosphagen is regenerated. Table 8.1 shows representative yields of ATP in humans. Phosphagen and O_2 stores permit only relatively small quantities of ATP to be made per episode of use. The yield from anaerobic glycolysis is larger but modest.

gen is limited by the quantity of phosphagen available; after the phosphagen originally present has been used, no more ATP can be made until (at some later time) the phosphagen is regenerated. Table 8.1 shows representative yields of ATP in humans. Phosphagen and O_2 stores permit only relatively small quantities of ATP to be made per episode of use. The yield from anaerobic glycolysis is larger but modest.

Question 2: How rapidly can ATP production be accelerated?

In vertebrates and many types of invertebrates (although not insects), aerobic catabolism using environmental O_2 requires a relatively long time (minutes) to accelerate its rate of ATP production fully to a new high level. Acceleration is slow because this mechanism of ATP production is *not self-contained in cells*. The mechanism requires inputs of O_2 , and the pulmonary and circulatory systems—which supply the needed O_2 by transporting it from the environment to the cells—*increase their rate of O_2 delivery gradually, not instantly*.

By contrast, the other three mechanisms can accelerate very rapidly because all *are self-contained in the cells*. At the start of a bout of exercise, for example, a vertebrate muscle cell contains not only all the enzymes of anaerobic glycolysis but also the glycogen fuel required. Nothing needs to be brought to the cell for anaerobic glycolysis to take place, and in fact a cell is capable of nearly instantly stepping up its glycolytic rate of ATP production to a high level. ATP production by use of phosphagen and O_2 stores can also accelerate rapidly because the phosphagen and O_2 stores are already present in cells when the mechanisms are called into play.

In both vertebrates and crustaceans such as crayfish, the first stages of burst exercise receive their ATP supply principally from anaerobic glycolysis, phosphagen use ([Box 8.2](#)), and use of O_2 stores, precisely because these are the three mechanisms that can rapidly accelerate ATP production. Vertebrates would be *incapable* of burst exercise without these mechanisms. As bizarre as it might be to imagine, if aerobic catabolism using O_2 from the environment were the only means of making ATP, vertebrates would be unable to start running suddenly at top speed; instead, they would have to accelerate their running gradually over a period of minutes.

TABLE 8.1 Comparative properties of mechanisms of ATP production in vertebrates, including numerical estimates for some of the properties in human beings

Mechanism of ATP production	Mode of operation (mandatory or assumed)	Total possible ATP yield per episode of use ^a (moles)	Rate of acceleration of ATP production at onset of use	Peak rate of ATP production ^b ($\mu\text{mol ATP/g}\cdot\text{min}$)	Rate of return to full potential for ATP production after use
Aerobic catabolism using O_2 from environment	Steady state	Very large (~200 in a marathon, $> 4 \times 10^6$ in a lifetime)	Slow	Moderate (30 with glycogen fuel, 20 with fatty acid fuel)	—
Anaerobic glycolysis	Nonsteady state	Moderate (1.5)	Fast	High (60)	Slow
Phosphagen use	Nonsteady state	Small (0.4)	Fast	Very high (96–360)	Fast
Aerobic catabolism using O_2 preexisting in body	Nonsteady state	Small (0.2)	Fast	High	Fast

^aNumerical estimates of total yields are computed from information in Åstrand and Rodahl 1986; a 75-kg person living 70 years is assumed.

^bPeak rates of production are from Hochachka and Somero 2002.

BOX 8.2 GENETIC ENGINEERING AS A TOOL TO TEST HYPOTHESES OF MUSCLE FUNCTION AND FATIGUE

Experiments based on genetic engineering are increasingly being used to test physiological hypotheses. Genetic engineering methods, for example, are being used extensively to study muscle function and fatigue. One example is provided by research on the role of the phosphagen *creatine phosphate*. Because creatine phosphate in mammalian muscle can be mobilized extremely rapidly to make ATP at a high rate (see Table 8.1), physiologists have long hypothesized that the phosphagen serves as a principal source of ATP during the first seconds of burst exercise. ATP synthesis from creatine phosphate depends on the enzyme *creatine kinase (CK)* (see Figure 8.7*b*). One way to test the hypothesis of phosphagen function is to lower or raise the levels of CK in muscle cells by genetic engineering

methods. If the hypothesized role of creatine phosphate in burst exercise is correct, lowering or raising the levels of CK should interfere with or facilitate burst exercise.

Mutant mice *deficient* in CK have been reared by genetic engineering methods. The muscles of these mice clearly exhibit compensatory adjustments that tend to make up for the effects of their CK deficiency (see page 79). Even with such compensations, however, the muscles exhibit a subnormal ability to perform burst activity, and this performance deficit increases with the extent of their CK deficiency. Mice have also been engineered to produce unusually *high* amounts of CK. Their muscles contract faster than normal muscles in the first moments of isometric twitches. These experiments support the hypothesized role of creatine phosphate in burst exercise.

Creatine kinase (CK)

Box Extension 8.2 discusses another example of the application of genetic engineering methods to the study of muscle, focusing on fatigue.

Question 3: What is each mechanism's peak rate of ATP production (peak power)?

After a mechanism has accelerated its ATP production to the fastest rate possible, how fast can ATP be made? As shown in Table 8.1, the peak rate at which anaerobic glycolysis can make ATP is much greater than the peak rate of ATP production by aerobic catabolism using environmental O_2 , and the rate of ATP production by use of phosphagen is greater yet. Although the phosphagen mechanism cannot make a lot of ATP, it can make its contribution very rapidly; thus it can briefly support very intense exertion. Anaerobic glycolysis can make a modest amount of ATP at a high rate, and aerobic catabolism using environmental O_2 can make an indefinite amount at a relatively low rate.

Question 4: How rapidly can each mechanism be reinitialized?

Whenever ATP has been made by a nonsteady-state mechanism, cells are left in an altered state and must be returned to their original state before the mechanism can be used again to full effect. When internal O_2 stores have been used, the stores must later be recharged. When phosphagen has been used, it must be remade. When lactic acid has accumulated, it must be metabolized. In a word, the nonsteady-state mechanisms must be *reinitialized*.

The reinitialization of anaerobic glycolysis requires much more time than the reinitialization of the phosphagen or O_2 -store mechanisms because the length of time required to rid tissues of lactic acid is much greater than the time required to rebuild phosphagen or O_2 stores. In people, for example, a substantial accumulation of lactic acid may require 15–20 minutes (min) for half dissipation and even 1–2 h for full dissipation, whereas the half-time for reconstituting phosphagen and O_2 stores is just 30 s. Fish, frogs, lizards, and other poikilothermic vertebrates require even more time than mammals to dissipate lactic acid; 1–10 h may be required for half dissipation.

Conclusion: All mechanisms have pros and cons

A review of Table 8.1 and the preceding discussion reveals that each mode of ATP production has pros and cons; none is superior in all respects. Let's consider, for example, the relative pros and cons of the two major sources of ATP in vertebrates: aerobic catabolism using environmental O_2 and anaerobic glycolysis.

When one looks simply at biochemical maps, aerobic catabolism tends to seem far superior to anaerobic glycolysis. Aerobic catabolism fully releases the energy of food molecules (producing 29 ATPs per glucose), whereas anaerobic glycolysis unlocks only a small fraction of the energy value of food molecules (producing 2 ATPs per glucose). Moreover, anaerobic glycolysis typically is able to use only carbohydrate fuels, produces only a limited total amount of ATP in any one episode, and creates a product, lactic acid, that requires a long time to be cleared from the body.

Anaerobic glycolysis also has advantages in comparison with aerobic catabolism, however. Because anaerobic glycolysis does not require O_2 , it can provide ATP when O_2 is unavailable, or it can supplement aerobic ATP production when O_2 is insufficient. Moreover, anaerobic glycolysis can accelerate very rapidly and reach an exceptionally high rate of ATP production almost instantly—making it well suited to meeting the ATP needs of burst exercise.

Two Themes in Exercise Physiology: Fatigue and Muscle Fiber Types

Fatigue has many, context-dependent causes

Muscle fatigue is an exercise-induced reduction in a muscle's ability to generate peak forces and maintain power output. It is a fascinating and critical physiological phenomenon—having life-and-death consequences in natural settings—that has defied full understanding. Fatigue clearly has multiple causes, depending on the type and duration of exercise, and on the physiological status of the individual performing the exercise.

The fatigue associated with lactic acid accumulation is one of the types of fatigue that is best understood phenomenologically. Humans or other vertebrates undergoing intense exercise that involves sustained net lactate production characteristically become profoundly overcome with fatigue when lactic acid accumulates to a certain level; virtual paralysis often sets in. Even in the case of this very regular and predictable type of fatigue, however, the cellular and molecular mechanisms are not well understood. In the 1960s and earlier, the lactate ion was considered to be a specific “fatigue factor.” By 1990, however, investigators had decided that the acid–base disturbance associated with lactic acid accumulation—acidification of muscle cells—was the real cause of this fatigue. By now, acidification—although it plays a role—seems unlikely to be the principal cause, based on studies in which muscle-cell pH has been directly manipulated to observe its effects. Investigators have not, however, reached a consensus on the actual mechanism. Accumulation of lactic acid clearly serves as an indicator—a proxy—for the development of this sort of fatigue without being the principal causative agent.¹⁴

Some types of fatigue seem to be partly caused by changes in organ-level systems. For example, a type of fatigue that meets this description and is fairly well understood is the fatigue that develops after a long time during intense, *sustained* (aerobically fueled) exercise (Figure 8.8). When people engage in this sort of exercise, fatigue is associated with and—in part—probably caused by inadequate muscle glucose. In the first tens of minutes of such exercise, glucose from muscle glycogen fuels the portion of muscle ATP production that is based on glucose oxidation. As time passes, however, muscle glycogen becomes depleted, and the muscles become dependent on glucose brought to them from other organs (notably the liver) by blood flow (see Figure 8.8). Inadequacies in the rate of this glucose resupply are associated

¹⁴Some investigators argue that lactic acid *aids* muscular work, such as through effects on cell-membrane ion channels that help prevent deleterious changes in intracellular and extracellular ion concentrations.

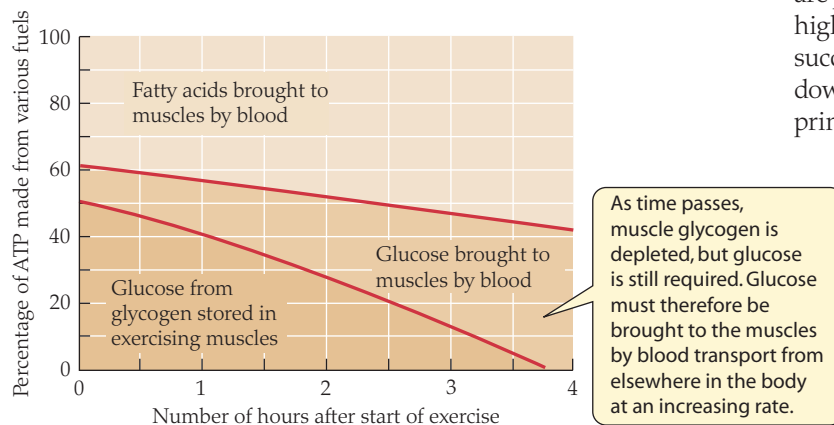

FIGURE 8.8 The fueling of intense, sustained muscular work in humans Shown are the fuels used to make ATP over the course of 4 h of exercise that requires about 70–80% of a person’s maximal rate of aerobic catabolism. In the later stages of this exercise, a failure of glucose resupply processes to keep up with muscle needs is believed to be an important cause of fatigue; the resupply processes include mobilization of liver glucose and blood transport to muscles. A fact that helps explain why shortage of glucose can be a fatigue factor is that the human body contains only about 450 g (1 pound) of glycogen even when glycogen stores are fully loaded (see Figure 6.2). (After Coyle 1991.)

with fatigue. Hyperthermia (unusually high body temperature) is another organismal factor that sometimes causes fatigue.

Usually, however, fatigue is caused by changes in cell function and molecular function in the exercising muscles, explaining why the overwhelming focus of modern fatigue research is on cellular-molecular mechanisms (see Box 8.2). As discussed in Chapter 20, the excitation of muscle contraction entails ion fluxes across cellular and intracellular membranes mediated by ion transporter proteins, and contraction itself entails interactions among the contractile proteins, ATP, and other cellular molecules. Disruption of any of these constituents has the potential to diminish a muscle cell’s ability to develop force and maintain power output. For instance, during the sort of sustained exercise discussed in the last paragraph, part of the cause of fatigue seems to be a gradual accumulation of critical ions (e.g., Ca^{2+}) in wrong cellular locations as a consequence of the ion fluxes involved in muscle excitation. Some fatigue mechanisms at the cellular-molecular level may be protective: Their most fundamental effect may be to interrupt or slow exercise-induced changes in the functional status of muscle cells—changes that could do permanent damage if permitted to progress without limit.

The muscle fibers in the muscles used for locomotion are heterogeneous in functional properties

The muscle tissue of an animal is typically heterogeneous in its metabolic and contractile properties. In vertebrates, for example, several different types of muscle fibers (muscle cells) occur in skeletal muscle. Two of the principal types in mammals are termed **slow oxidative (SO)** fibers and **fast glycolytic (FG)** fibers. The SO fibers are called *slow* because they contract and develop tension relatively slowly, in contrast to the FG fibers, which are *fast* in contracting and developing tension (see Table 20.2). The SO fibers are called *oxidative*, whereas the FG fibers are called *glycolytic*, because of differences in the physiology of their ATP production. The SO fibers are poised principally to make ATP by aerobic catabolism; they have high levels of key enzymes specific to aerobic catabolism, such as succinic dehydrogenase (a Krebs-cycle enzyme), and are well endowed with mitochondria. The FG fibers, by contrast, are poised principally to make ATP anaerobically; they are high in enzymes of anaerobic glycolysis, such as lactate dehydrogenase, and are relatively sparse in mitochondria.

Correlated with the differences in the catabolic pathways they use, the SO and FG fibers differ in how readily they can take up and store O_2 . SO fibers are relatively rich in myoglobin, which not only helps store O_2 within the fibers but also aids diffusion of fresh O_2 into the fibers. FG fibers are low in myoglobin. Because of the difference in myoglobin, SO fibers are reddish in color, whereas FG fibers are whitish, explaining why the SO fibers are sometimes called *red* fibers, and the FG fibers *white*.

SO and FG fibers also differ in their power-generation and fatigue properties in ways that correlate with the features already discussed. The properties of SO fibers are predictable from the fact that they mainly use steady-state aerobic catabolism to make ATP: Although SO fibers have relatively low peak mechanical-power outputs (see Table 8.1), they are relatively resistant to fatigue and readily sustain work over long periods. FG fibers represent the opposite extreme. They can generate a high power output, but they

rely strongly on nonsteady-state mechanisms of ATP production, accumulate lactic acid, and fatigue quickly.

In mammals, major skeletal muscles are typically built of mixes of intermingled SO fibers, FG fibers, and other fiber types (see Chapter 20). Fish, by contrast, often have large muscle masses composed principally of a single type of muscle fiber similar to the mammalian SO or FG fibers; thus entire blocks of muscle in fish are red or white and exhibit the performance properties of red or white fibers.

The Interplay of Aerobic and Anaerobic Catabolism during Exercise

When animals engage in exercise, their performance typically reflects the underlying mechanisms that they are using to produce the ATP required. Fish that are cruising about at relatively leisurely speeds, for example, do so with their red swimming muscles, employing steady-state aerobic catabolism to make ATP. Cruising, therefore, can be sustained for long periods. However, fish that engage in sudden, intense exertion—such as cod avoiding a trawling net or salmon leaping waterfalls—use their white swimming muscles and anaerobic glycolysis to generate the high power they require.¹⁵ They thus accumulate lactic acid, and if they must perform repeatedly in a short time, they are in danger of the sort of fatigue associated with lactic acid.

Crustaceans similarly illustrate that exercise performance reflects the underlying mechanisms of ATP production. When crayfish, lobsters, and crabs walk or cruise about at modest, sustainable speeds, they produce ATP by steady-state aerobic catabolism. When a crayfish or lobster employs tail flipping to power itself rapidly away from danger, however, the tail muscles require ATP at a greater rate than aerobic catabolism can provide. Thus the muscles turn to mechanisms that can produce ATP at exceptionally high rates. In species of crayfish studied in detail, the tail muscles exhibit high levels of arginine kinase and lactate dehydrogenase—enzymes instrumental in anaerobic ATP production—and low levels of aerobic catabolic enzymes. The primary mechanism of ATP production at the start of escape swimming by tail flipping is use of the phosphagen arginine phosphate. Later, if tail flipping continues, anaerobic glycolysis—producing lactic acid—is brought into ever greater play to meet the ATP demands of the tail muscles. Because both of these mechanisms are nonsteady-state and self-limiting, tail flipping cannot be sustained for long.

A huge amount of information exists on lactic acid concentrations in relation to fatigue. Although lactic acid is not the *cause* of fatigue, it is nonetheless often a useful, readily measured *index* of cell conditions causing fatigue. As a practical index, animals are often considered to have an upper limit of lactic acid accumulation. According to this view, after one bout of exercise has caused a buildup of lactic acid, a closely following second bout is limited in the degree to which anaerobic glycolysis can be used because newly made lactic acid adds to the preexisting amount. A human example is provided by athletes who compete in two burst-type races in a single track meet; performance

in the second race is often impaired if lactic acid accumulated in the first race has not yet been fully metabolized. Clearing lactic acid from the body takes tens of minutes in mammals and can take hours in poikilotherms. For animals in nature, the slow rate of removal of lactic acid may well mean that an animal is impaired for a substantial time in its ability to pursue prey or escape danger. These important behavioral consequences are additional manifestations of the high degree of relevance of the biochemistry of ATP production.

Some types of animals follow patterns that are different from those of vertebrates and crustaceans. Insects are the most dramatic and important example. Insect flight muscles typically have little or no ability to make ATP anaerobically and remain fully aerobic even when they suddenly increase their power output, as at the onset of flight. Correlated with the fact that virtually all flight-muscle work is aerobic, insect flight muscles contain very high levels of aerobic catabolic enzymes, and sometimes half of their tissue volume is mitochondria! The flight muscles of certain insects, in fact, are the most aerobically competent of all animal tissues as judged by the rate per gram at which they can synthesize ATP by aerobic catabolism. A characteristic of insects that helps explain their aerobic fueling of burst exercise is their tracheal breathing system, which provides O₂ directly to each flight-muscle cell by way of gas-filled tubes (see page 612).

Other, less dramatic, differences from the vertebrate and crustacean pattern are found in other animal groups. For example, when molluscs such as squids, octopuses, and scallops use anaerobic catabolism during burst swimming, their swimming muscles reduce pyruvic acid to *octopine* rather than lactic acid. The octopine-generating anaerobic pathway provides a high rate of ATP synthesis, as in vertebrates, but has different detailed biochemical implications.

Underlying much of scientific thinking about exercise in the wild is an assumption that a high capacity for exercise performance is of advantage for survival and reproduction—meaning that a high capacity for performance is favored by natural selection. Although some tests of this hypothesis have not obtained positive results, direct evidence is in fact accumulating that, in a state of nature, individual animals of a single species vary in exercise performance and this variation affects their survival and reproductive success as hypothesized. An example is provided by male collared lizards (*Crotaphytus collaris*) in the context of territorial defense—a circumstance in which they employ sudden, high-speed running to exclude intruders and otherwise defend territories within which they mate with females. The burst running they employ in this context almost surely depends largely on ATP produced by anaerobic glycolysis because (see Table 8.1), in such running, they accelerate almost instantly and achieve high work intensities. Individual males vary substantially in how fast they can cover distance during burst running, from about 3 to 5 m/s. Investigators measured the burst running speeds of 16 males in a free-living population. Then they used genetic paternity testing to determine the number of offspring fathered by each. They found a statistically significant trend for the faster males to father more offspring (Figure 8.9).

Metabolic transitions occur at the start and end of vertebrate exercise

Multiple metabolic processes are involved in the provision of ATP for vertebrate exercise of all types. Details depend on the intensity

¹⁵When we speak of red and white muscles in this context, we are referring to the distinction between the myoglobin-rich, SO-like muscles and the myoglobin-poor, FG-like muscles discussed in the previous section. This is an entirely different matter from the overall hue of a fish's muscle tissue, whether off-white in a cod or orange in a salmon.

FIGURE 8.9 Modern genetic paternity testing reveals that the number of offspring sired by male collared lizards (*Crotaphytus collaris*) depends directly on how fast they can sprint. Each symbol represents one male in a free-living population. Males defend territories where they mate with females. The defense of a territory depends in part on sudden, high-intensity running to repel male invaders or meet other threats. (After Husak et al. 2006.)

of exercise, which is usefully indexed by comparison with an individual's maximal rate of aerobic catabolism. A given individual in a particular state of training is capable of a certain maximal rate of O_2 consumption.¹⁶ Exercise that requires exactly this maximum is classified as **maximal exercise**. Exercise that requires less than the maximal rate of O_2 consumption is called **submaximal exercise**, and exercise that requires more than an individual's maximal rate of O_2 consumption is called **supramaximal exercise**.

Consider a bout of submaximal exercise that starts and ends abruptly, requires about 80% of an individual's maximal rate of O_2 consumption, and lasts 30 min or so. Let's assume we are talking about a person who is running, although the principles we will develop apply to all or most vertebrates. **Figure 8.10a** shows how the person's rate of O_2 consumption by breathing would change during this bout of exercise if *all* ATP were made on a moment-by-moment basis by aerobic catabolism using environmental O_2 . The person's rate of O_2 consumption would increase stepwise at the start of running and decrease stepwise at the end.

Actually, however, during this type of exercise, a person's rate of O_2 uptake by breathing changes as shown by the red line in **Figure 8.10b**. In the middle of the bout of exercise, the person's actual rate of O_2 uptake matches the theoretical O_2 demand of the exercise. However, there is a transition phase at the start of the exercise, when the person's actual rate of O_2 uptake is lower than the theoretical O_2 demand, and there is another transition phase at the end when the person's actual rate of O_2 uptake exceeds the theoretical O_2 demand.

THE TRANSITION PHASE AT THE START: THE OXYGEN DEFICIT The reason for the transition phase at the start of the exercise we are considering is the fact, already mentioned, that the respiratory and circulatory systems in vertebrates do not instantly increase the rate at which they deliver O_2 to the body. Instead, even if *exercise starts abruptly*, O_2 delivery to the tissues increases *gradually*. In people, 1–4 min are required for the pulmonary and circulatory systems to accelerate fully. During the period when the pulmonary and circulatory systems are accelerating their actual rate of O_2 delivery at the start

of a bout of exercise, the body's supply of O_2 from the environment (actual O_2 uptake) is less than its theoretical O_2 demand for the exercise. This difference is termed an **oxygen deficit** (see **Figure 8.10b**).

During the period of the oxygen deficit, the full ATP demand of exercise is *not* met by aerobic catabolism based on environmental O_2 . Where, then, does the other ATP come from? In the sort of exercise we are discussing, the answer is that ATP is contributed during the period of oxygen deficit by anaerobic glycolysis, use of phosphagen, and use of O_2 stores.¹⁷ These three mechanisms, in fact, are *essential* for exercise to start in a *stepwise* way. They make up for the slow acceleration of ATP production by aerobic catabolism based on environmental O_2 . They thereby permit the *overall* rate of ATP production to increase abruptly to a high level when exercise begins.

THE PAY-AS-YOU-GO PHASE During the exercise we are discussing or any other sort of submaximal exercise, the pulmonary and circulatory systems ultimately accelerate their rate of O_2 delivery sufficiently to meet the full O_2 demand of the exercise. The exercise is then said to enter a **pay-as-you-go phase** (see **Figure 8.10b**) because thereafter its full O_2 cost is met on a moment-to-moment basis by use of O_2 taken up from the environment by breathing. With all ATP being made by steady-state aerobic catabolism, the exercise can in principle be sustained indefinitely.

The onset of the pay-as-you-go phase in submaximal exercise occurs soon enough, in general, to prevent biochemical self-termination of anaerobic glycolysis, use of phosphagen, and use of O_2 stores. Although those three mechanisms are susceptible to self-termination, they are not called upon for long enough in this sort of exercise to reach their inherent limits.

THE TRANSITION PHASE AT THE END: EXCESS POSTEXERCISE OXYGEN CONSUMPTION At the end of the exercise we are describing, the exercising person suddenly stops running, but thereafter his or her actual rate of O_2 uptake does not suddenly drop in stepwise fashion. Instead, it declines gradually, remaining above the resting rate of O_2 consumption for many minutes (see **Figure 8.10b**). This elevation of the actual rate of O_2 uptake above the resting rate of O_2 uptake—even though the person is behaviorally at rest—is termed **excess postexercise oxygen consumption (EPOC)**. In everyday language, people describe the EPOC as “breathing hard” after exercise.¹⁸ The EPOC has multiple causes, and the reasons for it are not fully understood at present.

THE TRANSITION PHASES VARY IN THEIR NATURE DEPENDING ON THE INTENSITY OF EXERCISE Different intensities of exercise in vertebrates produce different sorts of transition phases. For

¹⁷ Anaerobic glycolysis, use of phosphagen, and use of O_2 stores are sometimes termed the *mechanisms of oxygen deficit*. In vertebrates, the three are subdivided into two categories. Anaerobic glycolysis is the **lactacid** mechanism of oxygen deficit because it produces lactic acid. Phosphagen use and the use of O_2 stores are the **alactacid** mechanisms of oxygen deficit.

¹⁸ For several decades in the mid-twentieth century, the EPOC was called *oxygen debt*. That term has been discredited, however, because it was based on an assumption that the cause of the EPOC is simply the need to metabolize lactic acid. Actually, there is often a nearly total lack of correspondence between the time course of the EPOC and the time course of lactic acid metabolism in vertebrates. The term *EPOC* is preferred over *oxygen debt* because it is functionally neutral and implies no particular mechanistic explanation.

¹⁶ See Chapter 9 for an extensive discussion of the maximal rate of O_2 consumption and its determinants.

FIGURE 8.10 The concepts of oxygen deficit and excess postexercise oxygen consumption

(a) The rate of O_2 demand of a person who is initially at rest, suddenly starts vigorous submaximal exercise, continues for 30 min or so, and then suddenly stops, assuming unrealistically that all ATP is produced aerobically, using atmospheric O_2 , at all times. (b) The actual rate of O_2 uptake from the environment (red line) of the person in (a), showing that there is an initial transition period during which the full ATP demand is not met by O_2 uptake, then a period when O_2 uptake matches the full O_2 demand, and finally a transition period when the person's actual rate of O_2 uptake exceeds the resting rate even though the person is at rest.

(a) Theoretical rate of O_2 consumption assuming that, moment-by-moment, all ATP is made using O_2 from the atmosphere

example, if a vertebrate undertakes *light submaximal* exercise that requires less than 50–60% of the individual's maximal rate of O_2 consumption, transition phases occur at the start and end, as shown in **Figure 8.11a**, but lactic acid does not accumulate at these exercise intensities. Without a lactic acid accumulation, the only processes required to “reinitialize” the body at the end of exercise are the replenishing of O_2 stores and phosphagen stores, both of which occur very rapidly (see Table 8.1).

In *heavy submaximal* exercise that requires more than 50–60% of maximal O_2 consumption (**Figure 8.11b**), net accumulation of lactic acid occurs at the start. Accordingly, lactic acid must be metabolized at the end—a long process. The EPOC lasts longer than in light submaximal exercise.

The most dramatic transition phases occur during *supramaximal* exercise (**Figure 8.11c**). Such exercise demands ATP at a greater rate than can *ever* be supplied by steady-state aerobic catabolism. Thus a pay-as-you-go phase is never reached, and anaerobic glycolysis must continue to be tapped for ATP for as long as the exercise continues—causing a steadily increasing oxygen deficit and buildup of lactic acid. *Supramaximal exercise is the principal form of exertion in which lactic acid accumulates to such high levels that the profound, debilitating, “lactic acid type” of fatigue occurs.* In fact, unless an individual electively stops exercising, supramaximal exercise typically undergoes metabolic self-termination within minutes. Then, associated with the large accumulation of lactic acid, a long time is required for the body to recover, during which the individual's capability for further supramaximal exertion is impaired.

The ATP source for all-out exercise varies in a regular manner with exercise duration

If you consider human competitive running and reflect on the progression from a sprint to a mile race to a marathon, you will notice that as the duration of all-out exertion increases, the pace slows. Mile races are run slower than sprints, and marathons are run slower than mile runs. This trend in performance, which is a fairly general property of animal exercise, is a *direct reflection of the biochemistry of ATP production.*

(b) Actual rate of O_2 consumption compared with theoretical

In a person or other vertebrate, when all-out exertion lasts 10 s or so, the total amount of ATP needed, from start to finish, is relatively small (simply because ATP must be provided for only a short time). This means that anaerobic glycolysis, phosphagen, and O_2 stores can in principle meet the full ATP requirement. In actual practice, when people run the 100-yard dash (or 100-m dash), these three mechanisms of ATP production meet at least 90% of the ATP cost; some champions hold their breath from start to finish! Anaerobic glycolysis and the use of phosphagen and O_2 stores—while unable to make a great quantity of ATP—are able to produce ATP at exceptionally high *rates* (see Table 8.1). Thus, when these mechanisms are sufficient to meet most of the cost of running, the pace of running can be very fast, as it is in the 100-yard dash.

In a mile race (about the same as a 1500-m race), the total ATP requirement is much greater than in a 100-yard dash. Even if anaerobic glycolysis, phosphagen, and O_2 stores are fully exploited to make as much ATP as they possibly can during a mile race, they cannot meet more than 25–50% of the total ATP need. The rest of the ATP must be made by steady-state aerobic catabolism using O_2 from the environment, a mechanism that cannot produce ATP as fast as the other mechanisms (see Table 8.1). Thus, taking into account the rates of all the processes that are required to contribute ATP during a mile race, the overall rate of ATP production is lower than that during a 100-yard dash. The pace of the mile must therefore be slower. The pace

KEY

- Theoretical O₂ demand
- Actual O₂ uptake from environment
- Oxygen deficit
- Excess postexercise oxygen consumption

FIGURE 8.11 Stylized O₂ supply–demand diagrams for light submaximal, heavy submaximal, and supramaximal exercise. The format is as in Figure 8.10. The patterns illustrated are those observed in mammals. Two important determinants of exercise performance are an individual's maximal rate of O₂ consumption and maximal oxygen deficit. Both are increased by repeated exercise, thereby increasing performance. A person, for example, might increase his or her maximal rate of O₂ consumption by 10–30% through appropriate training.

of a marathon must be slower yet because the total ATP requirement of a marathon is so great that only 2–3% of it can be met by use of anaerobic glycolysis, phosphagen, and O₂ stores. In the marathon, *almost all* the ATP is made by steady-state aerobic catabolism, limiting the pace to that which is permitted by that mechanism.

Figure 8.12 shows how the mechanisms of ATP production during all-out exertion vary with the duration of exertion in world-class competitive runs. The red line depicts the speed of running as a function of duration. The subdivision of the space below the red line shows how ATP is made. With increasing duration, ATP production shifts from being principally anaerobic (based on phosphagen and anaerobic glycolysis) to being chiefly aerobic. Moreover, at marathon and ultramarathon distances, aerobic catabolism shifts from exclusive use of carbohydrate fuels toward substantial use of lipid fuels, which permit only a lower rate of ATP synthesis than carbohydrate fuels (see Table 8.1).

The fraction of the vertical distance between the red line and the x axis that falls within each category of ATP production corresponds to the fraction of ATP made by each mechanism of production.

Most ATP is made by anaerobic glycolysis and use of phosphagen in short-duration events, whereas...

...essentially all ATP is made by aerobic catabolism in long-duration events.

FIGURE 8.12 The mechanisms of meeting the ATP costs of world-class competitive running. The red line shows the average pace of races as a function of the length of time the pace is maintained, based on world records for men in the specified competitive events. The space below the red line shows the approximate fraction of ATP made by aerobic catabolism, anaerobic glycolysis, and use of creatine phosphate. For simplicity, synthesis of ATP by use of O₂ stores is not shown as a separate category. (Data on ATP after Newsholme et al. 1992.)

Trends similar to those in Figure 8.12 apply to vertebrates living in the wild. Thus ecologically relevant performance depends in a regular way on the biochemical mechanisms by which ATP is made. As the primary mechanism of ATP synthesis shifts from phosphagen use to anaerobic glycolysis and then to aerobic catabolism based on carbohydrate and lipid fuels, the pace slows.

Related species and individuals within one species are often poised very differently for use of aerobic and anaerobic catabolism

Related species sometimes have evolved very different emphasis on aerobic and anaerobic ATP production during intense exertion, and these differences can have important life-history consequences. Thus the biochemistry of ATP production is one of the ways that species become specialized to live as they do.

The terrestrial amphibians we briefly noted in Chapter 2 (see Figure 2.10) provide a classic illustration. Some species, such as the common leopard frog (*Rana pipiens*) and many other ranid and hylid frogs, have a biochemistry that emphasizes anaerobic glycolysis as the principal mechanism of ATP production during all-out exertion. If you chase a leopard frog, at first the frog flees by jumping away very rapidly, but within a few minutes it collapses in fatigue. Both the high speed of the initial jumping and the quick fatigue reflect the emphasis on anaerobic glycolysis to make ATP. Many of the bufonid toads, such as the western toad (*Bufo boreas*), exemplify the opposite extreme. The toads have a biochemistry that emphasizes aerobic production of ATP during all-out exertion. When chased, they do not flee as quickly as leopard frogs, but they can continue jumping at a steady pace for a long time. Both their slow speed and their resistance to fatigue reflect the aerobic fueling of their exercise. Lactate dehydrogenase (LDH) represents a key respect in which the frogs and toads differ; the leg muscles of the frogs express LDH at higher concentration than those of the toads.

A parallel, and very dramatic, example is provided by species of fish. The skipjack tuna (*Katsuwonus pelamis*) is a supremely active species of fish. The activity of LDH in its white swimming muscles is more than 1000 times higher than the LDH activity observed in sluggish species of fish.¹⁹ The tuna is thereby able to engage in exceptionally intense burst exercise.

At a different scale, individuals within a single species are often poised differently for use of aerobic and anaerobic catabolic pathways. A particularly intriguing example of this sort of variation is that humans vary widely in the fiber composition of their muscles, as illustrated in Figure 8.13. The swimmer competes in sprints that require intense exertion for short periods. The cyclist, however, competes in sustained cycling races. Small pieces of tissue were removed from identical thigh muscles of the two men and subjected to a histochemical procedure that darkly stains slow oxidative (SO) muscle fibers. The images to the right in Figure 8.13 show that few of the muscle fibers of the swimmer are SO fibers, whereas most of the fibers of the cyclist are SO fibers. Most researchers believe that differences of this specific sort (percentage of SO fibers) are relatively fixed. That is, people like the cyclist, it is thought, have principally SO fibers from early childhood. They discover through

FIGURE 8.13 Two top athletes who differ in the fiber composition of their thigh muscles (a) The swimmer competes in 50-m sprints. (b) The cyclist competes in long-distance races. Shown to the right of each man is a microscopic section of his *vastus lateralis*, a thigh muscle, stained to make slow oxidative (SO) fibers dark. The sections are labeled with a different nomenclatural system from the one we use in this chapter: I = SO fibers; II = either FG fibers or other fast-contracting fibers. (From Billeter and Hoppeler 1992; courtesy of Rudolf Billeter-Clark and Hans Hoppeler.)

experience that their muscles, although not extremely powerful, are resistant to fatigue; and if such people are inclined toward athletic competition, they choose sports such as long-distance cycling that are well served by SO muscle fibers. In contrast, people like the swimmer, whose muscles are low in SO fibers and presumably high in fast glycolytic (FG) fibers, gravitate toward sports such as sprint swimming in which high power—rather than long-term endurance—is a key to success.

SUMMARY The Interplay of Aerobic and Anaerobic Catabolism during Exercise

- Behavior and biochemistry are linked during physical activity because attributes of performance depend on how the ATP for muscular effort is synthesized.

¹⁹ Enzyme **activity** is measured as the maximum rate at which substrate can be converted to product by a unit weight of tissue.

- Submaximal forms of exercise can be supported entirely (except during transition phases) by aerobic catabolism using O_2 taken in from the environment by breathing. From the viewpoint of ATP supply and demand, submaximal forms of exercise can thus be sustained indefinitely.
- Supramaximal forms of exercise in vertebrates, crustaceans, and some other animals require a continuing input of ATP from anaerobic glycolysis. The steady use of anaerobic glycolysis—manifested by a steady accumulation of lactic acid—eventually causes metabolic self-termination of the exercise.
- In vertebrates, metabolic transitions occur at the start and the end of even light submaximal exercise. An oxygen deficit occurs at the start, and excess postexercise oxygen consumption (EPOC) occurs at the end. The oxygen deficit is a consequence of the fact that the respiratory and circulatory systems increase O_2 delivery gradually, not stepwise, at the start of exercise, meaning that ATP-producing mechanisms that do not require circulatory O_2 delivery must participate in getting exercise started.
- As the duration of all-out exertion increases, ATP must increasingly be supplied by steady-state aerobic catabolism, rather than by nonsteady-state mechanisms that can produce ATP exceptionally rapidly but cannot produce a great deal of it. The pace of all-out exertion therefore declines as duration increases.
- Closely related species, and even individuals within one species, often differ greatly in their emphasis on aerobic and anaerobic mechanisms of producing ATP for exercise. These metabolic differences help explain differences in exercise performance.

Responses to Impaired O_2 Influx from the Environment

In addition to vigorous exercise, impaired O_2 influx from the environment is the second major reason that animals turn to anaerobic catabolic pathways to make ATP. Many animals experience reduced O_2 influx from their environments during parts of their lives. The situation can arise in two ways. First, O_2 influx may be reduced because the concentration of O_2 in the environment is low. Alternatively, animals may enter environments in which they cannot breathe, as when seals or whales dive. Under either set of conditions, it is common for at least some tissues to experience **hypoxia** or **anoxia**, defined respectively to be an especially low level of O_2 in tissues or an absence of O_2 in tissues.

Metabolic depression occurs in some animals when they are faced with reduced O_2 influx. **Metabolic depression** is a regulated reduction in the ATP needs of an animal (or specific tissue) to levels below the needs ordinarily associated with rest in a way that does not present an immediate physiological threat to life. Brine shrimp embryos, for example, switch to a very low rate of metabolism—which they can sustain for long periods—when deprived of O_2 (Figure 8.14). Study of the mechanisms of metabolic depression is in its infancy. In some cases, key, rate-limiting enzymes are downregulated—as by covalent modulation (e.g., enzyme phosphorylation)—or numbers of mitochondria decline. The hypoxia inducible factor-1 (HIF-1) control system is often involved (see Box 23.1), as are other control systems.

Animals must turn to anaerobic catabolic pathways to make ATP during anoxia, and they often use such pathways to help make ATP during hypoxia. When vertebrates—even species specially adapted

FIGURE 8.14 Metabolic depression in an invertebrate faced with anoxia Metabolic rate was quantified directly, by measurement of heat production. Two groups of embryos of brine shrimps (*Artemia*)—represented by the two lines—were studied. They were living in water near equilibrium with the atmosphere at the start of the experiment. Then, at the time marked “No O_2 ,” they were switched into O_2 -free water. The embryos were exposed to ammonia while in O_2 -free water, as a way of raising their pH. Their response to ammonia supports the hypothesis that metabolic depression in the embryos is partly dependent on a low pH. The drawing shows an adult brine shrimp. (After Hand and Gnaiger 1988.)

to low- O_2 conditions—turn to anaerobic catabolism, they almost universally produce lactic acid,²⁰ which they never excrete. In sharp contrast, invertebrates adapted to life without influx of O_2 rarely produce lactic acid. Instead, they usually employ anaerobic catabolic pathways that are more elaborate than anaerobic glycolysis and that yield a variety of different products, which often are excreted. All anaerobic catabolic pathways produce far less ATP per food molecule than aerobic catabolism does. Thus, when animals turn from aerobic to anaerobic catabolic pathways as their means for *long-term* ATP production, they are in a biochemically diminished position to make ATP. Metabolic depression helps with this situation because it reduces the rate at which animals *need* ATP.

Air-breathing vertebrates during diving: Preserving the brain presents special challenges

Most vertebrate brains are obligatorily aerobic; they must have O_2 . When air-breathing vertebrates dive for extended periods, therefore, the management of brain status is of special interest and concern.

In diving species of mammals and birds, most dives are kept short enough that the ATP needs of all tissues can be met aerobically using stored O_2 . Dives of exceptionally long duration, however, cause these vertebrates to resort to anaerobic glycolysis. The animals then metabolically subdivide their bodies (see Chapter 26 for details). They ensure continuing O_2 delivery to their brain by reserving certain of their O_2 stores for the brain, while simultaneously they deprive large portions of their bodies of O_2 delivery; the latter parts run out of O_2 and become dependent on anaerobic glycolysis. Diving crocodilians, sea turtles, lizards, and most freshwater and terrestrial turtles must also keep their brains aerobic.

Certain species of freshwater and terrestrial turtles, however, are dramatic exceptions in that they can tolerate total-body anoxia—*full*

²⁰ A few vertebrate species, notably two species of fish discussed later, are exceptions.

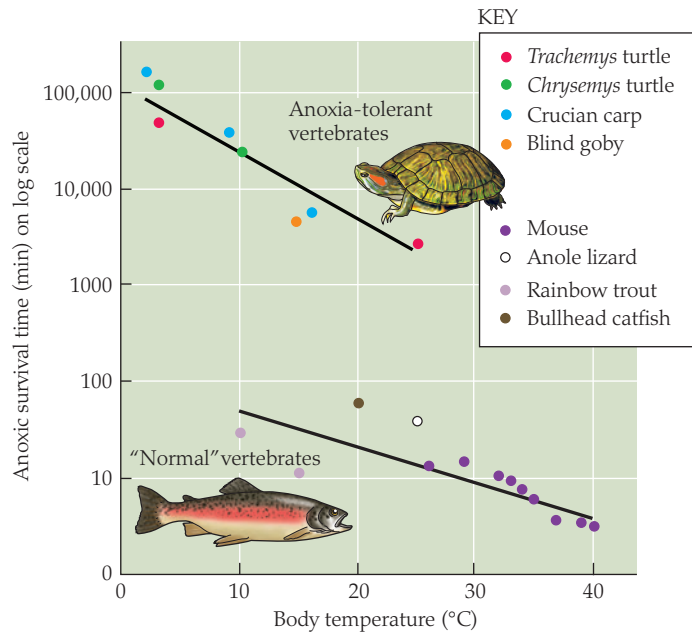

FIGURE 8.15 Survival times during anoxia in vertebrates as a function of body temperature Note that the survival times are plotted on a logarithmic scale. (After Nilsson and Lutz 2004.)

O_2 depletion of all tissues, including the brain—during protracted dives. These turtles are able to dive for exceptionally long periods. Figure 8.15 shows the lengths of time that various vertebrates can survive anoxia. Survival times are plotted against body temperature because there is a strong inverse relation between survival time and tissue temperature. Anoxia-tolerant turtles in which the brain can survive without O_2 , such as those in the genera *Trachemys* and *Chrysemys*, are able to survive about 1000 times longer at any given body temperature than most other vertebrates.

An informative way to understand the implications of brain anoxia in diving turtles is to look briefly at the threat anoxia poses to vertebrate central nervous tissue. In mammals, catastrophe strikes when the brain is deprived of O_2 because the ATP requirement of mammalian brain cells per unit of time far exceeds the rate at which those cells can make ATP by anaerobic means. Within seconds after O_2 influx to the mammalian brain is cut off, the concentration of ATP in brain cells starts to fall precipitously. Soon, ATP-dependent ion pumps (e.g., $Na^+-K^+-ATPase$) are unable to pump ions across the cell membranes rapidly enough to maintain normal membrane polarization. The cell membranes thus depolarize, with numerous cataclysmic consequences; for instance, nerve impulses (action potentials) become impossible, and voltage-gated Ca^{2+} channels are inappropriately triggered to open, allowing Ca^{2+} to flood into the cells in quantities that inappropriately and disastrously trigger a variety of Ca^{2+} -mediated responses.

The turtles that tolerate brain anoxia employ metabolic depression of the brain as a key mechanism of maintaining the integrity of their brain tissue during anoxia. Synaptic transmission between brain cells is suppressed in the absence of O_2 , and ion-mediated bioelectrical activity of cells is reduced so that the brain becomes electrically relatively silent. This response has a significant cost: The turtles cease to be behaviorally alert. They become comatose. Because of this response, however, the brain ion pumps have

much less work to do to maintain normal ion distributions and cell-membrane polarization. The ATP requirement of maintaining tissue integrity is lowered, anaerobic glycolysis is able to meet the ATP requirement, and brain ATP concentrations do not fall. With its entire body anoxic, a turtle accumulates lactic acid, which can reach extraordinary concentrations during prolonged anoxia. The shell and the bones of a turtle play key roles in preventing lethal acidification under these circumstances, by buffering the acid.²¹

Animals faced with reduced O_2 availability in their usual environments may show conformity or regulation of aerobic ATP synthesis

When animals are living in the environments in which they can breathe, such as fish in water or mammals in air, how do their rates of aerobic ATP production change when they are confronted with changes of O_2 concentration in the environmental water or air? As the environmental O_2 level is lowered, the usual pattern is for an animal's rate of O_2 consumption to be unaffected over a certain range of O_2 levels (Figure 8.16a). This maintenance of a steady rate of O_2 consumption (and aerobic ATP production) regardless of the level of O_2 in the environment is termed **oxygen regulation** (see Figure 1.5). It often involves active responses, such as an increase in breathing rate as the O_2 level in the water or air declines. Ultimately, if the environmental O_2 level is lowered further and further, oxygen regulation can no longer continue. Instead, the rate of O_2 consumption starts to fall as the environmental O_2 level falls. This condition is termed **oxygen conformity** (see Figure 8.16a). High altitudes are an intriguing situation in which these concepts apply to human beings (Box 8.3).

When related species are compared under similar test conditions, their abilities for oxygen regulation and conformity often correlate with the types of habitats in which they live. These abilities therefore seem to have evolved in parallel with habitat selection. An illustration is provided by two species of related freshwater fish living in a single Alabama watershed (Figure 8.16b). One species, the redline darter, occurs in fast-flowing streams where O_2 levels tend to be consistently high because turbulence promotes aeration. The other species, the slack-water darter, is found in slow-moving streams where the O_2 concentration may be only one-third as high as in fully aerated water. As the figure shows, the slack-water darter, which often experiences low- O_2 waters, exhibits a much broader range of oxygen regulation than the redline darter, which rarely must cope with low O_2 levels. Indeed, lowering the concentration of O_2 to 40–50% of the fully aerated level causes a sharp depression of O_2 uptake and deaths in redline darters while not affecting the O_2 uptake of slack-water darters at all.

Water-breathing anaerobes: Some aquatic animals are capable of protracted life in water devoid of O_2

Oxygen-free microenvironments are far more common in bodies of water than in terrestrial environments (see Chapter 22), and biologists have discovered quite a few cases of water-breathing aquatic animals that can live in O_2 -free settings because they can function as **anaerobes**, able to survive whole-body anoxia for long periods. Some of the best-studied examples among invertebrates are certain

²¹A parallel phenomenon has recently been discovered in certain crayfish, in which the shell buffers lactic acid produced when the animals are placed in air, where they cannot breathe.

species of clams, mussels, and other bivalve molluscs. Ribbed mussels (*Geukensia demissa*), for example, live in the mud of salt marshes, where they can become buried; they are able to survive in an atmo-

(a) The concepts of oxygen regulation and conformity

(b) Regulation and conformity in two species of related fish

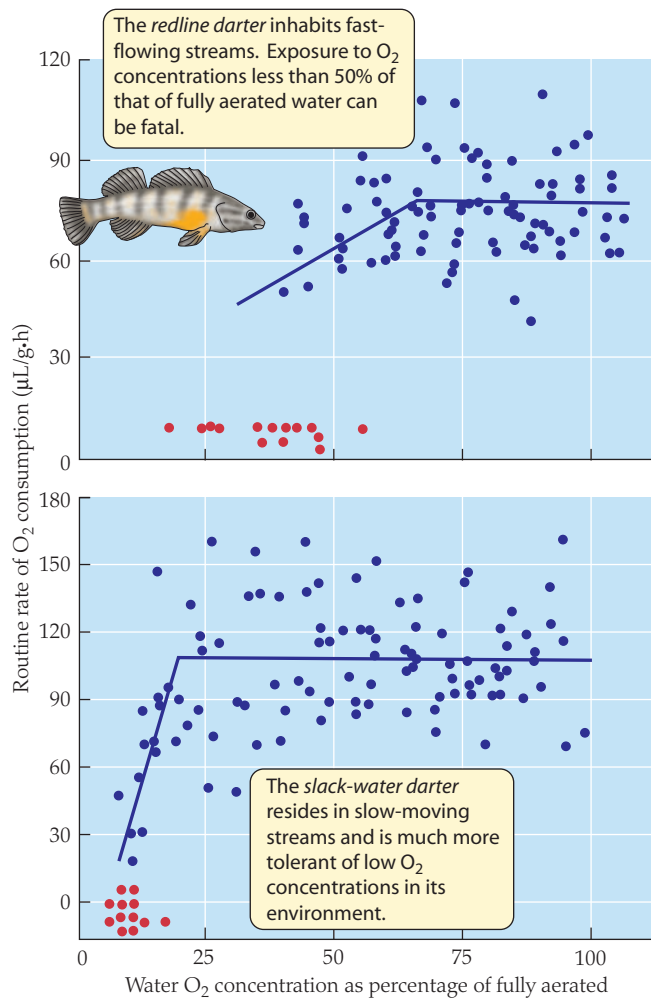

FIGURE 8.16 Oxygen regulation and conformity

(a) The general concepts of oxygen regulation and conformity. (b) Rates of O₂ consumption of two species of fish in the genus *Etheostoma*—the redline darter (*E. rufilineatum*) and the slack-water darter (*E. boschungii*)—during routine activity at 20°C. Red circles mark ambient O₂ levels at which deaths occurred. On the x axis, 100 is the O₂ concentration of water that is at equilibrium with the atmosphere and therefore fully aerated; values higher than 100 were created in some studies by bubbling water with pure O₂. In the technical literature, O₂ levels are expressed as O₂ partial pressures, as explained in Chapter 22. (After Ultsch et al. 1978.)

sphere of pure N₂ for 5 days. Certain marine clams that live in seas prone to O₂ depletion, such as the ocean quahog (*Arctica islandica*), can live for 1–2 months in O₂-free water. Worms and other invertebrates that live at the bottoms of lakes or ponds are other animals that may experience severe and prolonged O₂ deprivation (see Figure 1.14), and some are among the most tolerant to anoxia of all free-living animals. Certain annelid worms (*Tubifex*) that burrow in O₂-free sediments in pond or lake bottoms, for example, have been shown not only to survive but to feed, grow, and reproduce while deprived of O₂ for 7 months!

Anaerobes are rare among aquatic vertebrates. Nonetheless, two species of related cyprinid fish are known to have extraordinary abilities to live without O₂. One of these is the common goldfish (*Carassius auratus*), which is reported to survive in O₂-free water for 11–24 h at 20°C and 1–6 days at 10°C. No wonder goldfish survive the tender loving care of 5-year-olds! The second species, which is even more tolerant of anoxia than the goldfish, is the crucian carp (*Carassius carassius*), a common inhabitant of northern European ponds. It can survive without O₂ for several months at temperatures below 10°C (see Figure 8.15)! The ability of crucian carp to live without O₂ permits them to evade predators by living in ponds that become O₂ depleted, where the predators die. Their physiology, therefore, is a key to their ecological success.

For both invertebrate and vertebrate aquatic anaerobes, metabolic depression (see Figure 8.14) is typically a key strategy used to survive anoxia. Table 8.2 presents data on metabolic depression in goldfish. Although their O₂ consumption falls to zero during anoxia, direct measurements of heat production show that metabolism continues, but it does so at a highly depressed rate. This metabolic depression in goldfish is in fact relatively modest. Metabolic rates only 1–10% as high as ordinary are observed in several species of annelids and molluscs exposed to anoxia. Metabolic depression lowers ATP requirements and thus relaxes demands on the ATP-producing mechanisms that are available to make ATP in the absence of O₂.

MECHANISMS OF INVERTEBRATE ANAEROBIOSIS The most common principal products of the anaerobic biochemical pathways used for ATP synthesis by invertebrate aquatic anaerobes are acetic acid, succinic acid, propionic acid, and the amino acid alanine. These products obviously signal that the biochemical pathways

TABLE 8.2 Average rates of O₂ consumption, heat production, and carbohydrate use in goldfish (*Carassius auratus*) before and during exposure to anoxia at 20°C

Note that although metabolic rate decreases in anoxia, the rate of use of carbohydrate stores increases because production of ATP is far less efficient by anaerobic glycolysis than by aerobic catabolism.

Property measured ^a	At normal O ₂ levels	After 3 h of anoxia	After 8 h of anoxia
Oxygen consumption (mmol/kg·h)	1.51	0	0
Heat production (J/ kg·h)	709	203	206
Carbohydrate catabolism (mg/kg·h)	43	221	234

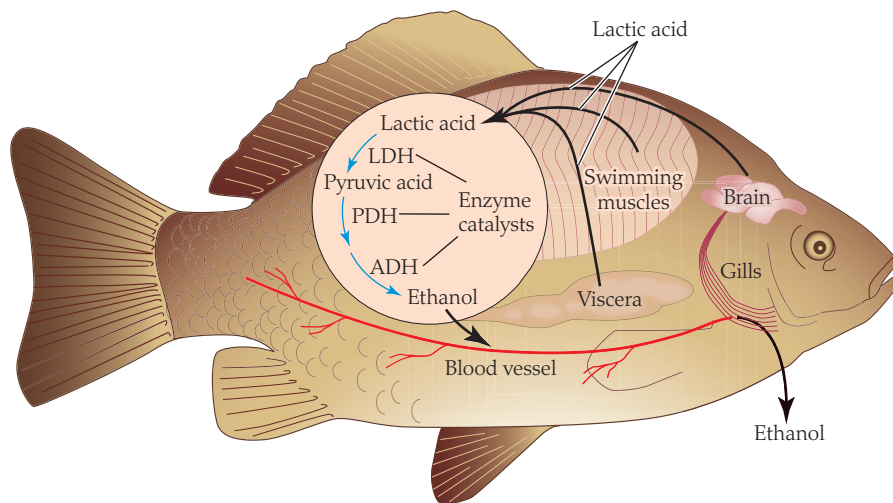

Source: van Waversveld et al. 1989.

^aAll rates are expressed per kilogram of adjusted body weight. Adjusted weights were calculated in a way intended to remove allometric effects of different body sizes.

of anaerobic catabolism in these animals differ from simple anaerobic glycolysis. The pathways are elaborate. They often permit the animals to catabolize anaerobically not only carbohydrates but also other classes of food molecules, notably amino acids, and they typically yield more ATP per food molecule than anaerobic glycolysis does. A challenge that all the pathways must meet to be biochemically viable is that redox balance must be maintained without O_2 . Invertebrate anaerobes often excrete their anaerobic end products or derivatives of them. Excretion wastes the energy value of the carbon compounds excreted, but it helps limit acidification of the body fluids and helps prevent self-limitation of the ATP-generating mechanisms, allowing the animals to sustain all their vital functions in the absence of O_2 for protracted periods.

MECHANISMS OF ANAEROBIOSIS IN GOLDFISH AND CRUCIAN CARP The goldfish and crucian carp provide a possibly amusing end to this chapter because they raise the question of whether certain animals are constantly drunk. Of all vertebrate animals, these fish are the most proficient known anaerobes because not only do they survive without O_2 for long periods (see Figure 8.15), but also, unlike the turtles we discussed earlier, they remain conscious and capable of responding behaviorally to their environments.

The *swimming muscles* of these fish possess biochemical specializations, including an unusual form of the enzyme alcohol dehydrogenase, a form that strongly favors the formation of etha-

nol under prevailing tissue conditions. All the tissues of the fish, including the brain, synthesize ATP by anaerobic glycolysis and produce lactic acid during anoxia. The swimming muscles convert this lactic acid (some of it brought to the muscles from the other tissues) to ethanol and CO_2 . The production of ethanol does not increase ATP yield. Rather, its principal advantage is believed to be that it makes possible the *excretion* of the carbon chains produced by anaerobic glycolysis. Unlike lactic acid, ethanol is lost across the gills into the water that the fish inhabit (Figure 8.17). This excretion limits end-product accumulation and body-fluid acidification, thereby helping to prevent self-limitation of the ATP-generating mechanisms.

BOX 8.3 HUMAN PEAK O_2 CONSUMPTION AND PHYSICAL PERFORMANCE AT HIGH ALTITUDES

When people (and other mammals) are exposed to decreased atmospheric concentrations of O_2 , they marshal vigorous physiological defenses, discussed in Boxes 23.2 and 24.5. Because of these responses, *resting or moderately active* people show a substantial degree of oxygen regulation as the ambient O_2 level falls with increasing altitude. Here, however, we consider the most demanding of circumstances: the capability of mountaineers for *all-out physical effort* at the highest altitudes on Earth.

As the figure shows, when people are asked to work hard enough that they take in O_2 at their peak rate, their maximal rate of O_2 consumption becomes a smaller and smaller fraction of their rate at sea level as altitude increases. The cost of any particular form of exercise remains the same regardless of altitude, however. Accordingly, a rate of climbing that is distinctly submaximal at low altitudes can become maximal, or even supramaximal, at high altitudes. At altitudes near the top of Mt. Everest (8848 m), the maximal rate of O_2 consumption is so low that even *minimal* rates of climbing require about the *maximal* possible

Maximal rates of O_2 consumption of human mountaineers at increasing altitudes Values are expressed as percentages of the values at sea level. (After Fulco et al. 1998.)

rate of O_2 consumption. Work that requires 100% of a person's maximal rate of O_2 consumption is always extremely taxing: barely possible. When, in 1978, Reinhold Messner and Peter Habeler became the first to reach the summit of Mt. Everest without supplement-

tal O_2 , they reported climbing so slowly near the top that, even though they felt they were working at their limits, they required an hour to cover the final 100 m!

Box Extension 8.3 provides more information on climbing Mt. Everest.

◀ **FIGURE 8.17 Excretion of the end product of anaerobic glycolysis as ethanol** When crucian carp (*Carassius carassius*, shown here) and goldfish are living in O_2 -free water, all tissues—including the brain—make ATP by anaerobic glycolysis from stored glycogen. In most fish, when lactic acid is made, it accumulates in the body. In the crucian carp and goldfish, however, the swimming muscles have an unusual ability to convert lactic acid to ethanol, which then is readily lost across the gills. In the swimming muscles, lactic acid is first converted to pyruvic acid, a reaction catalyzed by lactate dehydrogenase (LDH). Pyruvic acid is then converted to acetaldehyde—catalyzed by pyruvate dehydrogenase (PDH)—and acetaldehyde is converted to ethanol—catalyzed by alcohol dehydrogenase (ADH). (After a concept by Bickler and Buck 2007.)

The brains of goldfish and crucian carp exhibit far less metabolic depression than those of turtles. The more-limited metabolic depression permits the fish to remain conscious and responsive even during anoxia. It also increases demands for anaerobic ATP synthesis by brain cells. Crucian carp build up stores of brain glycogen with the approach of winter—the season when they are most likely to face anoxia. These stores provide fuel for making the ATP that keeps the brain functional.

The fish do not get drunk! Their rate of excretion of ethanol is great enough to keep their tissue concentrations of ethanol below inebriating levels.

SUMMARY Responses to Impaired O_2 Influx from the Environment

- Animals adapted to living without O_2 frequently undergo metabolic depression when deprived of O_2 . Metabolic depression can be so profound as to lower an animal's metabolic rate to less than 5% of the usual rate, thereby greatly reducing the rate that ATP must be supplied by catabolic mechanisms.
- Invertebrate anaerobes deprived of O_2 produce ATP by means of a diversity of complex anaerobic catabolic pathways that generate end products such as acetic acid, succinic acid, and propionic acid. The invertebrates commonly excrete these organic products during anoxia as a way of avoiding end-product accumulation in their bodies.
- Virtually all vertebrates use simple anaerobic glycolysis to produce ATP in tissues deprived of O_2 , and vertebrates invariably retain lactic acid in their bodies, setting the stage for potential metabolic self-limitation. Usually when vertebrates experience anoxia, it is strictly regional; whereas some tissues become anoxic, others—most notably the central nervous system—must retain an O_2 supply. Only a few vertebrates can tolerate total-body anoxia.
- Turtles capable of total-body anoxia employ anaerobic glycolysis to make ATP. A key part of their strategy for survival is a metabolic depression of the central nervous system sufficiently profound to produce a comatose state. Goldfish and crucian carp undergoing total-body anoxia remain alert. They have the unusual ability to convert lactic acid to ethanol, which they can excrete, thereby preventing end-product accumulation in their bodies.

Study Questions

1. One approach to conservation of fish populations is to release unwanted fish accidentally caught in trawling nets. Such fish often have very high concentrations of lactic acid in their bodies. Why do you think they have these high concentrations of lactic acid, and how might their survival after release be affected by their condition?
2. Explain how the reactions that produce and use ATP serve, together, as an *energy shuttle* mechanism in cells.
3. Explain the concept of redox balance. What conditions must exist, for example, for cytochrome oxidase to be in redox balance?
4. How does the reduction of pyruvic acid create a state of redox balance in anaerobic glycolysis?
5. Outline the chemiosmotic hypothesis for the mechanism by which oxidative phosphorylation is coupled with electron transport. How does uncoupling occur in tissues with uncoupling protein 1 (UCP1)? Under what circumstances would uncoupling be disadvantageous, and under what circumstances might it be advantageous?
6. Using two or three carefully chosen examples, illustrate the point that during physical activity, behavior and biochemistry are intimately linked, such that an animal's exercise performance depends on the mechanisms that are making ATP for the exercise.
7. Assuming that an animal uses a catabolic pathway that produces organic products, such as lactic acid or propionic acid, compare the pros and cons of retaining or excreting the organic molecules.
8. Why is it important to distinguish *temporary* electron (hydrogen) acceptors in cells from *final* electron acceptors? What are the unique advantages of O_2 as an electron acceptor?
9. Why does an oxygen deficit occur at the start of submaximal exercise in vertebrates? What are the mechanisms of ATP production during the oxygen deficit phase, and how is ATP made in the ensuing pay-as-you-go phase?
10. A single individual can differ from time to time in his or her maximal rate of O_2 consumption. For example, athletic training in people can raise the maximal rate of O_2 consumption by 10–30%, whereas going to high altitudes can lower it (see Box 8.3). Explain how these sorts of changes in the maximal rate of O_2 consumption can make a single type of exercise (such as jogging at 6 miles per hour) shift from being submaximal to supramaximal, or vice versa. What are the physiological implications of such shifts?
11. There has been a great deal of debate over whether the ratio of SO to FG fibers in the muscles of individual people or other animals is fixed genetically. Researchers have asked whether the ratio of fiber types can be altered during an individual's lifetime by various sorts of training or other experiences. Why would a change in the ratio of fiber types be of interest and importance? Design experiments or other sorts of studies that would help elucidate whether the ratio of fiber types can undergo change.

The Energetics of Aerobic Activity

Breeding colonies of seabirds are memorable for the amount of activity taking place, as great numbers of birds come and go all day and sometimes into the night. Adults congregate in large numbers on islands and beaches in these colonies. All their food, however—and all the food for their offspring—comes from the ocean. More than 100,000 masked boobies (*Sula dactylatra*) congregate for breeding each year on Clipperton Island, a tiny atoll far out in the Pacific Ocean off the coast of Costa Rica. Both sexes typically forage at sea each day (Figure 9.1). Some foraging trips are relatively short: only about 1 hour (h). Others last most of a day: 18 h. The average is 9 h. During an average 9-h trip, a bird spends about 80% of its time—7 h—flying out and back to fishing areas that, on average, are 103 km (64 miles) from land. In the fishing areas, the birds feed by use of short (3-second), spectacular plunge dives, during which they engage in aerodynamically controlled, high-speed free falls into the water to capture fish—mostly species of flying fish. Each adult booby (weighing 1.5–2 kg) must catch and digest about 0.5 kg of fish each day for its own metabolic needs, especially to meet its costs of flight. Parents must provide each offspring with about 0.3 kg of fish per day. All told, the breeding colony on Clipperton Island takes about 70 metric tons of fish from the surrounding Pacific Ocean each day.¹ According to a recent study, the seabirds of the world—summing up all species—remove about 190,000 metric tons of fish from the oceans daily, making the global fish consumption by seabirds approximately equal to global harvesting by humans.

The sustained foraging activity exhibited each day by masked boobies and other seabirds must be aerobic. That is, the ATP for the activity must be produced by aerobic catabolism, using O₂ delivered steadily to the exercising muscles from the atmosphere. Anaerobic mechanisms of ATP production could not possibly supply the ATP because—in birds, as in mammals—the anaerobic mechanisms can produce only very limited total amounts of ATP (see Table 8.1). Throughout the animal kingdom, as discussed in Chapter 8, the ATP requirements of routine daily living are mostly met by aerobic catabolism because the mechanism of aerobic ATP production can operate in steady state, and aerobic ATP synthesis therefore can go on and on without self-limitation.

In this chapter we examine the energy costs of routine daily living and of sustained, aerobically fueled exercise. This focus is justified because although highly anaerobic forms of exertion (e.g., sprints) sometimes spell the difference between life and death, as discussed in Chapter 8, aerobic types of activity predominate in the lives of most animals in regard to time spent and energy required.

As a first example of the energy costs of sustained, aerobically fueled activity, the metabolic rates of humans engaged in various physical activities are listed in Table 9.1. Walking increases a person's metabolic

¹ A metric ton is 1000 kg, or about 2200 pounds.

Masked boobies (*Sula dactylatra*) nest on islands but get all their food from the sea Their foraging flights to distant fishing areas far out over the ocean—in common with sustained activities of other animals—are fueled by aerobic ATP production and elevate the costs of daily life.

FIGURE 9.1 The routine daily flights of masked boobies (*Sula dactylatra*) to and from feeding areas over the ocean depend on aerobic catabolism to supply energy for muscular work. The map shows five daily foraging flights by birds that were nesting on Clipperton Island. Each color represents a different individual; for one individual, two flights are shown (blue plots). Dots along the flight paths show places where the birds engaged in fishing. The circle represents a flight distance from the island of 100 km (62 miles). (After Weimerskirch et al. 2008.)

rate—and therefore the rate at which ATP must be made—by two- to fourfold compared with rest. More intense types of sustained exercise can increase metabolic rate by tenfold or more.

How Active Animals Are Studied

Studies of actively moving animals present challenging methodological problems, whether carried out in the laboratory or in the wild. One important question that is usually studied under laboratory conditions is the relation between the speed of locomotion and the metabolic rate. The greatest challenge for such studies is controlling and measuring an animal's speed as it runs, flies, or swims.

For running or walking animals, the device most commonly used to control the speed of a moving individual is a motor-driven treadmill (Figure 9.2). The animal stands on a belt, which is driven round and round by a motor. For the animal to keep its position, it must run or walk at the same speed as the belt passing beneath its feet. The treadmill can be tilted at an angle relative to the horizontal to simulate uphill or downhill running. Animals as diverse as cockroaches, land crabs, turkeys, and cheetahs have been trained to run and walk on treadmills! Lobsters and crayfish have even been trained to use underwater treadmills. As the speed of a treadmill is varied, the subject's rate of O_2 consumption is measured, permitting investigators to describe the relation between the speed and the metabolic cost of locomotion.

Wind tunnels are used to control the speeds of flying animals. A bird, insect, or bat in a wind tunnel must fly into the forced air current produced by the tunnel at the same speed as the current if it is to maintain its position. For swimming animals such as fish, a

TABLE 9.1 Representative metabolic rates of young adult people of average build during sustained, aerobically fueled forms of exercise

Type of activity	Metabolic rate ^a (kJ/minute)
Lying down	6.3
Sitting	7.1
Standing	8.8
Walking at 2 miles per hour (mph)	12
Walking at 4 mph	21
Bicycling at 13 mph	32
Jogging at 7 mph	59
Crawl swimming at 2 mph	59
Running at 10 mph	84

^aAll forms of locomotion are assumed to be on level ground. In aerobic catabolism, 1 kJ = 49.5 mL O_2 .

device analogous to a wind tunnel—but filled with water instead of air—is commonly used to control speed.

In field studies of the energetics of activity, the greatest challenge is often that of measuring or estimating the metabolic rate, because standard laboratory metabolic techniques usually cannot be used. In some cases, O_2 consumption can be measured in the field by use of a mask and valve system, so that the subject breathes from a defined air stream rather than from the atmosphere at large (Figure 9.3). This sort of approach has been used in a wide variety of studies (Box 9.1). Typically, however, alternatives to the measurement of O_2 consumption must be used in field studies.

One of the most important innovations for studies of air-breathing animals in the wild is the **doubly labeled water method**. With this technique, researchers can measure the metabolic rate of an individual animal that is entirely free to engage in its normal behaviors in its natural habitat. The method takes its name from the fact that the individual under study is injected with water labeled with unusual

FIGURE 9.2 A treadmill provides a way to control the running or walking speed of an animal during study. When the motor-driven axle turns, the belt moves as indicated by the arrows. After being trained, animals run at the same speed as the belt to keep their position relative to the surrounding room.

FIGURE 9.3 Modern telemetry devices permit information on O_2 consumption to be radioed from a freely moving subject. In the cases shown, the rate of O_2 consumption is measured using the principle of open-flow respirometry (see Box 7.4). Valves in the mask allow the subject's breathing to cause a measured stream of air to flow through the mask. An O_2 probe measures how much O_2 is removed from each unit of volume of the flowing air. The device has been used to study racehorse performance and the energetics of running in Kenyan athletes (inset). (Courtesy of Marco Brugnoti and Cosmed S.r.l.)

isotopes of both hydrogen and oxygen. Deuterium (a hydrogen isotope) and oxygen-18 are the most commonly used isotopes.² The method is then called the $D_2^{18}O$ method. We explain the method here with reference to these particular isotopes, although the rationale is the same regardless of the isotopes used.

²The ordinary isotope of oxygen is oxygen-16.

For an animal to be studied using the $D_2^{18}O$ method, it is injected at the start of the study period with measured amounts of both $D_2^{16}O$ and $H_2^{18}O$, which mix with its body water. Later, at the end of the study period, a blood sample is taken to determine how rapidly the deuterium and oxygen-18 were eliminated from the animal's body during the study period. In the interval between the initial injection of the isotopes and the collection of the final blood sample, the subject is released and is free to live normally in its natural habitat. The method measures the individual's *average* rate of CO_2 production during the study period. Average metabolic rate is then computed from CO_2 production.³

The reason the doubly labeled water method works is that the oxygen atoms in expired CO_2 are in isotopic equilibrium with the oxygen atoms in body water; this means that if the body H_2O consists of given proportions of $H_2^{16}O$ (ordinary water) and $H_2^{18}O$, expired CO_2 contains oxygen-16 and oxygen-18 in the same proportions.⁴ After the concentration of $H_2^{18}O$ is elevated in an animal's body at the start of a study, the excess atoms of oxygen-18 are gradually lost by way of expired CO_2 . The *rate* of loss of oxygen-18 thus depends on the subject's rate of CO_2 production. A problem is that atoms of oxygen-18 are lost from the body in the form of H_2O as well as CO_2 because H_2O that leaves the animal's body by evaporation, urination, or other mechanisms consists in part of $H_2^{18}O$. Accordingly, after an animal has been injected with oxygen-18, its *total* rate of elimination of the oxygen-18 is in fact a function of *both* its rate of CO_2 expiration *and* its rate of H_2O loss. The hydrogen isotope—deuterium—is injected in the doubly labeled water method to obtain an independent measure of the rate of H_2O loss; because CO_2 contains no

³As discussed in Chapter 7 (see Table 7.1), uncertainties are involved in calculating metabolic rate from the rate of CO_2 production. These uncertainties need to be kept in mind in interpreting results of the doubly labeled water method.

⁴The reason for the isotopic equilibrium between oxygen in H_2O and oxygen in CO_2 is that atoms of oxygen are freely exchanged between molecules of H_2O and CO_2 during the reactions of the Krebs cycle (citric acid cycle; see Figure 8.2).

BOX 9.1 THE COST OF CARRYING MASSIVE LOADS

Nepalese porters carry massive loads up steep mountain trails at high altitudes. Investigators recently interviewed more than 500 male porters in a remote village at an elevation of 3500 m (11,500 feet) near Mt. Everest. The porters had just arrived in the village after a trek of 100 km (62 miles). The average load they carried was 93% of body weight. One-fifth of the porters carried loads greater than 125% of their body weight! The porters employ a unique head-supported system to carry these loads.

The investigators took a device similar to that in the inset of Figure 9.3 to the Himalayan village and used it to measure the O_2 consumption of eight porters. They discovered that for these Nepalese porters, the cost of carrying heavy loads was only 50–60% as

Nepalese porters: Their cost of carrying a load as a function of the size of the load The black line shows average results from a previous study of Europeans carrying heavy loads in standard backpacks. Error bars show standard deviations. (After Bastien et al. 2005.)

great as the cost incurred by Europeans carrying identical loads in backpacks, as shown by the data in the figure. African women carrying loads on their heads also exhibit relatively low carriage costs. The biomechanical explanation remains a mystery.

hydrogen, after an animal has been injected with deuterium, its rate of loss of the deuterium from its body depends just on its rate of H₂O elimination. Knowing the animal's rate of H₂O loss from the hydrogen-isotope data, one can calculate how much oxygen-18 is lost in H₂O during the study period. Knowing this value, one can then subdivide the total rate of oxygen-18 loss into two components: the rate of loss in H₂O and the rate of loss in CO₂. In this way, the rate of CO₂ expiration—and the metabolic rate—is calculated.

The most common use of the doubly labeled water method is to determine the average metabolic rate of an animal in the wild during the entire 24-h day, termed the **average daily metabolic rate (ADMR)** or **field metabolic rate (FMR)**. The animal might sleep for part of the day, stand guard for another part, and move about actively during still another part. The doubly labeled water method measures the metabolic cost of all these behavioral states lumped together.

Time–energy budgets represent an older, but still useful, approach for estimating the ADMRs of animals free in their natural habitats. To construct a time–energy budget, an investigator first categorizes all of an animal's behaviors into a few categories. For instance, the categories might be sleeping, standing guard, and actively moving. By using laboratory studies or other sources of information, the investigator then estimates the animal's rate of energy expenditure (metabolic rate) while it engages in each category of behavior. Finally, field observations are used to estimate the amount of time the animal spends in each sort of behavior during a day. To calculate the total energy cost of each behavior, the time spent in the behavior is multiplied by the rate of energy expenditure during the behavior. The energy costs of all behaviors are then summed to obtain the total daily energy expenditure.

Table 9.2 presents an example of a time–energy budget for African penguins (*Spheniscus demersus*). These penguins live on southern African shores and forage for fish by underwater swimming. In the time–energy budget, three categories of behavior are recognized: maintenance on land (which includes costs of thermoregulation), swimming underwater, and resting at the water's surface while at sea. The values in column C show the estimated daily costs of the three behaviors separately. Summation of the daily costs of all three yields the total daily energy expenditure of an African penguin, about 1900 kJ.

TABLE 9.2 A time–energy budget for an adult African penguin (*Spheniscus demersus*) during the breeding season

Behavior	A Hours per day devoted to behavior ^a	B Hourly cost of behavior ^b (kJ/h)	C Daily cost of behavior: A × B (kJ)
Maintenance on land	19.5	49	956
Swimming underwater	2.0	358	716
Resting at water's surface	2.5	83	208
Total daily energy expenditure (sum of column C):			1880 kJ/day

Source: After Nagy et al. 1984.

^aTime devoted to each behavior was determined from field studies of African penguins.

^bThe hourly energetic cost of each behavior was estimated from comparative laboratory studies of multiple bird species.

A third technique useful for studying the physiology of activity in the wild is the use of miniaturized electronic monitors, which are placed on or in a study animal. Two basic types of monitors are in use: **telemetric devices** that transmit data as the data are acquired, and **data loggers** that accumulate data in onboard digital memory for later retrieval. Miniaturized electronic monitors can be used to record heart rates, behavioral activity, and other useful indices in many sorts of animals. Heart-rate data can sometimes be used to estimate metabolic rates, and activity data may be useful in constructing time–energy budgets.

The Energy Costs of Defined Exercise

If we consider each of the major forms of animal locomotion—swimming, running, and flying—we find that there is often a characteristic relation between the metabolic cost per unit of time and the speed of locomotion. Consider swimming by fish, for example. In this form of exercise, metabolic rate typically increases in a *J-shaped* power function as speed increases (**Figure 9.4**).⁵ This

⁵If M is metabolic rate and u is speed, the expected relation between M and u for swimming fish is described by a power function: $M = a + bu^c$, where a , b , and c are constants for a particular fish species. The characteristics of power functions are discussed in Appendix F.

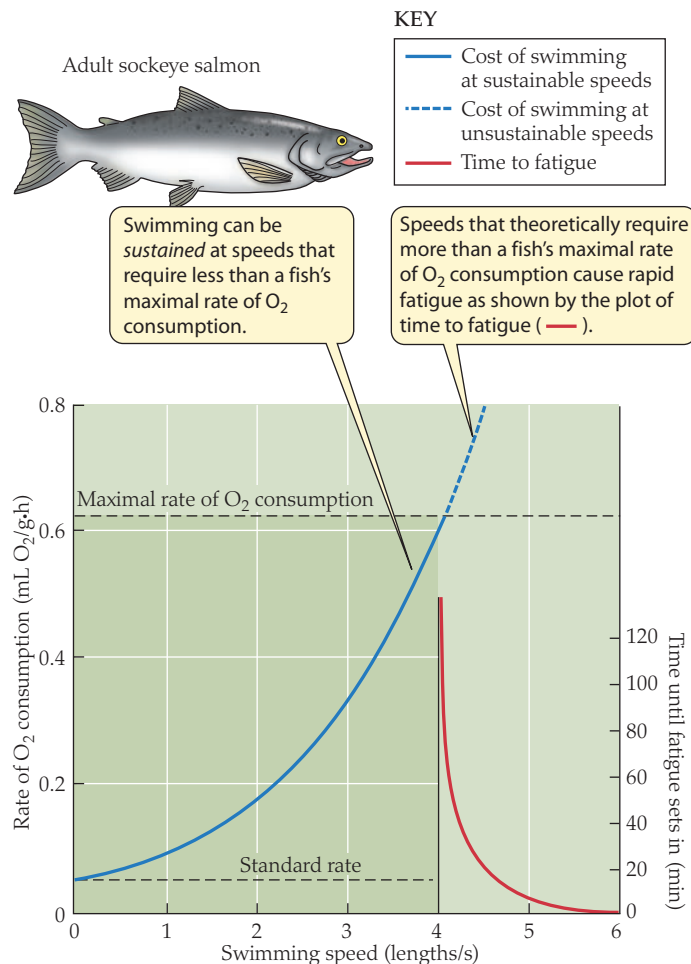

FIGURE 9.4 Rate of O₂ consumption as a function of swimming speed in yearling sockeye salmon (*Oncorhynchus nerka*) studied in a water tunnel. The fish studied were about 18 cm long and weighed about 50 g. (After Brett 1964.)

FIGURE 9.5 Rate of O₂ consumption as a function of running speed in six species of mammals of different body sizes studied on treadmills. The species are laboratory mouse (*Mus domesticus*, average weight 21 g), Merriam's kangaroo rat (*Dipodomys merriami*, 41 g), banner-tailed kangaroo rat (*D. spectabilis*, 100 g), laboratory rat (*Rattus norvegicus*, 384 g), round-tailed ground squirrel (*Xerospemophilus tereticaudus*, 236 g), and domestic dog (mongrels weighing 2.6 kg and Walker foxhounds weighing 18 kg). (After Taylor et al. 1970.)

relation occurs because the drag that a fish must overcome to move through water increases approximately in proportion to the square of its speed of swimming.

When a mammal runs, its metabolic rate usually increases as a *linear* function of its speed, as is shown for six species in **Figure 9.5**. Other running or walking animals, such as running insects and terrestrial crabs, also usually exhibit linear relations between metabolic rate and speed.

For birds flying by flapping their wings,⁶ aerodynamic theory predicts a *U-shaped* relation between metabolic rate and speed

⁶Flapping flight is distinguished from *soaring flight* and from *gliding* and *diving*.

(**Figure 9.6a**). The actual existence of this sort of relation has been difficult to test in practice, in part because of difficulties in measuring the metabolic rates of birds flying at low speeds in wind tunnels. Recently, investigators have conducted novel studies using analyses of wing movements and forces to estimate the rate of energy investment in flight at all possible flight speeds, ranging from 0 (hovering) upward. The results for magpies in **Figure 9.6b** (red line), obtained by this method, confirm in a rough sense that birds actually exhibit a U-shaped sort of relation between metabolic rate and flight speed, as aerodynamic theory predicts. The data for the four other species of birds in **Figure 9.6b** are from traditional studies of rates of O₂ consumption. Of the four species, only the budgerigars (a type of parakeet) exhibit a U-shaped relation (yellow line), but the data for the other three are incomplete because of no information at low speeds. A recent review of more than 20 studies reached the conclusion that most support, or are compatible with, the hypothesis of a U-shaped relation.

For all three forms of locomotion that we have discussed—swimming by fish, running by terrestrial animals, and flying by birds—small-bodied species tend to require greater weight-specific metabolic rates to move at any particular speed than large-bodied species require. Note, for example, in **Figure 9.5** that the weight-specific metabolic rate required to run at about 1 km/h is far higher for a mouse than for a rat. Similarly, small birds like budgerigars have higher weight-specific metabolic rates than large ones (e.g., gulls) when flying at the same speed (see **Figure 9.6b**). This trend is also evident in fish.

The most advantageous speed depends on the function of exercise

We are well aware that we can judge the ideal speed of a vehicle in more than one way, depending on what we are attempting to accomplish by travel in the vehicle. For instance, we might want to get to our destination as fast as possible, or we might want to travel at a speed that promotes energy efficiency. Similarly, there

(a) Predicted relation from aerodynamic theory

FIGURE 9.6 The metabolic rate of birds moving by flapping flight as a function of flight speed. (a) The predicted relation between energy output and airspeed (speed relative to the air) based on aerodynamic theory. (b) The empirically measured rate of output of metabolic energy as a function of flight speed in five species of birds studied in wind tunnels. The results for magpies (*Pica pica*) were obtained by analysis of data on wing movements and forces. The results for the other four species were gathered by the measurement of O₂ consumption and have been calculated to be in the same units as the magpie data. (a after Alerstam and Hedenström 1998; b after Dial et al. 1997.)

(b) Empirical data for five species of birds

FIGURE 9.7 Two ways to view the energetics of flapping flight by budgerigars (*Melopsittacus undulatus*) (a) Metabolic rate as a function of speed. (b) Cost of transport as a function of speed. To minimize *metabolic rate*, the flight speed must be significantly lower than the speed that minimizes *cost of transport*. Both graphs express energy expenditure in weight-specific terms. Figure 9.5b presents the data in (a) in transformed units. (After Tucker 1968, 1969.)

are several ways to judge the most advantageous speed for an animal to swim, run, or fly.

To illustrate this point, the study of flapping flight by birds is particularly revealing. In the analysis of animal locomotion, two measures of cost are useful: *energy cost per unit of time* (metabolic rate) and *energy cost per unit of distance traveled*—termed the **cost of transport**. Figure 9.7a shows the weight-specific *energy cost per unit of time* (i.e., weight-specific metabolic rate) of flying budgerigars as a function of their flight speed. Figure 9.7b shows the weight-specific *energy cost per unit of distance traveled* (i.e., weight-specific cost of transport) as a function of speed. The following equation explains how the two plots are related:

$$\frac{\text{energy}}{\text{time}} \div \frac{\text{distance}}{\text{time}} = \frac{\text{energy}}{\text{distance}} \quad (9.1)$$

On the left side of this equation, the first expression is the metabolic rate, and the second expression is speed. The equation shows that if an animal is traveling at any given speed, its energy cost per unit of distance is calculated by dividing its metabolic rate at that speed by the speed. Each of the six data points in Figure 9.7a depicts the metabolic rate at a particular speed. Dividing each metabolic rate by the corresponding speed produces the six data points in Figure 9.7b. *The two plots, therefore, are merely different ways of looking at the exact same information.*

To see the significance of the two ways of analyzing budgerigar flight costs in Figure 9.7, consider these two questions: First, if a budgerigar takes off with certain fuel reserves and does not eat during flight, at what speed should it fly to stay airborne for the longest time before it runs out of fuel? Second, at what speed should it fly to cover the greatest possible distance before it runs out of fuel? Clearly, to stay aloft for the longest possible *time*, the bird should fly at the speed that minimizes its energy cost per unit of time—the speed at which the metabolic rate in Figure 9.7a is minimal. By contrast, to cover the greatest *distance*, the bird should fly at the speed that minimizes its energy cost per unit of distance—the speed at which the cost of transport in Figure 9.7b is minimal. The two speeds are different. Thus, on the basis of these theoretical considerations, the most adaptively advantageous speed depends on the function being performed by flight. If the function of flight is best served by staying airborne as long as possible, the speed marked in Figure 9.7a would be most advantageous. However, if the function of flight is to cover as much distance as possible—as when a bird migrates—the speed marked in Figure 9.7b would be most beneficial.

Data collected on the behavior of birds in the wild over the last 20 years strongly suggest that birds actually tend to follow these principles in selecting their flight speeds. When skylarks (*Alauda arvensis*), for example, engage in song flights that act as displays to attract mates, they fly at about the speed that minimizes their energy cost per unit of time in the air. When they undertake migratory flights, however, their average speed increases more than twofold and more closely approximates the speed at which they require the least energy to cover a kilometer of distance.

Besides the perspectives already stressed, there are additional ways in which the adaptive advantage of speed can be assessed, depending on circumstances. When an animal must run a long distance to escape a pursuing predator, for example, *maximization of sustained speed* is likely to be paramount, regardless of the efficiency of travel at that speed. Another perspective arises when we consider animals undertaking long-distance migrations during which they feed along the way. If forward travel will likely bring an animal into a habitat where food is more abundant than in the habitat it is leaving, a substantial body of theory indicates that—energetically speaking—the optimal speed of travel is a bit higher than the speed at which the animal's cost of transport is minimized; this is so because faster travel allows faster access to enhanced feeding possibilities.

You can see from this discussion that travel at a speed that minimizes cost of transport is relevant only when certain functions are being performed by exercise; it is not a universal standard of performance. Nonetheless, the study of travel at the minimal cost of transport (minimal energy cost per distance covered) has provided powerful insights into many types of animal performance—insights we now discuss.

The minimal cost of transport depends in regular ways on mode of locomotion and body size

Suppose that for each species of animal we study, we identify the *minimal* weight-specific cost of transport. Specifically, we identify the minimal energy cost to move 1 kg of body weight 1 m during horizontal locomotion, regardless of the speed at which the minimum occurs. Then we plot the minimal cost of transport as a function of body weight, as in Figure 9.8. This sort of plot reveals one of the most striking patterns ever discovered in exercise physiology: Namely, species that engage in a particular primary mode of locomotion—running, flying, or swimming—tend to exhibit a regular relation between minimal cost of transport and body size. Furthermore, the relation for runners differs from that for fliers, and both relations differ from that exhibited by swimming fish. To interpret the lines showing these three relations in Figure 9.8, note that the graph employs log–log coordinates. Minimal cost of transport is an allometric function of body weight for animals that engage in each primary mode of locomotion, and for this reason the relations plot as straight lines when both axes are logarithmic.⁷

⁷For each mode of locomotion, minimal weight-specific cost of transport = aW^b , where W is body weight, a and b are constants, and b is typically about -0.2 to -0.4 . See Chapter 7 (page 174) and Appendix F for discussions of allometric functions and their shapes on various sorts of plots.

To appreciate the full significance of the regular relations shown in Figure 9.8, consider first the fliers—the species for which the primary mode of locomotion is flapping flight. These species are taxonomically very diverse—including insects, bats, and birds—yet they all fall approximately on a single line in terms of their relation between minimal cost of transport and body weight. Similarly, the walkers and runners plotted in Figure 9.8—which consist of lizards and running birds as well as mammals—fall on a single line. In fact, data are now available for more than 150 species of animals that move primarily by running—including running insects, semiterrestrial crabs, additional running birds (e.g., roadrunners and ostriches), centipedes, and millipedes, as well as additional lizards and mammals—and, with a few exceptions, all the species fall statistically along a single line. The line for swimming in Figure 9.8 is just for fish. Nonetheless, data are available now for more than 20 species of fish, some of which are very different from one another in body form and swimming style, and essentially all fall along one line. The overall picture that emerges from analyses such as the one shown in Figure 9.8 is remarkable: Among animals engaged in their primary form of locomotion, the minimal cost of transport displayed by a species of given body size typically *depends principally on the species' mode of locomotion rather than its phylogenetic position or the details of its locomotor mechanisms.*

FIGURE 9.8 Minimal weight-specific cost of transport in relation to body weight for running, flying, and swimming animals and for machines Representative species and machines are identified at random. The three solid lines show the relation between cost of transport and body weight for animals that employ walking or running, flapping

flight, or swimming as their *primary* modes of locomotion. Only fish are included in the swimming line. By now, huge numbers of data points have been added to this sort of analysis. However, this older plot—partly because it is relatively uncluttered—nicely brings out the basic principles. (After Tucker 1975.)

For animals of a particular body size engaging in their primary form of locomotion, running is the most costly way to cover distance, whereas swimming—as practiced by fish—is the least costly. The differences in cost among the three forms of locomotion are more substantial than they might appear from a simple visual inspection of Figure 9.8 because the logarithmic scale used for cost of transport tends to make differences look smaller than they are. For a 100-g animal, the cost of running a unit of distance is about 4 times higher than the cost of flying the same distance and about 14 times higher than the cost of swimming!

Among animals that share a single primary mode of locomotion, large-bodied species cover distance at considerably lower weight-specific cost than small-bodied species do. This means, among other things, that if two animals of different sizes set off on travels with equal proportions of body fat (which they use as fuel), the larger one will be able to cover more distance before running out of fat.

Swimming has proved to be a particularly interesting and revealing mode of locomotion for study. As we have noted, even though different species of fish employ a diversity of swimming styles, fish species usually fall along a single line in their relation between minimal cost of transport and body size. What about other types of animals that—like fish—travel by *underwater swimming* as their primary mode of locomotion, such as shrimps, sea turtles, and marine mammals? As shown in Figure 9.9, they typically exhibit higher costs of transport than fish, possibly because they often are less streamlined than fish. Costs of transport are in general even higher in animals that *swim at the water's surface* rather than underwater, such as humans, ducks, and other primarily terrestrial animals (see Figure 9.9). The high costs observed in most surface swimmers are consequences of two factors: (1) swimming is not the

primary mode of locomotion for the surface-swimming animals, and (2) based on hydrodynamic principles, swimming at the surface tends to be intrinsically more costly than underwater swimming.

For us humans, an interesting corollary of our high cost of swimming is that our own experience of the effort that must be expended to swim provides not the slightest insight into the effort required of a fish! In fact, if you want to get a sense of how strenuous it would be for a human-sized fish to cover distance by underwater swimming, climb on a bicycle. Bicycling ranks as one of the least costly of all animal-powered forms of locomotion, and the cost to cover distance by bicycling approaches the cost of swimming expected for fish of human size (see Figure 9.8).

When we consider the various sorts of animals that undertake long-distance migrations, we encounter a remarkable fact: Although certain small or medium-sized fish and flying animals (insects, bats, and birds) undertake long-distance migrations, such migrations are rare among small or medium-sized running animals. Some *large* running animals, such as reindeer (caribou), are noted for their long migrations, but as Figure 9.8 shows, their cost of covering distance is likely to be similar to that of relatively small fish! Vance Tucker pointed out years ago that if a line (which he called the *migratory line*) is drawn across Figure 9.8 at about 20 J/m·kg, most migratory species are found below the line, and species above the line are unlikely to be migrants. Apparently, long-distance migration has a high chance of being favored by natural selection only if the cost of covering distance is relatively low, and the body size that permits an adequately low cost depends on the mode of locomotion. We discuss long-distance migration at more length shortly.

FIGURE 9.9 Minimal weight-specific cost of transport during swimming The animals besides fish that swim underwater include shrimps (*Palaemon*), a species of squid (*Loligo*), the green sea turtle (*Chelonia*), the harbor seal (*Phoca*), the California sea lion (*Zalophus*), the bottlenose dolphin (*Tursiops*), and the gray whale (*Eschrichtius*). These various species roughly fall on a single line. Animals swimming at the water's surface include humans, several species of ducks and geese, a mink (*Mustela*), a penguin (*Eudyptula*), and the marine iguana (*Amblyrhynchus cristatus*); the iguana plots very close to the underwater-swimming sea turtles. (After Videler 1993.)

SUMMARY The Energy Costs of Defined Exercise

- When a mammal or other animal runs, its metabolic rate typically increases linearly with its speed. Metabolic rate and speed are related by a J-shaped power function in swimming fish. For animals engaged in flapping flight, metabolic rate is expected to exhibit a U-shaped relation to speed, but this theoretical expectation is not always observed in real animals.

- Cost of transport is the energy cost of covering a unit of distance. The speed that minimizes the cost of transport is the speed that maximizes the distance that can be traveled with a given amount of energy.
- Running animals, animals flying by flapping flight, and swimming fish exhibit three distinctive and coherent allometric relations between minimal cost of transport and body weight. For animals of any particular body size, running is the most expensive way to cover distance, flying is intermediate, and swimming by fish is the least expensive. Within any one locomotory group, the minimal weight-specific cost of transport decreases as body size increases.

The Maximal Rate of Oxygen Consumption

An animal's **maximal rate of oxygen consumption**, symbolized $\dot{V}_{O_2\max}$ and sometimes called **aerobic capacity** or **maximal aerobic power**, is a key property for the study of aerobic activity.⁸ One reason an animal's $\dot{V}_{O_2\max}$ is of interest is that it determines the peak rate at which the animal can synthesize ATP by aerobic catabolism. Thus it determines how intensely the animal can exercise in a pay-as-you-go mode (see Figure 8.10*b*). Suppose two species, A and B, exhibit the same relation between metabolic rate and speed, but species A has a higher $\dot{V}_{O_2\max}$ than species B. In that case, although A and B would require the same rate of energy expenditure to travel at *any*

⁸A symbolic convention used in some branches of physiology is to place a dot over a symbol to indicate *rate*. V_{O_2} symbolizes volume of O_2 . Placing a dot over the V symbolizes the rate at which the volume of O_2 is used (i.e., O_2 consumption in volume units). In this chapter we assume that to measure $\dot{V}_{O_2\max}$, investigators induce animals to exercise intensely, thereby raising their rates of O_2 consumption to peak levels. Another way to raise the rates of O_2 consumption of some animals, such as mammals, is to expose them to low environmental temperatures. Maximal rates of O_2 consumption induced by exercise and cold are often not the same because different organs participate in exercise and cold defense.

given speed, species A would be able to cover long distances *faster* because it would be able to make ATP more rapidly by aerobic catabolism and thus reach higher sustained speeds.

A second reason for interest in $\dot{V}_{O_2\max}$ is more subtle and remarkable: In studies of humans and other vertebrates, the maximal rate of O_2 consumption provides a benchmark by which to judge the *strenuousness* of all *aerobic* physical activity. Specifically, the strenuousness to an individual of any particular form of aerobic exercise depends roughly on how high a proportion of the individual's $\dot{V}_{O_2\max}$ is required by the exercise. In people on average, if a fully aerobic activity demands 35% or less of $\dot{V}_{O_2\max}$, the activity can likely be carried out for 8–10 continuous hours. As the percentage of $\dot{V}_{O_2\max}$ required by aerobic activity increases, the activity becomes more strenuous. An activity that requires 75% of $\dot{V}_{O_2\max}$, for instance, will probably, for most people, be exhausting in 1–2 h.

The use of $\dot{V}_{O_2\max}$ as a benchmark is informative in several ways. One is the analysis of human-powered flight (Box 9.2). A more practical application for most people is the analysis of the relation between exercise and aging. As people age beyond young adulthood, their $\dot{V}_{O_2\max}$ tends to decline; after age 30, the decline is about 9% per decade for sedentary people, although it is less than 5% per decade for people who stay active. Because of the decline in $\dot{V}_{O_2\max}$, an activity that requires any particular *absolute* rate of O_2 consumption tends to demand an ever-greater proportion of $\dot{V}_{O_2\max}$ as people age. Thus the activity becomes more strenuous. A form of exercise that demands 35% of $\dot{V}_{O_2\max}$ in youth might require 50% in old age; the exercise would therefore shift from being sustainable for 8–10 h in youth to being sustainable for perhaps half that time in old age. This process helps explain why jobs involving physical labor become more difficult for people to perform for a full workday as aging occurs.

Work that requires O_2 consumption at 100% of $\dot{V}_{O_2\max}$ is strenuous in the extreme; people can ordinarily continue it for only a

BOX 9.2 FINDING POWER FOR HUMAN-POWERED AIRCRAFT

The world was electrified in 1977 when a human-powered aircraft named *Gossamer Condor* first flew a mile. Two years later, Bryan Allen powered another such aircraft, the *Gossamer Albatross*, across the English Channel in a flight of 36 km (22 miles) that required almost 3 h. Human-powered aircraft fly at average altitudes of about 6 meters. At these heights, even a few *seconds* of loss of power are out of the question, because without continuous power the aircraft would quickly land or crash. Thus the feat achieved by Bryan Allen required 3 h of truly *uninterrupted* effort at a very high work intensity.

The physiological properties of human exercise discussed in this chapter dictate that the rate of O_2 consumption of a pilot must be no higher than 65–70% of his or her $\dot{V}_{O_2\max}$ for there to be a reasonable chance that a very motivated pilot will be able to maintain uninterrupted effort for 3 h. This biological fact set the engineering goals for the design of the

Bryan Allen powering the *Gossamer Albatross* over the English Channel on June 12, 1979

Gossamer Albatross: The aircraft could not demand more power from its “power plant” than 65–70% of $\dot{V}_{O_2\max}$. **Box Extension 9.2**

discusses pilot selection and the next stage in human-powered aircraft following the *Gossamer Albatross*.

few minutes. We saw in Box 8.3 that people exhibit a lower and lower $\dot{V}_{O_2\max}$ as they go to higher altitudes. In relatively young individuals, although slow uphill walking requires just a small percentage of $\dot{V}_{O_2\max}$ at low altitudes, it demands approximately 100% of $\dot{V}_{O_2\max}$ at the highest altitudes on Earth (because $\dot{V}_{O_2\max}$ is lower). Slow uphill walking therefore shifts from being simple at low altitudes to being barely possible, or impossible, in high mountains (see Box 8.3).

The physiological causes of the limits on maximal O_2 consumption are hotly debated. Some physiologists argue that particular organ systems set the limits on $\dot{V}_{O_2\max}$. For instance, some point to the circulatory system as being the “weak link” in mammals, arguing that all other organ systems could transport and use O_2 at a greater rate if it were not for more-restrictive limits on how fast the circulatory system can transport O_2 . An alternative position is the hypothesis of **symmorphosis**, which states that all organ systems that serve a single function in an animal are interactively adapted to have approximately equal limits because it would make no sense for any one system to have evolved capabilities that could never be used because of more-restrictive limits in other systems. For biologists who subscribe to the concept of symmorphosis, the reason an animal cannot attain a rate of O_2 consumption higher than its $\dot{V}_{O_2\max}$ is that multiple organ systems simultaneously reach their performance limits at $\dot{V}_{O_2\max}$.

Aerobic scope for activity and *aerobic expansibility* are two concepts that are sometimes employed in the study of $\dot{V}_{O_2\max}$. An animal's **aerobic scope for activity** at a particular temperature is usually defined to be the *difference* between its $\dot{V}_{O_2\max}$ at that temperature and its resting rate of O_2 consumption at the same temperature. Its **aerobic expansibility** is the *ratio* of its $\dot{V}_{O_2\max}$ over its resting rate of O_2 consumption.⁹ To illustrate, suppose that at a particular body temperature, a fish has a resting rate of O_2 consumption of 0.05 mL/g·h and a $\dot{V}_{O_2\max}$ of 0.30 mL/g·h. Its aerobic scope for activity would be $(0.30 - 0.05) = 0.25$ mL/g·h. Its aerobic expansibility would be $0.30/0.05 = 6$.

$\dot{V}_{O_2\max}$ differs among phyletic groups and often from species to species within a phyletic group

A rough but useful rule of thumb for vertebrates is that $\dot{V}_{O_2\max}$ —as elicited by strenuous exercise—is about ten times higher than the resting rate of O_2 consumption.¹⁰ That is, the aerobic expansibility of vertebrates tends to be about 10. The consistency of the aerobic expansibility in vertebrates has some remarkable implications. For example, consider that the standard metabolic rates of fish, amphibians, and nonavian reptiles are typically—at most—only one-tenth to one-fourth as high as the basal metabolic rates of mammals and birds of similar body size (see page 256). Given that aerobic expansibility averages about 10 in all vertebrate groups, you can see that the *peak* rates of O_2 consumption of fish, amphibians, and nonavian reptiles are of the same order of magnitude as the *basal* (resting) rates of mammals and birds.

⁹There has never been a successful effort to achieve universal consensus on the use of these terms. Thus, for example, aerobic *expansibility* values are sometimes called aerobic *scope* values. In reading the scientific literature, it is important to ascertain the meaning in each context.

¹⁰In the case of mammals and birds, the $\dot{V}_{O_2\max}$ is about ten times the *basal* metabolic rate.

TABLE 9.3 Rates of aerobic catabolism (mL O_2 /g·h) during rest and during sustained exercise of peak intensity in two pairs of vertebrates

One comparison is between a fish and mammal of similar body weight. The other is between a lizard and mammal of similar weight. The mammals were studied at 30°C. The other animals were studied at the temperatures that maximized their aerobic scopes (lizard, 40°C; salmon, 15°C).

Species	Basal or standard rate of O_2 consumption	$\dot{V}_{O_2\max}$
Animals weighing 230 g		
Rat (<i>Rattus</i>)	0.9	4.6
Salmon (<i>Oncorhynchus</i>)	0.05	0.49
Animals weighing 700–900 g		
Guinea pig (<i>Cavia</i>)	0.6	3.7
Monitor lizard (<i>Varanus</i>)	0.11	1.0

Source: From Hill and Wyse 1989.

Table 9.3 illustrates this important relation with data on two pairs of vertebrates: (1) a salmon and a rat of similar size and (2) a monitor lizard and a guinea pig of similar size. Salmon and monitor lizards are among the most aerobically competent of all fish and nonavian reptiles. Yet their *peak* rates of O_2 consumption ($\dot{V}_{O_2\max}$) resemble the *basal* rates of O_2 consumption in mammals, and $\dot{V}_{O_2\max}$ in the mammals is far above $\dot{V}_{O_2\max}$ in the salmon and lizards. Mammals and lizards of the same body weight typically resemble each other in the ATP cost to cover a unit of distance when they run at speeds that minimize their cost of transport (see Figure 9.8). Mammals, however, can make ATP aerobically far faster than lizards of the same size can. Thus mammals can achieve far higher *sustained speeds* than lizards can. One of the principal hypotheses offered for the evolution of homeothermy is that it permitted faster sustained locomotion.

Within any one vertebrate phyletic group, $\dot{V}_{O_2\max}$ per gram of body weight tends to be an allometric function of body weight, with small species having a higher $\dot{V}_{O_2\max}$ per gram than large ones (see Chapter 7). The line in Figure 9.10 shows the average relation between $\dot{V}_{O_2\max}$ and size in mammals. The line, in other words, shows what is statistically “expected” for mammals of each size. Physiologists have been interested in species that exhibit a $\dot{V}_{O_2\max}$ that is above the average or “expected” value, suggesting evolution of a particularly high capacity for sustained, aerobic exercise (see page 17). The pronghorn, found in grasslands of the American West, is the most extreme of these species (see Figure 9.10). Its $\dot{V}_{O_2\max}$ is more than four times higher than the value that would be average for a mammal of its size. Pronghorns are grazers that are legendary for the speeds at which they flee danger. They are not quite as fast as cheetahs. However, unlike cheetahs—which produce ATP anaerobically when running fast—pronghorns produce the ATP required for fast running *aerobically*. Cheetahs fatigue within a minute or two when they run fast. Pronghorns, however, can maintain speeds of at least 65 km/h (40 miles/hour) for long periods of time. Pronghorns are the fastest known sustained runners on Earth. They have enormous lungs for their size and exceptional abilities to maintain high rates of blood circulation. Compared with

FIGURE 9.10 The pronghorn (*Antilocapra americana*) represents an extreme case of evolutionary specialization for high $\dot{V}_{O_2\max}$. The line shows the average statistical relation between weight-specific $\dot{V}_{O_2\max}$ and body weight in mammals; it is curved rather than straight in this plot because although the x axis is logarithmic, the y axis is not. Five nonhuman species that are strong athletic performers and that have $\dot{V}_{O_2\max}$ values higher than average (for their body sizes) are plotted individually. The high $\dot{V}_{O_2\max}$ of the pronghorn enables it to be the fastest known sustained runner on Earth. (After Lindstedt et al. 1991.)

goats and dogs of the same total body weight, pronghorns have 1.2–1.7 times more muscle, and—*per gram* of muscle—they have 1.2–2.6 times more mitochondria.

The highest known weight-specific values for $\dot{V}_{O_2\max}$ occur in certain strong-flying insects among invertebrates and in certain small-bodied fliers—hummingbirds and bats (see Figure 9.10)—among vertebrates. In the flight muscles of such aerobic heroes, mitochondria often occupy 35–45% of tissue volume—very high values. With mitochondria packed this densely in muscle cells, a sort of competition arises between mitochondria and contractile elements for cell space; as mitochondria occupy more space, contractile elements have less. Animals seem never to go higher than about 45% mitochondria in working muscles, suggesting that the evolution of higher values would be pointless because the contractile apparatus would be too diminished to use the ATP that the mitochondria could make. The peak in mitochondrial packing helps set an ultimate peak on $\dot{V}_{O_2\max}$ per gram of muscle tissue.

$\dot{V}_{O_2\max}$ varies among individuals within a species

Individuals of a species vary in $\dot{V}_{O_2\max}$ as we saw in Figure 1.19. The phenomenon is readily documented in humans. For example, when groups of young men entering the military are tested for $\dot{V}_{O_2\max}$, they typically exhibit a normal statistical distribution (bell curve) in $\dot{V}_{O_2\max}$ with the low and high values being quite different (e.g., lows near 40 and highs near 70 mL O₂/kg·min for men drawn randomly from the general population). As we discuss in greater detail shortly, some of this variation is a consequence of life experience, whereas some (about half, according to recent research) is genetic.

Recall that the strenuousness of any given form of sustained exercise depends on the fraction of $\dot{V}_{O_2\max}$ that the exercise requires. This principle helps explain why a single form of sustained exercise can be differently taxing to different individuals. Suppose, to illustrate, that for a person to run at a particular speed, a rate of O₂ consumption of 30 mL O₂/kg·min is required. Suppose also that two otherwise identical people have $\dot{V}_{O_2\max}$ values of 40 and 70 mL O₂/kg·min, respectively. For the former individual the running would require 75% of $\dot{V}_{O_2\max}$ and would be very taxing; for the latter, it would require just 43% and would be sustainable for hours.

Investigators consistently find that, among successful human athletes, individuals who excel in different types of competition tend to exhibit striking differences in $\dot{V}_{O_2\max}$. As Table 9.4 shows, for example, men who compete at the world-class level in cross-country skiing or long-distance running have far higher average $\dot{V}_{O_2\max}$ values than men who compete in weight lifting or gymnastics. Based on careful analysis, the differences in Table 9.4—taken as a whole—cannot be attributed primarily to differences in training (except for the “general population”). The differences in $\dot{V}_{O_2\max}$ among successful athletes in various events are believed to result to a substantial extent from the athletes’ choosing to compete in events in which they have inherent abilities to succeed. A high $\dot{V}_{O_2\max}$, meaning a high peak rate of aerobic ATP production, is an asset in long-sustained events, especially ones like cross-country skiing in which most major muscle masses are employed. Athletes who are endowed by heredity or by early developmental influences with a high $\dot{V}_{O_2\max}$ choose sports such as cross-country skiing and others in which aerobic ATP synthesis is particularly important, and vice versa. Although almost nothing is known about nonhuman animals in this regard, it seems reasonable to hypothesize that in them also, individuals with different aerobic competence elect different lifestyles—as discussed at the close of this chapter.

$\dot{V}_{O_2\max}$ responds to training and selection

Training that emphasizes aerobic ATP production—known as *endurance training*—often increases an individual’s $\dot{V}_{O_2\max}$. When sedentary people, for example, participate in endurance training,

TABLE 9.4 Average $\dot{V}_{O_2\max}$ in male Swedish athletes who compete in various events at the world-class level

Event (or other category)	Average $\dot{V}_{O_2\max}$ (mL O ₂ /kg·min)
Highest values ever recorded	90–95
Cross-country skiing	84
Long-distance running	83
Canoeing	67
Ice hockey	63
Soccer	58
Weight lifting	53
Gymnastics	52
General population (young adult Swedish men)	44

Source: After Åstrand and Rodahl 1986.

they typically increase their $\dot{V}_{O_2\max}$ by 10–30%, although individuals vary widely and some show no change. The physiological reasons for the increase in $\dot{V}_{O_2\max}$ are starting to be well understood, at least in humans and lab animals. Training activates widespread changes in gene expression in exercising muscles (see Figure 3.9). One of several major consequences is an increase in numbers of mitochondria in muscle cells and upregulation of mitochondrial enzymes of aerobic catabolism, such as citrate synthase (a Krebs cycle enzyme) and cytochrome oxidase (an electron-transport enzyme), as exemplified in Table 9.5. Other changes include increases in the heart's capacity to pump blood, the density of blood capillaries in muscles, and muscle glucose transporters. Training is discussed in detail in Chapter 21.

On a different scale of time, there are several ongoing projects focused on *selection*—over many generations—for high or low aerobic competence. In one study, for example, investigators started with random-bred lab rats that were individually tested for their ability to run long distances during aerobic exercise. Rats with both high and low aerobic endurance were selected to be parents of future generations. As Figure 9.11 shows, ten generations of this process resulted in two populations of rats (shown in blue and red) that differed dramatically, emphasizing that there is a partial genetic basis for exercise performance; on average, rats in the population selected for high running capacity could run 905 m prior to exhaustion, whereas rats in the population selected for low running capacity could run only 217 m. $\dot{V}_{O_2\max}$ diverged in the two populations; by the 15th generation, it was 1.5 times

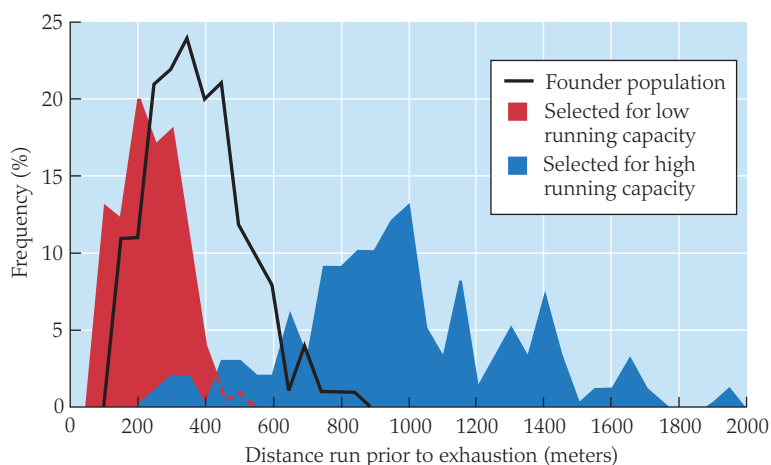

FIGURE 9.11 Consequences of selection on endurance running in rats. Hundreds of rats were tested on a treadmill tilted so they had to run uphill. The distance each rat could run prior to exhaustion was measured. Rats led a sedentary existence except during testing. Plotted here are frequency distributions: the percentages of rats that ran various distances prior to exhaustion. The study started with a “founder” population. Animals with exceptionally great endurance were chosen as parents for the next generation, and this process was repeated for a total of ten generations to give rise to the population shown here as “selected for high running capacity.” Similarly, animals in the founder population that displayed exceptionally low endurance were mated, and the process was repeated for ten generations to obtain the population “selected for low running capacity.” Both the high- and low-running-capacity populations exhibited shifted distributions in comparison with the founder population. (After Koch and Britton 2005.)

TABLE 9.5 Average physiological measures before and after 7 weeks of endurance training in young adult people

The training consisted of 60 min of cycling, requiring 60% of $\dot{V}_{O_2\max}$, 5 days a week. All before–after differences are statistically highly significant, except for the testosterone values. Muscle measures are for samples from the *vastus lateralis*, a thigh muscle.

Property	Gender	Before	After
$\dot{V}_{O_2\max}$ (mL O ₂ /kg·min)	Male	41.5	48.7
	Female	31.9	41.5
Muscle citrate synthase activity (μmol/mg·min)	Male	7.3	10.2
	Female	8.4	12.0
Muscle cytochrome oxidase activity (μmol/mg·min)	Male	4.8	5.9
	Female	4.1	5.3
Blood testosterone (nmol/L)	Male	19.3	21.5
	Female	1.7	1.3

Source: Carter et al. 2001.

higher, on average, in the high-endurance population. The capacity of the heart to pump blood was far higher in that population, blood-capillary density in the muscles was higher, and enzymes of aerobic catabolism were elevated. The research also brought to light a discovery that is disturbing in light of today's sedentary lifestyles: Rats in the population selected for low aerobic exercise capacity tended to exhibit symptoms of chronic cardiovascular and metabolic diseases, such as high blood pressure and diabetes.

SUMMARY The Maximal Rate of Oxygen Consumption

- An animal's maximal rate of O₂ consumption ($\dot{V}_{O_2\max}$) is significant for two principal reasons. First, it determines the maximal rate at which sustained, aerobic exercise can be performed. Second, it serves as a benchmark by which the strenuousness of submaximal aerobic work can be assessed. Sustained work becomes more strenuous—and more quickly fatiguing—for an individual as it demands a higher proportion of the individual's $\dot{V}_{O_2\max}$.
- Major phyletic groups sometimes exhibit consistent differences in $\dot{V}_{O_2\max}$. Among vertebrates—as a rough but important rule of thumb— $\dot{V}_{O_2\max}$ in mammals and birds is about an order of magnitude higher than $\dot{V}_{O_2\max}$ in fish, amphibians, and nonavian reptiles of similar body size, assuming that the latter groups are at body temperatures near mammalian and avian levels. Within a single phyletic group, $\dot{V}_{O_2\max}$ typically tends to vary with body size in an allometric fashion, small-bodied species having higher $\dot{V}_{O_2\max}$ per gram of body weight than large-bodied species.
- Individuals of a species that are similar in age and gender typically vary considerably in $\dot{V}_{O_2\max}$. Some of this variation can be attributed to differences in training. Usually a significant proportion of the variation can also be attributed to inheritance and/or early developmental effects.

The Energetics of Routine and Extreme Daily Life

From studies using the doubly labeled water method, physiologists now know a great deal about the *average daily metabolic rates* (ADMRs;

also called *field metabolic rates*) of terrestrial animals leading their routine lives in their natural habitats. Within sets of related animals, the ADMR is an allometric function of body size: The ADMR per unit of body weight typically decreases as body size increases. In wild mammals and birds, the ADMR of a species—measured under *routine* circumstances in free-living animals—tends to be about 2.5–3.5 times higher than the species' basal metabolic rate (BMR). In comparison with lizards, snakes, and other nonavian reptiles living in the wild, mammals and birds of the same body size living in the wild have ADMRs that are 12–20 times higher. As stressed in Chapters 7 and 10, homeothermy is expensive!

How do people compare? In both developed and developing societies, the ADMRs of hundreds of people going about their ordinary daily lives have been measured by use of the doubly labeled water method. ADMR tends to vary (in a roughly normal distribution) from about 1.2 times BMR to 2.5 times BMR in the general population of people in the age range of 20–50 years. A ratio of about 2.5 seems to be something of a ceiling. For the most part, only dedicated athletes exceed it.

Animals sometimes face periods of *particularly extreme* energy demand as they go about their daily lives. A question that has drawn the interest of physiologists is how high the ADMR can be. That is, what is an animal's maximum possible average metabolic rate that can be *sustained day after day*? Note that this is a very different question from asking how high the $\dot{V}_{O_2\max}$ can be, because $\dot{V}_{O_2\max}$ reflects a rate of metabolism that can be maintained for only tens of minutes, at most.

To gain insight into how high the human sustained metabolic rate can possibly be, investigators studied cyclists in the Tour de France, a long-distance bicycle race. In 1984 the race covered nearly 4000 km and lasted 22 days, during which the cyclists fought for the lead while going up and down 34 mountains. The athletes maintained stable body weights over the 3 weeks of the race by eating large amounts of food during their nighttime breaks. The metabolic rates of four cyclists, measured with the doubly labeled water method, averaged about 4.5 times higher than BMR. These data indicate that when well-conditioned people in a competitive situation expend the maximal effort that they can possibly maintain for periods of many days, their time-averaged metabolic rates are about 4.5 times BMR (even though $\dot{V}_{O_2\max}$ is at least 10 times BMR).

Table 9.6 presents data on the sustained metabolic rates of nonhuman mammals and birds under circumstances that could be expected to call forth all-out effort, analogous to the effort put forth by competitors in the Tour de France. Whereas some of the animals in the table were in cold environments requiring high energy costs to keep warm, others were rearing young. The data indicate that usually, at the extreme, the sustained ADMR can be as high as six to seven times the resting metabolic rate. Migrating birds are exceptions, in some cases reaching sustained ADMRs of about nine times resting metabolic rate.

Clearly, if animals could achieve higher peak sustained metabolic rates than they do, they could raise more young, migrate faster, or survive in more-demanding environments. Thus animals confront constraints—constraints that are imposed by limits on the rates at which they can use energy to their advantage in carrying out prolonged, ecologically critical activities. In view of the importance of such limits, we must wonder what *causes* them: Why are the peak sustained metabolic rates of mammals and birds not usually

TABLE 9.6 Particularly high sustained metabolic rates measured in nonhuman mammals and birds

Animals and circumstances	Average daily metabolic rate as ratio of resting metabolic rate
Female laboratory mice nursing litters of 14 young	6.5
Females of three other species of mice nursing litters	3.7–6.7
Four species of mice living at -10°C	3.7–6.1
Grey seals nursing pups	7.4
Three species of perching birds rearing young	2.4–3.9
Six species of seabirds rearing young	3.1–6.6
Migrating birds:	
Bar-tailed godwits migrating over Pacific Ocean	8.0–10.0
Several species flying in wind tunnels	9.0

Sources: After Gill et al. 2009; Hammond and Diamond 1997; Mellish et al. 2000; Piersma 2011.

higher than six to seven times their resting metabolic rates and never higher than ten times their resting metabolic rates? That is a current question for research.

Long-Distance Migration

When we see an osprey (*Pandion haliaetus*)—also called a fish hawk—at the seashore, going about its life, we might easily assume that the bird is always at that area where we see it. Applications of rapidly advancing satellite and global-positioning technology in the past 15 years, however, have provided an entirely different view. **Figure 9.12** shows the directly observed locations of a single osprey over a 3-year period of its life. The osprey traveled back and forth between Sweden and Ivory Coast—a one-way distance of 7000 km (4300 miles)—three times. Each autumn, having spent the summer in Scandinavia, it traveled a route that must have started to seem familiar—given that the route was almost the same each year. Stopping over on repeated occasions to rest and potentially refuel, the osprey took 34–55 days to reach its destination in Africa. There, it resumed the life it had left behind a half-year before: living in its individual wintering locality. Then, each spring, it returned in 21–33 days to Scandinavia to its individual breeding location. Migratory patterns of this sort already existed in the deep past of Earth's geologic history and continue today despite burgeoning human influences all along the routes traveled.

Some of the questions raised by this natural phenomenon are put into greater relief, perhaps, by studies recently completed on bar-tailed godwits (*Limosa lapponica*)—shorebirds weighing roughly 0.5 kg—in their southward migration from Alaska each autumn. Although the godwits do not feed at sea, these cutting-edge studies have revealed that they fly nonstop to New Zealand over the open water of the central Pacific Ocean—a trip of approximately 10,000

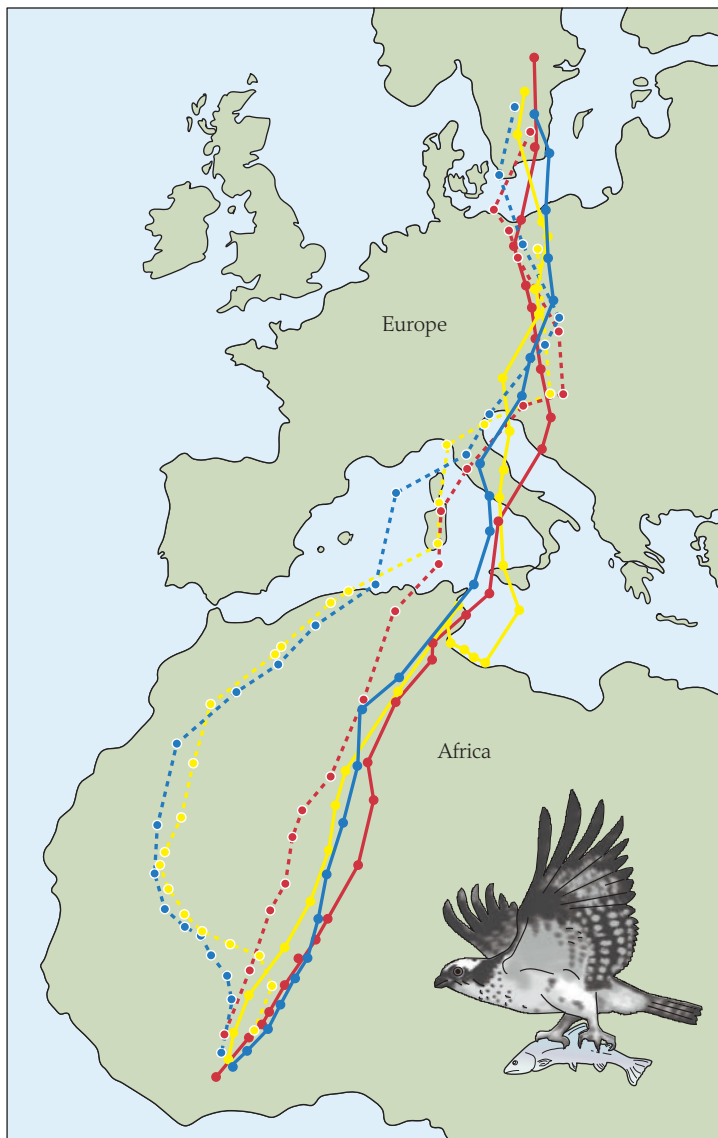

FIGURE 9.12 Three years in the life of a male osprey (*Pandion haliaetus*) Ospreys migrate singly rather than in groups. As this male flew between Scandinavia and Africa, a small radiotransmitter on him, mounted externally, radioed his position, which was detected by satellite. Three colors are used to distinguish the three successive years in the order yellow, red, and blue. Symbols along the lines represent locations at intervals of 1 day or more. Solid lines mark his south-bound migrations in autumn. Dashed lines mark his north-bound migrations in spring. (After Alerstam et al. 2006.)

km (6200 miles) that takes them 6–9 days. Over those 6–9 days, they starve; they have no freshwater to drink; presumably they do not sleep and thus suffer sleep deprivation; they must mobilize and transport the metabolic fuels they need from internal stores; and their flight muscles must engage in powering or controlling flight continually day and night—not to mention the necessity of navigating accurately over endless expanses of water. Although the godwits take advantage of tailwinds, this flight seems to challenge some of our most basic assumptions about the very nature of animal life.

Physiologists have long recognized that birds principally use stored fat as fuel for long-distance migrations. Fat is particularly suited for this function because of its high energy density (see Table

6.3). The *mobilization* and *distribution* of fatty acids from fat during migration are significant concerns. This point is highlighted by the fact that mammals that have been studied cannot mobilize fat rapidly enough for it to be the principal fuel for high-intensity, long-term exertion. In migrating birds, by contrast, roughly 90% of the fuel is fat. The birds evidently have highly developed mechanisms for fatty acid transport across cell membranes. Moreover, because the fatty acids are water insoluble, the birds evidently also have highly developed mechanisms for solubilizing fatty acids, as by formation of lipoprotein complexes, so the fatty acids can be distributed to the working muscles from storage depots.

Birds accumulate fat prior to migration (they often increase 50–100% in body weight) and use their stored fat during migration—giving rise to a long-held view that the process is much like fueling an aircraft. In the last 15 years, however, evidence has accumulated that—at least in some long-distance migrants—the nature of the aircraft changes! Specifically, some of the organs that are involved in building up fat stores (e.g., the intestines)—as well as other organs—shrink substantially after the fuel-storage phase and during migration, thereby lightening the load that must be transported (see the discussion of red knot sandpipers at the start of Chapter 1). Although animals do not store proteins for future use analogously to the way they store fat (see Chapter 6), organ reductions of this sort have the effect of freeing proteins for metabolism. In this and other ways, about 10% of the energy used during migration comes from protein catabolism. One advantage of metabolizing proteins is that glucose can be synthesized readily from amino acids. This provides a mechanism to meet the central nervous system’s requirement for glucose as a fuel.

The migrations of certain species of eels in the Atlantic and Pacific Oceans are among the other long-distance migrations that attract the interest of physiologists. **Box 9.3** discusses the spawning migration of European eels to the Sargasso Sea near Bermuda, the study of which has an especially long and revealing history.

Ecological Energetics

Ecological energetics is the study of energy needs, acquisition, and use in ecologically realistic settings. An example is provided by research on the energy needs and acquisition of breeding colonies of seabirds (**Figure 9.13**). Using the doubly labeled water method or time–energy budgets, investigators estimate the daily energy demand of a colony, including costs of growth in the young birds and costs of foraging flight in the adults, as discussed at the start of this chapter. The energy demand of the colony can then be compared with the energy available from the fish populations on which the birds feed. Studies of this sort have revealed that seabird colonies sometimes consume one-fourth to one-third of all the productivity of prey fish in their foraging areas. This sort of ecological energetic analysis has helped biologists better understand seabird population dynamics. For example, the high energy needs of some colonies help explain why some have been devastated by competition from human fishing.

A more elaborate illustration of the power of ecological energetic research is provided by Bernd Heinrich’s analysis of costs and rewards in bumblebee foraging—an example of what Heinrich terms *bumblebee economics*. The starting point of his analysis is the recognition that in ecologically realistic settings, the acquisition of food has energy costs as well as energy rewards.

BOX 9.3 EEL MIGRATION AND ENERGETICS: A 2300-YEAR DETECTIVE STORY

European eels (*Anguilla anguilla*) are currently believed to breed in the western Atlantic Ocean near Bermuda, although the distance between Europe and this purported breeding area is about 5500 km (3400 miles). Skeptics have questioned whether adult eels—which do not eat in the ocean—could swim that far and still have enough stored energy for reproduction. Recently, investigators placed eels in a water tunnel for a simulated 5500-km migration. The eels had to swim for almost 6 months to cover the equivalent of 5500 km. Not only did they succeed, but they did so at a remarkably low cost. As seen in the figure, the metabolic rates of the swimming eels tended to be only about twice as great as those of resting eels. The migrating eels achieved a cost of transport that was only about one-fifth as great as expected for their body size, pointing to exceptional swimming efficiency. As a result, they lost only about 20% of their body weight and would have had reasonable energy stores remaining on arrival in Bermuda.

European eels have been a focal mystery in marine biology ever since 350 BC, when

Metabolic rate measured on each day of a 6-month, 5500-km simulated migration Nine eels (*Anguilla anguilla*), 0.7 m in average body length, swam for 173 days in a water tunnel. They were compared with 6 resting eels. The eels were not fed. The temperature was 19°C. (After van Ginneken et al. 2005.)

Aristotle, in his writing on natural history, highlighted the literal statement that no one in Europe had ever seen sperm or eggs in a European eel or seen the eels breed! **Box Extension 9.3** outlines the long story of how

scientists ultimately concluded that the eels do in fact breed like other fish, but do so far from Europe. The box extension also discusses the latest efforts to confirm this hypothesis by direct observation.

When bumblebees (*Bombus*) forage, they fly from one flower (or flower cluster) to another, landing on each long enough to collect available nectar. Two major *costs* of bumblebee foraging must be considered:

1. Flight is itself very costly. It can easily elevate the metabolic rate of a bumblebee to 20–100 times its resting rate. The cost

Figure 9.13 A case study in ecological energetics A breeding colony of seabirds, such as this colony of terns, is ecologically dependent on the populations of fish in its vicinity to obtain energy for life and reproduction. With modern methods, physiologists can quantify the rate at which a colony harvests energy relative to the rates of production of prey populations.

of flight per unit of time is essentially independent of air temperature.

2. Temperature regulation may also be costly. To fly, bumblebees require the temperature of their flight muscles to be 30°C or higher (see page 271). When the bees are flying, temperatures that high are maintained by the heat produced by the wing-flapping contractions of their flight muscles. When bees land on flowers (and stop flying) in cool weather, however, they are at risk of quickly cooling to below the necessary flight temperature—which would make them unable to take off again. To keep their flight muscles warm while they are alighted on flowers, bees produce heat by a process analogous to human shivering (see Chapter 10). The intensity and *energetic cost* of this form of shivering become greater as the air temperature decreases. Although shivering may be unnecessary at an air temperature of 25°C, shivering at 5°C may raise a stationary bee's metabolic rate to as high a level as prevails during flight.

Considering the costs of *both* flying and shivering, the *average* metabolic expenditure per unit of time for a bee to forage tends to increase as the air becomes cooler. If the air is warm enough that no shivering is needed, a bee has a high metabolic rate when it is flying but a low rate when it is not. If the air is cold, the bee has a high metabolic rate all the time, whether flying or stationary.

Now let's turn to the energy *rewards* of foraging. The energy reward that can be obtained per unit of time from any particular species of flowering plant depends on (1) the volume of nectar obtained from each flower, (2) the sugar concentration of the nectar,

and (3) the number of flowers from which a bee can extract nectar per unit of time. The third property depends on the spacing of the flowers and the difficulty of penetrating flowers to obtain their nectar.

Some species of plants yield sufficient sugar per flower that bumblebees can realize a *net* energy profit when foraging from them regardless of the air temperature. For example, the rhododendron *Rhododendron canadense*, a plant with large flowers, typically yields sugar equivalent to about 1.7 J/flower. At 0°C, a large bee expends energy at a time-averaged rate of about 12.5 J/min while foraging. Accordingly, the bee could break even energetically by taking the nectar from about 7–8 flowers per minute. In fact, bees can tap almost 20 rhododendron flowers per minute. Thus, even at 0°C, bees foraging on the rhododendron are able to meet their costs of foraging *plus* accumulate a surplus of nectar to contribute to the hive.

In contrast, some plants yield so little sugar per flower that they are profitable sources of nectar only when air temperatures are relatively high (and the bees' costs of foraging are thereby reduced). For example, bees typically visit flowers of wild cherry (*Prunus*) only when the air is warm. The flowers yield sugar equivalent to only about 0.21 J/flower. At 0°C, a bee would therefore have to tap about 60 flowers per minute just to meet its costs of foraging. Tapping so many flowers is impossible, meaning the bees cannot profitably forage on cherry flowers when the air is cold.

The study of bumblebee foraging exemplifies how an ecologically realistic accounting of energy *costs* and *gains* can reveal constraints in animals' daily lives. Energetic considerations help dictate the suite of flowers that bees can profitably exploit: both rhododendron and cherry when the air is warm, but only rhododendron when the air is cold.

A branch of ecological energetics that is just starting to be developed is the study of *consistent individual differences* in energy metabolism characteristics. If we look back at the range of \dot{V}_{O_2max} values observed among different individuals within a population of wild mice (see Figure 1.19), we see that some individuals have a \dot{V}_{O_2max} that is 40% higher than that of others. In several populations of animals that have been studied, individual differences of this sort have proved to be impressively consistent: Individuals high in aerobic competence at one time tend to be high at other times. The variation in \dot{V}_{O_2max} among individuals raises the question of whether certain individuals consistently perform at a superior level in aerobic challenges, in comparison with others: In populations of wild animals there may be metabolically based differences in behavior among individuals, just as some humans perform well in long-distance races whereas others perform well in short-term exertion that relies less on aerobic competence. We are constantly aware that different people in our midst have different personalities. There is accumulating evidence that consistent individual differences—analogueous to personality—also exist in at least some species of animals, and some of these differences are based on energy metabolism characteristics.

Study Questions

- How does the doubly labeled water method depend on the existence of isotopic equilibrium between the oxygen in H₂O and that in CO₂?
- From a list of your friends, select one (theoretically) for study to determine his or her average daily metabolic rate. How would you carry out research to create a time–energy budget for your friend?
- In your own words, explain why foraging on wild cherry flowers is beneficial for bumblebees in warm weather but not in cold weather.
- As noted in this chapter, the \dot{V}_{O_2max} of people tends to decline after age 30 by about 9% per decade for sedentary individuals, but it declines less than 5% per decade for people who stay active. The average \dot{V}_{O_2max} in healthy 30-year-olds is about 3.1 L/min. Using the information given here, what would the average \dot{V}_{O_2max} be in 60-year-olds who have been sedentary throughout their lives and in 60-year-olds who have stayed active (keep in mind that the decline is exponential)? Consider the activities in Table 9.1, and recall from Chapter 7 that 1 kJ is equivalent to about 0.05 L of O₂ in aerobic catabolism. How would you expect sedentary and active people to differ in their capacities for each of those activities in old age? Explain.
- For an animal engaging in sustained exercise, why is there not one single ideal speed?
- List the possible reasons why two individuals of a certain species might differ in \dot{V}_{O_2max} .
- Suppose that a bird's metabolic rate while flying at 30 km/h is 8 kJ/h. What is the bird's cost of transport when flying at 30 km/h?
- Looking at Figure 9.8, how would you say animals and machines compare in their efficiencies in covering distance?
- African hunting dogs depend on sustained chases by groups of cooperating individuals to capture antelopes for food. If the members of two groups differ in their average \dot{V}_{O_2max} , how might the two groups differ in the strategies they use during hunting?
- In mammals of all species, the peak rate of O₂ consumption of each mitochondrion is roughly the same. On the basis of patterns of how \dot{V}_{O_2max} varies with body size in species of mammals, how would you expect the muscle cells of mammals of various body sizes to vary in how tightly they are packed with mitochondria? Explain your answer.
- What is the hypothesis of symmorphosis? How might you evaluate or test the hypothesis?
- Explain the concept that in high-performance muscle cells, mitochondria and contractile elements compete for space over scales of evolutionary time.

Thermal Relations

As this bumblebee flies from one flower cluster to another to collect nectar and pollen, temperature matters for the bee in two crucial ways. First, the temperature of the bumblebee's flight muscles determines how much power they can generate. The flight muscles must be at least as warm as about 35°C to produce enough power to keep the bee airborne; if the muscles are cooler, the bee cannot fly. The second principal way in which temperature matters is that for a bumblebee to maintain its flight muscles at a high enough temperature to fly, the bee must expend food energy to generate heat to warm the muscles. In a warm environment, all the heat required may be produced simply as a by-product of flight. In a cool environment, however, as a bumblebee moves from flower cluster to flower cluster—stopping at each to feed—it must expend energy at an elevated rate even during the intervals when it is not flying, either to keep its flight muscles continually at a high enough temperature to fly or to rewarm the flight muscles to flight temperature if they cool while feeding. Assuming that the flight muscles must be at 35°C for flight, they must be warmed to 10°C above air temperature if the air is at 25°C, but to 30°C above air temperature if the air is at 5°C. Thus, as the air becomes cooler, a bee must expend food energy at a higher and higher rate to generate heat to warm its flight muscles to flight temperature, meaning it must collect food at a higher and higher rate.

Overall, tissue temperatures have a two-fold significance in many animals, including ourselves. The temperatures of tissues help determine how the tissues perform. Tissue temperatures also help determine an animal's rate of energy expenditure. Bumblebees illustrate both of these points. The temperature of a bumblebee's flight muscles determines how intensely the muscles are able to perform their function of generating lift, and it determines how much food energy the bee must employ for heat production each day.

Physiologists now realize that animals are diverse in the types of thermal relations they maintain with their environments. To categorize the thermal relations of animals, one key concept is **endothermy**; if an animal's tissues are *warmed by its metabolic production of heat*, the animal is said to exhibit endothermy. A second key concept is **thermoregulation**, which refers to the maintenance of a relatively constant tissue temperature.¹ Suppose we classify animals according to whether or not they exhibit endothermy and whether or not they display thermoregulation. Doing so results in the matrix in **Figure 10.1**, which identifies the four most fundamental types of thermal relations that animals have with their environments.

Most animals are incapable of endothermy and thus fall on the left side of the matrix in **Figure 10.1**.² Animals of this sort are termed **ectotherms** because the thermal conditions outside their bodies determine their body temperatures (*ecto*, "outside"). They are also

¹Thermoregulation is a specific type of *regulation* as defined in Chapter 1 (see Figure 1.6).

²As stressed in Chapter 7, metabolic heat production is a universal feature of living organisms. When we say "most animals are incapable of endothermy," we do not mean they fail to produce heat metabolically. Remember, instead, that endothermy is *warming of the tissues* by metabolic heat production. Most animals are incapable of endothermy because, although they produce heat, they do not make heat fast enough or retain heat well enough for their tissues to be warmed by their metabolic heat production.

For a foraging bumblebee, warming the thorax to a high temperature is a critical requirement The process adds to the bee's energy costs and food needs on cool days. However, the flight muscles in the thorax require high temperatures to produce sufficient power for flight.

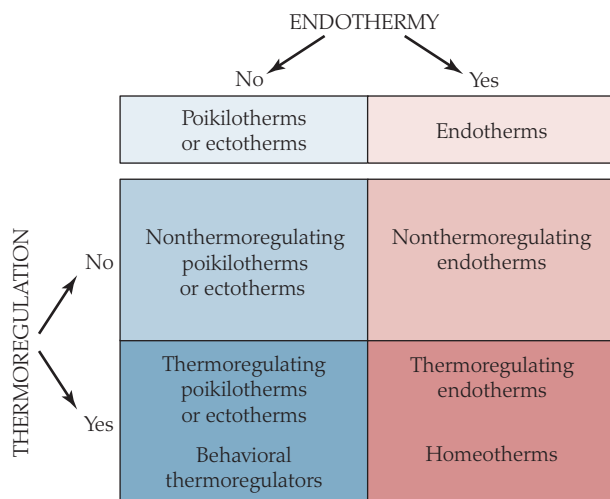

FIGURE 10.1 Animals fall into four categories of thermal relations based on whether they display endothermy and whether they display thermoregulation

called **poikilotherms** because they have variable body temperatures (*poikilo*, “variable”); their body temperatures are high in warm environments but low in cool ones. Most fish are excellent examples of ectotherms or poikilotherms; their tissues are not warmed metabolically and therefore are at essentially the same temperature as the environmental water in which the fish swim.

A poikilotherm or ectotherm may or may not exhibit thermoregulation (see the vertical dimension of Figure 10.1). When a poikilotherm displays thermoregulation and thus falls into the lower left category of our matrix, it does so by *behavior*: It keeps its tissues at a certain temperature by behaviorally choosing to occupy environments that produce that temperature in its body.

Animals that exhibit endothermy—that is, animals that warm their tissues by their production of metabolic heat—are termed **endotherms** and fall on the right side of the matrix in Figure 10.1. Although endotherms may or may not be thermoregulators, most in fact exhibit thermoregulation (placing them in the lower right category of the matrix). Mammals and birds are outstanding examples of animals that exhibit both endothermy and thermoregulation. Many medium-sized and large insects, such as the bumblebees we have already discussed, also exhibit both endothermy and thermoregulation (in their flight muscles when they are flying). A **homeotherm** is an animal that thermoregulates by *physiological* means (rather than just by behavior). Mammals, birds, and insects such as bumblebees are homeotherms. Under many circumstances, the principal way they thermoregulate is by adjusting how rapidly they produce and retain metabolic heat: They thermoregulate by modulating their endothermy!

In addition to the categories identified by our matrix, further complexity arises in categorizing animal thermal relations because of the frequent occurrence of temporal and spatial variation. Speaking first of *temporal variation*, individuals may adopt different thermal relations to their environments at different times. In species of mammals that hibernate, for example, individuals are homeotherms during the seasons of the year when they are not hibernating, but often they exhibit neither endothermy nor thermoregulation when hibernating. Thermal relations may also exhibit *spatial variation*, differing from one region of an animal’s body to another. The abdomens of

bumblebees and other active insects, for example, are typically neither endothermic nor thermoregulated, even in individuals that exhibit endothermy and thermoregulation in their thoracic flight muscles.

Heterothermy refers to a difference in thermal relations from one time to another, or one body region to another, within a single individual. Hibernating species of mammals exemplify **temporal heterothermy**. Flying bumblebees illustrate **regional** (i.e., spatial) **heterothermy**.

Temperature is *always* a major factor in the lives of individual animals, regardless of the particular thermal relations the animals exhibit. Whether animals are poikilotherms or homeotherms, for example, temperature is universally important in at least two ways:

- The environmental temperature—also known as *ambient temperature*—is a principal determinant of an animal’s metabolic rate and therefore the rate at which the animal must acquire food.
- The temperature of an animal’s tissues plays a principal role in determining the functional properties of the tissues and tissue constituents. For example, tissue temperature affects whether protein molecules are in high-performance or low-performance molecular conformations. Tissue temperature also affects the rates of biophysical processes (e.g., diffusion and osmosis), the rates of biochemical reactions, and the viscous physical states of cellular materials such as cell-membrane phospholipids.

The effects of temperature on the properties of entire ecosystems are just as notable as the effects on individual animals. Walking through a temperate woodland during the various seasons of the year provides a striking illustration. On a walk in summer, one is aware of vigorous photosynthesis by plants and sustained activity by mammals, birds, insects, turtles, snakes, amphibians, and other animals. In the winter, however, plants and most animals become cold and quiescent; activity in the woodland becomes restricted largely to the mammals and birds that keep their tissues warm. We cannot always say with certainty whether temperature is the primary determinant of the seasonal changes that we observe in a particular species, because in an entire community of this sort, the responses of any one species may be ripple effects of impacts on others. The evolution of winter quiescence in many animals, for example, has surely been influenced by the effects of cold on plant growth, because the animals face restricted food resources in winter. One cannot doubt, nonetheless, that much of the change in the animal life of a temperate woodland from summer to winter is a direct consequence of the seasonal change of temperature.

Biogeographers have built a strong case that temperature often plays one of the single greatest roles of all environmental factors in determining the geographical ranges of animal species. In North America, for example, the northern limits of the winter ranges of birds often correlate well with particular winter temperatures. Eastern phoebes illustrate this pattern. The northern limit of their geographical range in winter corresponds closely with a line that connects all the places where the average minimum air temperature is -4°C (Figure 10.2). Eastern phoebes in winter do not extend northward to a fixed latitude, mountain range, river, or other geographical limit. Instead, they extend northward to a relatively fixed severity of winter cold stress. Where winter nights average warmer than about -4°C , these birds are to be found. Where winter nights average colder than -4°C , they do not occur.

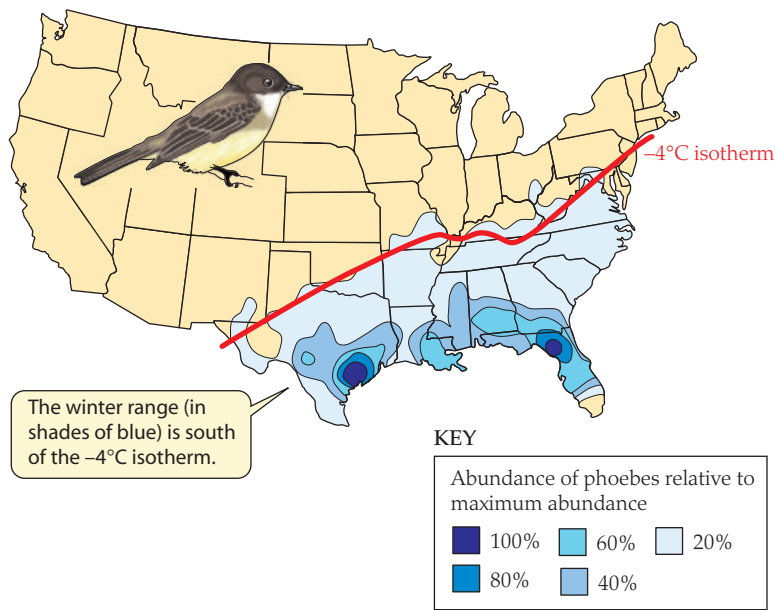

FIGURE 10.2 Eastern phoebes (*Sayornis phoebe*) overwinter where the average minimum air temperature in January is -4°C or warmer. Blue areas show where eastern phoebes overwintered when studied in the 1980s (relative abundance is coded by the shade of blue). The average minimum air temperature in January was -4°C or warmer below the red line (the “ -4°C isotherm”) and colder than -4°C above the line. (After Root 1988.)

One reason that biologists today are acutely interested in the influences of temperature is the threat of global warming (Box 10.1). The need for accurate predictions of global warming effects has become a major new reason for the study of animal thermal relations.

Temperature and Heat

The distinction between *temperature* and *heat* is tricky, and it is important for understanding the thermal relations of animals. To elucidate the distinction, consider a simple inanimate system: two blocks of copper—one of which is ten times more massive than the other, and both of which have been sitting in a room at 20°C long enough that they are at temperature equilibrium with the room. If you measure the *temperature* of each block, you will find that it is 20°C , even though one block is small and the other is large. Suppose, however, that you remove and measure the *heat* from each block; suppose, for instance, that you place each block at absolute zero and measure the amount of heat liberated as the block temperature falls from 20°C to absolute zero. You will find that the large block yields ten times more heat than the small one. Thus, as the two blocks sit in the room at 20°C , their *temperatures* are the same and independent of the amount of matter in each block, but their contents of *heat* are different and directly proportional to the amount of matter in each block.

To understand in greater depth these contrasting attributes of temperature and heat, recall from Chapter 5 (see page 101) that the atoms and molecules within any substance undergo constant random motions on an atomic-molecular scale. The **temperature** of a substance is a measure of the *speed*—or *intensity*—of these

incessant random motions.³ In the two copper blocks sitting in the room at 20°C , the average speed of atoms during the random atomic-molecular motions is identical; thus, even though the blocks differ in size, they are the same in temperature. **Heat**, unlike temperature, is a form of energy; it is the energy that a substance possesses by virtue of the random motions of its atomic-molecular constituents (see page 163). The amount of heat in a piece of matter thus depends on the *number* of atoms and molecules in the piece, as well as the *speed* of each atom and molecule. A copper block with many copper atoms moving at a given average speed contains proportionally more heat energy than one with fewer atoms moving at the same speed.

A key property of temperature is that it dictates the *direction of heat transfer*. Heat always moves by conduction or convection from a region of high temperature to one of low temperature. To refine this concept, suppose you have a large copper block at 20°C in contact with a tiny copper block at 30°C ; although the large block contains more heat than the small one, heat will move from the small block into the large one because temperature, not energy content, dictates the direction of energy transfer. The net addition of heat to any object causes an increase in the temperature of the object. All in all, therefore, *temperature* and *heat* have intimate interactions:

- Heat moves by conduction or convection from high temperature to low.
- The transfer of heat raises the temperature of the object receiving heat and lowers the temperature of the object losing heat.
- In a simple physical system such as two solid objects in contact with each other, objects are at thermal equilibrium when their temperatures are the same because then heat does not tend to move in net fashion between them.

Heat Transfer between Animals and Their Environments

A living animal positioned in an environment, besides making heat internally because of its metabolism, exchanges heat with its surroundings by four distinct heat-transfer mechanisms: *conduction*, *convection*, *evaporation*, and *thermal radiation* (Figure 10.3). The animal may well gain heat by one mechanism of heat transfer while it simultaneously loses heat by another. A familiar illustration of this important point is that on a hot day in summer, people may simultaneously gain heat from the sun by *thermal radiation* while they lose heat by the *evaporation* of sweat. Because the four mechanisms of heat transfer follow distinct laws and can operate simultaneously in opposite directions, they cannot simply be lumped together. Instead, each mechanism needs to be analyzed in its own right, and then the effects of all four can be summed to determine an animal’s overall heat exchange with its environment.

³Temperature, more specifically, is proportional to the product of molecular mass and the mean square speed of random molecular motions. The speeds of the motions are astounding. In a gas, molecules collide with each other, bounce apart, and then fly through free space until they collide with other molecules. At 20°C , the average speed during each period of free flight is about 500 m/s! The speed is lower at lower temperatures, and higher at higher temperatures.

BOX 10.1 GLOBAL WARMING

The great majority of scientists who have assessed the evidence on global climate change agree that effects of global warming are already right before our eyes or can be predicted with confidence.

Species are tending to shift their ranges poleward. Surveys of large sets of animal species find that there is a strong statistical bias for species in both hemispheres to be shifting their ranges toward the poles. For example, of 36 fish species studied in the North Sea over a recent 25-year period (1977–2001), 15 species changed their latitudinal center of distribution, and of those, 13 (87%) shifted northward (Figure A). This is the pattern

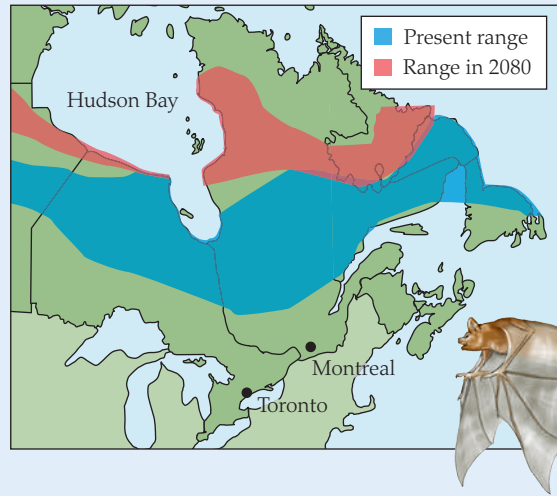

FIGURE B To survive, little brown bats (*Myotis lucifugus*) will need to find new hibernation caves in a new range by 2080. The map shows the ranges in eastern Canada where the bats can find suitable hibernation temperatures, based on a bioenergetic model. Blue shows the model prediction of the present range, whereas red shows the model prediction of the new range that will be required in 2080. The prediction of the present range is compatible with actual known hibernation sites, bolstering confidence in the prediction for the future. (After Humphries et al. 2002.)

expected as a response to global warming: Faced with a warming environment, many species will shift to more-polar latitudes. A synthetic study of almost 900 animal and plant species that were monitored over a median observation period of 66 years found that 434 of the species shifted their ranges, and of

FIGURE A Shifts in the centers of distribution of two fish species in the North Sea from 1977 to 2001. Arrows symbolize the latitudinal shifts of cod (*Gadus morhua*) and blenny (*Lumpenus lampretaeformis*). Average sea temperature increased 1.1°C over the period. Both shifts of species distribution have been monitored annually and have strong statistical support. (After Perry et al. 2005.)

those, 80% shifted as expected in response to a warming world.

Physiological principles enable researchers to predict with confidence that some species will need to shift their ranges poleward to survive. Little brown bats provide an example. When small mammals hibernate, they allow their body temperature to fall to environmental temperature. The fall of body temperature is critical because it helps inhibit metabolism and thereby save energy. However, temperature cannot safely decline without limit. When a hibernator's body temperature reaches the lowest tolerable level, the hibernating animal increases its metabolic rate to keep the temperature from falling further. Consequently, energy costs in hibernation are el-

FIGURE 10.3 An animal exchanges heat with its environment by conduction, convection, evaporation, and thermal radiation. The animal exchanges heat conductively with the ground and convectively with the wind. It loses heat by both respiratory and cutaneous evaporation. It receives thermal radiation from all objects in its surroundings and also emits thermal radiation toward all objects. Finally, it gains heat from its own metabolism. (The cutaneous evaporation from a rabbit is entirely of a nonsweating sort because rabbits lack sweat glands.)

BOX 10.1 (continued)

FIGURE C Rising water temperatures on the Great Barrier Reef could impair the ability of cardinalfish (*Ostorhinchus doederleini*) to engage in aerobic exercise. When water temperature is raised from 29°C to 31°, 32°, or 33°C, the difference between maximal and resting O₂ consumption becomes significantly smaller with each step. Symbols are means; error bars show ± 1 standard deviation. (After Nilsson et al. 2009.)

evated both if the temperature is too high and if it is too low. Many hibernators live entirely on fat stores. To survive, they must not exhaust their fat stores before winter's end. Temperatures determine their metabolic rates and therefore

the rates at which they use up their fat stores. Accordingly, a certain temperature range is required for overwinter survival. The latitudes at which hibernating little brown bats are likely to find suitable temperatures are predicted to shift as global warming proceeds, forcing the bats into a new winter range (Figure B).

Experiments on physiological effects of anticipated temperatures sometimes point to severe future challenges. Some species of fish on the Great Barrier Reef, for example, are in danger of losing much of their capability to be active, as exemplified by cardinalfish (Figure C). Experiments show that the difference between their maximal rate of O₂ consumption and their resting rate of O₂ consumption (i.e., their aerobic scope) becomes dramatically smaller if the water in which they live is warmed from its current temperature of 29°C to temperatures 2–4°C higher. A rise in water temperature on the reef could reduce the ability of the fish to increase their O₂ consumption, limiting their ability to engage in aerobic exercise (see Chapter 9).

Effects of environmental warming on some animals can pose ecological challenges for others. Because animals live in interconnected ecological communities, effects on one species affect others. At a study site in Holland, for example, peak caterpillar abundance in the spring has been occurring progressively earlier from year to year because spring temperatures have been rising, speeding caterpillar development and causing trees (food for the caterpillars) to leaf out earlier. For great tits (chickadee-like

FIGURE D Days between egg laying by great tits (*Parus major*) and peak caterpillar abundance in a Holland woodland. When young birds hatch out of the eggs and then undergo their nestling development, the abundance of caterpillars in the woodland affects how well parents can feed them. (After Visser et al. 1998.)

birds), caterpillars for feeding their nestlings are a key to reproductive success. However, the dates when the tits lay their eggs have hardly changed at all. Accordingly, although the time between egg laying and peak caterpillar abundance was about ideal in 1973, it had shortened—and become too short to be ideal—by 1995 and remains so today (Figure D). Food for nestlings has become detectably inadequate because of the mismatch of ever-earlier caterpillar abundance—caused by warming temperatures—while bird reproduction has not shifted to be equally earlier.

For the body temperature of an animal to be constant, the sum total of its heat gains by all mechanisms taken together must equal the sum total of all its heat losses. For instance, suppose that an animal is gaining heat from its environment by conduction and thermal radiation, as well as from metabolism, while losing heat by convection and evaporation. Its body temperature will be constant if and only if the sum of its heat gains by conduction, radiation, and metabolism per unit of time is exactly matched by the sum of its heat losses through convection and evaporation per unit of time.

Figure 10.4 presents a simple model of an animal that will be useful as we discuss the individual mechanisms of heat exchange. The core of an animal's body is considered to be at a uniform **body temperature**, symbolized T_B . The temperature of the environment is called **ambient temperature**, T_A . The temperature of the body surface often differs from T_B and T_A and thus is distinguished as **surface temperature**, T_S . Separating the body core from the body surface is the outer layer of the body, where temperature gradually changes from T_B on the inside to T_S on the outside.

FIGURE 10.4 A model of an animal's body showing key temperatures. The body core is at body temperature T_B , while the surrounding environment is at ambient temperature T_A . The temperature of the body surface is T_S . The outer layer of the body, separating the body core from the surface, has thickness d .

Conduction and convection: Convection is intrinsically faster

Conduction and convection are usefully discussed together because, in a sense, these two mechanisms of heat transfer define each other. What they have in common is that when heat moves through a material substance by either mechanism, the atoms and molecules of the substance *participate* in the transfer of heat. **Conduction** is the transfer of heat through a material substance that is macroscopically motionless. A familiar example of conduction is the transfer of heat through a block of copper. We know that if the temperature of one side of a copper block is raised, heat will move through the block and appear on the other side even though the copper undergoes no macroscopic motion. The way heat makes its way through such a macroscopically motionless substance is strictly by *atomic-molecular interactions*; if atoms (or molecules) on one side are especially agitated, they increase the agitation of atoms farther into the substance by interatomic collisions, and by repetition of this process, successive layers of atoms relay the increased agitation through the entire thickness of the substance. Conduction mechanistically has much in common with simple solute diffusion (the movement of solute through a macroscopically motionless solution; see page 101), and conduction in fact is sometimes called *heat diffusion*.

Convection, in sharp contrast, is transfer of heat through a material substance *by means of macroscopic motion of the substance*. Fluid flow is required for convection. If a wind or water current is present, the macroscopic motion of matter carries heat from place to place. This transfer of heat is convection.

A critical difference between conduction and convection is that, for a given difference of temperature, heat transfer by convection is *much* faster than that by conduction. Consider, for example, a horizontal surface that is 10°C warmer than the surrounding air. If the air is moving at just 10 miles/hour (4.5 m/s), convection will carry heat away from the surface about 70 times faster than if the air is perfectly still! The acceleration of heat transfer by fluid movement is familiar from everyday experience. We all know, for instance, that a wind greatly increases the thermal stress of a cold day.

THE LAWS OF CONDUCTION We can better understand conduction if we focus on a specific object, such as a sheet of material of thickness d . If the temperature on one side of the sheet is T_1 , that on the other is T_2 , and heat is moving through the sheet by conduction, then the rate of heat transfer H from one side to the other per unit of cross-sectional area is

$$H_{\text{conduction}} = k \frac{T_1 - T_2}{d} \quad (10.1)$$

where k is a constant. The ratio $(T_1 - T_2)/d$ is called the **thermal gradient**.⁴ You can see from the equation that the rate of heat transfer by conduction through a sheet of material increases as the temperature difference between the two sides increases. In addition, the rate at which heat moves from one side of the sheet to the other decreases as the thickness of the sheet (d) increases. The coefficient k depends in part on the type of material through which conduction is occurring. Some biologically important materials, such as air, conduct heat poorly; they are said to exhibit low *thermal conductivity* and have low

⁴Although the *thermal gradient* is technically defined to be $(T_1 - T_2)/d$ (i.e., temperature difference per unit of distance), the expression *thermal gradient* is sometimes used to refer simply to a temperature difference, $(T_1 - T_2)$.

values of k . Other materials, such as water, exhibit higher thermal conductivity and higher k values (water's conductivity is about 20 times that of air).

Heat transfer through the fur of a furred mammal, or through a winter jacket worn by a person, is typically analyzed as a case of conduction because fur traps a layer of relatively motionless air around the body of a furred mammal, and a winter jacket envelops a person's body in a shell of relatively still air. The stillness of the air layer trapped by fur or a jacket is the key to the insulative value of the fur or jacket. To the extent that the air is motionless, heat must move through it by conduction; thus heat moves much more slowly than if convection were at work. Indeed, from the viewpoint of physics, the benefit of fur or a jacket in a cold environment is that it favors an intrinsically slow mechanism of heat loss from the body, conduction, over an intrinsically faster mechanism, convection. In Figure 10.4, the "outer layer" of the body might be taken to represent the fur or jacket. Equation 10.1 shows that increasing the thickness (d) of the motionless air layer trapped by the fur or jacket will tend to slow heat loss from an animal or person to a cold environment.

THE LAWS OF CONVECTION When air or water flows over an object, the rate of heat transfer by convection between the object and the moving fluid depends directly on the difference in temperature between the *surface* of the object and the fluid. Suppose, for instance, that the model animal in Figure 10.4 is exposed to a wind. Then the rate of convective heat transfer between the animal and the air per unit of surface area is calculated as follows:

$$H_{\text{convection}} = h_c(T_S - T_A) \quad (10.2)$$

The animal will lose heat by convection if its surface temperature (T_S) exceeds the ambient air temperature (T_A); however, it will gain heat by convection if T_A is higher than T_S .

The coefficient h_c , called the **convection coefficient**, depends on many factors, including the wind speed, the shapes of the body parts of the animal, and orientation to the wind. If the shape of a body part is approximately cylindrical (as is often true of the limbs or torso) and the wind is blowing perpendicularly to the cylinder's long axis, then

$$h_c \propto \frac{\sqrt{V}}{\sqrt{D}} \quad (10.3)$$

where V is the wind speed and D is the diameter of the cylinder. This equation shows that the rate of heat transfer per unit of surface area by convection tends to increase with the square root of the wind speed. The rate of heat transfer per unit of surface area also tends to increase as the square root of the diameter of a cylindrically shaped body part is decreased; this physical law helps explain why body parts of small diameter (e.g., fingers) are particularly susceptible to being cooled in cold environments.

Evaporation: The change of water from liquid to gas carries much heat away

Evaporation of body water from the respiratory passages or skin of an animal takes heat away from the animal's body because water absorbs a substantial amount of heat whenever its physical state changes from a liquid to a gas. The amount of heat required to vaporize water, called the **latent heat of vaporization**, depends on the prevailing temperature. It is 2385–2490 J (570–595 cal) per gram of H_2O at physiological temperatures. These are *large* values.

FIGURE 10.5 An antelope jackrabbit (*Lepus alleni*) This species of jackrabbit is found principally in the low-altitude desert plains of southern Arizona and northern Mexico.

Whereas heating a gram of liquid water from 0°C to 100°C requires 100 cal, changing a gram from a liquid to a gas requires 570–595 cal—almost six times as much. The enormous heat absorption that occurs when water vaporizes means that evaporation can be a highly effective cooling mechanism for an animal. The heat is absorbed from the body surface where the vaporization occurs, and it is carried away with the water vapor.⁵

Thermal radiation permits widely spaced objects to exchange heat at the speed of light

For terrestrial animals, including people, thermal-radiation heat transfer often ranks as one of the quantitatively dominant mecha-

⁵The opposite of evaporation, *condensation*, usually does not occur in biological systems; when it does, however, heat is added to the site where water changes to its liquid form from its gaseous form. See Chapter 27 (page 706) for a detailed discussion of the physical laws of evaporation and condensation.

nisms of heat exchange with the environment, yet it tends to be the least understood of all the mechanisms. Although we are all familiar with radiant heating by the sun, such heating is only a special case of a sort of heat transfer that is in fact ubiquitous.

The first fact to recognize in the study of thermal-radiation heat transfer is that all objects *emit* electromagnetic radiation. That is, all objects are *original sources* of electromagnetic radiation. If you look at a wall, your eyes see electromagnetic radiation (light) coming from the wall, but that radiation is merely reflected; it originated from a lamp or the sun and reflected off the wall to enter your eyes. As a completely separate matter, the wall also is the original source of additional electromagnetic radiation. The radiation *emitted* by the wall is at infrared wavelengths and thus invisible. It travels at the speed of light, essentially unimpeded by the intervening air, until it strikes a solid surface (such as your body), where it is absorbed. Simultaneously, your body emits electromagnetic radiation, some of which strikes the wall. In this way the wall and your body can exchange heat even though they are not touching and in fact may be far apart. Any two objects that are separated only by air undergo exchange of heat at the speed of light by thermal-radiation heat transfer.⁶

An interesting application of the principles of thermal-radiation heat transfer is to the huge ear pinnae of jackrabbits (**Figure 10.5**). In some species, such as the one pictured, the ear pinnae constitute 25% of the total body surface area. Despite decades of interest, physiologists still do not definitely know the function of these pinnae. The most likely function is that they act as radiators. Jackrabbits modulate blood flow to the pinnae. When blood flow is brisk and the pinna blood vessels are engorged (as in Figure 10.5), the pinnae are warmed, and they thereby increase the intensity at which they emit electromagnetic radiation. When heat is lost in this way, it need not be lost by panting or other forms of evaporation—a water-saving benefit for animals that live in deserts or semideserts.⁷

When objects emit electromagnetic radiation, they do so over a *range* of wavelengths. A key principle of thermal-radiation physics, illustrated in **Figure 10.6**, is that the range of wavelengths emitted by an object depends on the *surface* temperature of the object (T_s) and shifts toward shorter wavelengths as the surface temperature

⁶Water, being far more opaque to infrared radiation than air, largely blocks this sort of heat transfer in aquatic environments.

⁷When the pinnae are warmer than the air, heat will also be carried away from them by convection if a breeze or wind is present. Like heat loss by thermal-radiation heat transfer, loss by convection also occurs without making demands on body water.

FIGURE 10.6 As objects reach higher surface temperatures, the ranges of wavelengths at which they emit thermal radiation extend to shorter wavelengths. Temperatures specified are surface temperatures. All three of the objects shown also emit energy at wavelengths longer than 6 μm (not shown).

increases. The lowest thin black bar in Figure 10.6 shows the wavelengths emitted by an animal or other object with a surface temperature of about 30°C. Note that the shortest wavelengths emitted by a surface at this temperature are between 3 and 4 μm ; energy is also emitted over a broad range of longer wavelengths. All the emitted wavelengths are in the infrared range and thus invisible. The embers of a fire (middle thin black bar in the figure) emit at shorter wavelengths because they are hotter. They are in fact hot enough that the shortest wavelengths they emit are within the visible range. Because we *see* those wavelengths, we see the coals *glow*. The visible wavelengths emitted by the coals are limited to the red-orange end of the visible spectrum; thus the glow of the coals is red-orange. The sun is so hot that it emits electromagnetic energy (upper thin black bar in the figure) at all wavelengths of the visible spectrum and therefore glows with a nearly white light. The most important concept illustrated by Figure 10.6 is that the radiative emissions from organisms are of the same basic nature as those from a fire or the sun. The only reason we do not see organisms glow is that the wavelengths they emit are out of our visible range.

An important principle of thermal-radiation physics is that the *total intensity* of radiation emitted by an object—summing the radiation emitted at all wavelengths—increases as surface temperature increases:

$$H_{\text{radiative emission}} = \epsilon\sigma T_s^4 \quad (10.4)$$

In this equation, which is known as the **Stefan-Boltzmann equation**, H is the rate of emission per unit of surface area at all wavelengths combined, ϵ is a surface property called *emissivity (emittance)*, σ is a constant called the Stefan-Boltzmann constant, and the surface temperature T_s must be expressed in absolute degrees (K).

Another important principle of thermal-radiation physics is that when electromagnetic radiation strikes an object, the radiant energy may be *absorbed* or *reflected*, or it may *pass through*. The fractions of the energy absorbed, reflected, and transmitted depend on the surface properties of the object and are wavelength-specific. Energy that is absorbed is converted into heat at the surface of the absorbing object, as illustrated in everyday experience by the fact that our skin is warmed by radiant energy from the sun or from the embers of a fire.

RADIANT EXCHANGES IN THE BIOSPHERE THAT DO NOT INVOLVE THE SUN In natural biological communities, the sun is usually the only object that is hot enough to emit energy at wavelengths shorter than 3–4 μm . The surface temperatures of animals, plants, rocks, and all other objects besides the sun are typically between –50°C and 50°C, and surfaces at such temperatures emit only wavelengths of 3–4 μm or longer (see Figure 10.6). Thus, if we exclude the sun from consideration, all radiant exchanges among objects in the biosphere are at such wavelengths: Various organisms and objects emit at 3–4 μm and longer, and the emitted radiation that they receive from other organisms and objects is at 3–4 μm and longer. This fact massively simplifies the analysis of radiant exchanges because although organisms and objects in the biosphere commonly differ from one another in surface temperature, all are essentially identical in their other radiative properties at wavelengths of 3–4 μm and longer. Specifically, all exhibit about the same value for ϵ in the Stefan-Boltzmann equation (Equation 10.4) at these wavelengths; and all are highly absorptive at these

wavelengths, meaning that they absorb (rather than reflect or transmit) most energy that strikes them. Put loosely, organisms and objects in the biosphere do not differ in color at these wavelengths. If this idea sounds strange, recognize that the color you see with your eyes is a property at *visible* wavelengths of 0.4–0.72 μm . Whether the visible color of an organism or object is brown, green, or even white, the color at wavelengths of 3–4 μm and longer is, in all cases, nearly black.

Because all organisms and objects in the biosphere are virtually identical in ϵ and in their absorptive properties at wavelengths of 3–4 μm and longer, surface temperature (T_s) is the sole major determinant of radiative heat exchange when the sun is excluded from consideration. If two organisms or objects are exchanging heat radiatively, each can be considered to emit a beam of energy toward the other. Whereas the warmer of the two emits a relatively strong beam (see Equation 10.4), the cooler emits a relatively weak beam. Each absorbs most of the energy that it receives from the other. For these reasons, energy is passed in *net* fashion from the warmer object to the cooler one. Quantitatively, if the surface temperatures of the two objects (on the Kelvin scale) are T_1 and T_2 , the net rate of heat transfer between them is proportional to $(T_1^4 - T_2^4)$, and the direction of net heat transfer is from the one with the higher T_s to the one with the lower T_s .

As examples, consider first a relatively cool lizard standing in the early nighttime hours near a rock that remains hot from the preceding day. The rock emits a relatively strong beam of radiant energy toward the lizard, and the lizard absorbs most of this radiant energy; simultaneously, the lizard emits a weaker beam of energy toward the rock, and the rock absorbs that energy. The net effect is that the lizard is warmed by standing near the rock. A less familiar example is provided by a bird flying past cold trees on a frigid winter night (Figure 10.7). The surface temperature of the bird (+15°C in Figure 10.7) is higher than that of the tree trunks (–10°C). In this case the beam of energy carrying heat away from the bird is more intense than the beam striking the bird from each tree, and the net effect of thermal-radiation heat transfer is to cause a loss of heat from the bird to the trees.

THE NIGHT SKY AS A RADIANT OBJECT The sky is one of the objects in the biosphere that deserves special note. Here we consider just the night sky; because the sun is absent at night, the discussion in this section is a special case of the last section's discussion. In the atmosphere above us at night, each gas molecule—whether positioned just above Earth's surface or at the limits of outer space—emits radiation as a function of its temperature. In this way, the surface of Earth steadily receives a beam of radiation emitted from the sky above. One way to express the intensity of this radiation is to pretend that the sky is a solid surface and ask what the temperature of that surface would have to be for it to emit at the intensity observed (assuming $\epsilon = 1.0$). This temperature is called the **radiant temperature of the sky** (or the *black-body sky temperature*). A characteristic of the radiant temperature of the clear night sky is that it is far lower than the simultaneous air temperature at ground level. For example, during a particular summer night in the Arizona desert when the air temperature near the ground was +30°C, the radiant temperature of the clear sky was simultaneously –3°C; that is, the sky on that warm night behaved like a subfreezing object! The low radiant temperature characteristic of the clear night sky

The widths of the arrows symbolize the relative intensities of the beams of thermal radiation.

FIGURE 10.7 A bird loses heat in net fashion to tree trunks by thermal radiation as it flies past them on a cold winter night

The bird also loses heat in net fashion to the night sky. More than half of a bird's total heat loss may be by thermal-radiation heat transfer. The temperatures shown for the tree and bird are their surface temperatures; that shown for the sky is the radiant sky temperature expected on a night when the air temperature near the ground is -10°C . Quantitatively, thermal-radiation heat transfer depends on temperature on the absolute (Kelvin) scale. On that scale, $+15^{\circ}\text{C} = 288\text{ K}$; $-10^{\circ}\text{C} = 263\text{ K}$; and $-40^{\circ}\text{C} = 233\text{ K}$.

explains how frosts can form on nights when the air temperature at ground level stays above freezing.

When animals are exposed to the clear night sky, they emit a beam of radiation toward the sky. In return, they receive only a relatively weak beam of radiation from the sky (see Figure 10.7). Accordingly, animals tend to lose energy in net fashion to the clear night sky, which is often, therefore, said to act as a “radiant heat sink.” The radiative loss of heat to the clear sky is often of substantial importance. Because of this, animals confronted with cold stress may benefit considerably by avoiding exposure to the clear sky. When small mammals burrow under the snow in winter, for example, one of the advantages they obtain is that they reduce their radiant heat losses at night by interposing the snow as a barrier to radiant exchange between themselves and the sky; however cold the snow may be, it is warmer than the clear night sky.

SOLAR RADIATION The sun is the one object in the biosphere that routinely emits radiation at wavelengths shorter than $3\text{--}4\ \mu\text{m}$ (see Figure 10.6). Much of the solar radiant energy is at visible or near-visible wavelengths. Accordingly, when we consider objects exposed to solar radiation, the visible colors of the objects matter; visible color affects the fraction of the energy that is absorbed. If an animal's body surfaces are opaque (nontransparent),⁸ the analysis

⁸If the body surfaces of an animal are significantly transparent, additional complexities are introduced. For example, the pelages of mammals and plumages of birds are partly transparent (radiant energy can pass through them to some extent) and therefore do not necessarily follow the simple rule that black means high absorption and white means low absorption of solar visible energy.

of the effects of the animal's visible color on the absorption of the visible and near-visible solar radiation is straightforward: Dark surfaces absorb more of this solar radiation—and are heated more by it—than light ones. Black beetles, for instance, absorb the visible and near-visible wavelengths relatively well, whereas light-colored beetles tend more to reflect these wavelengths and absorb them relatively poorly. Animals that can change their skin color, such as many species of lizards, can increase and decrease the solar heating of their bodies by darkening and lightening, respectively.

SUMMARY Heat Transfer between Animals and Their Environments

- In addition to making heat metabolically, animals exchange heat with their environments by conduction, convection, evaporation, and thermal radiation. An animal's body temperature depends on heat gains and losses; it is constant only if the sum total of gains equals the sum total of losses.
- Conduction and convection have in common the property that when heat moves through a material substance by either mechanism, the atoms and molecules of the substance participate in the transfer of heat. Conduction, also called thermal diffusion, occurs when a material substance is macroscopically motionless. Convection is heat transfer brought about by flow of a material substance (e.g., by wind). Convection is much faster than conduction.
- Evaporation is a potentially potent mechanism for heat transfer because the change of state of water from a liquid to a gas absorbs a great deal of heat per gram of water. The heat is absorbed from the surface where evaporation occurs and is carried away with the water vapor.
- Thermal-radiation heat transfer occurs by means of beams of radiant energy that all objects emit and that travel between objects at the speed of light. Because of thermal-radiation heat transfer, objects can exchange heat at a distance. In most instances of thermal-radiation heat transfer in the biosphere, the heat transfer occurs at invisible infrared wavelengths; because all objects are nearly black at such wavelengths, visible color plays little role, and the net transfer of heat is from the object with higher surface temperature to the one with lower surface temperature. Visible color, however, is a major factor in how well objects absorb the visible and near-visible wavelengths of solar radiation.

Poikilothermy (Ectothermy)

Poikilothermy is by far the most common type of thermal relation exhibited by animals. Amphibians, most fish, most nonavian reptiles, all aquatic invertebrates, and most terrestrial invertebrates are poikilotherms. The defining characteristic of poikilothermy is that the animal's body temperature is determined by equilibration with the thermal conditions of the environment and varies as environmental conditions vary. *Poikilothermy* and *ectothermy* are the same thing. The two terms simply emphasize different aspects of one phenomenon; whereas *poikilothermy* emphasizes the variability of body temperature, *ectothermy* emphasizes that outside conditions determine the body temperature (see page 226).

Poikilothermy manifests itself differently depending on whether an animal is aquatic or terrestrial. Aquatic poikilotherms typically have body temperatures that are essentially the same as water temperature. Terrestrial poikilotherms, however, do not necessarily have body temperatures that equal “air” temperature, because thermal-radiation heat transfer or evaporation on land can tend to draw the body temperature away from air temperature. For instance, if a frog or snail on land basks in the sun, its body temperature may be much higher than the air temperature. Such animals nonetheless still meet the definition of poikilothermy or ectothermy, because their body temperatures are determined simply by equilibration with the sum total of thermal conditions in their environments.

Poikilothermic or ectothermic animals are often called *cold-blooded* in nonscientific writing, in reference to their coolness to the touch under certain conditions. Many species, however, may have high body temperatures when in warm environments. For example, desert lizards and insects that are perfectly fine poikilotherms often have body temperatures that substantially exceed human body temperature! *Cold-blooded* is therefore not a suitable general term to describe poikilotherms or ectotherms.

Poikilotherms often exert behavioral control over their body temperatures

The natural environments of poikilotherms typically vary from place to place in thermal conditions. In a forest, for example, the temperature on the exposed forest floor might be higher than that under a log, and the temperature in a spot of sunlight might be higher yet. Poikilotherms in the wild can behaviorally choose where they position themselves and, in this way, control their body temperatures. One reason to stress this point near the start of our discussion of poikilothermy is that the situation of captive poikilotherms is so different and potentially misleading. In an aquarium or cage, environmental thermal conditions are usually uniform, meaning that the body temperatures of captive poikilotherms are deterministically set by the environmental conditions. In dramatic contrast, when the thermal environment is heterogeneous—as it nearly always is in nature—poikilotherms typically can and do exert some control over their body temperatures.

If a poikilotherm behaviorally maintains a *relatively constant* body temperature, it is said to exhibit **behavioral thermoregulation**. Sometimes behavioral thermoregulation is rather simple. In a lake or the ocean, for instance, various large water masses (such as those at the surface and at greater depth) often differ in temperature (see Figure 1.14). Fish that elect to stay in one water mass, rather than another, take on the temperature of the water they occupy and remain at that temperature for extended periods. The behavior of the fish is accordingly a simple form of behavioral thermoregulation.

In other cases, behavioral thermoregulation is far more complex and dynamic. Many lizards, for example, maintain relatively stable body temperatures during daylight hours, and they do so by complex, moment-to-moment behavioral exploitation of environmental opportunities for heating and cooling. A desert lizard, for instance, ordinarily emerges in the morning and basks in the sun until its body temperature rises to be within a “preferred” range that it maintains during its daily activity. Thereafter, the lizard keeps its body temperature within that range until nightfall by a variety of

mechanisms. One common strategy is to shuttle back and forth between sun and shade; when its body temperature starts to drop too low, the lizard moves into sunlight, and then later, when its body temperature starts to rise too high, it enters shade. The lizard might also modify the amount of its body surface exposed to the direct rays of the sun by changing its posture and orientation to the sun. It might flatten itself against the substrate to lose or gain heat (depending on substrate temperature), and when the substrate has become very hot during midday, the lizard might minimize contact by elevating its body off the ground or even climbing on bushes. By thus exploiting the numerous opportunities for heating and cooling in its thermally heterogeneous environment, a lizard may well maintain a body temperature that varies only modestly for long periods. The desert iguana illustrated in Figure 1.12, for instance, typically maintains an average abdominal temperature of 38–42°C during daylight hours, and it often keeps its temperature within 2–3°C of the mean for hours on end.

Investigators have worried a lot about the question of documenting true behavioral thermoregulation. They thus have compared living animals with inanimate model animals. In one study, living lizards in a natural setting on a Mediterranean island were found to exhibit far less variable body temperatures than lizard models placed widely in the same environment (Figure 10.8). Such evidence documents that real lizards do not simply position themselves at random, but *behave* in ways that keep their body temperatures within a relatively narrow preferred range.

Poikilotherms must be able to function over a range of body temperatures

A limitation of behavioral thermoregulation is that it is dependent on the thermal opportunities available in the environment, and thus it may be thwarted by changes of weather or other conditions outside an animal’s control. A desert iguana, for example, may never reach a body temperature that is even close to its “preferred” level of 38–42°C on a day that happens to be cloudy and cool. Similarly, a fish that would select a cool water mass if it could, cannot do so if all the water in its lake or pond is warm.

For these and other reasons, poikilotherms must typically be thermal generalists: They must be capable of functioning at a variety of different body temperatures. Species differ in how wide a range of body temperatures is acceptable. Some species, termed **eurythermal**, can function over wide ranges of body temperature; goldfish, for instance, maintain normal body orientation, feed, and swim at body temperatures of 5–30°C. Other poikilotherms, termed **stenothermal**, have comparatively narrow ranges of body temperature over which they can function.

Poikilotherms respond physiologically to their environments in all three major time frames

The three major time frames of physiological response to the environment identified in Chapter 1 (see Table 1.2) provide a useful way to organize knowledge of the relations of poikilotherms to their thermal environments. In three of the next four sections, we discuss poikilotherms in each of the three time frames. First, in the next section, we address the *acute responses* of poikilotherms to changes in their body temperatures. The acute responses are those that individual animals exhibit *promptly* after their body temperatures are altered. After that we address the *chronic responses*

FIGURE 10.8 Behavioral thermoregulation documented by comparison of real lizards with inanimate lizard models

Multiple daytime measurements of the body temperatures of real lizards (a) and inanimate lizard models (b) were made. The lizards (*Podarcis hispanica*) were living freely on a Mediterranean island. The lizard models were placed as comprehensively as possible in all the various microhabitats available to real lizards during their daytime activities on the same island. Data on the y axes are the percentages of all observations in various 1°C intervals of temperature. (After Bauwens et al. 1996.)

of poikilotherms, termed *acclimation* and *acclimatization*.⁹ What changes do individual animals undergo when they live in an altered thermal environment (and have altered body temperatures) for a

⁹The distinction between *acclimation* and *acclimatization* is discussed on page 15. As also discussed there, they are forms of *phenotypic plasticity*.

prolonged period? Finally, after discussing temperature limits, we discuss *evolutionary changes*—the ways in which the physiology of poikilotherms may be modified by changes in the frequencies of genes when populations live in different environments over many generations.

Acute responses: Metabolic rate is an approximately exponential function of body temperature

When the body temperature of an individual poikilotherm is raised in a series of steps and its metabolic rate is measured promptly after each upward step, the usual pattern is that the resting metabolic rate increases approximately exponentially with the animal's body temperature (Figure 10.9a).¹⁰ An *exponential* relation signifies that the metabolic rate increases by a particular *multiplicative factor* each time the body temperature is stepped up by a particular *additive increment* (see Appendix F). For example, the metabolic rate might increase by a factor of 2 for each increment of 10°C in body temperature. Then, if the metabolic rate were 1 joule per minute (J/min) at 0°C, it would be 2 J/min at 10°C, 4 J/min at 20°C, and 8 J/min at 30°C (see Figure 10.9a). The acute relation between metabolic rate and body temperature is usually, in fact, only *approximately* exponential. That is, the factor by which the metabolic rate increases for a given increment in temperature is usually not precisely constant from one temperature range to the next but might, for example, be 2.5 between 0°C and 10°C but only 1.8 between 20°C and 30°C.

The reason that the metabolic rate of a poikilotherm increases as its body temperature goes up relates back to the concept of activation energy discussed in Chapter 2. Each biochemical reaction involved in metabolism is characterized by a particular activation energy, a certain minimum energy level that a reacting molecule must attain in order to undergo the reaction (see Figure 2.13). As the temperature of a cell increases, all molecules in the cell tend to become more agitated and have higher energy levels. Svante Arrhenius (1859–1927) demonstrated in the late nineteenth century that if one specifies any particular activation energy, the fraction of molecules that have that level of energy—or more—at any moment increases approximately exponentially as temperature increases. Reactions tend, therefore, to speed up approximately exponentially as cellular temperature rises. In this context, it is vital to recall that

¹⁰There are limits to this process: An exponential increase is seen only within a particular range of body temperatures, a range that depends on the species and individual. We discuss the limits later in the chapter.

FIGURE 10.9 An exponential relation between metabolic rate and body temperature plotted in two ways

(a) A plot employing linear scales for both variables. (b) A semilogarithmic plot of the same data as in part (a); metabolic rate is plotted on a logarithmic scale, whereas body temperature is plotted on a linear scale. Metabolic rate is expressed in the same arbitrary units in both parts. See Appendix E for background on logarithmic scales.

most metabolic reactions are enzyme catalyzed, and the enzymes determine the activation energies. Thus the detailed, quantitative relations between biochemical reaction rates and cellular temperature depend on the particular enzyme proteins that cells synthesize.

If the resting metabolic rate of a poikilotherm, symbolized M , were a true exponential function of its body temperature (T_B), the relation would be described by an exponential equation (see Appendix F):

$$M = a \cdot 10^{n \cdot T_B} \quad (10.5)$$

where a and n are constants. If one takes the common logarithm of both sides of Equation 10.5, one gets

$$\log M = \log a + n \cdot T_B \quad (10.6)$$

According to this second equation, $\log M$ is a *linear* function of T_B ($\log a$ and n are constants).

Thus, if M is an exponential function of T_B as in Equation 10.5, $\log M$ is a linear function of T_B (Equation 10.6). This result represents the basic reason why physiologists usually plot metabolism–temperature data for poikilotherms on semilogarithmic coordinates. The logarithm of the animal’s metabolic rate is plotted on the y axis, and the animal’s body temperature itself is plotted on the x axis. The curve of Figure 10.9a is replotted on semilogarithmic coordinates in Figure 10.9b, illustrating the “linearizing” effect of semilogarithmic coordinates. A similar comparison is seen in Figure 10.10 using data on actual animals. As we have emphasized, metabolic rate in fact is usually an *approximately* exponential function of body temperature, not a truly exponential one. Thus the semilogarithmic plot for actual animals is typically not precisely linear, as exemplified in Figure 10.10b.

One simple way to describe an exponential relation between metabolic rate (or any other physiological rate) and temperature is to specify the multiplicative factor by which the rate increases when the body temperature is increased by a standardized increment of 10°C. This factor is called the **temperature coefficient, Q_{10}** :

$$Q_{10} = \frac{R_T}{R_{(T-10)}} \quad (10.7)$$

where R_T is the rate at any given body temperature T , and $R_{(T-10)}$ is the rate at a body temperature 10°C lower than T . To illustrate, if the resting metabolic rate of an animal is 2.2 J/min at a body temperature of 25°C and 1.0 J/min at 15°C, the Q_{10} is 2.2. As a rough rule of thumb, the Q_{10} for the metabolic rates of poikilotherms is usually between 2 and 3. If metabolic rate were a truly exponential function of body temperature, you could calculate the Q_{10} of an animal from data for *any* two body temperatures that are 10°C apart and always get the same value. Because metabolic rate is not a truly exponential function of temperature, however, the Q_{10} of an animal in fact varies with the particular range of body temperatures considered.¹¹

Chronic responses: Acclimation often blunts metabolic responses to temperature

When an individual poikilotherm is kept chronically at one body temperature for a number of weeks and then is kept chronically at

¹¹ An equation called the *van’t Hoff equation* permits Q_{10} to be calculated for ranges of temperature that are less than 10°C wide. Thus, for detailed analysis, the temperature scale need not be artificially divided into 10°C segments.

(a) Plot on linear coordinates

(b) Plot on semilogarithmic coordinates

FIGURE 10.10 The relation between metabolic rate and body temperature in tiger moth caterpillars (family Arctiidae), plotted in two ways The metabolic rate was measured as the rate of O_2 consumption. (a) A plot employing linear scales for both variables. (b) A semilogarithmic plot. Note that the data do not plot exactly as a straight line in (b). This fact signifies that the relation is not truly exponential, although it is approximately exponential. (After Scholander et al. 1953.)

a different body temperature for a number of weeks, the details of its acute metabolism–temperature relation usually change. Such a change is an example of *acclimation* (see page 15). Understanding this sort of acclimation and its implications can be tricky. The best way to gain clear insight is to start with the actual procedures that are followed to study acclimation. To this end, let’s discuss the acclimation study in Figure 10.11.

In the experiment represented by Figure 10.11, a group of lizards, named the “33°C-acclimated” group, was maintained for 5 weeks at 33°C. At the end of this chronic exposure to 33°C, the lizards were exposed acutely (i.e., briefly) to three different body temperatures—16°C, 28°C, and 33°C—and their resting metabolic rates were measured at each of the three. The line labeled “33°C-acclimated” shows the results. It represents the *acute* relation between resting metabolic rate and body temperature for lizards

FIGURE 10.11 Acclimation of the metabolism–temperature relation to a change in chronic temperature in a poikilotherm One group of fence lizards (*Sceloporus occidentalis*) was acclimated for 5 weeks to 33°C prior to testing. A second, otherwise identical group was acclimated to 16°C for 5 weeks prior to testing. After the 5 weeks, the animals in each group were placed briefly at body temperatures of 16°C, 28°C, and 33°C, and their standard metabolic rates were measured at all three temperatures as rates of O₂ consumption. The circles show the average metabolic rates; error bars indicate ± 2 standard deviations of the mean. (After Dawson and Bartholomew 1956.)

that were living *chronically* at 33°C during the weeks before the measurements were made.

Another group of lizards, called the “16°C-acclimated” group, was maintained for 5 weeks at 16°C. These 16°C-acclimated lizards were a closely matched but different set of individuals from the 33°C-acclimated group; however, physiologists know from other research that if the individuals that had been acclimated to 33°C were themselves later acclimated to 16°C, the results for the 16°C-acclimated group would be the same as shown. After 5 weeks at 16°C, the 16°C-acclimated lizards were exposed acutely to the same three study temperatures employed for the 33°C-acclimated group, and their metabolic rates were measured. The line labeled “16°C-acclimated” in Figure 10.11 shows the results and thus represents the *acute* relation between resting metabolic rate and body temperature for lizards that were living *chronically* at 16°C.

As Figure 10.11 shows, the acute metabolism–temperature relation is altered when lizards have been living chronically at 16°C rather than 33°C. Lizards acclimated to the cooler ambient temperature, 16°C, have a higher average metabolic rate at any given body temperature than those acclimated to the warmer ambient temperature, 33°C. Although this specific sort of change during temperature acclimation is not universal, it is the most common type of acclimation response in poikilotherms and has been observed in well over half the species studied.

What is the *significance* of this acclimation response? One way to understand the significance is provided by Figure 10.12. As a thought exercise, imagine that we have some lizards that have been living at 33°C for 5 weeks. The average metabolic rate of these lizards—that is, the metabolic rate of 33°C-acclimated lizards at

33°C—is marked *x* in Figure 10.12. Imagine now that we suddenly lower the temperature of these lizards to 16°C and leave the lizards at 16°C for 5 weeks. The key question we need to address is: How will their average metabolic rate change from the moment their temperature is lowered? Let’s begin by considering the *first hour*. In other words, what is the *acute* (prompt) response of the lizards to the change of their temperature? As the animals cool from a body temperature of 33°C to 16°C during the first hour, their average metabolic rate will decline along the acute-response line for 33°C-acclimated animals, following the thin arrows from *x* to *y*. Immediately after the lizards have cooled fully to 16°C, their average metabolic rate will be *y*, the metabolic rate of 33°C-acclimated lizards at 16°C. Note that the drop of body temperature causes a profound fall in metabolic rate. Now we come to the most critical question to answer for understanding acclimation: *What will happen to the average metabolic rate of the lizards during the following 5 weeks at 16°C?* The answer is that the metabolic rate will *rise* from *y* to *z* because during those 5 weeks the lizards will become 16°C-acclimated animals! At the end of the 5 weeks, they will have the metabolic rate of 16°C-acclimated animals at 16°C (*z*). Acclimation in these lizards thus reduces—blunts—the effect of the change of their body temperature. Although cooling to 16°C initially lowers the lizards’ average metabolic rate by a profound amount, the metabolic rate is lowered to a lesser extent after acclimation has occurred. Put another way, acclimation tends to return the metabolic rate toward its level prior to the drop in body temperature (see Figure 10.12).

After a physiological rate has been raised or lowered by an abrupt change in body temperature, any subsequent, long-term tendency

FIGURE 10.12 Compensation through acclimation This diagram shows one way to interpret the data on acclimation by fence lizards in Figure 10.11 (the blue and red lines in the diagram are carried over from Figure 10.11). If lizards that initially are 33°C-acclimated and living at 33°C are switched abruptly to 16°C and left at 16°C, their metabolic rate changes from *x* to *y* during the first hour as they cool acutely from 33°C to 16°C. Then their metabolic rate rises from *y* to *z* over the next 5 weeks as they become acclimated to 16°C: an example of partial compensation.

FIGURE 10.13 Because of acclimation, the chronic metabolism–temperature curve is relatively flat compared with the acute metabolism–temperature curves. The three solid lines show the acute relations between metabolic rate and body temperature for hypothetical fish when 10°C-, 20°C-, and 30°C-acclimated; symbols on the lines highlight metabolic rates measured during the acute exposure of each acclimation group to body temperatures of 10, 20, and 30°C. The dashed line shows the relation between metabolic rate and body temperature when the fish live *chronically* at each temperature.

for the rate to return toward its original level even though the new temperature continues is called **compensation**. The rise from y to z in Figure 10.12 illustrates compensation. Compensation is **partial** if the rate returns only partially to its original level, as in Figure 10.12. When compensation occurs, it is nearly always partial.

An alternative way to understand the *significance* of the sort of acclimation response we have been discussing is presented in Figure 10.13. Fish of a particular species were acclimated to 10°C, 20°C, and 30°C by being kept at the three temperatures for several weeks. The 30°C-acclimated fish were then tested acutely at all three temperatures, resulting in the lowermost solid line in Figure 10.13. Similarly, the 20°C- and 10°C-acclimated fish were tested acutely at the three temperatures. Note that each of the three solid lines is an *acute-response line*: Each shows how the metabolic rate of fish varies when it is measured promptly after changes in their body temperature. Now let's construct the *chronic-response line* for these fish: The chronic-response line will show how metabolic rate varies with temperature when the fish are permitted to live at each temperature for several weeks before their metabolic rate is measured. The three bold, black circles are the metabolic rates of the fish when living chronically at the three temperatures. For instance, the black circle at the left is the metabolic rate at 10°C of fish that have been living at 10°C for several weeks (10°C-acclimated fish), and the black circle at the right is the metabolic rate at 30°C of fish that have been living at 30°C. We obtain the chronic-response line by connecting the three black circles. The chronic-response line has a shallower slope than any of the acute-response lines. This means that if the fish are allowed to acclimate to each temperature before their metabolic rate is measured, their metabolic rate is less affected by changes of body temperature than if they are shifted rapidly from one temperature to another. Acclimation blunts the response to changes of temperature.

What are the mechanisms of metabolic acclimation? During acclimation, what responses occur in the biochemistry and molecular biology of metabolism? The best understood response

is that cells modify their *amounts* of key, rate-limiting enzymes, notably enzymes of the Krebs cycle and the electron-transport chain. During acclimation to cold temperatures, greater amounts of these enzymes are synthesized.¹² For example, in the red swimming muscles of fish, the number of mitochondria per unit of tissue increases dramatically during cold acclimation in some species (Figure 10.14a); the mitochondria, of course, are the sites where the enzymes of the Krebs cycle and electron-transport chain reside and operate. In other species of fish, although the numbers of mitochondria change little, if at all, the amounts of key enzymes per mitochondrion are increased during cold acclimation (Figure 10.14b). Responses of these sorts require time; this is one reason why the acclimation response is not observed immediately after a drop in temperature but requires a more extended length of time to be expressed. As the amounts of key, rate-limiting enzymes increase in cells, the presence of the increased enzymes tends to speed metabolic reactions, helping to account for the compensation observed (see Figure 10.12). During acclimation to warm temperatures, enzyme amounts are reduced. Thus, although a shift to a higher body temperature initially speeds an animal's metabolism dramatically, the metabolic rate tends to slow as acclimation occurs (another manifestation of compensation).

These acclimation responses illustrate in an outstanding way that animals can modify their own cell composition and biochemistry in potentially adaptive ways. In studying biochemistry, it is sometimes easy to get the impression that cells are simply like miniature reaction vessels in which test-tube reactions take place. However, because most reactions must be catalyzed by enzymes to occur and the cells make the enzymes, cells in fact orchestrate their own biochemistry.

A classic study of *acclimatization* by poikilotherms living in their natural habitats (see page 15) was conducted on three groups of

¹² Chapter 2 reviews the effects of enzyme concentration and the processes by which cells modify it.

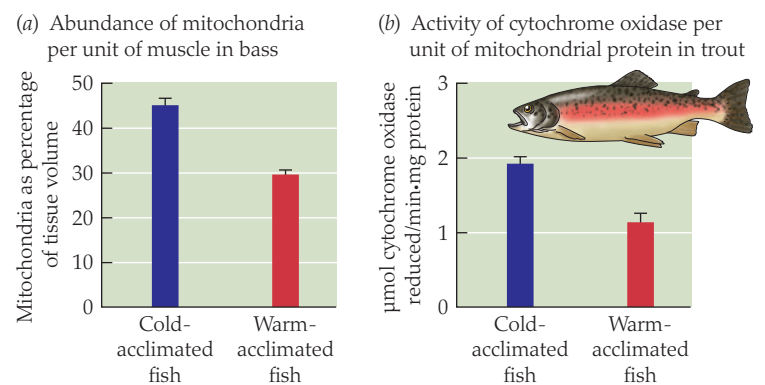

FIGURE 10.14 Mitochondrial and biochemical mechanisms of cold acclimation in the red swimming muscles of fish. (a) Striped bass (*Morone saxatilis*) increase the abundance of mitochondria per unit of muscle tissue when acclimated to 5°C (cold-acclimated) rather than 25°C (warm-acclimated). (b) Rainbow trout (*Oncorhynchus mykiss*) increase the activity per unit of mitochondrial protein of the key electron-transport enzyme cytochrome oxidase when acclimated to 5°C (cold-acclimated) rather than 15°C (warm-acclimated). Error bars show ± 1 standard error. (a after Egginton and Sidell 1989; b after Kraffe et al. 2007.)

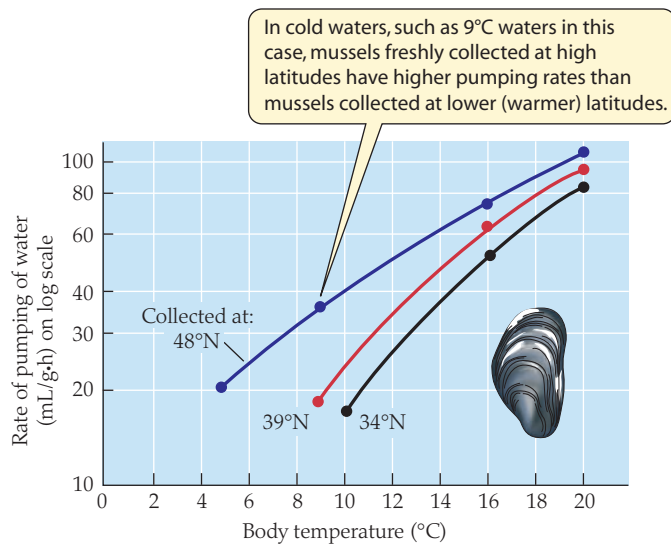

FIGURE 10.15 Acclimatization in mussels Mussels (bivalve molluscs) are extremely important members of intertidal and subtidal marine communities. They pump water through their bodies by ciliary action. Being suspension feeders (see Chapter 6, page 139), they acquire food as well as O_2 from the water they pump. Mussels of the most abundant West Coast species (*Mytilus californianus*) were collected from nature at the three latitudes indicated. The three lines are acute-response lines for the three groups of mussels, which were acclimatized to different latitudes; symbols along the lines represent actual data, to which the lines were fitted. (After Bullock 1955.)

mussels (believed to be genetically similar) of a single species that were collected at three latitudes along the West Coast of the United States. Each group was acutely exposed to several test temperatures, and the rate at which the animals pumped water across their gills was measured. Because of acclimatization, as seen in Figure 10.15, the populations of mussels living in relatively cold, high-latitude waters and warm, low-latitude waters were more similar to each other in pumping rates than they otherwise would have been.

As a consequence of acclimation and acclimatization, the physiology of an individual animal often depends significantly on its recent individual *history*. This point is important in many ways. For example, when doing research on poikilotherms, investigators need to recognize that the recent histories of the individuals studied may affect the results obtained.

At the present time in the history of biology, a question given emphasis is whether the acclimation and acclimatization responses are always beneficial for animals. Evolutionary physiologists interested in this question stress that a response cannot be assumed to be beneficial just because it occurs (see page 25). The weight of evidence at present is that the responses observed are usually advantageous to the animals, but ever-more-sophisticated insight can be expected in the decades ahead.

The rate–temperature relations and thermal limits of individuals: Ecological decline occurs at milder temperatures than acute stress

Animals need to *perform* in a variety of ways to succeed. They need to move, grow, raise their rate of O_2 delivery so they can be active, and so forth. With these points in mind, we can ask how the performance of an individual animal varies with its body temperature. From research on this question, the concept of a generalized, asymmetrical *performance curve*, seen in Figure 10.16a, has emerged.

Many types of performance roughly follow a curve of this shape. The rate of performance is low at low body temperature. It increases gradually as body temperature rises, over a relatively wide range of temperatures, up to a certain body temperature where the rate of performance peaks. Then, however, if body temperature goes still higher, the rate of performance declines relatively rapidly, over a relatively narrow range of temperatures, to a low level. In discussing the performance curve, we will focus here mostly on the high-temperature end, because doing so simplifies discussion while still illuminating the most important basic concepts. It is also the end most relevant to understanding the effects of global warming.

If an animal dies because of too-high a body temperature, people often say “it died because of protein denaturation.” Actually, as shown in Figure 10.16a, irreversible protein denaturation

(a) Generalized performance curve

(b) Actual performance curve for aerobic scope in sockeye salmon

FIGURE 10.16 Performance curves (a) A generalized performance curve, showing key benchmarks discussed in the text. Numbers along the x axis show body temperatures that cause performance to be at the numbered spots on the performance curve. The term “critical temperature” can mean entirely different things in different contexts; in the study of performance curves, it is the temperature at which the rate of O_2 consumption can barely be raised above the resting rate (but this meaning cannot be extrapolated to other contexts). (b) An example of an actual performance curve: maximal ability to increase rate of O_2 consumption above the resting rate (i.e., aerobic scope) in a population of sockeye salmon (*Oncorhynchus nerka*) during migration (see Figure 17.3). The ability to increase O_2 consumption is highly relevant to the fish in this population because they must generate swimming power to swim up the Fraser River (British Columbia) to reach spawning areas that are more than 1000 km from the sea. (b after Eliason et al. 2011.)

typically occurs only at body temperatures significantly higher than the temperature that kills. When animals die because their body temperature becomes a bit higher than the tolerable temperature, they typically die, with their proteins intact, of causes other than irreversible protein denaturation. What kills them, then? A crisp, general answer is not yet available. Often, however, *performance limitations* are thought to be the answer.

To clarify the significance of performance limitations, we can consider points ❶ to ❹ on the generalized performance curve (Figure 10.16a). When body temperature is at the level associated with ❶, the rate of performance is at its peak. This means that if the type of performance we are studying is elevation of O₂ delivery, the rate of O₂ delivery is highest at ❶; if the performance we are studying is growth, growth is fastest at ❶. If body temperature rises above ❶, performance will shift to the range labeled ❷. European researchers have created a new term—**pejus temperatures**—to refer to the range of body temperatures at ❷. *Pejus* is from Latin and means “turning worse.” If we assume that the highest possible rate of performance is best—that is, if we assume that an animal’s fitness is highest when its capacity to perform is highest¹³—then a rise in body temperature from ❶ to ❷ will place the animal in a weakened (“turning worse”) condition. If we are interested in O₂ delivery, the animal will not be able to deliver O₂ at the rate that is best for its fitness; if we are interested in growth, it will not be able to grow at the rate that is best. If body temperature rises still further to ❸, the animal is still alive, but it is unable to *do* much. Point ❸ marks the body temperature at which an animal’s maximal rate of O₂ consumption is little higher than its resting rate of O₂ consumption. At ❸ the animal is passive, and its survival—if it cannot lower its body temperature—is time-limited. Point ❹ is the temperature at which elevated body temperature is itself directly lethal.

The most important message of this analysis is that, as body temperature rises beyond the point of peak performance, an animal’s circumstances probably usually “turn worse” in subtle ways before the body temperature becomes high enough to render the animal passive or kill it outright. This distinction is believed to explain why animals *living in natural ecological communities* can be weakened—and their populations may even go extinct—at temperatures distinctly lower than lethal temperatures measured *in laboratories*. In a natural ecological community, a capacity for mere survival is often far from adequate. “Turning worse” may reduce an animal’s competitive ability so that it is eliminated by superior competitors, or “turning worse” may impair the animal’s ability to swim or run so that it cannot catch sufficient prey.

Where is the performance curve positioned on the scale of body temperature? Various species differ greatly in this regard. For a terrestrial species that evolved at temperate latitudes, the low and high critical temperatures¹⁴ might be -10°C and $+33^{\circ}\text{C}$. For a terrestrial species that evolved in tropical rainforests, they might be $+10^{\circ}\text{C}$

and $+35^{\circ}\text{C}$. As a specific example, Figure 10.16b shows the range for an aquatic species, the sockeye salmon. The performance curve is a general concept of how the rate of performance varies within each species’ range of body temperatures compatible with life.

Is the performance curve determined acutely or chronically? It can be determined either way, depending on research objectives. A curve based on chronic responses is usually most informative for analyzing animals living in natural ecological communities, because body temperatures usually change slowly in natural settings (in part because of behavioral thermoregulation), permitting animals to express their chronic responses.

A recent study of the common eelpout—a nonmigratory fish—in the Wadden Sea in northern Europe illustrates the sorts of insight that can be gained by interpretation of performance curves. Figure 10.17a shows the eelpouts’ performance curve for growth. One can see that as water temperature rises, the pejus range of “turning worse” starts at 17°C , a temperature 6°C lower than temperatures the fish can tolerate in a laboratory setting! Eelpouts are abundant at water temperatures cooler than 17°C . However, as shown in Figure 10.17b, their abundance declines sharply as the water temperature increases within the pejus range—indicating that “turning worse” has severe

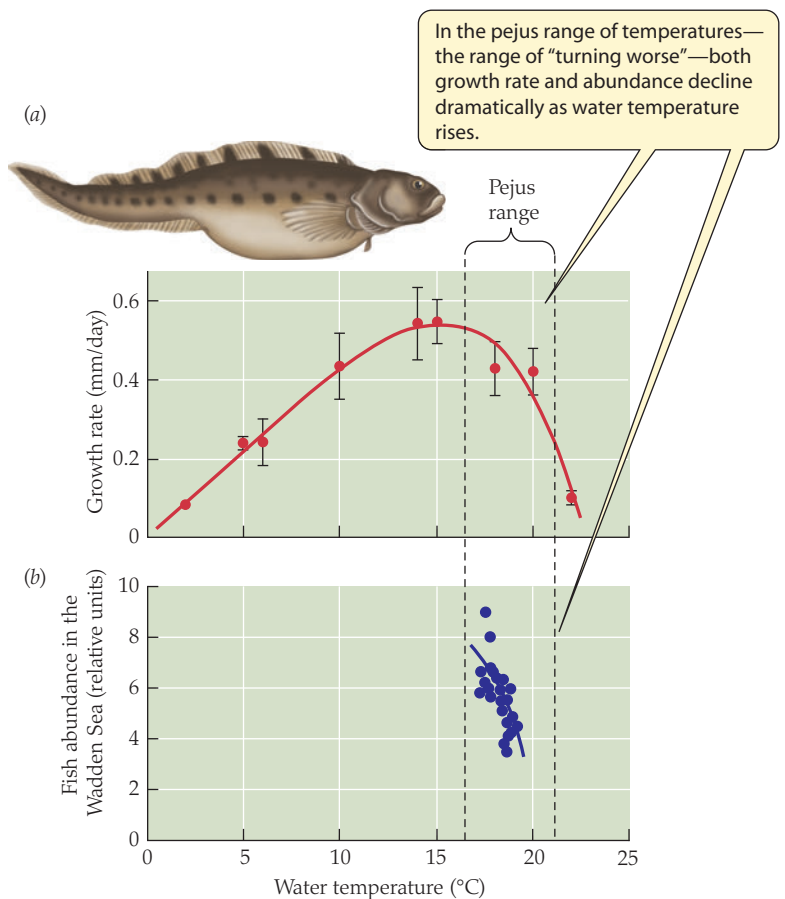

FIGURE 10.17 Nonlethal water temperatures that suppress growth are also associated with ecological decline in populations of common eelpouts (*Zoarces viviparus*) The fish were studied in the Wadden Sea, where water temperature has risen 1.1°C over the past 40 years. The upper plot is the performance curve for growth: rate of growth as a function of water (= body) temperature. The lower curve shows fish abundance. As water temperature becomes higher in the pejus range for growth, fish abundance plummets. (After Pörtner and Knust 2007.)

¹³ Although a peak capacity for performance probably often confers greatest fitness, this is not necessarily true. Some authors call the body temperature at ❶ the *optimal* temperature—an unfortunate practice. The concept that the *highest* rate of performance represents *optimal* performance must be tested empirically in the analysis of each particular case.

¹⁴ Later, when we discuss homeotherms, we will again encounter critical temperatures. Because the term “critical” is used in many different contexts and its meaning sometimes varies, the “critical” temperatures of ectotherms are entirely unrelated to those of homeotherms. Be sure, therefore, to apply the analysis here only to ectotherms.

consequences. Temperatures in the pejus range—although not high enough to kill the fish outright—are associated with *ecological* demise of the fish.

Why are animals impaired at temperatures in the pejus range? In aquatic poikilotherms, O_2 limitation seems to be the most likely general answer. As the ambient water warms, its ability to dissolve O_2 declines (see page 579 yet the metabolic needs of animals for O_2 tend to rise (see Figure 10.9). These clashing trends evidently impair function in subtle ways at temperatures (the pejus temperatures) that are distinctly lower than those that bring about an all-out O_2 crisis. The concept that rising temperatures cause O_2 limitation (see Figure 10.16b), which in turn limits other critical functions, is termed the *theory of oxygen- and capacity-limited thermal tolerance*.

Evolutionary changes: Species are often specialized to live at their respective body temperatures

Related species of poikilotherms often spend much of their time at different body temperatures. Dramatic examples are provided by animals that live in different geographical regions. For example, species of fish, sponges, and sea urchins living on coral reefs in the tropical oceans (see Figure 1.15) live at tissue temperatures that are 25–30°C higher than those of related species of fish, sponges, and urchins that live in polar seas (see Figure 1.10). As another example, among species of lizards that live in the American West, some differ substantially from others in the behaviorally regulated “preferred” body temperatures they maintain during the daylight hours of each day. Whereas one species might employ behavior to thermoregulate at an average body temperature of 34°C, another coexisting species might thermoregulate at a body temperature of 40°C. A key question for physiologists is whether related species that live and reproduce at different body temperatures have evolved adaptations to their respective temperatures.

Some physiological differences among species living at different body temperatures are so dramatic that there can be no doubt about the existence of evolved, adaptive specializations. For example, certain Antarctic species of molluscs promptly die if their body temperature rises above +2°C, even though other species of molluscs live with great success in tropical oceans. Many Antarctic species of fish thrive at temperatures near freezing and die of *heat* stress when warmed to 4–6°C. Meanwhile, many tropical species of fish thrive at tropical temperatures and die of *cold* stress if cooled to 4–6°C. One can hardly doubt that these Antarctic and tropical species have evolved adaptive specializations to their respective body temperatures. Most differences among species, however, are not so categorical and are more challenging to interpret.

One problem for the study of evolutionary adaptation to temperature is that most animal species cannot be bred in captivity, and therefore individuals must be collected from nature for study. When biologists try to interpret data gathered on wild-caught adults, they must always worry that differences may exist between sets of animals of different species—not because the species differ genetically, but because the study animals underwent their early development under different conditions in their respective natural habitats. Another problem for the study of evolutionary adaptation is that species from thermally different environments are often unable to live successfully at a single temperature; in such cases, biologists cannot do the “obvious” experiment of comparing species in a single laboratory environment. These concerns and

others pose methodological challenges for physiologists working on evolutionary differences among species.

LIZARD SPECIES WITH DIFFERENT PREFERRED BODY TEMPERATURES Of what advantage is thermoregulation? A plausible hypothesis is that when a species thermoregulates, its tissues and cells can improve their performance by becoming thermally specialized to function at the body temperatures maintained. In the complete absence of thermoregulation, tissues are equally likely to be at almost any temperature; accordingly, specialization to function at particular temperatures might be disadvantageous. However, if thermoregulation occurs and tissue temperatures are thereby maintained for substantial periods of time in a narrow range, a tissue might profit by becoming specialized (over evolutionary time) to function at temperatures in that range.

Species of lizards with different preferred body temperatures provide excellent models for testing the hypothesis that tissues become specialized to function at the body temperatures maintained by thermoregulation. If the hypothesis is correct, species with relatively high preferred body temperatures should have tissues specialized to function at relatively high temperatures, whereas species with lower preferred temperatures should exhibit tissue specializations to lower temperatures.

Many tissue functions of lizards, when tested, seem in fact to be carried out best in various species when the species are at their respective preferred body temperatures. For example, in species that have preferred body temperatures near 40°C, testicular development at the onset of the breeding season is often most rapid and complete at such high temperatures; in other species that prefer body temperatures near 30°C, the testicles develop optimally near 30°C and are damaged by 40°C. For another example, consider the optimum body temperature for sprint running by various species of lizards. This temperature is well correlated in certain groups of related lizards (but not in all groups) with the respective preferred body temperatures of the species (Figure 10.18). Hearing, digestion,

FIGURE 10.18 The body temperatures at which 19 species of iguanid lizards are able to sprint fastest correlate well with the behaviorally regulated preferred body temperatures of the species. In each species of lizard, as the body temperature is raised, sprinting speed increases to a certain point, but then if the body temperature is raised further, sprinting speed starts to decline (a typical performance curve). The body temperature at which the sprinting speed is maximized is plotted on the y axis for each of the 19 species. Preferred body temperatures maintained by behavioral thermoregulation in nature are on the x axis. (After Huey and Kingsolver 1993.)

and the response of the immune system to bacterial invasion are just some of the other processes known to take place optimally, in at least certain sets of related species, when body temperatures are at preferred levels. There are exceptions to these patterns, and there are traits that seem in general not to be optimized at preferred temperatures. Nonetheless, the data on lizards indicate that thermoregulation and tissue thermal specialization have often evolved in tandem.

FISH AND INVERTEBRATES OF POLAR SEAS Many decades ago, investigators hypothesized that the species of fish and invertebrates in polar seas maintain higher resting and average metabolic rates in cold waters than related temperate-zone or tropical species could maintain in the same waters. Today, most specialists conclude that the hypothesis is correct, at least for certain groups of polar poikilotherms. This conclusion, however, follows 60 years of contentious debate, which continues.

Studies of isolated tissues provide more-certain evidence for evolutionary specialization in polar poikilotherms. For instance, investigators have studied the rate of protein synthesis in isolated fish livers. At near-freezing tissue temperatures, protein synthesis is much more rapid in livers taken from polar species than in those taken from temperate-zone species. Similarly, the skeletal muscles of polar fish are able to generate more mechanical power at polar temperatures than are the muscles of temperate-zone fish; one reason, in at least some cases, is that the polar muscles are richer in mitochondria (and mitochondrial enzymes). These sorts of evidence point to the evolution in polar fish of distinctive physiological properties that permit them to function more vigorously at low body temperatures than unspecialized fish can.

Temperature and heat matter to animals because they affect the rates of processes and the functional states of molecules

One of the most important reasons to study poikilotherms is that they clarify the fundamental ways in which temperature and heat are significant factors for the tissues of animals. Recall from Chapter 7 that heat energy cannot be used to do work by organisms. If heat cannot do work, why does it even matter?

Temperature and heat are important for animal tissues for two reasons. The first we have already discussed: The temperatures of tissues (which are determined by heat inputs and outputs) *affect the rates of tissue processes*.¹⁵ The second is that the temperatures of tissues *affect the molecular conformations and therefore the functional states of molecules*.

The exact three-dimensional conformation of a protein molecule depends on prevailing temperature because three-dimensional conformation is stabilized by weak, noncovalent bonds—not strong, covalent bonds (see Box 2.1). When the temperature is modified, the various weak bonds in a molecule change in their relative strengths, and thus the molecule assumes a different conformation at each temperature.¹⁶ The *functional properties* of a protein molecule

¹⁵These rates include metabolic rates, rates of particular biochemical reactions, and rates of biophysical processes such as diffusion and osmosis.

¹⁶To be more exact, one current view is that a given molecule has multiple microconformations, which it “flickers” among from instant to instant. In this view, changes of temperature alter the probabilities that a molecule will be in its various microconformations. Thus changes of temperature alter the time-averaged conformation of the molecule. From this viewpoint, when we speak of *conformation*, we mean *time-averaged conformation*.

depend on its molecular conformation.¹⁷ With this background in mind, we can understand in principle why the functional properties of protein molecules often vary with the prevailing temperature.

One of the most significant discoveries of the last few decades in the study of comparative physiology is the realization that animals living in different temperature regimes often have evolved *different molecular forms* of proteins: forms that are differentially suited to function in the divergent temperature regimes. **Figure 10.19** provides a dramatic visual illustration of this point. At the left in Figure 10.19b are the freshly dissected eye lenses of three vertebrates that live in different temperature regimes. The eye lens of the cow normally functions at 37°C. The two fish are from coral-reef ecosystems (the soldierfish) and the Antarctic Ocean (the toothfish), and their lenses normally function at 25°C and –2°C, respectively. Ostensibly the three lenses at the left are all the same: All are composed of a type of protein—called crystallin protein—that is perfectly clear. Testing the lenses revealed, however, that they are not the same. When the cow lens and tropical-fish lens were placed at 0°C, they underwent denaturation: a type of protein-conformation change that disrupts normal protein function. As a consequence of the denaturation, instead of being clear, they became opaque (a phenomenon called cold cataract). This sort of change would have blinded the animals! The lens of the Antarctic toothfish, however, exists for a lifetime (up to 30 years) at –2°C without undergoing denaturation; and tests showed that it could be cooled to –12°C without denaturing. In brief, all these vertebrates have crystallin proteins, but they have *different molecular forms* of the proteins: forms differentially suited to the distinct temperatures at which their eye lenses function. This is a theme that is repeated throughout the study of proteins and other macromolecules.

The enzyme–substrate affinity of an enzyme molecule is one of the molecule’s most important functional properties because it determines how readily the molecule is able to form an enzyme–substrate complex (see page 43). The enzyme–substrate affinity, however, is not a fixed property of an enzyme molecule. Instead, it changes as the prevailing temperature is raised and lowered. Biochemists believe that a certain intermediate level of enzyme–substrate affinity is ordinarily ideal. Whereas too low an affinity can render an enzyme molecule incapable of forming complexes with substrate molecules, too high an affinity can make the enzyme molecule so prone to forming complexes with substrate that it becomes uncontrollable by regulatory processes. **Figure 10.20a** illustrates how the enzyme–substrate affinity of one particular enzyme molecule—lactate dehydrogenase (LDH) isolated from the muscles of a goby fish—varies with the prevailing temperature because of reversible, temperature-induced conformational changes in the protein.

Because the functional properties of enzymes depend on the prevailing temperature, any particular enzyme protein can be highly functional at certain tissue temperatures while being only marginally functional (or even nonfunctional) at other tissue temperatures. How, then, can animals living in different thermal regimes all have suitably functional enzymes?

An important part of the answer is that during evolution, species that have different body temperatures have often evolved

¹⁷This is probably true for several reasons. One important reason is that (as discussed in Chapter 2) a protein molecule often must *flex* (change shape) to carry out its functions, and conformation affects how readily various molecular subregions are able to flex.

(a) An Antarctic toothfish

(b) Eye lenses of a cow, a coral-reef soldierfish, and an Antarctic toothfish

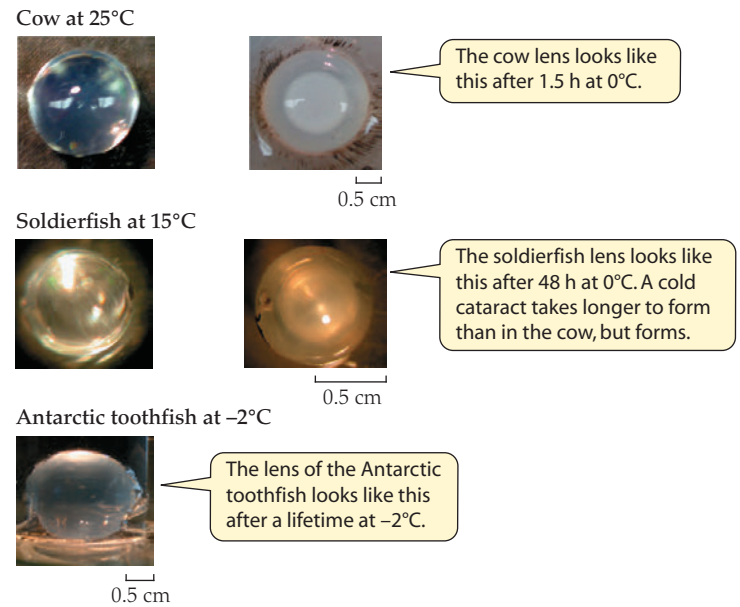

FIGURE 10.19 Seeing at -2°C requires specialized eye-lens crystallin proteins (a) An Antarctic toothfish (*Dissostichus mawsoni*) living at -2°C in the ocean near Antarctica. Toothfish sometimes live for 30 years, and their eye lenses remain crystal clear throughout. (b) At the left are normal eye lenses taken from three species: a cow, a coral-reef fish called the blackbar soldierfish (*Myripristis jacobus*), and the Antarctic

toothfish. In life, the lenses of these three species function at about 37°C , 25°C , and -2°C , respectively. Note at the right in (b) that the lenses of the cow and soldierfish develop cold cataracts—which would blind the animals—with only short-term exposure to 0°C . (Photographs in b courtesy of Andor Kiss and C.-H. Christina Cheng; photographs from Kiss et al. 2004.)

(a) Enzyme–substrate affinity as a function of temperature in a goby

(b) Enzyme–substrate affinity as a function of temperature in six species of poikilotherms

All the blue line segments, which identify the ordinary body temperatures of the species, fall within the narrow vertical distance marked by the shaded band. Thus, affinity for substrate is kept relatively constant at the respective ordinary body temperatures of the species because of the evolution of different LDH homologs.

FIGURE 10.20 The affinity of the enzyme lactate dehydrogenase (LDH) for substrate as a function of temperature This relation is shown in (a) for a goby fish (*Gillichthys mirabilis*) and in (b) for six species of poikilotherms—five fish and a desert lizard—that ordinarily live at different body temperatures. The blue, thickened portion of each line identifies the range of body temperatures ordinarily experienced by the species. The enzyme–substrate affinity shown in both plots is the affinity

of muscle LDH (LDH-A_4) for pyruvic acid. Affinity is expressed as the inverse of the apparent Michaelis constant (mM pyruvate); see Chapter 2 (page 43) for background. The Antarctic fish is an Antarctic notothenioid; the South American fish is also a notothenioid; the barracuda is *Sphyaena idiaestes*; the temperate-zone goby is *Gillichthys mirabilis*; the warm-water goby is *Gillichthys seta*; and the desert iguana is *Dipsosaurus dorsalis* (see Figure 1.12). (After Hochachka and Somero 2002.)

different molecular forms of enzyme proteins. Not all species of vertebrates, for instance, have the same molecular form of LDH that the goby fish in Figure 10.20a has. If they did, species that ordinarily have low body temperatures would routinely have far higher enzyme–substrate affinities than species that have high body temperatures. Instead, as Figure 10.20b shows, different species have evolved different molecular forms of LDH. The six species of poikilotherms shown in Figure 10.20b, some of which ordinarily live at very different body temperatures than others, have six different (although homologous) LDH proteins.¹⁸ Although all six LDH proteins catalyze the same reaction, they differ in their detailed structures and functional properties, so the six exhibit different relations between enzyme–substrate affinity and temperature. The line for each species in Figure 10.20b is thickened and colored blue at the temperatures that correspond to the usual body temperatures of the species. For example, the line for the warm-water goby is thickened and colored blue at temperatures between 25°C and 40°C because that species of fish ordinarily has body temperatures of 25–40°C, and the line for the Antarctic fish is thickened and colored blue at temperatures near –1°C because that species ordinarily has a body temperature near –1°C. All the blue, thickened segments are at about the same height on the y axis. Specifically, all fall within the vertical distance marked by the shaded band. What this shows is that *all six species have about the same enzyme–substrate affinity when they are at their respective body temperatures*. The way they have achieved this remarkable condition, even though they live at body temperatures as much as 40°C apart, is by having evolved different molecular forms (homologs) of the enzyme.

The conservation of enzyme–substrate affinity by the evolution of enzyme homologs that are adapted to function best at different temperatures is very common. One of the most striking and instructive examples is provided by the four species of barracudas in Figure 10.21. These four species, all closely related evolutionarily, behaviorally elect to live in waters that are just modestly different in temperature. For example, the waters occupied by *Sphyræna lucasana* average just 3–4°C warmer than those occupied by *S. argentea*, and those occupied by *S. ensis* average just 3–4°C warmer yet. Even these relatively small differences in habitat temperature (and body temperature) have led to the evolution of different molecular forms of the LDH protein. Consequently, the four species all have similar enzyme–substrate affinities when living at their respective (and different) temperatures.

Earlier we noted that there are two major ways in which temperature and heat matter for animals. The second of those ways should now be clear enough that we can state it succinctly: *Particular enzyme molecules (and other sorts of protein molecules) are typically specialized to function best within certain temperature ranges. The protein molecules therefore require certain temperatures to function optimally.* With few

FIGURE 10.21 Enzyme adaptation in four species of barracudas The four species, all in the genus *Sphyræna*, live at somewhat different temperatures. The enzyme studied is LDH. All details are the same as in Figure 10.20b. (After Somero 1997.)

known exceptions, the tissues of the adults of any particular species are fixed in the homolog of each enzyme they synthesize; although a tissue may change the *amount* of the enzyme it synthesizes (as often occurs during acclimation or acclimatization), it cannot change the *type* of enzyme.¹⁹ Thus individuals of a species of fish (or other aquatic poikilotherm) ordinarily found in warm waters typically *require* warm tissue temperatures for their enzyme molecules to have ideal functional forms. Conversely, individuals of a cold-water species of fish typically *require* cold tissue temperatures for their particular types of enzyme molecules to have ideal functional forms. The same principles apply to homeotherms. For instance, the LDH of cows needs to be at about 37°C to have an appropriate enzyme–substrate affinity, just as the crystallin proteins of cows need to be warm to be clear. Certain tissue temperatures, in brief, are crucial because the conformations and functional properties of proteins are not deterministically set by the chemical compositions of the proteins but depend as well on the prevailing temperature.

IMPLICATIONS FOR GLOBAL WARMING A key question in the study of global warming is *how much* the tissue temperature of animals must change for the change to have significant consequences. Data such as those on the barracudas (see Figure 10.21) suggest that the answer is sometimes “not very much.” The species of barracudas, which live in waters differing by 3–4°C and have evolved different enzyme homologs, appear to be telling us that a 3–4°C change in body temperature is sufficiently consequential that natural selection favors the evolution of new molecular variants of key enzymes. A worry about human-induced global warming is that it may occur so rapidly that evolution will not immediately “keep up,” and many poikilotherms may be forced to function for years with nonoptimized molecular systems.

In situations in which tissue temperatures are different from ideal, an important question is the steepness of the relation between molecular functional properties and temper-

¹⁸These are *interspecific enzyme homologs*. See page 46 in Chapter 2 for an extensive discussion of both LDH and the concepts of protein homology.

¹⁹As discussed later in the chapter, this statement does not necessarily apply to other proteins.

FIGURE 10.22 An enzyme that shows extreme sensitivity to temperature change The plot shows the affinity of brain acetylcholinesterase for acetylcholine in a stenothermal, polar fish (*Pagothenia borchgrevinki*, pictured) and a eurythermal, warm-water species of fish, a mullet. Because acetylcholinesterase is a lipoprotein enzyme, lipid moieties may be involved in interspecific differences. Affinity is expressed as the inverse of the apparent Michaelis constant (mM acetylcholine). (After Somero 1997.)

ature. A classic example of a very steep relation is provided by the acetylcholinesterase homolog found in the brains of *Pagothenia borchgrevinki*, a red-blooded Antarctic fish (Figure 10.22). Acetylcholinesterase is essential for brain function because it keeps the neurotransmitter acetylcholine from building up excessively at synapses (see page 343). The enzyme–substrate affinity of *Pagothenia*'s acetylcholinesterase is exceptionally sensitive to changes of temperature, so much so that the enzyme undergoes functional collapse—it loses almost all affinity for its substrate—when warmed to 5–10°C. An enzyme form of this sort would cause any species possessing it to be unusually vulnerable to climate change. It also probably helps explain why *Pagothenia* is one of the most stenothermal fish known; it ordinarily lives its entire life at temperatures near –2°C and dies of heat stress at +4–6°C.

MORE ON ENZYME ADAPTATION TO TEMPERATURE Besides enzyme–substrate affinity, another critical functional property of enzymes is the *catalytic rate constant*, k_{cat} , which measures the number of substrate molecules that an enzyme molecule is capable of converting to product per unit of time. If the k_{cat} of a particular type of enzyme, such as LDH, is measured under fixed conditions, the usual pattern is that homologs of the enzyme from cold-water species tend to exhibit higher k_{cat} values than homologs from related warm-water species. Thus the enzyme homologs of the species living in cold waters have a greater intrinsic ability to speed reactions, an attribute that in nature helps offset the reaction-slowing effects of low temperatures. An example is provided by the four barracuda species shown in Figure 10.21. The k_{cat} of their LDH enzymes, measured at a fixed study temperature, increases as the temperature of their habitat decreases.²⁰ The k_{cat} s of LDH forms in Antarctic fish are four to five times higher than the k_{cat} s of LDH forms in mammals.

²⁰ Enzyme–substrate affinity and k_{cat} tend to coevolve because of molecular structural reasons that are only starting to become clear. Thus the evolution of particular interspecific patterns in k_{cat} is not entirely independent of the evolution of particular patterns in enzyme–substrate affinity.

An important question from the viewpoint of evolutionary biochemistry is how much the amino acid composition of an enzyme must change for the enzyme to take on new functional properties. One of the most interesting studies on this question also involved the barracudas. Using modern sequencing techniques, researchers found that in the LDH protein—which consists of about 330 amino acid units—four amino acids at most are changed from one barracuda species to another; only one amino acid is different between some of the species. Of equally great interest, none of the changes in amino acid composition in these LDH homologs is at the substrate-binding site; the changes, therefore, affect the function of the enzyme by altering properties such as molecular flexibility, not the properties of the catalytic site per se. These characteristics, exemplified by the barracudas, are emerging as important generalizations: (1) Homologous enzyme molecules often differ in only a relatively few amino acid positions—helping explain how species can readily evolve adaptively different enzyme homologs; and (2) the altered amino acid positions are located outside the substrate-binding site, so the substrate-binding site is constant or near-constant, explaining why all homologs catalyze the same reaction.

MYOSIN ISOFORMS EXEMPLIFY THAT PROTEIN ISOFORMS SOMETIMES CHANGE DURING ACCLIMATION AND ACCLIMATIZATION

Muscle contractile function depends on a variety of proteins, such as myosin, troponin, and actin (see Chapter 20). An individual of any particular species is typically capable of synthesizing multiple molecular forms of each of these proteins, providing the basis for a wide range of phenotypic plasticity in muscle function. The various molecular forms of a particular protein that can be synthesized by a species are termed *isoforms* of the protein—a term with similar meaning to *isozymes* (see page 46) but preferred in this context because not all muscle proteins have enzymatic activity. How is it possible for an individual to synthesize multiple forms of one protein? One reason is that multiple genes in the gene family coding for the protein are present in one individual.

The isoforms of the *myosin heavy-chain* protein in fish fast muscle provide an elegant and instructive example of the importance of the properties just outlined. This protein plays a central role in muscle contraction (see Chapter 20) and thus is critical for swimming—one of the most important of all activities of a fish. After individual carp (*Cyprinus carpio*) or goldfish (*Carassius auratus*) that have been living in warm water are switched to cold water, they initially cannot swim particularly fast, but over several weeks, they exhibit increasing swimming performance in the cold water. A change in isoforms of the myosin heavy-chain protein is a key part of this acclimation. That is, according to available evidence, the muscle cells of the fish synthesize isoforms in altered proportions, and they switch out old isoforms for new ones in the contractile apparatus! Although the proteins in thoroughly cold-acclimated individuals are relatively unstable if subjected to warm temperatures, at cold temperatures they have molecular properties that enhance contractile performance. The change in isoforms is thus a key reason that the swimming performance of the fish increases as cold acclimation takes place. Whereas the enzymes of glycolysis and the Krebs cycle that have been so thoroughly studied (see the preceding sections of this chapter) typically are adjusted only in *amount*, not in *type*, during acclimation, the myosin isoforms illustrate that some proteins undergo isoform changes.

LIPIDS AND HOMEOVISCIOUS ADAPTATION As is true of proteins, the functional properties of lipids depend on the prevailing temperature as well as the chemical compositions of the molecules. One of the most important functional properties of lipids is the fluidity of the phospholipids in cell membranes and intracellular membranes. As stressed in Chapter 2 (see page 33), individual phospholipid molecules—and protein molecules embedded in the phospholipid matrix—diffuse from place to place within the leaflets of cell membranes and intracellular membranes, and this mobility is exceedingly important for membrane function. **Membrane fluidity** is a measure of how readily the phospholipid molecules in a membrane move.

Figure 10.23 depicts membrane fluidity as a function of temperature for membrane lipids extracted from the brains of nine vertebrate species—seven fish from a broad range of habitats, a mammal, and a bird. If you focus on any *particular* species, you will note that fluidity is a regular function of the prevailing temperature. Fluidity increases as temperature increases, much as any particular household lipid, such as butter, becomes more fluid as it is warmed.

When different species of animals are taken from their natural habitats and analyzed, they typically differ in the compositions of their membrane phospholipids. Consequently, as can be seen when all nine species in Figure 10.23 are compared, species differ in the details of their relations between membrane fluidity and temperature. The line for each species is thickened and colored blue at temperatures that correspond to the usual body temperatures of the species. As in Figures 10.20*b* and 10.21, the blue, thickened line segments all fall within a narrow range on the *y* axis, marked by the shaded band. In this case, the meaning of this result is that *all nine species have about the same membrane fluidity when they are living at their respective, normal body temperatures*. Such maintenance of a

relatively constant membrane fluidity regardless of tissue temperature is called **homeoviscous adaptation** (*homeoviscous*, “steady viscosity”).

Homeoviscous adaptation is possible because the chemical composition of membrane phospholipids is not fixed but instead can differ among species. If all animal species had the same membrane phospholipid composition, the species with high body temperatures would have very fluid membranes, whereas those with low body temperatures would have stiff membranes. In reality, all have about the same membrane fluidity because species that have evolved to operate at different body temperatures have also evolved systematically different phospholipid compositions. As we saw in studying proteins, again this means that tissue temperature is critical because it must be “matched” to the particular molecules present: *A tissue in which cell membranes are built of particular phospholipids will have the “correct” membrane fluidity only if its temperature is correct.*

The best-understood chemical basis for homeoviscous adaptation is modification of the number of double bonds in the fatty acid tails of the membrane phospholipids. Double bonds create bends in the fatty acid tails (see Figure 2.2*a*), and these bends interfere with close packing of the tails in a membrane. Thus membrane fluidity tends to increase as the number of double bonds increases—that is, as the lipids become more chemically unsaturated. We saw in Chapter 2 (see Figure 2.3) that among fish species native to different thermal environments, the degree of unsaturation of brain phospholipids increases as habitat temperature decreases: Whereas polar species have highly unsaturated lipids that, because of their chemical structure, remain reasonably fluid at polar temperatures, tropical species have much more saturated lipids that, because of their chemical structure, resist becoming too fluid at tropical temperatures.

Individual animals are able to alter the membrane phospholipids that they synthesize: Phospholipid composition is phenotypically plastic (often greatly so). The phospholipid composition of cell membranes and intracellular membranes is commonly restructured during acclimation and acclimatization in ways that promote homeoviscous adaptation. The restructuring of membrane phospholipids by an individual exposed to a chronically changed temperature typically requires many days or more. However, some fish in desert ponds undergo substantial phospholipid restructuring on a day–night cycle, thereby keeping membrane fluidity relatively constant even as the ponds heat up during the day and cool at night.

FIGURE 10.23 The fluidity of lipid-bilayer membranes from brain tissue as a function of temperature This relation is shown for nine species of vertebrates—seven fish that ordinarily live at different body temperatures (see temperatures listed after each species name), a mammal, and a bird. The blue, thickened portion of each line marks the body temperatures ordinarily experienced by the species. Fluidity is measured in terms of the mobility of a molecular probe, to which the units of measure refer. (After Hochachka and Somero 2002.)

Poikilotherms threatened with freezing: They may survive by preventing freezing or by tolerating it

If poikilotherms are exposed to temperatures even slightly colder than those necessary to freeze water, they face a threat of freezing. A classic example of this threat is provided by barnacles, mussels, and other animals attached to rocks along the seacoast. In places such as Labrador in the winter, when the tide is out, such animals may be exposed to extremely cold air and become visibly encased in ice (Figure 10.24). In this way, they themselves may freeze. Animal body fluids

FIGURE 10.24 Barnacles encased in ice during low tide along a northern seacoast. The animals—glued to rocks and unable to flee when exposed to frigid air at low tide—face a threat of freezing. They have met the threat, not by preventing freezing, but by evolving an ability to tolerate—and thereby survive—extensive freezing of their body fluids, as discussed later in the text.

have lower freezing points than pure water because the freezing point is ordinarily a colligative property and becomes lower as the total concentration of dissolved matter increases.²¹ Because of their solute content, animal body fluids have lowered freezing points. Nonetheless, they typically freeze at -0.1°C to -1.9°C (depending on the animal group) unless they are specially protected.

THE FREEZING PROCESS IN SOLUTIONS AND TISSUES To understand the threat of freezing and the possible strategies that animals might use to avoid freezing damage, the first step is to examine the freezing process. An important and seemingly strange point to mention at the outset is that when aqueous solutions are progressively cooled, they commonly remain unfrozen even when their temperatures have fallen below their freezing points, a phenomenon called **supercooling**. Supercooling is an intrinsically unstable state, and a supercooled solution can spontaneously freeze at any moment. Nonetheless, solutions in the supercooled state sometimes remain supercooled for great lengths of time.

An important determinant of a supercooled solution's likelihood of freezing is its *extent* of supercooling; freezing becomes more likely as the solution's temperature drops further below its freezing point. If the temperature of a supercooled solution is gradually lowered while the solution is not otherwise perturbed, a temperature is reached at which the likelihood of freezing becomes so great that the solution spontaneously freezes within a short time. This temperature is called the **supercooling point** of the solution.

Exposure to ice *induces* freezing in a supercooled solution. This has two important implications. First, an unfrozen but supercooled solution immediately freezes if it is seeded with even just a tiny ice crystal, regardless of its extent of supercooling. Second, if a solution,

initially at 0°C , is gradually cooled in the presence of an ice crystal, the crystal will prevent supercooling.

An important application of this second point is that the cooling of a solution in the presence of an ice crystal permits determination of the solution's **freezing point**. The freezing point is the temperature above which a solution cannot freeze and below which it deterministically freezes in the presence of preexisting ice. A solution's freezing point is typically a colligative property, depending on the concentration of dissolved entities (see page 117). If a frozen solution is gradually warmed, its **melting point** is the lowest temperature at which melting occurs. The freezing point and the melting point are usually equal.

In tissues, additional complexity is involved in understanding freezing because the *location* of freezing is an important factor. Under natural conditions, freezing *within cells* (*intracellular freezing*) almost always kills the cells in which it occurs. Intracellular freezing is thus fatal for animals unless they can survive without the cells that are frozen. However, many animals are remarkably tolerant of widespread ice formation in their *extracellular* body fluids. This tolerance of extracellular freezing is significant because, for reasons only partly understood, when freezing occurs in an animal, the formation of ice often begins in the extracellular fluids and thereafter tends to remain limited to the extracellular fluids.

To understand the implications and dangers of extracellular freezing more thoroughly, we need to look at the *process* of extracellular ice formation (Figure 10.25). An important attribute of the slow freezing of a solution is that water tends to freeze out of the solution in relatively pure form. Thus, when ice crystals form in extracellular fluid, solutes (excluded from the ice crystals) tend to accumulate in the portion of the extracellular fluid that remains unfrozen, raising the total solute concentration of the unfrozen fluid (see Figure 10.25*b*). The freezing point of the unfrozen fluid is lowered by the increase in its solute concentration. Thus, at a fixed temperature, the formation of ice in extracellular fluid is a *self-limiting* process: Water freezes out of the extracellular fluid only until the freezing point of the unfrozen fluid becomes low enough to equal the prevailing temperature.

The intracellular and extracellular fluids have similar osmotic pressures in an unfrozen animal, meaning that water has little or no tendency to enter or leave cells by osmosis. This benign state is

FIGURE 10.25 The process of extracellular freezing in a tissue. Dots represent solute molecules. (a) The unfrozen condition. The intracellular fluid inside the cell and the surrounding extracellular fluid have the same osmotic pressure. (b) Slow extracellular freezing produces ice that consists of virtually pure water. Solutes excluded from the ice elevate the osmotic pressure of the unfrozen extracellular fluid. (c) Because of the difference in osmotic pressure created in part (b), water leaves the cell by osmosis, shrinking the cell and raising the osmotic pressure of the intracellular fluid.

²¹ See Chapter 5 (see page 117) for a discussion of the colligative properties of solutions, including the freezing point.

disrupted by freezing in an animal's extracellular fluids. Immediately after extracellular ice forms, the unfrozen extracellular fluids are osmotically more concentrated than the intracellular fluids (see Figure 10.25*b*). Thus the ice formation leads to the osmotic loss of water from cells (see Figure 10.25*c*). This loss of intracellular water is itself self-limiting; it stops after the intracellular osmotic pressure has risen to equal the extracellular osmotic pressure. Within limits, the osmotic loss of water from cells is protective: By concentrating the intracellular fluids and thus lowering the intracellular freezing point, the loss of water from cells helps prevent intracellular freezing, which usually is fatal.

THE ADAPTIVE RESPONSES OF ANIMALS TO FREEZING CONDITIONS: INTRODUCTION Many poikilotherms behaviorally avoid environments where freezing conditions prevail. For example, many species of frogs, turtles, and crayfish move to the bottoms of lakes and ponds during winter. This location is a safe microhabitat because lakes and ponds do not normally freeze to the bottom.

Many poikilotherms, in contrast, are actually exposed to freezing conditions and must cope physiologically. The mechanisms by which they do so are classified into three types: (1) production of antifreeze compounds, (2) supercooling, and (3) tolerance of freezing. Antifreeze production and supercooling are mechanisms of *preventing* freezing. Usually, species that employ antifreezes and supercooling are **freezing-intolerant**; they die if they freeze and thus are absolutely dependent on successful prevention. By contrast, some species are **freezing-tolerant**; they have evolved the ability to survive extensive freezing of extracellular body water and typically respond to freezing conditions by freezing. It remains largely a mystery why some species have evolved along lines of freezing intolerance, whereas others, sometimes closely related, have evolved toward freezing tolerance.

PRODUCTION OF ANTIFREEZE COMPOUNDS Many animals gain protection against freezing by synthesizing **antifreeze compounds**, defined to be dissolved substances that are added to the body fluids specifically to lower the freezing point of the body fluids. Two types of physiologically produced antifreezes are recognized.

1. *Colligative antifreezes.* Some antifreezes lower the freezing point of the body fluids strictly by colligative principles: They affect the freezing point by increasing the total concentration of solutes in the body fluids, not by virtue of their particular chemical properties. The most common of these colligative antifreezes are polyhydric alcohols, especially glycerol, sorbitol, and mannitol.
2. *Noncolligative antifreezes.* Some antifreezes lower the freezing point of the body fluids because of specialized chemical properties. Certain proteins and glycoproteins produced by a variety of insects and marine fish are the best-understood antifreezes of this sort. They are believed to act by binding (through weak bonds such as hydrogen bonds) to nascent ice crystals in geometrically specific ways, thereby suppressing growth of ice by preventing water molecules from freely joining any crystals that start to form. The noncolligative antifreezes can be quite dilute and yet highly effective because they depress the freezing point hundreds of times more than can be accounted

for by simple colligative principles. The noncolligative antifreezes, however, do not depress the melting point any more than colligative principles explain. Thus solutions containing these antifreezes exhibit the unusual property—termed **thermal hysteresis**—that their freezing points are substantially lower than their melting points. The noncolligative antifreezes are usually called **thermal hysteresis proteins (THPs)** or **antifreeze proteins**.

Antifreezes are synthesized principally by certain species in two sets of animals: the marine teleost fish (bony fish) and the insects. The marine teleost fish, in comparison with most other aquatic animals, face unique problems of freezing because their body fluids are osmotically more dilute than seawater (see page 725).²² Specifically, marine teleosts have blood and other body fluids that—without special protection—freeze at temperatures of -0.6°C to -1.1°C . Seawater, being more concentrated, has a lower freezing point: -1.9°C . Marine teleost fish therefore can potentially freeze even when they are swimming about in unfrozen seas!

A great many of the marine teleost species that live at polar and subpolar latitudes prevent freezing by synthesizing antifreeze proteins. These proteins are found in the blood and most other extracellular fluids of the fish. Although some polar species maintain high antifreeze-protein concentrations in all months, most species synthesize antifreeze proteins just in the cold seasons. The winter flounder (*Pleuronectes americanus*) is one of the best-known antifreeze-producing species. It has an unusually large number of copies of the gene for antifreeze-protein synthesis (about 100), and these gene copies are transcribed and translated in an anticipatory way as winter approaches (Figure 10.26), under photoperiodic control.

Antifreezes are also found in the body fluids of many species of insects during winter. Colligative antifreezes such as glycerol, sorbitol, and mannitol are common and sometimes accumulate to impressive levels; in extreme cases, 15–25% of an insect's overwintering body weight consists of glycerol and other polyhydric alcohols. Antifreeze proteins—noncolligative antifreezes—are also known in many insects, probably having evolved independently several times. When insects are devoid of antifreezes, they have freezing points higher than -1°C . With high levels of antifreeze solutes, however, insects may exhibit freezing points as low as -10°C or, in one known case, -19°C . Even freezing points this low, however, may be well above temperatures that insects encounter in many terrestrial environments. Prevention of freezing in freezing-intolerant insects is thus often a result of both antifreezes and supercooling working in concert. Both polyhydric alcohols and antifreeze proteins promote supercooling and may have other favorable effects in addition to their antifreeze effects.

SUPERCOOLING Supercooling is a perfectly ordinary, commonplace phenomenon in both the inanimate and animate worlds; animals do not *cause* themselves to supercool. However, animals

²² Marine invertebrates generally have body fluids that are as concentrated as seawater. Their freezing points thus match the freezing point of seawater, and—when they are immersed in seawater—they are not threatened with freezing unless the seawater itself freezes. Freshwater animals of all kinds have body fluids that are more concentrated than freshwater. Thus their freezing points are below the freezing point of freshwater, and—when they are immersed in freshwater—they also do not freeze unless the water in which they are living freezes.

FIGURE 10.26 Seasonal changes in antifreeze protection in winter flounder (*Pleuronectes americanus*) The concentration of antifreeze protein in the blood plasma (blue line) rises as winter approaches, because of increased expression of the genes coding for antifreeze protein. The freezing point of the plasma is synchronously lowered (red line) and in winter is below the lowest winter temperatures the fish experience, ensuring protection against freezing. The winter flounder—an important commercial species—is named for the fact that it spawns in frigid waters in late winter or early spring. (After Fletcher et al. 1998.)

can modify their probabilities of spontaneous freezing during supercooling. Many animals, in fact, undergo adjustments whereby they exhibit low probabilities of spontaneous freezing even when they are supercooled to temperatures far below their freezing points. At one level of understanding, animals achieve this result by altering the quality or quantity of **ice-nucleating agents** in their bodies. Ice-nucleating agents are dissolved or undissolved substances that act as foci for the initiation of freezing. An animal containing an abundance of ice-nucleating agents may freeze when its body temperature is barely below the freezing point of its body fluids. In contrast, an animal that has substantially cleansed its body of ice-nucleating agents may have a supercooling point that is far below its freezing point.

Extensive supercooling is the principal means by which the overwintering life stages of many freezing-intolerant species of insects survive, and it is among these insects that the greatest known capacities to supercool are found. An ability to supercool to 20–25°C below the freezing point of the body fluids—and remain unfrozen because of supercooling for prolonged periods of time—is about average for such insects, and prolonged supercooling to 30–35°C below the freezing point is not uncommon. At the extreme, there are now several known examples of insects that remain unfrozen at –50°C to –65°C by virtue of extensive supercooling, combined with antifreeze depression of their freezing points. These species

can overwinter, unfrozen, in exposed microhabitats, such as plant stems, in some of the most severe climates on Earth.²³

Less-extreme supercooling is employed by a variety of other types of animals to avoid freezing. For example, some species of *deep-water* marine teleost fish found in polar seas have been shown to have freezing points of about –1.0°C, yet they swim about unfrozen in waters that have a temperature of about –1.9°C. Supercooled fish in deep waters are unlikely to encounter floating ice crystals that might induce them to freeze.

TOLERANCE OF FREEZING An ability to survive extracellular freezing is far more widespread than was appreciated even 30 years ago. In the intertidal zone along ocean shores at high latitudes, sessile or slow-moving invertebrates clinging to rocks frequently experience freezing conditions when exposed to the air during winter low tides (see Figure 10.24). Many of these animals—including certain barnacles, mussels, and snails—actually freeze and survive; some tolerate solidification of 60–80% of their body water as ice. Increasing numbers of insect species are also known to tolerate freezing of their blood; tolerance of freezing is probably the most common overwintering strategy of Arctic insects, and some survive temperatures lower than –50°C in their frozen state. One of the extreme examples is a larval insect (*Gynaephora*)—one of the type called woolly bears—that lives in places such as Ellesmere Island in the Arctic. These woolly bears live for many years as larvae and thus must survive many winters before they can metamorphose into adults. They overwinter, frozen, in relatively exposed sites, tolerating body temperatures as low as –70°C! Certain amphibians that overwinter on land, such as spring peepers (*Hyla crucifer*) and wood frogs (*Rana sylvatica*), survive freezing at body temperatures of –2°C to –9°C (Figure 10.27).

For freezing-tolerant animals, whereas intracellular freezing is destructive, extracellular freezing is safe and helps prevent intracellular freezing (see Figure 10.25). These animals commonly undergo physiological changes in winter that limit *the degree of supercooling* that is possible in their extracellular fluids—thereby promoting freezing in the extracellular fluids, where the freezing is safe. Some synthesize ice-nucleating agents (e.g., proteins or lipoproteins) and add them to their extracellular fluids. In some cases, the animals expose themselves to environmental ice and have body surfaces that permit external ice to induce freezing (inoculative freezing) of their extracellular fluids.

The ability of animals to *tolerate* freezing depends in part on the addition of certain organic solutes to their body fluids. Polyhydric alcohols (principally glycerol) are the primary organic solutes promoting tolerance of freezing in insects. Glucose and glycerol are the solutes of primary importance in most freezing-tolerant amphibians. These organic solutes enter both the intracellular and the extracellular fluids of the animals, thereby increasing the amount of solute in both places. The increased solute in the extracellular fluids limits the amount of extracellular ice formation that occurs before the concentration of the unfrozen extracellular fluids rises high enough to prevent further freezing (see Figure 10.25b). The increased solute in the intracellular fluids limits the amount of

²³ Disruption of supercooling is a potential tool for insect control. Some bacteria and other microbes are known to act as highly effective ice-nucleating agents. Such microbes are being investigated as biological control agents against insect pests that depend on supercooling for winter survival.

FIGURE 10.27 Frozen wood frogs (*Rana sylvatica*) thaw approximately synchronously throughout the body. Magnetic resonance imaging (MRI) was used to detect the state of water in the body of a thawing wood frog. In the images, ice is dark; liquid water is light. The images were taken at specified times after the frozen frog was placed at +4°C. Contrary to what might be expected, wood frogs do not thaw from outside to inside. Instead, deep and superficial regions of a frog's body thaw approximately simultaneously, probably because deep regions have lower melting points than superficial ones have. Synchronous thawing may ensure that blood flow to thawed tissues can start promptly. g = gut; h = heart; i = ice; l = liver; m = leg muscle. (Photographs used with gratitude; from Rubinsky et al. 1994.)

water that must be lost from the cells for cells to come to osmotic equilibrium with freeze-concentrated extracellular fluids (see Figure 10.25c), thus limiting cell shrinkage. These are thought to be some of the principal ways by which the organic solutes aid the tolerance of freezing by poikilotherms.

SUMMARY Poikilothermy (Ectothermy)

- Poikilotherms, also called ectotherms, are animals in which body temperature (T_B) is determined by equilibration with external thermal conditions. They often thermoregulate. Their mechanism of thermoregulation is behavioral; a poikilotherm controls its T_B by positioning its body in environments that will bring its T_B to the set-point (“preferred”) level.
- The resting metabolic rate of a poikilotherm is usually an approximately exponential function of its T_B . The Q_{10} is typically 2 to 3. The metabolism–temperature curves of poikilotherms are often plotted on semilogarithmic coordinates because exponential functions are straight on such coordinates.
- From the viewpoint of metabolic rate, when poikilotherms acclimate to cold or acclimatize to low-temperature environments in nature, their most common response is partial compensation. Partial compensation returns an animal's metabolic rate toward the level that prevailed prior to the change in environment, and thus it blunts the effect of environmental change. The most common known mechanism of partial compensation is for cells to change their concentrations of key, rate-limiting enzymes.
- Different species of poikilotherms that have long evolutionary histories of living at different body temperatures frequently display evolved physiological differences that suit them to function best at their respective body temperatures. Species of lizards sprint fastest at their respective preferred body temperatures, and polar species of fish function at higher rates in frigid waters than temperate-zone species can. The important mechanisms of evolutionary adaptation to different body temperatures include molecular specialization: Species with evolutionary histories in different environments often synthesize different molecular forms of protein molecules and different suites of cell-membrane phospholipids. The evolution of *structurally* distinct protein forms and phospholipids conserves *functional* properties of the molecules; because of evolved molecular specialization, species living in different thermal environments exhibit similar enzyme–substrate affinities and similar membrane-lipid fluidities.

- When exposed to threat of freezing, some poikilotherms actually freeze and are freezing-tolerant; freezing must be limited to the extracellular body fluids, however. Other poikilotherms are freezing-intolerant and exploit one of three strategies—behavioral avoidance, antifreeze production, or supercooling—to avoid freezing. Antifreezes lower the freezing point. Stabilization of supercooling permits animals to remain unfrozen while at temperatures below their freezing points.

Homeothermy in Mammals and Birds

Homeothermy, the regulation of body temperature by physiological means, gives mammals and birds a great deal more independence from external thermal conditions than is observed in lizards, frogs, or other poikilotherms. On a cool, cloudy day, a lizard or other behaviorally thermoregulating poikilotherm may be unable to reach its preferred body temperature, because warming in such animals depends on a source of outside heat. A mammal or bird, however, produces its own heat for thermoregulation and thus can maintain its usual body temperature whether the environment is warm, moderately cold, or subfreezing.

Mammals and birds *independently* evolved the full-fledged forms of homeothermy they exhibit today. Although the extent of convergence in their physiology of homeothermy is remarkable, they also exhibit consistent differences, one being in their average body temperatures.

Placental mammals typically maintain deep-body temperatures averaging about 37°C when they are at rest and not under heat or cold stress.²⁴ Birds maintain higher temperatures under similar conditions: about 39°C. One of the most remarkable attributes of mammals and birds is that in both groups, the average body temperatures of thermally unstressed animals do not vary much with climate. One might expect, for instance, that species of mammals living in the Arctic would have lower average body temperatures than related species living in the tropics. Actually, however, differences of this sort are slight, if present at all.

²⁴Marsupials, some of the primitive placental mammals, and especially monotremes have lower body temperatures; the platypus, for example, exhibits a deep-body temperature of 30–33°C.

Deep-body temperature is not absolutely constant. Daily cycles occur; the body temperatures of mammals and birds are typically 1–2°C higher during their active phases each day than during their resting phases. Moreover, in some species the body temperature is permitted to rise when individuals are under heat stress, or it is permitted to fall in winter.

Regardless of the variations that occur, the body temperatures of mammals and birds are among the most stable in the animal kingdom. Thus one consequence of homeothermy is that cellular functions are able to be specialized to take place *especially reliably* at certain temperatures. However, as we will see, homeothermy has a very high energy cost and greatly increases the food requirements of mammals and birds in comparison with like-sized nonavian reptiles or fish.

Thermoregulation by a mammal or bird requires neurons (nerve cells) that sense the current body temperature and also requires thermoregulatory control centers in the brain that, by processing thermal sensory information, properly orchestrate the use of heat-producing and heat-voiding mechanisms in ways that stabilize the body temperature (Box 10.2). The detection of body temperature in a mammal or bird occurs in multiple parts of the body; thermosensitive neurons of importance are found in the skin, spinal cord, and brain, and sometimes also in specialized locations such as the scrotum. The principal control centers—which process the multiple sensory inputs and command the thermoregulatory mechanisms—are located in the hypothalamus and the associated preoptic regions of the brain.

A behavioral thermoregulator like a fish or a lizard must also have thermoregulatory control centers that receive and process thermosensory information and that orchestrate the processes of thermoregulation (see Box 10.2). Physiologists generally hypothesize that during the course of vertebrate evolution, there has been a thread of continuity in the control centers. According to this hypothesis, the control centers were already present in a rudimentary way when the only vertebrates were fish and the only thermoregulatory mechanisms to be controlled were behaviors. Recognizing that some modern lizards pant, change color to aid their thermoregulation, or employ other physiological mechanisms, physiologists usually conclude that the early reptilian ancestors of mammals and birds probably had some physiological thermoregulatory mechanisms that supplemented their dominant behavioral mechanisms. The control centers of those early reptiles would therefore have had both physiological and behavioral mechanisms to control. Then, as mammals and birds appeared, the control centers assumed control of predominantly physiological mechanisms. There is some evidence for this sort of scenario—with the evidence from the study of fever being particularly intriguing (see Box 10.2).

A comparison of modern nonavian reptiles with mammals and birds suggests that the single most revolutionary step that occurred in the evolution of mammalian and avian homeothermy was the evolution of endothermy. Modern lizards, turtles, crocodylians, and snakes (with isolated exceptions) cannot warm their bodies by metabolic heat production. Mammals and birds, in dramatic contrast, have an endogenous ability to stay warm in cold environments because of endothermy. With endothermy plus their physiological mechanisms of keeping cool in hot environments, mammals and birds are able to maintain relatively constant tissue temperatures over exceedingly wide ranges of environmental conditions.

Metabolic rate rises in cold and hot environments because of the costs of homeothermy

The resting metabolic rate of a mammal or bird typically varies with ambient temperature, as shown in Figure 10.28. Within a certain range of ambient temperatures known as the **thermoneutral zone (TNZ)**, an animal's resting metabolic rate is independent of ambient temperature and constant. The lowest ambient temperature in the TNZ is termed the **lower-critical temperature**; the highest is the **upper-critical temperature**.²⁵ The lower-critical and upper-critical temperatures depend on the species, and they can also be affected by acclimation or acclimatization. An animal's **basal metabolic rate (BMR)** is its metabolic rate when resting and fasting²⁶ in its thermoneutral zone.

The resting metabolic rate of a mammal or bird increases as the ambient temperature falls below the animal's lower-critical

²⁵The meaning of *critical temperature* in the study of homeotherms is very different from the meaning of the same term in the study of poikilotherms (see Figure 10.16). The critical temperatures of a homeotherm are simply benchmarks within the spectrum of ordinary, nonstressful ambient temperatures. The critical temperatures of a poikilotherm are temperatures at which the animal is in danger of becoming nonfunctional and dying.

²⁶In this context, *fasting* means that the animal has not eaten for long enough that the specific dynamic action of its last meal has ended. *Postabsorptive* is a synonym.

BOX 10.2 THERMOREGULATORY CONTROL, FEVER, AND BEHAVIORAL FEVER

Of all the physiological control systems, the system for thermoregulation is the one that usually seems the most straightforward conceptually. Virtually every introductory treatment of control theory in physiology uses the thermoregulatory control system as its central example. This is undoubtedly true because analogies can so readily be drawn with engineered thermal control systems, which are common in our everyday lives.

In a house with a furnace and air conditioner, the thermostat controls heat production by the furnace and heat removal by the air conditioner to maintain a stable air temperature. Using the terminology of control theory to describe this system, the air temperature is the **controlled variable** (see Box 1.1), and the furnace and air conditioner are **effectors**, instruments that are capable of changing the controlled variable. The thermostat itself actually includes three separate elements that are essential for a control system:

1. A **sensor**, a device that can measure the controlled variable so that the control system knows its current level (the current air temperature).
2. A **set point** or **reference signal**. The set point is a type of information that remains constant in a control system even as the controlled variable goes up and down, and that tells the system the desired level

of the controlled variable. We usually call the set point of a home thermostat its “setting.” If, for example, we “set” the thermostat to 20°C, the device is able to retain that set-point information in an invariant form, so that the air temperature detected by the sensor can be compared with it. An important point to recognize is that a thermostat does not remember its set point by having inside it an object that is kept literally at the set-point temperature. Instead, the set-point temperature is represented in the thermostat by a physical system that is not a temperature, but corresponds to a temperature.

3. A **controller**, a mechanism that compares the set point with the current level of the controlled variable to decide whether the controlled variable is too high or low.

The control system in a house, considered as a whole, operates as a **negative feedback** system (see Box 1.1). It controls the effectors to bring the controlled variable back toward the set point. For example, if the air temperature goes below the set point, the furnace is commanded to add heat to the house.

By analogy, it is easy to describe the thermoregulatory control system of a lizard or mammal (or any other thermoregulator) in terms of the same basic concepts. The principal *effectors* in a lizard (a behavioral thermoregulator) are the skeletal muscles that

move the limbs and control posture. Effectors in a mammal include muscle cells that can produce heat by shivering, sweat glands that can promote evaporative cooling, hair-erector muscles that determine how fluffed the pelage is, and so forth. A lizard or mammal has multiple *sensors*: temperature-sensitive neurons that measure the current temperatures of the skin, spinal cord, and brain. These sensors send their temperature data to a *controller* in the brain that compares the current temperatures with a *set point* to decide what to do.

The exact nature of the controller and set point remain far from fully understood because they consist of many tiny neurons in the depths of the brain. As in the case of the home thermostat, however, we recognize that the set point is not literally a temperature in the brain but is *represented* in some way by neurons.

If we disregard the uncertainties that exist about the nature of the set point and simply use the terminology of control theory, the set point of a lizard or mammal can be adjusted to different “settings” at different times, just as the setting of a home thermostat can be adjusted. **Fever** in a mammal provides an elegant example of resetting of the thermostat (see the figure). Fish, amphibians, and nonavian reptiles sometimes develop fevers—called **behavioral fevers** because the effectors are skeletal muscles that modify behaviors. **Box Extension 10.2** discusses thermoregulatory control and especially fever in more detail.

KEY

- Set point of the thermoregulatory control system
- Deep-body temperature

A bout of fever in a placental mammal: The relation between the set point of the thermoregulatory control system and body temperature
When the set point jumps up at the start of a bout of fever and falls back down at the end, the thermoregulatory control system detects the mismatch between the set point and the body temperature and commands vigorous effector responses to correct the mismatches. These responses include shivering at the start and sweating at the end.

temperature or rises above its upper-critical temperature (see Figure 10.28a). These increases in metabolic rate in both cold and warm environments arise from the animal’s need to perform physiological work to keep its deep-body temperature constant regardless of whether the ambient temperature is low or high.

The shape of the metabolism–temperature curve depends on fundamental heat-exchange principles

Before we study the physiological mechanisms used by mammals and birds to thermoregulate, it is important to analyze why the metabolism–temperature curve has the specific shape it does. A

useful first step for this analysis is to recognize the concept of **dry heat transfer**, defined to be heat transfer that does not involve the evaporation (or condensation) of water. Dry heat transfer occurs by conduction, convection, and thermal radiation. As stressed earlier, these three mechanisms of heat transfer must be analyzed separately in heterogeneous thermal environments. However, in a *uniform thermal environment* such as a laboratory cage or test chamber, where the radiant temperatures of all objects are typically similar to air temperature, these three mechanisms of heat transfer can be meaningfully lumped together. They can be lumped in this circumstance because, in all three cases, the rate of heat transfer between an animal and its environment tends to increase approximately in proportion to the difference in temperature between the animal's body and the environment ($T_B - T_A$) (see Figure 10.4). By lumping the three together, we can study dry heat transfer as a whole (because dry heat transfer = conduction + convection + thermal-radiation heat transfer).

In a uniform thermal environment, if factors other than temperature are held constant,

$$\text{Rate of dry heat transfer} \propto T_B - T_A \quad (10.8)$$

Heat moves out of an animal's body by dry heat transfer when T_B exceeds T_A ; conversely, heat moves into the body when T_B is less than T_A . The rate of dry heat transfer is proportional to $(T_B - T_A)$ in either case, and thus $(T_B - T_A)$ can be thought of as being the "driving force" for dry heat transfer.

To analyze the shape of the metabolism–temperature curve, Equation 10.8 *taken by itself* can be used at ambient temperatures that are *within* and *below* the thermoneutral zone (TNZ). At temperatures above the TNZ, evaporative heat transfer is too important to be ignored. At ambient temperatures within and below the TNZ, however, evaporative heat transfer is in general sufficiently minor that it can be disregarded for purposes of a conceptual analysis, explaining why the equation for dry heat transfer (Equation 10.8) can be used. The body temperature of a mammal or bird is typically higher than the animal's upper-critical temperature. Thus, when the ambient temperature is within or below the TNZ, $(T_B - T_A)$ is always positive, and dry heat transfer carries heat out of the body.

Under such conditions, in which an animal is losing heat to its environment, the only way the animal can maintain a constant body temperature is to make heat *metabolically* at a rate that matches its rate of heat loss. Accordingly, if M is the animal's metabolic rate, M must equal the animal's rate of heat loss. Thus, if we assume that Equation 10.8 describes the rate of heat loss at ambient temperatures within and below the TNZ, then (at those ambient temperatures) $M \propto (T_B - T_A)$. We can rewrite this expression as an equation by introducing a proportionality coefficient (C):

$$M = C (T_B - T_A) \quad (10.9)$$

This equation, which is a famous equation for analyzing a mammal's or bird's thermal relations, is called the **linear heat-transfer equation**, also described sometimes as **Newton's law of cooling** or **Fourier's law of heat flow**. The coefficient C , which is termed the animal's **thermal conductance**, is a measure of *how readily* heat can move by dry heat transfer from an animal's body into its environment.

To see the significance of C , suppose that two placental mammals are in the same environment and therefore have the same driving force for dry heat loss ($T_B - T_A$), but one has a higher thermal

conductance than the other. The one with the higher C will lose heat faster because heat can move out of its body more readily than heat can move out of the body of the other. Therefore, the one with the higher C will require a higher metabolic rate to stay warm.

An animal with a *high* C can be thought of as having a *low resistance* to dry heat loss. Conversely, an animal with a *low* C can be thought of as having a *high resistance* to dry heat loss. Physiologists, accordingly, define an animal's **resistance to dry heat loss** to be the inverse of C : $1/C$. The resistance to dry heat loss is often called **insulation** (I). Thus $I = 1/C$. The linear heat-transfer equation can therefore also be written as:²⁷

$$M = \frac{1}{I} (T_B - T_A) \quad (10.10)$$

An important point to note about the concept of insulation (I) introduced here is that it is not simply a measure of the heat-retaining properties of the fur or feathers. Instead, insulation (I) is a measure of an animal's *overall* resistance to dry heat loss. For instance, because both posture and fur affect a mammal's resistance to dry heat loss, the value of I for a mammal depends on its posture as well as its fur (and also on additional factors).

THE THERMONEUTRAL ZONE: INSULATION IS MODULATED TO KEEP THE RATE OF HEAT LOSS CONSTANT

Let's now use the concepts we have developed to understand why the metabolism–temperature curve of a mammal or bird has the shape it does in the thermoneutral zone. The defining property of the TNZ is that an animal's metabolic rate (M) remains constant at all the different ambient temperatures in the TNZ. This property probably seems impossible or paradoxical at first. After all, if T_A changes, then $(T_B - T_A)$ changes, and Equation 10.10 suggests that M would have to change. The answer to this paradox is that in its TNZ, a mammal or bird *varies* its insulation. *Modulation of insulation against a background of constant metabolic heat production is the principal means by which a mammal or bird thermoregulates in its thermoneutral zone.*

Let's discuss this key concept in more detail. As the ambient temperature is lowered in the TNZ and $(T_B - T_A)$ accordingly becomes greater, a mammal or bird responds by increasing its insulation, I .²⁸ This increase in the animal's resistance to heat loss *counterbalances* the increase in the *driving force* for heat loss, $(T_B - T_A)$, so that the animal's *actual rate of heat loss* remains constant (or nearly so). The animal's rate of metabolic heat production, therefore, can also remain constant. These points are mathematically apparent in Equation 10.10. In the TNZ, as T_A decreases and $(T_B - T_A)$ therefore increases, I is increased in a precisely counterbalancing way so that the ratio $(T_B - T_A)/I$ remains constant. The metabolic rate of the animal, M , can therefore be constant.

The *width* of the TNZ varies enormously from species to species, depending in part on the extent to which various species are able to modulate their insulation. Small-bodied species tend to have narrower TNZs than large-bodied species do. Species of mice, for instance, often have TNZs extending only from about 30°C

²⁷In this form, the linear heat-transfer equation bears a close similarity to Ohm's Law. $(T_B - T_A)$, the driving force, is analogous to potential difference (voltage); I is analogous to electrical resistance; and M is analogous to current flow. Current = voltage/resistance.

²⁸Starting on page 256, we discuss the actual mechanisms of increasing insulation.

to 35°C. At another extreme, Eskimo dogs have a TNZ extending from −25°C to +30°C—a range of 55°C!

TEMPERATURES BELOW THERMONEUTRALITY Unlike the case within the thermoneutral zone, the principal means by which a mammal or bird thermoregulates at ambient temperatures below thermoneutrality is modulation of its rate of metabolic heat production. Specifically, below the TNZ, as the environment becomes colder, a mammal or bird must raise its rate of metabolic heat production to higher and higher levels if it is to stay warm. In this way, mammals and birds resemble a furnace-heated house in which the furnace must increase the rate at which it produces heat as the air outside becomes colder.

How exactly is the lower-critical temperature determined? To see the answer, consider an animal, initially in its TNZ, that is subjected to a steadily declining ambient temperature. As the T_A declines while remaining in the TNZ, the rate at which the animal loses heat to its environment stays constant because the animal increases its insulation, I . Insulation cannot be increased without limit, however. An animal's lower-critical temperature represents the T_A below which its insulatory adjustments become inadequate to counterbalance fully the increase in the driving force favoring heat loss. As the T_A falls below the lower-critical temperature, the rate at which an animal loses heat increases, and the animal must therefore increase its rate of heat production to match the increased rate of heat loss.

The insulation of a mammal or bird sometimes becomes maximized at the lower-critical temperature. Cases like this are particularly straightforward to understand in terms of the linear heat-transfer equation (Equation 10.9 or 10.10).

If an animal maximizes its insulation at the lower-critical temperature, then its value of I at ambient temperatures below the TNZ is a *constant* (equaling its maximum value of I). In addition, because $C = 1/I$, the animal's value of C below the TNZ is a *constant* (equaling its minimum value of C). For such an animal, therefore, T_B , I , and C in the linear heat-transfer equation are all constants below the TNZ. Accordingly, the linear heat-transfer equation—whether written as Equation 10.9 or 10.10—is a simple linear equation (accounting for its name) that has two variables: M and T_A . If we plot M as a function of T_A for this linear equation—using Equation 10.9—we obtain a straight line having two particular properties, illustrated in **Figure 10.29a**: First, the slope of the line is $-C$. Second, the line intersects the x axis at the ambient temperature that is equal to T_B .

As a model of an animal's metabolism–temperature curve, the plot in Figure 10.29a is flawed because it ignores the fact that an animal's metabolic rate (M) does not truly fall below the basal level. **Figure 10.29b** is thus more realistic. By comparing Figures 10.29a and b, you can see that *the portion of an animal's metabolism–temperature curve below the TNZ is simply a plot of the linear heat-transfer equation*.

The fact that the slope of the metabolism–temperature curve below the TNZ is equal to $-C$ (for animals that maintain a constant C) provides a useful tool for the visual interpretation of metabolism–temperature curves. As shown in **Figure 10.29c**, if two otherwise similar animals differ in thermal conductance (C) below the TNZ, the relative slopes of their metabolism–temperature curves mirror their differences in C : The animal with a high value of C (low insulation) has a steeper slope than the animal with low C (high insulation). Using this principle, one can look at Figure 10.40b

(a) $M = C(T_B - T_A)$ with C and T_B constant ($T_B = 37^\circ\text{C}$)

(b) The plot from (a), recognizing that M actually falls only to the basal level

(c) Comparison of two animals that differ in C below thermoneutrality

FIGURE 10.29 A model of the relation between metabolic rate and ambient temperature in and below the thermoneutral zone

(see page 264), for example, and tell at a glance that the winter fox has lower conductance and higher insulation than the summer fox. Figure 10.29c also highlights the energy advantages of high insulation. Note that the animal with relatively high insulation (low C)—analogous to a well-insulated house—has a relatively low requirement for metabolic heat production and a low metabolic rate at any given ambient temperature below the TNZ.²⁹

²⁹ Although the slopes of metabolism–temperature curves were used to calculate C quantitatively some years ago, better approaches for the calculation of C have been developed. Thus the use of slopes today should be reserved for just qualitative, visual interpretation.

TEMPERATURES ABOVE THERMONEUTRALITY Mammals and birds employ two principal processes to respond to ambient temperatures above their thermoneutral zones:

- Most mammals and birds actively increase the rate at which water evaporates from certain of their body surfaces, a process called **active evaporative cooling**. Sweating, panting, and gular fluttering (Figure 10.30) are the most common mechanisms of active evaporative cooling.
- Some mammals and most birds allow their body temperatures to rise to unusually high levels, a phenomenon called **hyperthermia**.

Both active evaporative cooling and hyperthermia can cause an animal's metabolic rate to rise at temperatures above thermoneutrality. Active evaporative cooling causes a rise in metabolic rate because physiological work must be done to enhance water evaporation (panting, for example, requires an increase in the rate of breathing). Hyperthermia can also cause a rise in metabolic rate because tissues tend to accelerate their metabolism when they are warmed; according to recent research, hyperthermia does not always cause metabolic acceleration in mammals and birds, but in some cases it does.

To appreciate more fully the processes at work above the TNZ, it is informative to take a dynamic approach by considering an animal that is initially within its TNZ and subjected to a steadily increasing ambient temperature. As the T_A rises, the driving force for dry heat loss ($T_B - T_A$) decreases, meaning that the animal faces a greater and greater challenge to get rid of its *basal* metabolic heat production. While the T_A remains in the TNZ, the animal responds to the rising T_A by decreasing its resistance to dry heat loss, its insulation. Consequently, even high in the TNZ, metabolic heat is carried away as fast as it is produced by a combination of dry heat transfer and *passive* evaporation. This handy state of affairs comes to an end when the T_A reaches the upper-critical temperature and goes higher. Near the upper-critical temperature, insulation either reaches its minimum or at least becomes incapable of sufficient further reduction to offset additional decreases in ($T_B - T_A$). Thus, as the T_A rises above the upper-critical temperature, the rate of dry heat loss tends to fall too low for the combination of dry heat loss and passive evaporation to void metabolic heat. Both of the principal responses of mammals and birds—active evaporative cooling and hyperthermia—serve to promote heat loss so that animals are not overheated by their metabolic heat production. Hyperthermia does this because a rise in T_B increases the driving force for dry heat loss ($T_B - T_A$).

If the T_A keeps rising and becomes so high that it exceeds T_B , heat stress becomes extraordinary because—when the T_A is above the T_B —dry heat transfer carries environmental heat *into* the body!³⁰ Then active evaporative cooling must assume the entire burden of removing heat from the body.

From a quick glance at the metabolism–temperature curve above the TNZ (see Figure 10.28), it may seem extremely paradoxical that a mammal or bird increases its metabolic rate—its rate of internal heat production—when it is under heat stress. To understand this paradox, it is important to recall the very large amount of heat

³⁰For the T_A to exceed T_B , it must rise substantially above the upper-critical temperature. When the T_A is just moderately above the upper-critical temperature, it is typically below the T_B .

FIGURE 10.30 Gular fluttering is one means of actively increasing the rate of evaporative cooling. During gular fluttering, which occurs in birds but not mammals, an animal holds its mouth open and vibrates the floor of the mouth, termed the gular area (arrow). In this way, airflow is increased across the moist, vascular mouth membranes, promoting a high rate of evaporation. The bird seen here is a young great egret (*Casmerodius albus*) on a hot day in Florida. In some species the gular area vibrates up and down at 800–1000 cycles/minute during gular fluttering.

carried away by the evaporation of each gram of water (see page 230). Although an animal must increase its metabolic rate to pant, gular flutter, or otherwise actively increase its rate of evaporation, the amount of heat carried away by the evaporation of each gram of water far exceeds the heat produced per gram by the physiological processes that accelerate evaporation.

Homeothermy is metabolically expensive

One of the most important attributes of homeothermy in mammals and birds is that it is metabolically expensive in comparison with vertebrate poikilothermy. Homeothermy in mammals and birds in fact provides an outstanding example of a point stressed in Chapter 1: When physiological *regulation* and *conformity* are compared, the greatest downside of regulation is that its energy costs are high.

To quantify the cost of homeothermy, physiologists have compared the metabolic rates of vertebrate homeotherms and poikilotherms at similar tissue temperatures. Specifically, they have compared the basal metabolic rates of mammals and birds with the resting metabolic rates of like-sized poikilotherms held at the same body temperatures as the mammals and birds. A typical experiment would be to obtain a 100-g placental mammal and place it in its thermoneutral zone, and simultaneously obtain

a 100-g lizard and place it in a chamber at 37°C so that its body temperature matches that of the mammal. If both animals are at rest and fasting and you measure their metabolic rates, you will obtain (1) the basal metabolic rate (BMR) of the mammal, and (2) the standard metabolic rate (SMR) of the lizard *at mammalian body temperature*. Typically what you will find is that the metabolic rate of the mammal is four to ten times higher than that of the lizard, even though the cells of the two animals are at one temperature and the mammal's metabolic rate under these conditions is its *minimal* rate! Many studies of this sort have been carried out on a variety of species, and they have confirmed repeatedly that the BMRs of mammals and birds are four to ten times the SMRs of poikilothermic vertebrates at mammalian or avian body temperatures (see Figure 7.9). *Metabolic intensity stepped up dramatically when vertebrates evolved homeothermy.*

If mammals, birds, and poikilothermic vertebrates studied as we have just described are transferred to cold ambient temperatures, the metabolic rates of the mammals and birds *rise* (see Figure 10.28), whereas the metabolic rates of the poikilotherms *fall* (see Figure 10.9). At cold ambient temperatures, therefore, the difference in metabolic intensity between homeotherms and poikilotherms is far greater than just four- to tenfold.

Animals living in the wild experience both high and low ambient temperatures at various times. Their *average* metabolic rates thereby integrate the effects of different temperatures. As discussed in Chapter 9, field metabolic rates have now been measured in many free-living terrestrial vertebrates by use of the doubly labeled water method. Those measures reveal that the average field metabolic rate is typically 12–20 times higher in mammals and birds than in lizards or other nonavian reptiles of the same body size! The mammals and birds must therefore acquire food at a much higher rate.

Insulation is modulated by adjustments of the pelage or plumage, blood flow, and posture

Now we turn (in this section and several that follow) to the *mechanisms* that mammals and birds employ to thermoregulate physiologically. First we discuss the mechanisms by which mammals and birds modulate their resistance to dry heat transfer, their insulation. As we have seen, these are the predominant mechanisms of thermoregulation within the thermoneutral zone.

One means of varying insulation is erection or compression of the hairs or feathers. Each hair or feather can be held upright or allowed to lie flat against the skin by the contraction or relaxation of a tiny muscle at its base, under control of the sympathetic nervous system. These responses are termed **pilomotor responses** in mammals and **ptilomotor responses** in birds. If the ambient temperature declines within the TNZ, the hairs or feathers are erected to an increased degree. In this way the pelage or plumage is fluffed out and traps a thicker layer of relatively motionless air around the animal, thereby increasing the resistance to heat transfer through the pelage or plumage (see Equation 10.1).

Another mechanism of modulating insulation is the use of **vasomotor responses** in blood vessels (see page 659)—responses that alter the rate of blood flow to the skin surface and other superficial parts of the body. Arterioles supplying superficial vascular beds are constricted at cool ambient temperatures because of stimulation by the sympathetic nervous system. This response retards transport of heat to the body surfaces by blood flow. Conversely, vasodilation

at warm ambient temperatures enhances blood transport of heat to body surfaces where the heat is readily lost.

Insulation may also be modified by **postural responses** that alter the amount of body surface area directly exposed to ambient conditions. At low ambient temperatures, for example, mammals often curl up, and some birds tuck their heads under their body feathers or squat so as to enclose their legs in their ventral plumage. Many birds hold their wings away from their bodies when ambient temperatures are high.

In addition to the insulative properties that can be modulated by an individual animal, there are also properties that affect insulation but are more or less fixed for any given individual. Outstanding among these is body size. At temperatures *below thermoneutrality*, small size tends to increase the weight-specific rate at which animals lose heat—and thus the weight-specific cost of thermoregulation—because relatively small animals have more body surface per unit of weight than large ones have.³¹ Another reason that small size tends to enhance heat loss is that small animals cannot have as thick pelage or plumage as large ones. Whereas large mammals commonly have pelage that is at least 5–6 cm thick, mice could not conceivably have such thick pelage; a mouse with 5–6 cm of pelage would be trapped inside its own hair!

Heat production is increased below thermoneutrality by shivering and nonshivering thermogenesis

When a mammal or bird is below its lower-critical temperature, it must increase its rate of heat production as the ambient temperature declines. Although all metabolic processes produce heat as a by-product, mammals and birds have evolved mechanisms, termed **thermogenic mechanisms**, that are specialized to generate heat for thermoregulation. One of these, shivering, is universal in adult mammals and birds.

SHIVERING **Shivering** is unsynchronized contraction and relaxation of skeletal-muscle motor units in high-frequency rhythms, mediated by motor neurons (nerve cells) of the somatic nervous system. Skeletal muscles can basically contract in two patterns. When muscles are being employed in locomotion to move a limb, all the motor units in each muscle contract synchronously, and antagonistic muscles contract in ways that they do not work against each other. When the same muscles are employed in shivering, various motor units within each muscle contract more or less at random relative to each other, antagonistic muscles are activated simultaneously, and the muscles quiver. Either mode of contraction uses ATP and liberates heat. When a muscle shivers, the conversion of ATP-bond energy to heat becomes the primary function of contraction because no useful mechanical work is accomplished.

NONSHIVERING THERMOGENESIS The concept of **nonshivering thermogenesis (NST)** is most readily understood by taking a look at the classic studies on laboratory rats that originally led to the discovery of NST. If lab rats that have been living at warm temperatures are transferred to a room at 6°C, they shiver violently during their first days there. If one observes them visually over the next few weeks as they acclimate to 6°C, however, they appear gradually

³¹ Be certain that you do not extend this argument to the thermoneutral zone. The argument is valid below thermoneutrality but probably does not apply in the thermoneutral zone (see page 178).

to stop shivering even though they continue to maintain elevated metabolic rates. This visual observation suggests that during acclimation to cold, the rats develop mechanisms of thermogenesis that do not involve shivering. To test if this is in fact the case, cold-acclimated rats can be injected with curare, a plant extract that blocks the contraction of skeletal muscle and therefore prevents shivering. Curare-injected, cold-acclimated rats continue to have elevated metabolic rates and thermoregulate, confirming that they have well-developed nonshivering thermogenic mechanisms.

Whereas shivering is universal in mammals and birds, NST is not. NST is best known, and very common, in placental mammals. It has been reported in the young of a few species of birds (e.g., ducklings), but its occurrence in adult birds remains controversial.

Of all the possible sites of NST in placental mammals, the one that is best understood and dominant is **brown adipose tissue (BAT)**, also called **brown fat**.³² This is a specialized type of adipose tissue—often reddish brown—that differs greatly in both structure and function from the commonplace white fat that is more familiar.³³ Brown fat tends to occur in discrete masses, located in such parts of the body as the interscapular region, neck, axillae, and abdomen (Figure 10.31). Deposits of BAT receive a rich supply of blood vessels and are well innervated by the sympathetic nervous system. The cells of BAT are distinguished by great numbers of relatively large mitochondria. The rich, red blood supply of BAT and the abundant, yellow cytochrome pigments in its mitochondria impart to the tissue its distinctive color.

When the sympathetic nervous system releases norepinephrine in BAT, the BAT responds by greatly increasing its rate of oxidation of its stored lipids, resulting in a high rate of heat production. BAT is biochemically specialized to undergo uncoupling of oxidative phosphorylation from electron transport (see Figure 8.4c) and uses this mechanism to produce heat rapidly. Uncoupling does two things that result in rapid heat production: (1) It suspends the ordinary controls on the rate of aerobic catabolism, permitting unbridled rates of lipid oxidation; and (2) it causes the chemical-bond energy of oxidized lipid molecules to be released immediately as heat (rather than being stored in ATP). The property that gives BAT its specialized ability to undergo uncoupling is that BAT expresses a distinctive proton-transport protein, **uncoupling protein 1 (UCP1; thermogenin)**, in the inner membranes of its mitochondria (see Figure 8.4c).

Norepinephrine released in BAT binds to β -adrenergic receptors (and other receptors) in the cell membranes of the BAT cells. These receptors are G protein-coupled receptors; as discussed in Chapter 2 (see Figure 2.27), the binding of norepinephrine to the receptors activates G proteins in the cell membranes and leads to the intracellular production of the second messenger cyclic AMP. Cyclic AMP then activates (by phosphorylation) an intracellular lipase enzyme that rapidly hydrolyzes triacylglycerols stored in the cells to release free-fatty-acid fuels for mitochondrial oxidation. Simultaneously, by a mechanism that remains ambiguous, existing

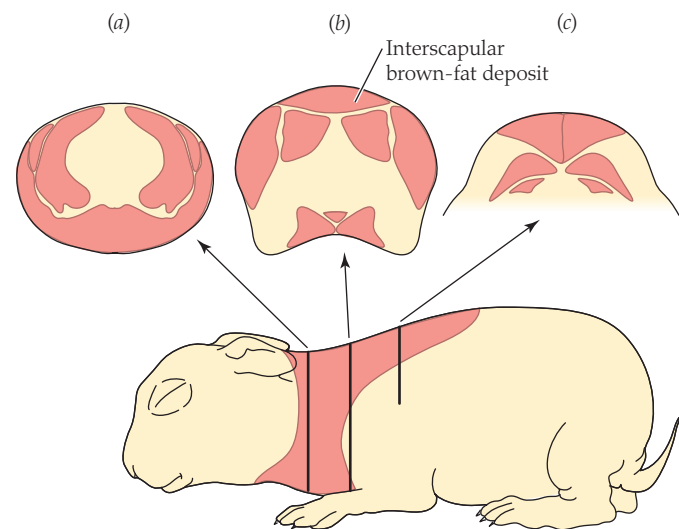

FIGURE 10.31 The deposits of brown adipose tissue in a newborn rabbit (a), (b), and (c) are cross sections of the body at the positions indicated on the side view. Brown adipose tissue also occurs typically in discrete deposits in adult mammals that have the tissue. (After Dawkins and Hull 1964.)

molecules of the uncoupling protein UCP1 are activated, and thus the mitochondria carry out the lipid oxidation in an uncoupled state. In addition, if norepinephrine stimulation continues for tens of minutes or longer, increased amounts of UCP1 are synthesized because β -adrenergic activation stimulates increased transcription of the gene that encodes UCP1. Still another effect of stimulation of BAT is that a fatty acid transport protein (FATP) in cell membranes is upregulated, permitting the cells to carry out rapid uptake of fatty acids brought from elsewhere in the body.

Brown fat—like NST in general—is particularly prominent in three types of placental mammals: (1) cold-acclimated or winter-acclimatized adults (particularly in species of small to moderate body size), (2) hibernators, and (3) newborn individuals. During acclimation to cold or acclimatization to winter, BAT often markedly increases its potential to produce heat; deposits of the tissue grow, BAT cells increase their numbers of mitochondria, and the mitochondria become richer in uncoupling protein. In part, this development of BAT probably serves to free the skeletal muscles to perform exercise. A muscle cannot shiver and exercise at the same time; as BAT develops, muscles are less likely to need to be employed in shivering, leaving them free to be used in exercise. BAT in newborns (including human babies; see Figure 11.7), hibernators, and human adults is discussed in detail in Chapter 11.

Regional heterothermy: In cold environments, allowing some tissues to cool can have advantages

Appendages such as legs, tails, and ear pinnae present particular thermal challenges when mammals and birds are below thermoneutrality. The appendages are potentially major sites of heat loss because they have a great deal of surface area relative to their sizes, are often thinly covered with fur or feathers, and exhibit (because of their dimensions) intrinsically high rates of convective heat exchange (see Equation 10.3). If a mammal or bird in a cold environment were to keep its appendages at the same temperature as its

³²Brown adipose tissue does not occur in birds. Nor does uncoupling protein 1, which we soon discuss. In young birds that show NST, skeletal muscles are apparently the NST site.

³³Although brown fat is a type of adipose tissue like white fat, recent evidence indicates that the two types of fat do not develop from a single type of precursor cell during the development of mammals. Brown fat develops from a type of precursor cell that also gives rise to skeletal muscle!

FIGURE 10.32 Regional heterothermy in Alaskan mammals

The air temperature was -30°C when these data were gathered. The temperatures shown are subcutaneous temperatures ($^{\circ}\text{C}$) at various locations on the body. Note that the footpad tissues of the sled dog were at 0°C . Both animals had deep-body temperatures in the typical mammalian range: $37\text{--}38^{\circ}\text{C}$. (After Irving and Krog 1955.)

body core, the appendages would contribute disproportionately to the animal's overall weight-specific metabolic cost of homeothermy.

A mammal or bird can limit heat losses across its appendages in cool environments by allowing the appendage tissues to cool. The difference between the temperature of an appendage and the ambient temperature is the driving force for heat loss from the appendage. Allowing the appendage to cool toward ambient temperature reduces this driving force, in effect compensating for the appendage's relatively low resistance to heat loss. Cooling of the appendages, a type of *regional heterothermy*, is in fact very common. When the ambient temperature is low, the tissues of appendages—especially their distal parts—are often $10\text{--}35^{\circ}\text{C}$ cooler than tissues in the core parts of an animal's thorax, abdomen, and head (Figures 10.32 and 10.33).³⁴

The usual mechanism by which appendages are allowed to cool is by curtailing circulatory delivery of heat to them. Appendages (or parts of appendages) often consist in large part of bone, tendon, cartilage, skin, and other tissues that metabolically are relatively inactive. Such appendages typically do not have sufficient endogenous heat production to keep themselves warm in cold environments. Their temperatures depend, therefore, on how rapidly heat is brought to them from the thorax, abdomen, or head by the circulating blood. Accordingly, curtailing circulatory heat delivery to the appendages lets them cool. Heat delivery to an appendage may be curtailed simply by the restriction of blood flow to the appendage, but as we will see in the next section, more-elaborate mechanisms of restricting heat delivery are usually employed.

Species that have long evolutionary histories in frigid climates often display exquisite control over the extent of appendage cooling. For example, in a variety of Arctic canids—including foxes

³⁴Because regional heterothermy reduces the total metabolic cost of maintaining a given core body temperature, it effectively increases the animal's overall insulation (I) in the linear heat-transfer equation (Equation 10.10).

and wolves, as well as sled dogs—the tissues of the footpads are routinely allowed to cool to near 0°C in winter (see Figure 10.32), but even when the feet are in contact with much colder substrates (e.g., -30°C to -50°C), the footpads are not allowed to cool further. The footpads, therefore, are thermoregulated at the lowest temperature that does not subject them to a risk of frostbite!

Appendages also often play special roles in the dissipation of excess metabolic heat. If a high rate of circulatory heat delivery is provided to an appendage, the heat is lost readily to the environment because of the ease of heat loss from appendages. Accordingly, whereas animals curtail circulatory heat delivery to their appendages when heat conservation is advantageous, they often augment heat delivery to their appendages when they need to get rid of heat. In a cool environment, for example, when jackrabbits are at rest, they limit blood flow to their huge ear pinnae (see Figure 10.5)—so much so that the pinnae become as cool as the air. However, when the jackrabbits run, they increase blood flow and pinna temperature considerably (Figure 10.34). Running evidently produces an excess of metabolic heat, and the pinnae are used to void the excess heat. Opossums, rats, and muskrats sometimes warm their tails when they exercise; seals heat up their flippers; and goats warm their horns.

Countercurrent heat exchange permits selective restriction of heat flow to appendages

Although circulatory heat flow into an appendage can be curtailed simply by reduction of the rate of blood flow to the appendage, this mechanism has the disadvantage of being highly nonspecific. Reducing the rate of blood flow not only limits heat flow into an appendage but also subjects the appendage to a reduced rate of O_2

FIGURE 10.33 A thermal map of an opossum showing regional heterothermy in the pinna of the ear In this image, which was produced by infrared radiography, shades of gray represent the temperatures on the animal's body surface. Surfaces that were at or close to ambient temperature are black; those that were much warmer than ambient are white; intermediate temperatures are represented by intermediate gray tones. The animal, a Virginia opossum (*Didelphis marsupialis*), was resting at an ambient temperature of 10°C . Note that the surface temperature of its ear pinna, a naked flap of skin, was virtually the same as ambient temperature.

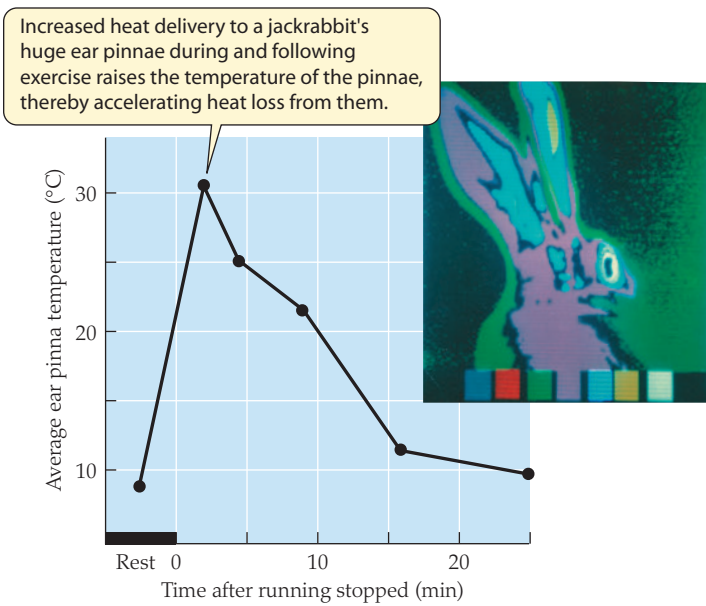

FIGURE 10.34 Heat loss across appendages is sometimes modulated in ways that aid thermoregulation. The average surface temperature of the ear pinnae of this black-tailed jackrabbit (*Lepus californicus*) was near ambient temperature (8°C) when the rabbit was resting but increased to more than 30°C following running. The inset is an infrared radiograph of the jackrabbit when it had an elevated ear-pinna temperature after exercise. In this presentation, temperature is color-coded. The color blocks at the bottom symbolize increasing temperatures from left to right. The environment fell into the range of temperatures coded by green. Part of the right ear pinna was warm enough to fall within the much higher temperature range coded by yellow. (After Hill et al. 1980.)

supply, for example. Heat flow to an appendage can be *selectively* curtailed by *countercurrent heat exchange*, a process that depends on a specialized morphological arrangement of the blood vessels that carry blood to and from the appendage.

To understand countercurrent heat exchange, let's examine the two different arrangements of the arteries and veins in a limb diagrammed in Figure 10.35. The arteries (red) are located deep within the appendage. In Figure 10.35a the veins (blue) are superficial, but in Figure 10.35b the veins are closely juxtaposed to the arteries. The vascular arrangement in Figure 10.35a does nothing to conserve heat; as blood flows into the appendage through the arteries and then flows back through the veins, it loses heat all along the way, without any opportunity to regain it. In contrast, the vascular arrangement in Figure 10.35b promotes heat conservation because it encourages a transfer of heat from the arterial blood to the venous blood; the venous blood then can carry that heat back to the body core, thereby helping to keep heat in the body. If the area of contact between the veins and arteries in Figure 10.35b is sufficiently extensive, blood may be little cooler when it reenters the body core in veins than it was when it flowed out into the appendage in arteries. The heat exchange in Figure 10.35b is **countercurrent heat exchange**. By definition, such heat exchange depends on the transfer of heat between two closely juxtaposed fluid streams flowing in opposite directions (*counter* = "opposite"; *current* = "flow").

A particularly useful way to conceive of the effect of countercurrent heat exchange in an appendage is to think of it as *short-circuiting*

the flow of heat into the appendage. Figure 10.36 illustrates that in the presence of a suitable vascular arrangement, although blood flows all the way to the end of an appendage before returning to the body core, heat tends to flow only part of the length of the appendage before it short-circuits from the arteries to the veins and starts its return to the body core. This short-circuiting impedes the access of heat to the outer extremities of the appendage. The outer extremities are therefore cooler than they otherwise would be, limiting heat loss to the environment.

A vascular countercurrent exchange system short-circuits the flow of only those commodities that are able to pass through the walls of the blood vessels involved. Heat is short-circuited by the vascular systems we have been discussing precisely because heat can pass through the walls of arteries and veins. If O₂, nutrients, or wastes could pass through the walls of arteries and veins, they too would be short-circuited. However, they cannot pass through the walls of such thick-walled vessels, and thus they travel with the blood all the way to the outer limits of an appendage and back. This is how selectivity is achieved: This is how a vascular system can conserve heat while not affecting the flow of other commodities in and out of an appendage.

FIGURE 10.35 Blood flow with and without countercurrent heat exchange. Arrows show blood flow in both parts. All temperatures are in degrees Celsius (°C). (a) In this arrangement, which does not permit countercurrent heat exchange, the veins (blue) returning blood from the limb are just under the skin and separate from the arteries (red) that carry blood into the limb. (b) In this case, countercurrent heat exchange can occur because the veins returning blood from the limb are closely juxtaposed to the arteries carrying blood into the limb. In part (b) the arterial blood is cooled more than in part (a) because of the close proximity of cool venous blood. Furthermore, in (b), more heat is returned to the body than in (a) because heat that enters the venous blood is carried back to the body rather than being lost to the environment.

FIGURE 10.36 Countercurrent heat exchange short-circuits the flow of heat in an appendage. In a vascular countercurrent exchanger, commodities that can pass through the walls of the blood vessels short-circuit from one fluid stream to the other. Other commodities travel with the blood. This illustration shows heat being short-circuited. The widths of the arrows symbolize the relative magnitudes of heat flow and blood flow from place to place.

Vascular arrangements that meet the prerequisites for countercurrent heat exchange (close juxtaposition of arteries and veins) are commonly found in appendages that display regional heterothermy. Such vascular arrangements are known, for example, in the arms of humans, the legs of many mammals and birds, the flippers and flukes (tail fins) of whales, the tails of numerous rodents, and the ear pinnae of rabbits and hares. Anatomically the vascular arrangements vary from relatively simple to highly complex. The vessels in some cases are simply ordinary veins and arteries touching each other; this is the case in the human arm. Greater complexity is found in the flippers and flukes of whales, where the major arteries are almost *completely surrounded* by venous channels; with this arrangement, heat leaving the arteries virtually has to enter venous blood. Another type of complex arrangement found in some animals (e.g., armadillos and some storks) is that the main arteries and veins in a limb split up to form a great many fine vessels that intermingle. A complex network of tiny vessels like this is termed a **rete mirabile** (“wonderful net”) or simply a **rete**.³⁵

A common way for countercurrent heat exchange to be controlled is for an appendage to have *two* sets of veins, only one of which is juxtaposed to the arteries. Countercurrent exchange can then be activated or deactivated by control of the set of veins in use. In the arm of a person, for example, one set of veins is deep in the arm and closely juxtaposed to the arteries, whereas a second set is just under the skin. Under control of the autonomic nervous system, the deep set of veins is used when there is a premium on heat conservation, but the superficial set is used when heat loss is advantageous. These controls explain why the superficial veins of our arms seem to disappear on cold days while bulging with blood on warm days.

Mammals and birds in hot environments: Their first lines of defense are often not evaporative

Sweating, panting, and other modes of actively increasing the rate of evaporative cooling are so easy to observe when they occur that they are often thought to be the principal or only means by which

mammals and birds cope with high environmental or metabolic heat loads. Evaporation, however, has a potentially lethal price: It carries body water away. Although evaporative cooling may *solve* problems of temperature regulation, it may *create* problems of water regulation. For many mammals and birds, especially species that have long evolutionary histories in hot, arid climates, active evaporative cooling is in fact a *last* line of defense against heat loading. Other defenses are marshaled preferentially, and only when these other defenses have done as much as they can is body water used actively to void heat. In this section we discuss the nonevaporative defenses. When these defenses are employed as the preferential or first-line defenses, they act as water-conservation mechanisms.

Behavioral defenses are one set of commonly employed nonevaporative defenses. Desert rodents, for instance, construct burrows, which they occupy during the day (see Figure 1.16), and most emerge on the desert surface only at night. They thus evade the extremes of heat loading that could occur in deserts. Mammals and birds that are active during daylight hours often rest during the heat of the day, thereby minimizing their metabolic heat loads. Resting camels shift the positions of their bodies to present a minimum of surface area to the sun throughout hot days.

Insulatory defenses are also important nonevaporative defenses in some cases. For example, some species of large, diurnal mammals and birds native to hot, arid regions have evolved strikingly thick pelages and plumages. The dorsal pelage of dromedary camels in summer can be at least 5–6 cm thick, and when ostriches erect their plumage, it can be 10 cm thick. Such thick pelages and plumages probably evolved because in very hot environments they can act as heat shields, increasing body insulation and thereby acting as barriers to heat influx from the environment. The outer surface of the dorsal pelage of camels and sheep has been measured to get as hot as 50–80°C when exposed to solar radiation on hot days! The pelage shields the living tissues of the animals from these enormous heat loads.

Body temperature is a third nonevaporative attribute of mammals and birds that can be used in the first line of defense against the challenges of hot environments. Both high-amplitude cycling of body temperature and profound hyperthermia can act as defenses and, in fact, are commonly employed as water-conservation mechanisms by species adapted to hot environments.

CYCLING OF BODY TEMPERATURE Dromedary camels provide a classic and instructive example of how animals can employ high-amplitude cycling of body temperature as a nonevaporative defense and water-conservation mechanism in hot environments (see also Figure 30.11). A dehydrated dromedary in summer permits its deep-body temperature to fall to 34–35°C overnight and then increase to more than 40°C during each day. Its body temperature therefore cycles up and down by about 6°C. The advantage of such cycling is that it permits some of the heat that enters the body during the intensely hot part of each day to be temporarily *stored in the body* and later voided by nonevaporative rather than evaporative means. When dawn breaks on a given day, a camel’s body temperature is at its lowest level. As the day warms and the sun beats down on the camel, the animal simply lets heat accumulate in its body, rather than sweating to void the heat, until its body temperature has risen by 6°C. Physiologists have measured that about 3.3 J (0.8 cal) is required to warm 1 g of camel flesh by 1°C. From this figure,

³⁵The word *rete* is pronounced with both syllables rhyming with sea: “ree-tee.” *Rete mirabile* and *rete* are general terms used to refer to intricately complex systems of small-diameter arterial and venous vessels wherever they occur. We will encounter many additional examples in this book.

one can calculate that a 400-kg camel will accumulate about 7920 kJ (1900 kcal) of heat in its body by allowing its body temperature to rise 6°C; to remove this amount of heat by evaporation would require more than 3 L of water, but the camel simply stores the heat in its body. Later, after night falls and the environment becomes cooler, conditions become favorable for convection and radiation to carry heat out of the camel's body. At that point the camel is able to get rid of the heat stored during the day by nonevaporative means. Its body temperature falls overnight to its minimum, poising the animal to take full advantage of heat storage during the following day, thereby again saving several liters of water.

HYPERTHERMIA Many mammals and birds employ controlled, profound hyperthermia as a principal nonevaporative, water-conserving mechanism of coping with hot environments. Because a rise in body temperature entails heat storage, the benefits of hyperthermia are to some extent the very ones we have just noted in discussing cycling. In addition, however, a high body temperature *in and of itself* holds advantages for water conservation. As mentioned already, under conditions when dry heat *loss* occurs, a high T_B promotes such nonevaporative heat loss by elevating the driving force ($T_B - T_A$) that favors it. A high T_B also aids water conservation under conditions when an animal has stored as much heat as it can and yet the environment is so hot that dry heat *gain* occurs. Under such conditions, evaporation of water must be used to get rid of all the heat that enters an animal's body. A high T_B impedes heat gain from the environment by decreasing the driving force ($T_A - T_B$) that favors heat influx, and thus the high T_B reduces the rate at which body water must be evaporated to void the incoming heat.

Birds commonly permit their body temperatures to rise to profoundly high levels when in hot environments; whereas resting birds typically have body temperatures near 39°C in the absence of heat stress, they commonly have body temperatures as high as 43–46°C in hot environments. Among mammals, profound hyperthermia typically occurs only in species with long evolutionary histories in hot, arid climates, but among such species it is common. Certain antelopes native to the deserts and dry savannas of Africa provide the extreme examples. Two such species, the beisa oryx (*Oryx beisa*) and Grant's gazelle (*Gazella granti*), sometimes permit their rectal temperatures to reach 45.5–47°C (114–116°F) without ill effect!

KEEPING A COOL BRAIN A large body of evidence indicates that the brain is kept cooler than the thorax and abdomen in many species of mammals and birds when the animals are in warm or hot environments, especially during exercise. To cite an extreme example, when a Thomson's gazelle (*Gazella thomsonii*) runs vigorously in a warm environment, its brain is kept as much as 2.7°C cooler than its thorax. Camels, dogs, pronghorns, and sheep are other animals that exhibit brain cooling.

The advantage of brain cooling is believed to be that it permits an animal to take enhanced advantage of the benefits of high-amplitude body-temperature cycling and hyperthermia. The brain tolerates less elevation of temperature than most organs. Thus the bulk of an animal's body can cycle to a higher temperature, and become more hyperthermic, if the brain can be kept from becoming as hot as most of the body.

What is the mechanism of brain cooling? In many cases, the key process is cooling of the arterial blood supplying the brain by

FIGURE 10.37 Structures hypothesized to be responsible for cooling the brain in sheep and other artiodactyls The carotid artery branches and anastomoses in the cavernous sinus, forming the carotid rete mirabile. Venous blood from the upper respiratory passages (e.g., nasal passages) flows around the vessels of the carotid rete. The insets above the snout show representative cross sections of the nasal passages of an artiodactyl (specifically, reindeer), illustrating that surface area in many species is greatly elaborated by folds and scrolls of tissue termed the *nasal turbinates*. The high surface area facilitates evaporation—and thus evaporative cooling of blood—in the nasal passages, as well as having other effects. (Principal drawing after Maloney and Mitchell 1997; turbinates after Johnsen 1988.)

countercurrent heat exchange (Figure 10.37). The arteries carrying blood toward the brain from the heart come into intimate contact with veins or venous blood draining the nasal passages and other upper respiratory passages. The site of this contact in many of the mammals involved is the cavernous sinus located at the base of the skull; there the arteries divide into a plexus of small vessels (the *carotid rete mirabile*) that is immersed in a lake of venous blood. As noted, the venous blood juxtaposed to the arteries is traveling back toward the heart from the upper respiratory passages. Blood in the upper respiratory passages is cooled by the inevitable evaporation of water from the walls of the respiratory passages into breathed air. As the cooled venous blood traveling back to the heart flows by the arteries, it cools the arterial blood traveling toward the brain.

Active evaporative cooling is the ultimate line of defense against overheating

Active facilitation of evaporation is the ultimate line of defense for mammals and birds faced with high environmental or metabolic (e.g., exercise-induced) heat loads. If heat is accumulating in the body to excessive levels and all the other means we have already discussed fail to stop the accumulation, active evaporative cooling becomes the only mechanism available to reestablish a balance between heat gain and heat loss. As stressed earlier, the loss of water during evaporative cooling can dehydrate an animal if replacement water is not readily available; this probably explains why species native to arid habitats employ other defenses against overheating

before turning to evaporative cooling. Three major mechanisms of active evaporative cooling are known: sweating, panting, and gular fluttering.³⁶

SWEATING During **sweating**, a fluid called *sweat* is secreted, by way of the ducts of sweat glands, through the epidermis of the skin onto the skin surface. Even when an animal is not sweating, water loss occurs through the substance of the skin—but at a low rate.³⁷ Sweating increases the rate of cutaneous evaporation by a factor of 50 or more by wetting the outer surface of the skin. Sweat is not pure water but instead is a saline solution. Concentrations of Na⁺ and Cl⁻ in sweat are lower than in the blood plasma, and during acclimation to hot conditions the salinity of sweat becomes reduced. Nonetheless, prolonged sweating can cause a significant depletion of the body's pool of Na⁺ and Cl⁻. Secretion by the sweat glands is activated by the sympathetic nervous system.

A capability to sweat vigorously is found in a variety of mammals, including humans, horses, camels, and some kangaroos. Sweat production can be profuse. Humans working strenuously in the desert, for example, can attain sweating rates of 2 L/h! Many types of mammals, however, do not sweat. Rodents, rabbits, and hares lack integumentary sweat glands. Although dogs and pigs have sweat glands, the secretion rates of the glands are so low that sweating appears to play little or no role in thermoregulation. Birds do not sweat.

PANTING **Panting** is an increase in the rate of breathing in response to heat stress. It is common in both birds and mammals. Panting increases the rate of evaporative cooling because water evaporates from the warm, moist membranes lining the respiratory tract into the air that is breathed in and out.

In some species, the respiratory frequency (number of breaths per minute) during panting increases progressively as the extent of heat stress increases. In others, the respiratory frequency changes abruptly at the onset of panting, and within a wide range of thermal stress, the rate of breathing during panting is independent of the degree of heat stress. Dogs exemplify this second pattern; whereas in cool environments they breathe 10–40 times per minute, their respiratory frequency jumps abruptly to 200 or more breaths per minute when panting begins. Analysis indicates that animals with such a stepwise change in respiratory frequency often pant at the *resonant frequency* of their thoracic respiratory structures. At the resonant frequency, the thorax has an intrinsic tendency to “vibrate” between its inspiratory and expiratory positions. Thus less muscular work needs to be done—and less heat is produced by the muscular work—than at other frequencies.

By comparison with sweating, panting holds certain advantages. One is that no salts are lost during panting because evaporation occurs within the body and only pure water vapor leaves the body

in the exhalant air. A second advantage of panting is that it *forcibly* drives air saturated with water vapor away from the evaporative surfaces.

Panting also has liabilities in comparison with sweating. Because of the muscular effort required for panting, evaporation of a given quantity of water is likely to require more energy—and entail more heat production—when panting is employed than when sweating is. Another potential liability of panting is that it can induce *respiratory alkalosis*, an elevation of the pH of the body fluids caused by excessive removal of carbon dioxide (see page 645). Ordinarily, when animals are not panting, ventilation of the respiratory-exchange membranes deep in the lungs (e.g., the alveolar membranes of mammals) is closely regulated so that the rate at which CO₂ is voided is equal to the rate of metabolic production of CO₂. During panting, the potential exists for breathing to carry CO₂ away faster than it is produced, because the rate of breathing is increased for thermoregulation rather than being governed only by metabolic needs. If CO₂ is carried away by breathing faster than it is produced by metabolism, the concentration of CO₂ in the blood will fall, causing the following reactions in the blood to shift to the left:

Consequently, the concentration of H⁺ in the blood will fall, and the pH of the blood will rise. Such excessive alkalinity—*alkalosis*—can have major deleterious effects because many enzymes and cellular processes are acutely sensitive to pH. (In middle school, we probably all witnessed friends make themselves dizzy by deliberately breathing too rapidly.)

From extensive research, physiologists now know that little or no alkalosis develops during panting in many species of mammals and birds when the heat stress to which they are exposed is light to moderate. These animals avoid alkalosis by restricting the increased air movement during panting to just their *upper* airways,³⁸ where no exchange of CO₂ occurs between the air and blood (**Figure 10.38**); the respiratory-exchange membranes *deep* in the lungs receive about the same rate of airflow during panting as they usually do. By contrast, when heat stress becomes extreme, resting but panting animals often develop severe alkalosis. Some panting species have evolved superior tolerance to alkalosis.

GULAR FLUTTERING Many birds (but not mammals) augment evaporative cooling by rapidly vibrating their gular area (the floor of the buccal cavity) while holding their mouth open, a process termed **gular fluttering** (see Figure 10.30). The process is driven by flexing of the hyoid apparatus and promotes evaporation by increasing the flow of air over the moist, highly vascular oral membranes. Gular fluttering usually occurs at a consistent frequency, which apparently matches the resonant frequency of the structures involved. Birds commonly use gular fluttering simultaneously with panting.

Gular fluttering shares certain positive attributes with panting: It creates a vigorous, forced flow of air across evaporative surfaces and does not entail salt losses. Unlike panting, gular fluttering cannot induce severe alkalosis, because it enhances only *oral* airflow, and CO₂ is not exchanged between air and blood across oral membranes.

³⁶A fourth mechanism is **saliva spreading**, seen in many rodents and marsupials, which spread saliva on their limbs, tail, chest, or other body surfaces when under heat stress. Spreading of saliva on furred regions of the body is a relatively inefficient use of body water for cooling because the evaporative surface created—on the outer surface of the fur—is insulated from the living tissues of the animal's body by the pelage. For many rodents, however, saliva spreading is the only means available to increase evaporative cooling, and the animals use it in heat-stress emergencies.

³⁷Water lost through the skin in the absence of sweating is termed *transpirational water loss* or *insensible* (“unperceived”) *water loss*.

³⁸In birds, both the upper airways and air sacs may be involved.

(a) Shallow breaths superimposed on deep breaths (compound breathing)

(b) Shallow breaths occasionally interrupted by deep breaths

FIGURE 10.38 Two breathing patterns that limit hyperventilation of the respiratory-exchange membranes during panting Both of these breathing patterns permit the upper airways to receive a greatly increased flow of air during panting while simultaneously the respiratory-exchange membranes deep in the lungs are ventilated about as much as usual. In (a), shallow breaths are superimposed on deep breaths. In (b), periods of shallow breathing alternate with periods of deep breathing.

Gular fluttering involves the movement of structures that are less massive than those that must be moved in panting; thus it entails less muscular work—and less heat production—to achieve a given increment in evaporation.

Mammals and birds acclimatize to winter and summer

When individual mammals and birds live chronically in cold or warm environments, they usually undergo long-term alterations in their thermoregulatory physiology. During acclimatization to winter, for example, a mammal or bird typically exhibits one or more of three sorts of chronic responses, discussed in this section.³⁹ Because the change of seasons is complex, these responses are not necessarily triggered solely (or even primarily) by the drop in temperature as winter approaches, but may be triggered by photoperiod (shortening day length) or other seasonal cues.

One possible chronic response to the approach of winter is **acclimatization of peak metabolic rate**. When a mammal or bird exhibits this response, it increases the maximal rate at which it can produce heat by sustained, aerobic catabolism. If an animal displays *only* this sort of acclimatization, the metabolic rate it requires to thermoregulate at any given ambient temperature remains un-

³⁹ Acclimatization to summer, to some extent, involves simply the same chronic responses in reverse. *Acclimation* of mammals or birds to cold in a laboratory sometimes has dramatically different effects than *acclimatization* to winter has (see page 15 for the distinction). Results of laboratory acclimation studies on mammals and birds, therefore, cannot confidently be extrapolated to acclimatization in nature. One reason for the difference between acclimation to cold and acclimatization to winter is that some of the winter responses occur only when there are changes in photoperiod, and usually just temperature is altered in laboratory studies.

changed, but it can thermoregulate in colder environments than it could before, as shown by **Figure 10.39a**. The development in winter of enlarged brown adipose tissues in which cells are biochemically especially poised for heat production is a common mechanism by which small and medium-sized mammals increase the rate at which they can produce heat and thus undergo acclimatization of peak metabolic rate.

A second possible chronic response to the approach of winter is **acclimatization of metabolic endurance**, meaning an increase in the length of time that a high rate of metabolic heat production can be maintained. Although current evidence indicates that this sort of acclimatization is common, little is known about its mechanisms.

The third major sort of chronic response that a mammal or bird might exhibit in winter is **insulatory acclimatization**, an increase in the animal's maximal resistance to dry heat loss (maximal insulation). If this sort of acclimatization occurs, the metabolic rate required to thermoregulate at any particular ambient temperature below thermoneutrality is reduced. Accordingly, even if an animal's peak metabolic rate remains unchanged, the animal is able to thermoregulate in colder environments than it could before (**Figure 10.39b**). The most obvious way for insulatory acclimatization to occur is for an animal to molt into a more protective pelage or plumage in winter, but other determinants of insulation (such as peripheral blood flow) can also change. Of the three chronic responses to winter we have described, two—or all three—can occur together.

(a) Acclimatization of peak metabolic rate

(b) Insulatory acclimatization

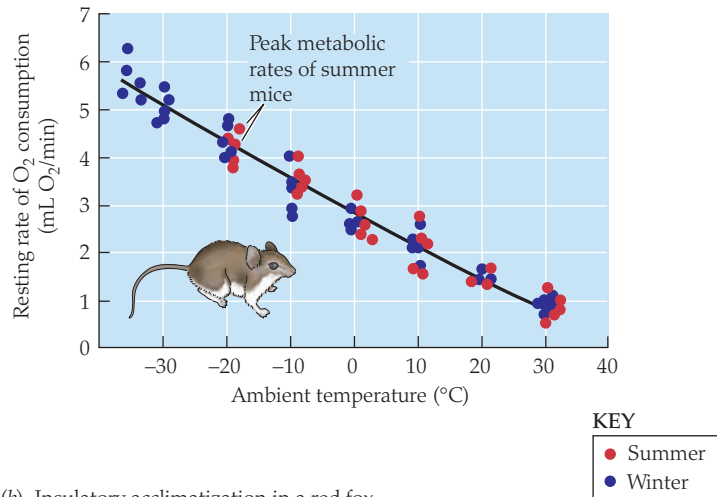

FIGURE 10.39 Two types of seasonal acclimatization

(a) Acclimatization of peak metabolic rate without insulatory acclimatization. (b) Insulatory acclimatization without acclimatization of peak metabolic rate. The plateau at the left of each curve indicates where metabolic rate has peaked.

(a) Acclimatization of peak metabolic rate without insulatory acclimatization in deer mice

(b) Insulatory acclimatization in a red fox

FIGURE 10.40 Seasonal acclimatization in two species of mammals (a) The deer mice (*Peromyscus maniculatus*) studied had the same insulation in winter and summer, but their peak metabolic rates rose in winter, meaning they could thermoregulate at lower ambient temperatures. (b) A single red fox (*Vulpes vulpes*) individual, studied in both seasons, had far greater insulation in winter than in summer. (After Hart 1957.)

Acclimatization of peak metabolic rate occurs in perhaps half of small birds and is the norm in small and medium-sized mammals. As for insulatory acclimatization, some small-bodied species of mammals and birds fail to exhibit it and thus undergo only metabolic forms of acclimatization (Figure 10.40a). Among the mammals that undergo insulatory acclimatization, medium-sized and large species tend to exhibit greater changes in insulation between summer and winter than do small species. Red foxes (Figure 10.40b), collared lemmings, and varying hares in northern Alaska all exhibit substantial increases in insulation in winter. The air temperature in northern Alaska averages -30°C in winter and $+5^{\circ}\text{C}$ in summer. For the foxes, lemmings, and hares, the metabolic cost of thermoregulating at -30°C in winter is little higher than the cost of thermoregulating at $+5^{\circ}\text{C}$ in summer, because of their winter increase in insulation (see Figure 10.40b).

Mammals and birds commonly acclimatize to heat stress as well as cold stress, as seen in Chapter 1 (see Figure 1.8). Among humans, acclimatization to heat stress occurs much more rapidly than that to cold stress. Partly for that reason, we tend to notice our own acclimatization to heat more than our acclimatization to cold.

Evolutionary changes: Species are often specialized to live in their respective climates

Abundant evidence indicates that the thermoregulatory physiology of mammals and birds has undergone evolutionary adaptation to different climates. One sort of evidence is shown in Figure 10.41, which is one of the classic sets of data in animal physiology. As the figure shows, species of mammals native to the Arctic and the tropics differ dramatically in their thermal relations; Arctic species—compared with tropical species—have lower-critical temperatures that are lower (i.e., they have broader TNZs), and they increase their metabolic rates proportionally less above basal levels at ambient temperatures below thermoneutrality. Direct studies of pelage insulation demonstrate that the Arctic species typically have thicker and better insulating pelages than do similarly sized tropical species. As a consequence of all these differences, Arctic

FIGURE 10.41 Mammalian physiological specialization to different climates

Species found in the Arctic (Alaska) expend less energy to thermoregulate at cold ambient temperatures, and they can thermoregulate at lower temperatures, than species found in the tropics (Panama) can. In this presentation, each species' basal metabolic rate is set equal to 100, and metabolic rates outside the thermoneutral zone are expressed relative to basal; this convention facilitates comparison in certain ways but means that the slopes of the metabolism-temperature curves below thermoneutrality can be used in only a qualitative way to compare insulation. (After Scholander et al. 1950.)

species are in a far better position to thermoregulate under Arctic conditions than tropical species are. Arctic foxes (*Alopex*) and reindeer (*Rangifer*) have lower-critical temperatures in winter that are below -30°C ! This means that they can maintain homeothermy with only their basal rates of heat production until the air becomes exceedingly cold.

In hot climates, a major pattern that has emerged with ever-increasing clarity in recent decades is that species of both mammals and birds native to such climates often have lower basal metabolic rates than are observed in related species native to temperate or cold climates. The evolution of an exceptionally low BMR has probably been favored in hot climates because, with a low BMR, an animal has a particularly low internal heat load.

As mentioned earlier, body temperature is basically a *conserved* character; within any taxonomic group of mammals or birds, the core body temperature maintained in the absence of heat or cold stress tends to be the same in species from various climates. Adaptation of body temperature to climate is clearly evident, however, in one specific respect among mammals exposed to heat stress: Mammal species native to hot climates typically tolerate greater degrees of hyperthermia than species native to temperate or cold climates do.

Mammals and birds sometimes escape the demands of homeothermy by hibernation, torpor, or related processes

Many species of mammals and birds allow their body temperatures to fall in a controlled manner under certain circumstances. **Controlled hypothermia** is a general term for this sort of phenomenon; **hypothermia** is the state of having an unusually low body temperature, and in the cases we are discussing, it is “controlled” because the animals orchestrate their entry into and exit from hypothermia rather than being forced.

The most well known and profound forms of controlled hypothermia are **hibernation**, **estivation**, and **daily torpor**. According to definitions that have been in place for several decades, these are all states in which an animal *allows its body temperature to approximate ambient temperature within a species-specific range of ambient temperatures*.⁴⁰ Hibernation, estivation, and daily torpor are generally viewed as being different manifestations of a *single* physiological process. They are distinguished by differences in their durations and seasons of occurrence. When an animal allows its body temperature to fall close to ambient temperature for periods of several days or longer during winter, the process is termed *hibernation*. When this occurs during summer, it is called *estivation*. When an animal permits its body temperature to fall close to ambient temperature for only part of each day (generally on many consecutive days), the process is termed *daily torpor* in any season. **Figures 10.42** and **10.43** illustrate the sorts of changes in body temperature and metabolic rate that occur in episodes of controlled hypothermia.

Hibernation, estivation, and daily torpor permit mammals and birds to escape the energy demands of homeothermy. As stressed earlier, homeothermy is energetically costly. A hamster, for example, needs to acquire and consume a great deal of food energy to keep its body temperature at

FIGURE 10.42 Changes in body temperature during hibernation A woodchuck (groundhog) (*Marmota monax*) was implanted with a small temperature transmitter that broadcast its body temperature continuously, and after it healed from the surgery, it was studied at an air temperature of 6°C . The record shows its body temperature during a 12-day episode of hibernation. (After Armitage et al. 2000.)

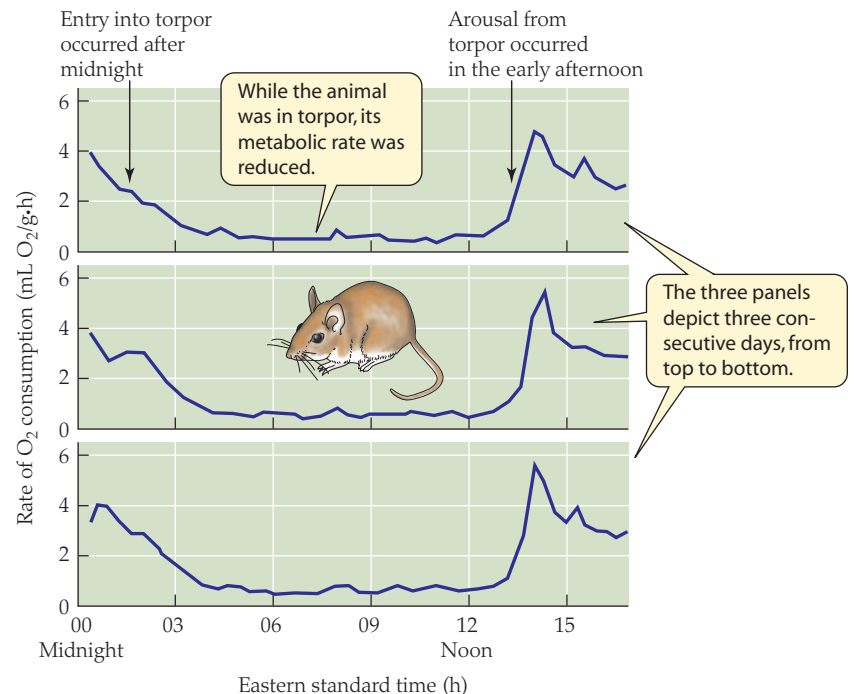

FIGURE 10.43 Changes in metabolic rate during daily torpor The rate of O_2 consumption of a white-footed mouse (*Peromyscus leucopus*) studied at an air temperature of about 14°C is shown for three consecutive days. The x axis shows time of day on a 24-h scale (e.g., 15 = 3:00 pm). The animal required a resting metabolic rate of about $3.0 \text{ mL O}_2/\text{g}\cdot\text{h}$ to be able to maintain high body temperatures. It underwent a prolonged episode of daily torpor on each day, as indicated by the drop in its metabolic rate. Its body temperature measured during an episode of torpor was 17°C . (After Hill 1975.)

⁴⁰We return to definitions at the end of this section.

37°C when the temperature of its environment is near freezing. If the hamster abandons homeothermy and temporarily allows its body temperature to fall close to ambient temperature, it is temporarily freed of homeothermy's energy costs. Animals capable of hibernation, estivation, or daily torpor are in essence able to switch back and forth between two very different thermal worlds. They are *temporal heterotherms*. When they function as ordinary homeotherms do, they reap the benefits of homeothermy, such as physiological independence of external thermal conditions; but they pay the high energy cost. When they suspend homeothermy, they take on many of the attributes of poikilotherms: Their tissues are subjected to varying tissue temperatures, but they have low energy needs.

Quantitatively, the amount of energy saved by controlled hypothermia depends on the ambient temperature at which hypothermia occurs and the duration of the hypothermia. To elucidate the importance of ambient temperature, **Figure 10.44** shows the different metabolism–temperature relations that exist in a single species when the animals are homeothermic and when they are in controlled hypothermia. At any given ambient temperature, the difference between the two curves shows the degree to which animals can reduce their energy costs per unit of time by entering hypothermia; the amount of energy saved per unit of time becomes greater as the ambient temperature falls. If a hibernating animal remains in hibernation at low ambient temperatures for long periods of time, its total energy savings can be enormous. For example, free-living ground squirrels of at least two species, living in cold climates, have been measured to expend only 10–20% as much energy per month by hibernating as they would if they failed to

FIGURE 10.44 Energy savings depend on temperature In common with other species that undergo hibernation, estivation, or daily torpor, kangaroo mice (*Microdipodops pallidus*) alternate between two metabolism–temperature relations, shown here. The double-headed arrow shows how much a kangaroo mouse's rate of energy use is reduced when the animal is in hypothermia instead of being homeothermic. The amount of energy saved by being in hypothermia is greater at low ambient temperatures than at higher ones because the metabolic cost of homeothermy is particularly high at low ambient temperatures, whereas the cost of hypothermia is particularly low at low ambient temperatures. At ambient temperatures between 5°C and 25°C, the body temperatures of these mice when they are in hypothermia are just 1.0–3.5°C higher than ambient. (After Brown and Bartholomew 1969.)

hibernate, and they reap these monthly savings throughout their 7- to 8-month hibernating seasons.

Controlled hypothermia also permits mammals and birds to escape the high water demands of homeothermy. This point is not as widely significant as the escape from energy demands, because the escape from water demands matters only for animals that face water shortages. Sometimes, nonetheless, the escape from water demands can be the most important consequence of entering controlled hypothermia; this is especially true for animals that enter estivation or daily torpor in hot, dry environments. As we will discuss in detail in Chapter 28, homeotherms have relatively high rates of water loss. One reason is simply that they must breathe rapidly to acquire the amounts of O₂ they need for their high metabolic rates. Another is that the air they exhale tends to be relatively warm, and warm air holds more water vapor (which is exhaled with the air) than cooler air. Entry into controlled hypothermia reduces an animal's rate of water loss by reducing both (1) its breathing rate and (2) the temperature, and therefore the water vapor content, of its exhaled air.

WHAT ARE THE MECHANISMS BY WHICH METABOLIC RATE IS LOWERED DURING CONTROLLED HYPOTHERMIA?

Recent research has established that—in at least some mammalian hibernators—*biochemical downregulation of metabolism* takes place during hibernation. Until about 20 years ago, the almost-universal view was that animals initiate their entry into controlled hypothermia simply by turning off thermoregulation. According to this view, the sequence of events during entry into hypothermia is that thermoregulation is deactivated, body temperature falls because of cooling by the environment in the absence of thermoregulatory responses, and tissue metabolic rates then decline because the tissues cool. This sort of lowering of metabolic rate—driven by tissue cooling and therefore following the Q_{10} principle (see Equation 10.7)—is often described as a “ Q_{10} effect.” The newer view is that the first step in the sequence of events during entry into hypothermia is biochemical downregulation of tissue metabolism, and body temperature then falls as a consequence of the reduced metabolic rate. In this sequence of events, after biochemical downregulation initiates the fall of body temperature, the declining body temperature can potentially exert a Q_{10} effect that reinforces the biochemical downregulation in depressing metabolism.

The evidence currently available indicates that both of the sequences of events discussed are observed during controlled hypothermia in mammals. One recent analysis identifies a divergence between species that undergo only daily torpor and those that hibernate. According to this analysis, the former tend to employ just a Q_{10} effect (a drop in tissue temperature) to suppress metabolism, whereas the latter tend to employ biochemical downregulation to suppress metabolism, plus potentially a Q_{10} effect. In some hibernators, the metabolic rate during hibernation is determined by biochemical controls in a way that body temperature, over wide ranges, does not matter.

IN WHAT RESPECTS IS “CONTROLLED” HYPOTHERMIA CONTROLLED?

Mammals and birds that display controlled hypothermia orchestrate their entry into and exit from hypothermia, and they exhibit control over their situation in other respects as well. The most dramatic evidence of the controlled nature of hibernation, estivation,

and daily torpor is the fact that animals are able to arouse from these conditions. **Arousal** is the process of rewarming the body by metabolic heat production. The animals do not require outside warming to return to homeothermy. Instead, they are in control: They return to homeothermy on their own by employing intense shivering and, in mammals, intense nonshivering thermogenesis to warm their tissues. All episodes of controlled hypothermia end with arousal. In addition, hibernating animals universally undergo periodic, short arousals during the period of time they are hibernating; for instance, an animal that hibernates for 6 months might arouse for a few hours every 14 days or so. The possible functions of periodic arousals are discussed in Chapter 11.

A second, particularly fascinating sort of control exhibited by animals in controlled hypothermia is the control they display when their body temperatures start to fall too low. Each species that undergoes hibernation, estivation, or daily torpor has a species-specific range of body temperatures that it can tolerate, and for an animal to survive hypothermia, it must respond if its body temperature starts to go below the tolerable range. *Within* the tolerable range, animals typically let their body temperatures drift up and down as the ambient temperature rises and falls. For instance, if an animal can tolerate a T_B as low as 3°C and the T_A varies between 5°C and 15°C , the animal typically allows its T_B to vary as the T_A varies (always being a bit higher than the T_A). What happens, however, if the ambient temperature falls below 3°C ? Frequently (although not always), the animal exerts control in one of two life-preserving ways. It may arouse. Alternatively and more remarkably, it may start to *thermoregulate* at a reduced body temperature, its thermoregulatory control system functioning with a lowered set point. For example, an animal that must stay at a body temperature of at least 3°C to survive may keep its body temperature at 3°C even if the ambient temperature drops to -10°C or -20°C , increasing its metabolic rate as the ambient temperature falls so as to offset the increasing cooling effect of the air (see Figure 11.11).⁴¹

DISTRIBUTION AND NATURAL HISTORY Hibernation is known to occur in at least six different orders of mammals. Species that hibernate include certain hamsters, ground squirrels, dormice, jumping mice, marmots, woodchucks, bats, marsupials, and monotremes. Because of its seasonal nature, hibernation is often preceded by long-term preparation. Hibernating mammals, for instance, typically store considerable quantities of body fat during the months before their entry into hibernation (see Figure 6.25). Hibernation is rare in birds; it may occur in only a single species, the poorwill (*Phalaenoptilus nuttallii*). We discuss mammalian hibernation at considerably more length in Chapter 11.

Estivation is not nearly as well understood as hibernation, partly because it is not as easy to detect. It has been reported mostly in species of desert ground squirrels.

Daily torpor is widespread among both mammals and birds, and it occurs not only in species facing cold stress but also in species occupying tropical or subtropical climates. It occurs in numerous species of bats and rodents and in certain hummingbirds, swallows, swifts, and caprimulgid birds (e.g., nightjars and poorwills). Animals undergoing daily torpor are homeothermic for part of

each day, and they feed during their homeothermic periods. When bats are undergoing daily torpor, they become hypothermic during daylight hours and forage at night; hummingbirds, in contrast, become torpid at night and feed in daylight. In some species, the proclivity to enter daily torpor is seasonally programmed. However, daily torpor seems to be employed most commonly, regardless of season, as an immediate response to hardship. Many species, for example, undergo daily torpor only when they are suffering food shortage; in some cases they increase the length of time they spend in torpor each day as food shortage becomes more severe.

CONTROLLED HYPOTHERMIA IN WHICH THE BODY TEMPERATURE REMAINS WELL ABOVE AMBIENT TEMPERATURE

Over the last 30 years, there has been an escalating realization that many species of small birds undergo hypothermia without ever allowing their body temperatures to approximate ambient temperature. Black-capped chickadees (*Poecile atricapillus*) provide an excellent example. They sometimes allow their core body temperature to fall by roughly 7°C while sleeping overnight in freezing-cold winter weather. They then have body temperatures ($31\text{--}34^\circ\text{C}$) that are distinctly hypothermic but nonetheless far above ambient temperature. This hypothermia does not eliminate their need to expend metabolic energy to stay warm. However, because the hypothermia reduces the difference between body temperature and ambient temperature, the birds lose heat more slowly—and have lower costs for thermoregulation—than if they maintained higher body temperatures. Chickadees do not feed at night and are so small (11 g) that they may virtually exhaust their body fat in a single night of frigid weather; their hypothermia helps them survive until they can feed the next day.

A variety of mammals also exhibit subtle forms of hypothermia in which core body temperature falls to only a relatively small extent, or it may even happen that the core temperature remains unaltered, but the extent of peripheral regional hypothermia increases. Bears of some species are the most famous examples of mammals exhibiting moderate core hypothermia.

HIBERNATING BLACK BEARS Until recently, many physiologists doubted that black bears (*Ursus americanus*) should be considered hibernators because, although they allow their core body temperature to fall for 5–7 months in winter, their body temperature stays at 30°C or higher and therefore is far above ambient temperature, violating the traditional criterion for hibernation. Bears stand out because of their size. Nearly all hibernating species of mammals weigh 5 kg or less, whereas black bears weigh 30–150 kg. Recent research has revealed that black bears, during their winter hypothermia, exhibit a dramatic degree of biochemical downregulation of metabolism, so much so that their metabolic rates are only one-quarter as high as their basal rates; metabolic downregulation is the principal control of their metabolic rates, with body temperature (Q_{10} effect) playing little role. Under these circumstances, despite their body temperatures being only mildly hypothermic, the bears have weight-specific metabolic rates similar to those of most hibernators. Hibernation physiologists now, therefore, rank the black bear as a specialized hibernator. Its size may preclude it from reaching a body temperature as low as ambient temperature even though it metabolically resembles other hibernators.

⁴¹This phenomenon features prominently in the prediction of bat hibernation ranges discussed in Box 10.1.

SUMMARY Homeothermy in Mammals and Birds

- Homeothermy—thermoregulation by physiological means—is energetically expensive.
- The principal way that a mammal or bird thermoregulates in its thermoneutral zone is that it varies its body insulation to offset changes in the driving force for dry heat loss ($T_B - T_A$). Insulation can be modulated by changes in posture, cutaneous blood flow, the thickness of the relatively motionless air layer trapped by the pelage or plumage, and regional heterothermy.
- Below thermoneutrality, variation in the rate of metabolic heat production (thermogenesis) is the principal mechanism of thermoregulation. The two most prominent mechanisms of increasing heat production are shivering—found in both mammals and birds—and nonshivering thermogenesis (NST)—found mainly in placental mammals. The principal site of NST in mammals is brown adipose tissue, which, by expressing uncoupling protein 1, is able to employ uncoupling of oxidative phosphorylation to achieve very high rates of lipid oxidation with immediate heat release.
- Regional heterothermy, which is often exhibited when animals are at ambient temperatures below thermoneutrality, usually depends on countercurrent heat exchange. Close juxtaposition of arteries and veins short-circuits the flow of heat into appendages.
- Above thermoneutrality, species with long evolutionary histories in hot, dry environments typically use nonevaporative mechanisms—notably hyperthermia and cycling of body temperature—as first lines of defense. When active evaporative cooling occurs, the specific mechanisms usually employed to increase the rate of evaporation are sweating (only in certain mammals), panting (mammals and birds), and gular fluttering (only birds). Both hyperthermia and the effort involved in active evaporative cooling can cause metabolic rate to rise at ambient temperatures above thermoneutrality.
- Acclimatization to changing seasons is the norm and may involve one or more of three mechanisms: acclimatization of peak metabolic rate, acclimatization of metabolic endurance, and insulatory acclimatization.
- Controlled hypothermia permits animals to evade temporarily the high energy costs and water costs of homeothermy. During hibernation, estivation, and daily torpor, T_B is generally allowed to fall close to T_A within a species-specific range of T_A . Forms of shallow hypothermia also occur.

Warm-Bodied Fish

The body temperatures of 99% of all species of fish closely approximate water temperature. However, in tunas, lamnid sharks, and billfishes, temperatures within *certain body regions* exceed water temperature, sometimes substantially. All the warm-bodied fish are large, streamlined, fast-swimming predators that lead wide-ranging lives and feed on such speedy prey as squid and herring. The lamnid sharks include the great white shark, mako, porbeagle, and salmon shark. The billfishes include the marlins and swordfish.

In tunas and lamnid sharks, the red (dark) swimming muscles are warmed above water temperature.⁴² These muscles provide the

FIGURE 10.45 A cross section of a tuna showing the nature of the blood supply to the red swimming muscles. The longitudinal arteries, which carry blood along the length of the body, give off small arteries that penetrate (toward the backbone) into the muscles. Small veins running in close juxtaposition to the small arteries return blood peripherally to the longitudinal veins, which lead back to the heart. Red vessels and arrows refer to arterial blood flow; blue vessels and arrows refer to venous flow.

power for steady swimming in these vigorously active animals, and the contractile activity of the muscles produces the heat that warms the muscles. A critical principle to recognize, however, is that *a high rate of heat production is never in itself adequate to elevate tissue temperature in water-breathing animals*. If metabolic heat is carried freely to the gills by the circulation of the blood, the heat is lost so readily to the surrounding water across the gills that no significant elevation of body temperature can occur. Thus, for a region of the body to be warmed, transport of heat away from that body region by the circulation must be impeded. Not only in the red swimming muscles of tunas and lamnid sharks, but universally in warm-bodied fish, the mechanism of impeding heat loss is countercurrent heat exchange.

The vasculature of the red swimming muscles in tunas and lamnid sharks is diagrammed in **Figure 10.45**. Note that the red muscles are found deep in the body near the spinal column in these fish (an unusual placement compared with that in most other fish). The major longitudinal arteries and veins that carry blood along the length of the body, to and from the swimming muscles, run just under the skin on each side of the body (again, an unusual placement). Small arteries branch off from the longitudinal arteries and penetrate inward to the red muscles. In turn, blood is brought outward from the muscles in veins that discharge into the longitudinal veins leading back to the heart. The arteries carrying blood inward to the red swimming muscles and the veins carrying blood outward from those muscles are closely juxtaposed, forming

⁴²The roles of the red and white muscles in powering swimming in fish are discussed in Chapter 8 (see page 196).

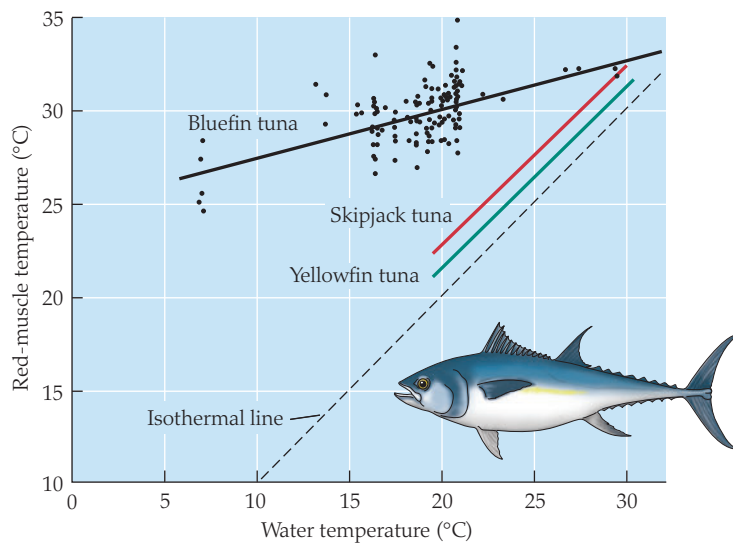

FIGURE 10.46 Red-muscle temperatures of tunas at various ambient water temperatures The upper line and data points are for wild bluefin tunas (*Thunnus thynnus*) captured in waters of various temperatures. The other two solid lines show the average relation between red-muscle temperature and water temperature in small, captive skipjack tunas (*Katsuwonus pelamis*) and yellowfin tunas (*Thunnus albacares*) swimming in an aquarium; larger, wild fish of these species are sometimes observed to exhibit greater temperature differentials between muscles and water (e.g., 5–10°C in skipjacks). The isothermal line shows how tissue temperature would vary with water temperature if there were no endothermy and tissue temperature simply equaled water temperature. The fish shown is a bluefin tuna. (After Carey and Teal 1969; Dizon and Brill 1979.)

countercurrent exchange networks. Figure 10.45 is highly simplified in the way it presents these networks. In actuality, the arteries and veins going to and from the red muscles branch profusely, forming thick layers of vascular tissue in which huge numbers of minute arterial and venous vessels, each only about 0.1 mm in diameter, closely intermingle—a true rete mirabile (see page 260). Because of the countercurrent-exchange arrangement, much of the heat picked up by the venous blood in the red muscles is transferred to the ingoing arterial blood rather than being carried by the venous flow to the periphery of the body and the gills, where it would readily be lost to the water. Thus heat produced by the red swimming muscles tends to be retained within them.

Bluefin tunas, which reach body weights of 700 kg and are the largest of all tunas, maintain fairly constant red-muscle temperatures over a wide range of water temperatures (Figure 10.46). In most other tunas, such as the yellowfin and skipjack tunas, red-muscle temperature is elevated over water temperature by a relatively constant amount regardless of the water temperature. Referring back to our scheme for classifying animal thermal relations (see Figure 10.1), all the tunas are endotherms, but species differ in whether they also thermoregulate. Whereas yellowfin and skipjack tunas are endotherms without being thermoregulators,⁴³ bluefin tunas are endothermic thermoregulators (homeotherms).

The warming of the red swimming muscles in tunas and lamnid sharks is generally thought to aid power development and locomotory performance, although exactly how is debated. Any aid to the

performance of the swimming muscles would be significant for fish that are so dependent on high-intensity exertion for their livelihood.

The swimming muscles are not the only tissues kept warm in tunas and lamnid sharks. In certain species, the stomach and other viscera are warmed when food is being digested. The brain and eyes are also warmed in some species. Each warmed organ is served by arteries and veins that form a rete mirabile, which short-circuits the outflow of heat produced in the organ, thereby favoring heat accumulation in the organ.

Now let's turn to the billfishes. They differ in two ways from the tunas and lamnid sharks. First, in the billfishes, only the brain and the retinas of the eyes are warmed. Second, the billfishes possess "heater tissues" specialized for exceptional heat output.⁴⁴

The heater tissues of billfishes are derived from portions of the extraocular eye muscles (the muscles on the outside of each eyeball that serve to turn the eyeball to look in various directions). These portions of the muscles have lost most of their contractile apparatus and are very rich in mitochondria. Current evidence suggests that they produce heat at a high rate by a "futile cycle" of Ca^{2+} pumping: ATP is used to transport Ca^{2+} actively from one intracellular compartment to another, and then the Ca^{2+} leaks back to where it started, where once again ATP is used to pump it; the principal net result is breakdown of ATP at a high rate to release heat. The heat produced by the heater tissues is retained in the head by countercurrent vasculature and in that way warms the brain and retinas. If warming of the brain by specialized eye muscles sounds impossible, remember that in a fish, the eyes and eye muscles are far larger than the brain! Warming of the brain and the retinas is hypothesized to aid marlins, swordfish, and other billfishes in their pursuit of prey because the tissues are kept from becoming cold when the fish swim through cold water.

A family tree (phylogeny) has been developed for the warm-bodied teleost fish and their close relatives (Figure 10.47), to provide a basis for better understanding the evolution of the warm-bodied condition.⁴⁵ In a manner similar to the family trees discussed in Chapter 3, this family tree is based entirely on information other than physiology and thus is independent of physiological knowledge of the fish.

One of the physiological features mapped onto the tree is endothermy in the red swimming muscles. Specifically, all the little boxes that represent fish with such endothermy are colored red. When endothermy is mapped in this way onto the independently derived family tree, a coherent pattern emerges, which strongly suggests that red-muscle endothermy appeared in the evolutionary history of these fish at a single time, at the spot marked A. Not just tunas, but also bonitos, exhibit some degree of morphological shift of their red swimming muscles toward the unusual location near the spinal column, and they are the only teleost fish that do. Thus spot B is apparently where the shift in red-muscle position started. Evidently, the new red-muscle position evolved first, and then the tunas (but not the bonitos) capitalized on it to evolve red-muscle endothermy. The concept that the new red-muscle position set the stage for the evolution of endothermy in the red swimming muscles is bolstered by information on the lamnid sharks; they and the tunas

⁴³There is some evidence for active thermoregulation in these fish. For example, they decrease heat retention when they are highly active in warm water, thus preventing their activity from driving their muscle temperature too high.

⁴⁴In tunas and lamnids, the rate of heat production in each warmed organ or tissue is believed to be simply the ordinary rate, based on available evidence.

⁴⁵The sharks, which are not teleosts, were not included in the study to produce the family tree.

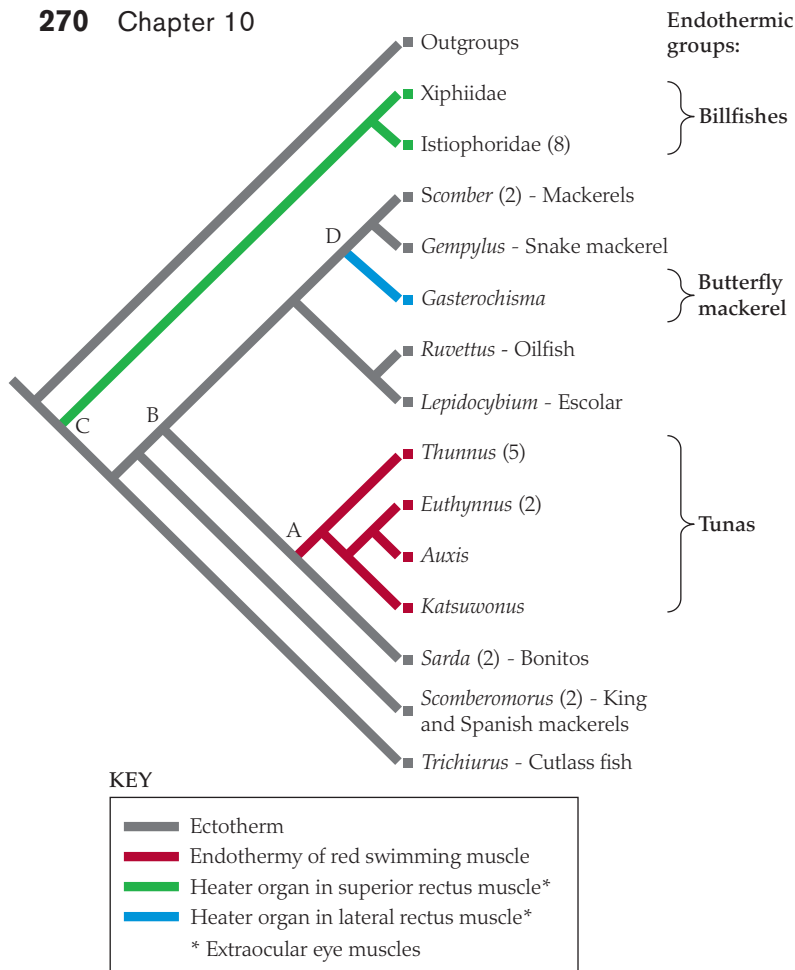

exhibit a remarkable convergence in the mechanics of how they swim, and part of that convergence is that the lamnids as well as the tunas have red swimming muscles positioned in an unusual position near the spinal column. Another discovery from the family tree in Figure 10.47 is that the three teleost groups with some sort of endothermy—the billfishes, tunas, and butterfly mackerel—do not form a coherent group; they are separated by lines of the family tree in which there is no endothermy. The family tree thus indicates that endothermy evolved separately three times in teleost fish (spots A, C, and D)—plus at least one additional time in the lamnid sharks.

SUMMARY Warm-Bodied Fish

- Tunas, lamnid sharks, and billfishes are distinguished from other fish by exhibiting endothermy in certain body regions. The tissues that are endothermic in tunas and lamnids are (1) the red swimming muscles and (2) sometimes the stomach, other viscera, brain, and retinas. In billfishes, only the brain and retinas are endothermic.
- A countercurrent vascular array that short-circuits outflow of heat from a tissue is required for the tissue to be endothermic in water-breathing animals such as these fish.
- Ordinary metabolic heat production is the source of heat for endothermy in all cases except the billfishes, which have specialized “heater” tissues that are derived from extraocular eye muscles.

FIGURE 10.47 A family tree (phylogeny) of teleost fishes belonging to the suborder Scrombroidei Physiological features (see key) are mapped onto the family tree. The tree, however, was derived entirely independently of physiological information, being based on an analysis of DNA nucleotide sequences in the gene for mitochondrial cytochrome *b* in the species included. The colors in the little boxes on the right side of the tree indicate the actual, known physiological nature of the various modern-day fish specified. The coloring of the lines of the family tree represents an interpretation of past history. Endothermy occurs only in the groups so identified at the right side of the diagram. Numbers are numbers of species studied if greater than one. “Outgroups” are other species of fish used to establish a base of comparison. Refer to the text for an explanation of the letters at branch points of the tree. (After Block and Finnerty 1994.)

Endothermy and Homeothermy in Insects

A solitary insect at rest metabolizes at a sufficiently low rate that no part of its body is warmed by its metabolic heat production. Insects in flight, however, often exhibit very high metabolic rates; species that are strong fliers in fact release more heat per gram than active mammals or birds. This high heat production is localized in the flight muscles in the thorax. Given that insects do not have the profound problems of retaining heat that characterize water-breathers, it is quite possible for the thorax to be warmed by the high metabolism of the flight muscles during flight, and thus, as we saw at the beginning of this chapter, the thorax may be endothermic.

Some insects that display thoracic endothermy during flight do not thermoregulate; examples are provided by certain species of small geometrid moths, which maintain a thoracic temperature that is about 6°C above air temperature regardless of what the air temperature is. Other sorts of insects physiologically thermoregulate during flight and thus exhibit *thoracic homeothermy*. The thermal relations of endothermic insects are particularly complex because they exhibit both *temporal* and *spatial* heterothermy. The insects exhibit endothermy only when they are active, not when they are resting. Moreover, even when they exhibit endothermy, they usually do so just in their thorax, not their abdomen.

Historically, sphinx moths were the first group of insects discovered to display thoracic physiological thermoregulation during flight, and to this day they are model examples of the phenomenon. Sphinx moths are stronger fliers and often (for insects) are particularly large; some species weigh as much as several grams and thus are similar in weight to some of the smallest mammals and birds. Flying sphinx moths closely regulate their thoracic temperatures. Those in [Figure 10.48](#), for example, maintained thoracic temperatures within a narrow range, 38–43°C, over a wide range of air temperatures. Thermoregulation is not limited just to insects of such large body size. Worker bumblebees (*Bombus vagans*), averaging 0.12 g in body weight, for instance, maintain thoracic temperatures near 32–33°C whether the air temperature is 9°C or 24°C when they are foraging. Honeybees, averaging 0.09 g in body weight, exhibit impressive thoracic thermoregulation over a somewhat narrower range of air temperature, and also illustrate the usual insect pattern that—at moderate to cool air temperatures—the abdominal temperature tends approximately to match air temperature ([Figure 10.49](#)). The list of insects known today to exhibit thoracic homeothermy during flight also includes many other lepidopterans and bees, some dragonflies, and some beetles.

FIGURE 10.48 The average thoracic temperature of freely flying sphinx moths (*Manduca sexta*) as a function of air temperature. The isothermal line shows how thoracic temperature would vary with air temperature if there were no endothermy or thermoregulation and the temperature of the thorax simply equaled air temperature. (After Heinrich 1971.)

Although endothermy and physiological thermoregulation occur principally during flight in insects, a few types of insects display the phenomena during solitary terrestrial activities. In nearly all such cases, the primary source of heat is the flight muscles, which instead of being used to fly, are activated to “shiver” (as discussed shortly). Dung beetles—which transport energy-rich elephant dung or other dung to preferred locations by forming the dung into balls—sometimes become markedly endothermic while working in dung piles and rolling their dung balls. Some crickets and katydids thermoregulate while they sing.

The insects that thermoregulate during flight require certain flight-muscle temperatures to fly

The flight muscles of an insect must be able to generate mechanical power at a certain minimal rate (which is species-specific) for the insect to be able to fly. Within a broad range of temperatures, the power output that flight muscles can attain increases as their temperature increases. Thus the temperature of an insect’s flight muscles is potentially an important determinant of whether the insect can fly.

Tiny insects such as fruit flies, mosquitoes, and midges have such high surface-to-volume ratios that the activity of their flight muscles cannot warm the thorax significantly. Correlated with their inability to be endothermic, the tiny insects commonly can fly with very broad ranges of thoracic temperatures, including, in some species, thoracic temperatures as low as 0–5°C. An important property of the flight physiology of these tiny, poikilothermic fliers is that they apparently require only a modest fraction of their maximal power output to stay aloft; thus they can fly at relatively low thoracic temperatures, at which their power output is substantially submaximal.

In sharp contrast, many medium-sized and large insects, including the species known to thermoregulate, require a near-maximal power output from their flight muscles to take off and remain airborne. They therefore require that their flight muscles be at high temperatures to fly. The sphinx moth *Manduca sexta*, for example,

(a) Temperatures of thorax and abdomen

(b) Metabolic rates

FIGURE 10.49 Temperature and metabolism in steadily flying honeybees (*Apis mellifera*). Honeybees vary considerably in how well they fly under controlled circumstances, and the data presented here are specifically for individuals that flew without prodding. (a) Temperatures in the thorax and abdomen at the end of flight; lighter-colored symbols are for four bees that showed particularly great reductions in wing-beat frequency while flying. (b) Metabolic rates during flight. (After Woods et al. 2005.)

cannot fly unless its thorax is at least as warm as 35–38°C, and worker bumblebees (*Bombus vagans*) require about 29°C.

The need for high flight-muscle temperatures for flight raises the question of how resting insects are able to get warm enough to take off. Because insects typically cool to environmental temperature when they are fully at rest, an insect that requires a high flight-muscle temperature to fly will often be too cold to take off after it has been resting for a while. Diurnal species may be able to warm their flight muscles to flight temperature by basking in the sun. Most species, however, have an endogenous ability to warm their flight muscles to flight temperature, a phenomenon known as **physiological preflight warm-up**.

Physiological preflight warm-up is accomplished by contraction of the flight muscles in a nonflying mode, a process often called **shivering** (not homologous to vertebrate shivering). Several forms of shivering are known. In many types of insects, including moths and butterflies, what happens during shivering is that the muscles responsible for the upstroke and downstroke of the wings contract simultaneously (rather than alternately as they do in flight), thus working against each other. The wings merely vibrate during shivering, rather than flapping, but heat is evolved by the muscular contraction, warming the flight muscles. When a sphinx moth warms from a low temperature, its flight muscles shiver in this manner at an ever-higher intensity as its thoracic temperature increases to the flight level. Then suddenly the pattern of muscular contraction changes, the wings are driven through the flapping motions of flight, and the moth takes to the air.

Solitary insects employ diverse mechanisms of thermoregulation

Innovative investigators continue to progress in understanding the mechanisms that insects employ to thermoregulate, despite the obstacles of working on such small animals.

As the ambient temperature drops, one mechanism of maintaining a constant thoracic temperature is for an insect to increase its rate of heat production, much as mammals and birds do below thermoneutrality. Many insects do this when they are *not flying*. Heat is generated in these circumstances by shivering of the flight muscles, and because the muscles can engage in various intensities of shivering, they can modulate their rate of heat production to serve thermoregulatory needs. Honeybees and bumblebees working in the hive, for example, often maintain high and stable body temperatures for long periods by increasing and decreasing their rates of shivering heat production as the air temperature falls and rises. An intriguing example is also provided by the brood incubation of queen bumblebees (Figure 10.50). A queen, which overwinters alone and thus is solitary when she rears her first brood in the spring, incubates her brood by keeping her abdomen at an elevated temperature and pressing it against the brood. Heat is brought to her abdomen from her thorax, where it is produced by her flight muscles. As the ambient air temperature falls, the queen thermoregulates by increasing her rate of heat production (see Figure 10.50).

Modulation of shivering can also be used to thermoregulate during *intermittent flight*. Bumblebees are known to do this, for instance. As a bumblebee, such as that pictured at the start of this chapter, flies from flower to flower during foraging, it can shiver or not shiver while it is clinging to each flower. More shivering of this sort occurs as the air temperature falls, and thus the bumblebee's overall, time-averaged metabolic rate increases as air temperature decreases.

When insects *fly continuously*, their flight muscles are employed in flight movements all the time and cannot shiver. Investigators hypothesized years ago that under these circumstances, the rate of heat production by the flight muscles would be determined by the requirements of flight and not modulated to serve thermoregulation. Early, seminal experiments on sphinx moths supported the truth of this hypothesis, because when the moths flew at a certain speed, their metabolic rates were essentially constant whether the air temperature was 15°C or 30°C. If insects in continuous flight do not modulate their rates of heat production as a means of thermoregulating, how do they thermoregulate?

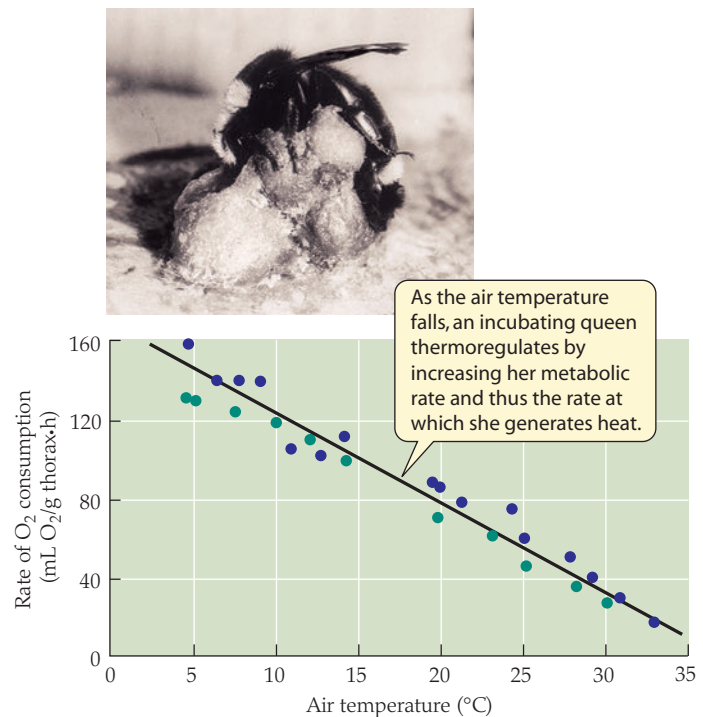

FIGURE 10.50 The rate of O₂ consumption by queen bumblebees as a function of air temperature when they are incubating their broods. In the species studied, *Bombus vosnesenskii*, a queen incubates her brood by pressing her abdomen against it as seen in the photograph. In the plot, the two colors of symbols refer to two different individuals. (After Heinrich 1974; photograph courtesy of Bernd Heinrich.)

Studies of sphinx moths, bumblebees, and some other insects reveal that their primary mechanism of thermoregulation during continuous flight is much akin to that used by mammals and birds in the thermoneutral zone; namely, they vary their insulation—in this case their *thoracic insulation*. A flying insect keeps its thorax at a steady temperature by modulating how readily heat can exit the thorax. This modulation is accomplished in some moths, dragonflies, and bumblebees by control of the rate of blood flow between the thorax and abdomen. In a continuously flying sphinx moth, for example, when the air temperature is low, the heart beats weakly and blood circulates slowly between the thorax and abdomen; thus heat produced by the flight muscles tends to remain in the thorax, which retains the heat effectively because it is densely covered with furlike scales. As the air temperature is raised, the heart beats more vigorously and circulates blood to the abdomen more rapidly; in this way, heat is transported at an increased rate out of the thorax into the abdomen, where it can be relatively easily lost to the environment because the abdomen has a large and thinly “furred” surface. Honeybees sometimes carry out an analogous process in which they modulate blood transport of thoracic heat to the head; at elevated air temperatures, heat is transported at an increased rate into the head, where it is lost in part by evaporation of fluid regurgitated out of the mouth.

Over the last 15 years, the old paradigm of thermoregulation during continuous flight—which held that all flying insects thermoregulate by modulating thoracic heat loss but not heat production—has been challenged by studies on certain species. Some investigators, for example, have observed at times that continuously flying honeybees increase their rates of metabolic heat production as the air temperature falls, at least in part by raising their wing-beat

frequency. Other investigators, however, find that the metabolic rate during honeybee flight is the same at all air temperatures (see Figure 10.49b): the result expected if the demands of flight rather than those of thermoregulation exclusively govern the activity of the flight muscles.

Colonies of social bees and wasps often display sophisticated thermoregulation

Physiological regulation of colony temperature is widespread within colonies of social bees and wasps. Honeybee hives (*Apis mellifera*) provide the best-studied example. Thermoregulation by honeybee hives is so dramatic that it was recognized for almost two centuries before thermoregulation by solitary insects was first demonstrated.

A honeybee hive that is rearing a brood maintains the temperature of its brood combs within a narrow range, about 32–36°C, even if the air temperature outside the hive falls to –30°C or rises to +50°C. When the air outside the hive is cold, worker bees cluster together within the hive and shiver. When the air outside becomes warm enough that the hive is threatened with metabolic overheating, workers disperse within the hive and fan with their wings in a cooperative pattern that moves fresh air from outside the hive across the brood combs. At very high outside air temperatures, workers also collect water and spread it within the nest, where it evaporates into the airstream produced by fanning. Honeybees provide an outstanding example of coevolution between thermal requirements and thermoregulation. Their broods of young must have temperatures of about 32–36°C for proper development. Thus the sophisticated thermoregulation of the hive by the workers is essential for a hive’s reproductive success.

SUMMARY Endothermy and Homeothermy in Insects

- Many solitary insects, especially those of medium to large size, display thoracic endothermy or homeothermy during flight or certain other sorts of activity. Warming of the flight muscles increases their power output. Often in these insects, a certain minimum flight-muscle temperature is required for flight.
- When insects are not flying, activation of the flight muscles in a nonflight mode—termed *shivering*—is the mechanism they employ to warm the thorax. Shivering is used for preflight warm-up. Nonflying insects also sometimes thermoregulate by modulation of shivering, as observed in bees working in their hives.
- When insects are flying, the best-known mechanism of thermoregulation is modulation of thoracic insulation, brought about by raising and lowering circulatory transport of heat out of the thorax.
- Colonies of social bees and wasps sometimes employ group efforts to maintain exquisitely stable hive temperatures.

Coda

Endothermy can provide organisms with distinct advantages. Accordingly, despite the fact that endothermy usually has a high energy cost, it has evolved independently in animals multiple times. It even occurs—as still another independently evolved example—in plants (Box 10.3).

BOX 10.3 WARM FLOWERS

In the early spring when snow is still on the ground, the flower structures of the arum lily called eastern skunk cabbage (*Symplocarpus foetidus*) melt their way to the snow surface by being as much as 30°C warmer than the ambient temperature. In this way, this species dramatically announces that plants have evolved endothermy! The eastern skunk cabbage in fact displays thermoregulatory properties, in that its flower structures increase their rate of metabolic thermogenesis—responsible for endothermy—as the ambient temperature becomes colder. The function of endothermy in this case is believed to be to enhance the volatilization of odor compounds that attract pollinators. **Box Extension 10.3** discusses this fascinating topic further.

Study Questions

1. As discussed in Chapter 1 (see page 13), Claude Bernard, a nineteenth-century French physiologist often considered the father of modern animal physiology, is still remembered today for his famous dictum: “Constancy of the internal environment is the condition for free life.” Does the study of thermal relations lend support to his dictum? Explain.
2. There is currently a worldwide movement to create protected marine parks. If the parks have an Achilles heel, it is that they have fixed geographical positions, just in the way that Yellowstone National Park is at a fixed geographical location. Suppose that a certain endangered species of fish exists only in a marine park. If the ocean temperature rises in the park because of global warming, explain what physiological problems the species of fish might confront. How might the species face a brighter future if parks could have moveable boundaries rather than fixed ones?
3. Referring to Figure 10.11, suppose you have some lizards that are at 16°C and have been living at that temperature for 5 weeks. What is their resting metabolic rate? If the lizards are suddenly shifted to a room at 33°C, trace on the graph how their metabolic rate will change from the moment they are placed in the new room until 5 weeks have passed. According to the graph, will they exhibit compensation?
4. Discuss ways that the cryobiology (“freezing biology”) of insects could be manipulated to control insect pests. One factor to consider is that certain bacteria and fungi act as highly effective ice nucleators.
5. In the animal kingdom today, poikilotherms outnumber homeotherms by a great margin. Why is poikilothermy a successful way of life even though poikilotherms sometimes must compete successfully with homeotherms to survive?

6. Suppose you travel to a tropical place such as the Bahamas and watch the coastal poikilotherms, such as fish, crabs, and starfish, swim and crawl about in the warm waters. Suppose then that you travel to northern Maine and watch the related species of poikilotherms in the cold waters there. In the abstract, it would not be unreasonable to expect to see the animals in Maine moving about in slow motion compared with those in the Bahamas. In fact, however, rates of locomotion are likely to look to your eye to be more similar than different in the two places. Design experiments to assess whether the Maine animals are especially able to be active in cold waters. If you find that they are, how might their high ability for activity in cold waters be explained? For each hypothesis you present, design an experiment to test the hypothesis.
7. During winter, when people are in a well-insulated house, they usually feel comfortable if the air temperature is near 22°C (72°F). If you have ever spent a night in a poorly insulated cabin in winter, however, you will recognize that paradoxically, when people are in poorly insulated buildings, they often feel chilly even when the air inside is heated to 22°C or higher. One important reason for the difference in how warm people feel in the two sorts of buildings is that even if a well-insulated and poorly insulated building are identical in the air temperature inside, they differ in thermal-radiation heat transfer. Specifically, a person standing in the two types of buildings experiences different heat exchange by thermal radiation in the two. Explain how thermal-radiation heat transfer accounts for the sense of chill in the poorly insulated building. (Hint: Think of the outer walls of the two types of buildings, and think specifically of the temperatures of the interior surfaces of those walls.)
8. What is homeoviscous adaptation? Although we discussed it in our study of poikilotherms, the phenomenon was actually first discovered about a century ago in studies of pigs in Sweden. Some pigs were dressed in blankets during winter while others were allowed to roam about stark naked. When their subcutaneous fat was analyzed, the two sets of pigs turned out to have laid down lipids of differing chemical composition. How could different lipids give the two groups similar lipid fluidities?⁴⁶
9. Suppose you are trying to choose between two winter jackets. Suppose also that you have a heat-producing mannequin available for your use and you are able to adjust the mannequin's rate of heat production. According to Equation 10.10, insulation is equal to $(T_B - T_A)/M$ (this is in fact a general equation for insulation). How would you make a quantitative comparison of the insulation provided by the two jackets?
10. In the rete mirabile serving the red swimming muscles of tunas, some key enzymes of catabolism show gradients of concentration: They are more concentrated at the cold end of the rete, and less concentrated at the warm end. These variations parallel variations that are often seen in the thermal acclimation of poikilotherms, when enzyme concentrations rise during acclimation to cold and fall during acclimation to heat. What do you think could be some of the reasons for these spatial and temporal variations in enzyme concentration? Why not have the highest observed enzyme concentrations everywhere at all times?
11. Humphries, Thomas, and Speakman presented a bioenergetic model to predict how global warming might force insectivorous bats to alter the latitudes at which they seek hibernation sites. The investigators stress that not only is the model fairly simple, but also it allows the *existing* distribution of hibernation sites to be predicted reasonably well. Study their model, and assess its pros and cons. Why is the little brown bat a particularly suitable species for the application of this method? See M. M. Humphries, D. W.

Food, Energy, and Temperature *at Work:* The Lives of Mammals in Frigid Places

Reindeer (*Rangifer tarandus*), which occur in Siberia and other far-northern regions, typically give birth in May, when the ground remains snow-covered and the air often cools to below 0°C overnight. At the moment of its birth, a reindeer calf experiences a drop in its environmental temperature from 37°C inside its mother's uterus to the prevailing air temperature. If the air temperature is -3°C , the calf's environmental temperature plummets by 40°C at birth. The air sometimes is much colder, and some calves experience a drop of $50\text{--}60^{\circ}\text{C}$ when they are born. Newborns are wet—covered with amniotic fluid—and a strong wind may blow.

Reindeer calves must thermoregulate on their own from the moment they are born, or die, because they do not huddle with each other or with adults, and they have no nest to protect them. They are perhaps the most precocial (adultlike) of all the newborns of land mammals. They stand the moment they are born. When 2 days old, they can run faster than a person. Because herds typically move from place to place incessantly to find food, the newborn calf has no luxury of resting to gather strength. It must keep up. Within a week, a reindeer calf can swim across broad rivers.

As stressed in Chapter 4, the physiology of young animals is as important as the physiology of adults, because each individual animal must survive first as a youngster if it is ever to have the chance of surviving (and reproducing) as an adult. We will return to the young of reindeer shortly. First, however, let's focus on adult reindeer and the environment in which they live—matters that set the context for fully understanding the young.

Food, Nutrition, Energy Metabolism, and Thermoregulation in the Lives of Adult Reindeer

Reindeer, as a species, are probably the most adapted of all inland mammals to cold exposure; some herds live year-round in places where the average annual temperature is below -5°C . An intriguing aspect of animal species that are extremely well suited physiologically to live in stressful habitats is that their very presence can permit *other* species to exist there as well. In deserts, the existence of rodents that have evolved extremely low requirements for ingested water permits many water-dependent predators to exist as well; the rodents provide the watery food the predators need. Similarly, in the Far North, the existence of reindeer permits the existence there of wolves and other predators—including indigenous human cultures. During preindustrial times, people could not possibly have survived in the interior of the Far North on their own. The existence of humankind there was made possible, all around the Arctic, by herds of reindeer, which served as sources of food and of highly insulating pelts that people employed for necessary shelter and clothing. The same points still apply today to a number of indigenous human cultures that live apart from modern comforts, such as some communities of Sami people in Scandinavia.

A newborn reindeer calf must thermoregulate on its own
Although mother reindeer feed their young, they do not keep them warm, and the Arctic environment where birth occurs may be very cold.

Because of the intimate relations between reindeer and people over long periods in the past, reindeer were domesticated to some degree in many regions. Today, therefore, the species consists of both wild populations and numerous domesticated strains or races. Caribou are considered by most mammalogists to be the same species. As adults, reindeer in some populations are roughly the same size as humans.¹

Reindeer have many characteristics that help them prosper in the Far North. Although adult reindeer weigh, on average, about one-third as much as adult moose (another northern species), the feet of reindeer are so unusually broad that the contact area of a reindeer with the ground is about the same as that of a moose. Accordingly, the downward gravitational force on each unit of area of a reindeer's feet is very low compared with that of a moose, explaining how reindeer can readily negotiate snow fields that stop moose.

Adult reindeer in their winter pelage have lower-critical temperatures of -30°C or lower in still air. The air temperature in the Arctic rarely goes below -50°C . Thus the air temperature does not drop far below their lower-critical temperature, and reindeer in their winter pelage in still air never have to increase their metabolic rates by much above basal (Figure 11.1). As an amusing comparison, Laplanders and Norwegians equipped just with the insulation "nature gave them" (i.e., naked) have lower-critical temperatures of $+24$ – 27°C ! Only by dressing in something like a reindeer pelt can a person have a lower-critical temperature that is compatible with Arctic life.

One reason for the low energy costs of adult reindeer in the frigid air of winter is their pelage. A dense underfur of fine hairs thickly covers their skin, and the longer "guard" hairs of the pelage, which protrude beyond the underfur and hang over its outer surface, are extensively vacuolated ("hollow"). In common with other large species of mammals, reindeer undergo dramatic seasonal molts. In winter, a reindeer's fur is 3–4 cm thick over much of its body

¹Various subspecies and herds of reindeer differ in average adult weight. In some, the average adult weight is 60–70 kg, the same as the nominal average adult weight of people. In others, the average is twice as great, or even, in some cases, three times as great.

FIGURE 11.1 Resting metabolic rate as a function of air temperature down to -50°C in adult reindeer The same Norwegian animals, weighing about 70 kg, were studied in winter and summer. The air was still. Lines are drawn by eye to approximate the trends in the data. (After Nilssen et al. 1984.)

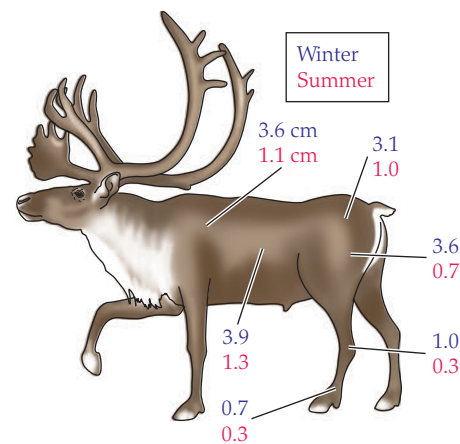

FIGURE 11.2 Fur thickness of adult reindeer in winter and summer The thickness was measured perpendicular to the skin surface and is expressed in centimeters. (After Johnsen et al. 1985.)

(Figure 11.2). All body surfaces of a reindeer, even the nose, have a hair covering.

Besides the pelage, another reason for the low energy costs of adult reindeer in frigid air is that they employ regional heterothermy. Reindeer do not keep the tissues of their legs and other exposed body parts as warm as their body core (see Figure 10.32).

Reflecting on what we learned about lipid fluidity in our study of fish and other poikilotherms in Chapter 10, an interesting question about the heterothermic legs of reindeer is whether the lipids in their legs are hard and stiff where the limbs are cold, much as butter is hard when cold. Actually, it is a matter of ancient knowledge that lipids from the outer extremities of reindeer legs—and also those from the hooves of cattle—are particularly fluid, compared with body-core lipids. People have long used lipids (oils) from the outer extremities to soften boot leather and give flexibility to leather bow strings in cold climates.

Homeoviscous adaptation exists from one end of a heterothermic leg to the other: Whereas the lipids in the upper leg of a reindeer or cow have chemical structures that give them a gel-like texture at 37°C and cause them to become hard at 0°C , the lipids from the outer extremities have different chemical structures that give them a gel-like or oily texture near 0°C . One way to examine the spatial diversity of chemical structure is to look at the abundances of key, diagnostic fatty acids in the marrow lipids of the limb bones. As seen in Figure 11.3, oleic acid—an unsaturated fatty acid—becomes a dramatically more abundant constituent of the marrow lipids as one moves out along a leg, whereas palmitic acid and stearic acid—both saturated fatty acids—become less abundant. In this way, the bone marrow lipids in the legs of reindeer are reminiscent of the brain phospholipids of fish from various climates (see Figure 2.3). The same basic trends exist even in the legs of many tropical mammals. Thus, although the trends are significant for reindeer, they do not seem to be specific adaptations to a truly frigid climate.

Food and nutrition represent great challenges in the environments where reindeer live. Like other deer, reindeer are ruminants. Thus rumen processes, as well as digestive and absorptive processes, play pivotal roles in their physiology of food and nutrition. A key to the survival of reindeer in the Far North is that they eat a great diversity of plants (37 genera were found in the rumens of one herd). Moreover, they obtain an exceptional degree of nutritional benefit from species of lichens ("reindeer moss") and a variety of

FIGURE 11.3 Fatty acid composition of bone marrow lipids in the legs of reindeer. Marrow lipids were sampled at 12 locations from the proximal (upper) end of each limb to the distal (lower) end. The proximal locations were the proximal ends of the humerus and femur; the midlimb locations were the distal ends of the radius and tibia; the distal locations were the third phalanges. In the numbering system for the fatty acids (discussed in Chapter 6, see page 132), the number before the decimal is the number of carbon atoms; that following the decimal is the number of double bonds; and that following ω (omega) designates the position of a key double bond (ω is not written when there are no double bonds). (After Meng et al. 1969.)

that dominate the winter diets of reindeer are collectively the opposite: low in protein, low in minerals, low in highly digestible carbohydrates, and high in cellulose and hemicelluloses. Lichens are often the salvation of reindeer in winter *in terms of supplying energy* because they are abundant, and as we have already said, reindeer can tap a high proportion of their nutrient value. Lichens, however, typify the nutritional problems that reindeer face in winter, in that, being low in protein and low in minerals such as Na^+ , they are not even close to being nutritionally complete. **Figure 11.4**, which summarizes the composition of the foods available to reindeer throughout the year in Finland, is well worth close study, because it illustrates dramatically that animals in the wild—away from veterinarians and manufactured feeds—often face substantial nutritional stresses.

Reindeer and the microbial symbionts in their rumens make adjustments as the seasons change. For instance, certain strains of reindeer fatten dramatically as winter approaches, thereby reducing their need for winter food. In addition, the community of fermenting microbes in the rumen changes in composition in ways that respond to the shifts in the types of foods eaten. **Table 11.1** presents one example, indicating that microbes that digest woody, fibrous plant material (including cellulose and hemicellulose) increase in winter when reindeer ingest considerable amounts of such material. A recent study showed that the mixed rumen microbial community in Norwegian reindeer became four to six times more capable of breaking down lichens when lichens were chronically

other species of far-northern plants that are not much eaten by other mammals.² The exact mechanisms by which reindeer are able to exploit their unusual foods remain poorly known, although studies of ingestion and egestion show, for example, that reindeer obtain twice the nutrient value from lichens as sheep or cows do. Some lichens produce and accumulate toxic phenolic compounds such as usnic acid, raising the question of how reindeer handle these compounds. Recent research points to degradation by specialized rumen microbes. Usnic acid in ingested lichens is evidently fully broken down during rumen processing and never enters the tissues of the reindeer.

The seasonal cycle of plant growth in the Far North is dramatic—not just because winters are cold, but also because of winter darkness (in some places that reindeer occupy, the sun does not rise above the horizon for 3 months in winter). The summer foods of reindeer in most places are collectively high in protein and mineral nutrients, and they are high in the proportion of total carbohydrate that is in readily digestible forms (rather than cellulose or hemicelluloses). By contrast, the lichens and senescent vascular plants

²For simplicity of language, we use the term *plants* in a loose, comprehensive sense to refer to all the photosynthetic organisms that reindeer eat, including lichens and mosses, as well as true plants.

FIGURE 11.4 Seasonal changes in diet: the protein and mineral content of the foods eaten by Finnish reindeer. The foods available to—and eaten by—reindeer vary from place to place. The particular seasonal changes seen here are not, therefore, observed everywhere. (After Nieminen 1980.)

TABLE 11.1 Responses of the rumen microbes of reindeer to seasonal changes in diet

The mixed communities of fermenting microbes in rumen fluid were classified using standard microbiological methods. Compared with the summer microbial community, the winter microbial community was more able to ferment plant fiber, including particular structural carbohydrates such as cellulose, and less able to carry out hydrolysis of proteins.

Food breakdown activity	Percentage of microbes that could carry out each activity (%)	
	Summer	Winter
Fiber digestion	31	74
Cellulose digestion	15	35
Hemicellulose (xylan) digestion	30	58
Proteolysis (protein hydrolysis)	51	28
Starch digestion	68	63

Source: After Orpin et al. 1985.

in the diet than when lichens were chronically not eaten. Despite such adjustments, by the time spring arrives after a long winter, reindeer have lost body weight, often are somewhat emaciated, often exhibit other signs of having been in negative nitrogen balance for months, and may exhibit blood mineral levels diagnostic of mineral deficiency. In some places, they are renowned for having high “mineral appetites” in spring.

In addition to the physiological and anatomical features we have already discussed, the distinctive feeding behaviors and migratory behaviors of reindeer herds play key roles in their success in the Far North. Food is thinly distributed there, even for animals that feed on a diversity of plants. Thus herds must range widely to obtain enough food. Reindeer herds are legendary, in general, for being incessantly on the move during daylight hours, covering large areas of ground every day, nibbling as they go. The extraordinary annual migrations of reindeer herds are additional behavioral adaptations, helping them to find not only food but also shelter from wind during winter. Although some herds do not migrate, most do. As winter approaches, the norm is for a herd to migrate about 1000 km from its summer site to its winter site. Some travel farther: Recent satellite-based tracking studies in Alaska and the Yukon revealed that some herds make a round-trip of 5000 km per year. Of all animals that travel by walking or running, reindeer migrate the greatest distances!

The movements of the adults in a herd are a part of reality for all calves born into the herd. Calves must join in the wide-ranging daily movements of their herd soon after birth, as we have already mentioned, and by autumn of their first year of life, they must be ready for the annual migration.

Newborn Reindeer

When reindeer are born, they already have a well-developed pelage, consisting of woolly, hollow hairs. Their fur provides substantial insulation as soon as the uterine fluids have evaporated away and the hairs are dry. From the moment of birth, reindeer also exhibit a typical homeothermic relation between their metabolic rate and the air temperature, as shown by the red line in **Figure 11.5**. Newborns

FIGURE 11.5 Resting metabolic rate as a function of air temperature in newborn and growing reindeer The air was still when these measurements were made. Dots are averages for the sets of animals studied at various conditions. (After Markussen et al. 1985.)

are able to raise their rate of metabolic heat production to at least twice their resting rate. By virtue of the combined effects of their pelage insulation and this thermogenic ability, newborns are able to keep their body temperatures at 39–40°C when the air is –20°C to –25°C (a difference of 60°C or more) for at least a few hours in still air. This performance probably represents the pinnacle or near-pinnacle of thermoregulatory ability among all the terrestrial newborns on Earth.³ That said, it remains true that reindeer are born into an environment that can be very harsh, and the thermoregulatory abilities of newborns are far inferior to those of adults. Many newborns die if they get wet from precipitation, or if the wind blows briskly or the air temperature remains very low for a day or more.

Reindeer calves grow rapidly compared with other deer. Partly as a consequence of their increasing body size, their metabolism–temperature relation becomes noticeably more favorable with each passing week (see **Figure 11.5**). When calves are 2 weeks old, the weight-specific rate of heat production that they require to stay warm at an air temperature of –20°C is already reduced to only 70% of that required at birth. For understanding the rapid growth of reindeer calves, it is undoubtedly significant that the milk produced by their mothers is about 20% lipid, compared with about 4% lipid in cow’s milk. Reindeer milk is accordingly very energy dense (see **Table 6.3**), having about three times the energy value per liter as cow’s milk has. It is also particularly rich in protein. The nutrient-rich milk of reindeer aids the rapid growth of the calves. In addition, calves may start eating vegetation within 2–3 days of being born, and by 2 weeks after birth they eat considerable amounts of plants, while continuing to nurse. By late autumn of their first year, when they are 5–6 months old and fully stop nursing, they have reached 50–60% of their adult weight. This extent of growth in the first season of life far exceeds the average for other, related mammals and is believed to be important in enabling young reindeer to participate successfully in their herd’s long migration to its wintering area.

³Newborn muskox (*Ovibos moschatus*) may be superior, partly because of greater body size. At birth, reindeer calves weigh about 4–5 kg, whereas muskox calves weigh about 8 kg (on average, adult muskox are about twice the size of adult reindeer). Newborn muskox have a highly insulating pelage and large deposits of brown fat.

BOX 11.1 KNOCKOUT MICE CLARIFY THE FUNCTION OF BROWN FAT

Molecular genetic tools have been used to produce laboratory mice that cannot synthesize the type of mitochondrial protein, *uncoupling protein 1 (UCP1)*, that mediates nonshivering thermogenesis (NST). The gene coding for UCP1 is inactivated in these mice. As explained in **Box Extension 11.1**, research using these knockout mice has provided strong support for two critical concepts: (1) brown fat is the sole tissue in which NST occurs and (2) UCP1 is the only molecular form of UCP that mediates NST.

A great deal of interest has focused on the mechanisms by which newborn reindeer and other young mammals increase their metabolic heat production for thermoregulation. Nonshivering thermogenesis (NST) by brown fat plays an extraordinary role in this regard. Brown fat is nearly always the principal thermogenic tissue in newborn placental mammals, and NST is thus the principal mechanism of thermogenesis in newborns (**Box 11.1**). *Why* brown fat and NST should be of paramount importance in newborns is largely an unresolved mystery, as we discuss later.

The ways in which brown adipose tissue and NST have been identified in reindeer calves illustrate well the steps that physiologists typically take to identify the tissue and process. The first study indicating that brown fat occurs in newborn reindeer involved microscopic examination of adipose tissues. The investigators observed that the fatty tissue between the scapulae (shoulder blades) of newborn calves is reddish brown and, suspecting it to be brown fat, prepared it for microscopy. The microscopic approach to identifying brown fat is based on the fact that the tissue usually differs from white fat in several structural ways. For example, brown fat is much richer in mitochondria than white fat, and its intracellular fat deposits are multilocular (meaning there are many small lipid droplets per cell) rather than unilocular (one droplet per cell) as in white fat. Microscopic studies performed in about 1980 indicated that *most of the major deposits of adipose tissue in the body of a newborn reindeer are brown fat*. Nonetheless, physiologists assume that function, not just morphology, must ultimately be directly studied for function to be understood. Thus, soon after microscopy had established the likely presence of brown fat in newborn reindeer, investigators tested calves to determine their responses to injected norepinephrine.

As discussed in Chapter 10, thermogenesis by brown fat is ordinarily activated by the sympathetic nervous system, secreting norepinephrine. On the basis of this fact, an animal's response to a norepinephrine injection has often been used as an informative (although relatively crude) test for brown-fat function. When newborn reindeer are injected subcutaneously with a standard dose of norepinephrine, they respond with a large increase in their rate of O₂ consumption (**Figure 11.6**). This response to norepinephrine, coupled with the microscopic observations discussed earlier, convinced physiologists that brown fat and NST are important for heat production in newborn reindeer.

Always, however, thoughtful scientists are wondering if their standards of evidence are adequate. Anyone who has spent

FIGURE 11.6 A test for brown-fat thermogenesis in newborn and growing reindeer Reindeer of various ages were injected subcutaneously with a standard dose of norepinephrine per kilogram of body weight. (After Soppela et al. 1986.)

months of his or her life gathering data becomes aware that there is a risk of being fooled. Maybe, one fears at times, the hard-won data do not say exactly what we have imagined they say. Because of these concerns, people using the microscopic approach kept reassessing whether the microscopic criteria used to identify brown fat were infallible. By the last decade of the twentieth century, these investigators had concluded—from hundreds of studies on brown fat in various mammals—that in fact the traditional microscopic criteria are not 100% reliable. On unusual occasions, when the traditional criteria are used, white fat can seem to be brown fat, or vice versa.

A third test for brown fat was therefore devised. It employed a distinctive molecular marker: the mitochondrial protein *uncoupling protein 1 (UCP1)*, which is believed to occur exclusively (or virtually exclusively) in brown fat, not white fat or other tissues. Antibodies to UCP1 can be produced in a laboratory. Then, UCP1 in a newborn reindeer or other animal can be unambiguously identified by its antigen–antibody reaction (immunocytochemistry). Studies have shown that all of the major adipose-tissue deposits in newborn reindeer react with UCP1 antibodies, demonstrating more convincingly than ever that the tissues are brown fat.

Reindeer newborns are not alone in being well endowed with brown fat. In fact, most placental mammals, including humans (**Figure 11.7**), have extensive masses of brown fat at birth (pigs are exceptions, as discussed in **Box 11.2**). In large-bodied species, such as reindeer and humans, the brown fat of newborns typically declines rapidly with age. This decline is particularly rapid in ruminants. In reindeer, sheep, goats, and other species of ruminants that have been studied, all the brown fat present in newborns undergoes a genetically programmed transformation into white fat by 1 month of age; this is demonstrated by the fact that in 1-month-old animals, the gene for UCP1 is no longer expressed and no tissue reaction with UCP1-specific antibodies occurs. Simultaneously, the metabolic response of the young animals to a norepinephrine injection declines substantially (see **Figure 11.6**).

FIGURE 11.7 Brown adipose tissue in a human infant The tissue occurs in discrete masses in many parts of the body. (After Hull 1973.)

In the sorts of species we are discussing, as the capacity of a young mammal for *nonshivering* thermogenesis declines, *shivering* becomes more important as a source of heat production; ultimately, shivering becomes the sole mechanism of increasing heat production for thermoregulation. This transition is quite obvious in people; whereas we rely principally on nonshivering thermogenesis when we are newly born, we become dependent principally on shivering thermogenesis in youth and adulthood. In reindeer, as already said, the transition occurs relatively rapidly. Shivering becomes their only substantial mechanism of increasing metabolic heat production for thermoregulation by the time they are 1 month old, as far as is now known. This is not to say that young reindeer shiver a lot. By the time reindeer are 1 month old, the warm air temperatures of summer have started to prevail, and the need for any sort of thermoregulatory thermogenesis is reduced. When winter arrives,

the young reindeer are 6 months old and—similar to adults—have lower-critical temperatures of about -30°C (see Figure 11.1).

The primary role of brown fat in newborn ruminants, such as reindeer and sheep, seems to be to act as a transition source of heat production: the dominant site of thermogenesis when the animals first make the transition from life in the uterus to life outside their mother. For brown fat to play this role, it must develop extensively prior to birth, a fact that raises numerous interesting questions.

Do fetuses, for example, develop more brown fat when the environment into which they will be born is cold rather than warm? This question has been studied in sheep, in an indirect way, by shearing off the fur of some mothers during their final month of pregnancy and comparing their newborns with the newborns of unshorn mothers (shearing serves in these experiments to mimic colder weather for the mothers by lowering their insulation). Lambs born to shorn mothers have more brown fat at birth than lambs born to unshorn mothers have. Moreover, when newborns are exposed to an air temperature that is chilly for lambs (14°C), the newborns of shorn mothers never shiver, whereas many of the newborns of unshorn mothers shiver. These results indicate that the intrauterine development of brown fat by fetuses is modified, depending on the cold stress experienced by their mothers, in ways that help ensure that NST will be sufficient for thermoregulation in the newly born.

Another interesting question is how the large masses of brown fat in unborn, near-term young are regulated so that they do not catabolize large amounts of the young's foodstuffs. Logic suggests that, prior to birth, a young animal will profit most from the foodstuffs it has by using them to grow and mature; brown fat, if uncontrolled, could turn large quantities of the foodstuffs into heat and chemical wastes. Experiments reveal that if near-term

BOX 11.2 GENOMICS CONFIRMS THAT PIGLETS LACK BROWN FAT

The completion of a partial sequence of the genome of domestic pigs in 2005 set the stage for a remarkable discovery. Investigators located the gene for uncoupling protein 1 (UCP1) in this genome, but when they looked in detail, they found the gene to be disrupted by several mutations and deletions, including complete deletion of two exons. The gene is nonfunctional, a fact that greatly strengthens a conclusion reached through earlier morphological studies, that piglets lack brown fat.

Studies of additional types of pigs quickly revealed that the UCP1 gene is disrupted in all of them. European wild boars, warthogs, red river hogs, and Bornean bearded pigs display the same exon deletions that are observed in domestic pigs.

Phylogenetic analysis indicates that the UCP1 gene became disrupted in the pig lineage about 20 million years ago. As yet, no one can be certain why this occurred. Nor can anyone be certain whether the gene became nonfunctional first and then brown fat disap-

A European wild boar, the only wild pig that lives in cold climates

peared, or vice versa. In any case, members of the pig family today are unusual among mammals in that the newborns lack nonshivering

thermogenesis and depend entirely on shivering for physiological heat production. Piglets tend to be especially vulnerable to cold stress.

FIGURE 11.8 A near-term sheep fetus in the uterus prepared for study of “simulated birth” (From Power et al. 1987.)

sheep fetuses are cooled inside the uteruses of their mothers (Figure 11.8), they do not activate their brown fat or engage in NST. However, if blood flow from the placenta of a near-term fetus is blocked by pinching shut the umbilical cord, the fetus rapidly exhibits substantial NST. These results and others indicate that a near-term sheep fetus in the uterus receives from its placenta one or more types of signaling molecules (probably prostaglandins) that inhibit its activation of brown fat. These signaling molecules are cut off at birth by the severing of the umbilical cord, and the brown fat is then able to respond vigorously to the chilly outside environment by producing heat! A similar process may occur in reindeer. Future research will tell.

The Future of Reindeer: Timing and Ice

Demographers have sounded an alarm that wild reindeer may be in decline throughout their circumpolar distribution. Since the 1980s, 80% of populations studied have exhibited declines. If we presume that these data represent a long-term trend, the causes are of great interest. Some of the causes may be intimately related to the environmental physiology of the animals in a changing world.

Migratory ungulates commonly have evolved life histories closely synchronized with cycles of plant growth. This phenomenon is very evident in reindeer. As spring unfolds, herds of reindeer migrate back to the areas where they will spend the summer, and after arriving there, the pregnant females in a herd give birth almost synchronously with each other. Historically, births have tended to occur at a time when mothers and young can make maximal use of the peak period of spring plant growth on the summering grounds. For several reasons—one being that when reindeer start

their migration, they are at a distant place from their summering grounds—the question arises, in a changing world, of whether birthing will continue to coincide with peak spring plant growth. A recent study on West Greenland herds indicates that it will not. Over the past 20 years, the peak of spring plant growth has occurred earlier and earlier because of warming spring temperatures. The reindeer, however, have birthed always at about the same time each spring. A growing mismatch of 5–10 days has consequently developed between the time when young are born and the time when food for them is most readily available. As this mismatch has developed, death rates of offspring have risen.

The consequences of this sort of mismatch highlight, among other things, the precariousness of reindeer life history. Reindeer have evolved to be specialists in leading lives of lifelong (“cradle to grave”), direct exposure to an especially harsh environment. That environment is also particularly unforgiving: small changes can impose large consequences. In addition to the mismatch just discussed, another “small” change that may be driving the decline of reindeer populations is the change of snow type. Arctic indigenous peoples often have dozens of words for the forms of ice, snow, and precipitation—reflecting the fact that subtle differences (often unrecognized by non-Arctic people) may be of large importance. Evidence exists that in some areas where reindeer live, precipitation is falling to a greater extent as rain (and a lesser extent as snow) as years go by because of global warming. When precipitation falls as rain, it can freeze on the ground into a hard, thick crust that has been observed to block reindeer from reaching food plants, leading to hunger and starvation.

Thermoregulatory Development: Small Mammals Compared with Large

Mammals the size of mice and rats have only very modest capabilities to thermoregulate when they are first born. The white-footed mouse (*Peromyscus leucopus*), one of the most abundant native small mammals in North America, provides a typical example of the course of development in such animals. The species occurs in northern states such as Michigan and Wisconsin, as well as into Canada. In these areas, the mice give birth to their first litters of young each year in March and April, when the cold of late winter still prevails. Their litters consist of 4–6 young born without fur.

In the days immediately following birth, young white-footed mice can respond to cold exposure by increasing their metabolic rates to a small extent, and if all the young in a litter huddle together within the nest their mother provides, they are able collectively to thermoregulate reasonably well for a few hours even when the air outside the nest is near freezing. A newborn litter, therefore, can stay relatively warm for a while when its mother is away foraging. However, if a single newborn mouse is removed from the nest and studied by itself, it cannot marshal a high enough metabolic rate to stay warm even when the air temperature is +25°C—a temperature higher than “room temperature” in American buildings. At an ambient temperature of 25°C, the body temperature of a solitary 2-day-old soon drops from 37°C to about 28°C—not because the animal is in some sort of controlled hypothermia, but because its thermoregulatory abilities are overwhelmed. The young of lemmings and other small mammals characteristic of the Far North are not much different; to thermoregulate in their first days of life, they

require a protective microhabitat, including the nest their mother provides and their siblings with which they huddle.

The length of the nestling period of white-footed mice is typical of that of most mice and rats: about 3 weeks. During those 3 weeks, young mice must become physiologically capable of setting off on their own. They must, for example, become able to thermoregulate as isolated individuals in the environment outside the nest, however cold that environment may be. As Figure 4.4 shows, individuals dramatically increase their body insulation and the rate at which they can produce heat during their 3 weeks of nestling life. Consequently they become capable of thermoregulating by themselves.

Regarding the *mechanisms* of thermogenesis in developing mice and rats, the evidence available indicates that shivering is not functional in most species for roughly the first week of postnatal life. Brown fat, in contrast, is present at birth. The brown fat grows as the young grow. In fact, studies of laboratory rats have shown that the maturation of brown fat as a thermogenic tissue outpaces body growth for a period during nestling development, so that the brown fat is able to produce ever more heat per unit of body weight as time passes.

Let's focus now on *small* mammals as compared with *large* mammals. The trajectory of brown-fat development in small mammals is extremely different from the trajectory in large mammals. In reindeer and sheep, brown fat is maximally or near maximally developed at birth, and it starts to wane soon after birth, so it is gone or approximately gone by about a month of age. In small mammals such as mice and rats, by contrast, brown fat is far from fully developed at birth, and during much of the first month of life, it develops an ever-greater thermogenic ability. Correlated with these differences in developmental trajectory, the adults of large and small mammals tend to exhibit consistent differences in brown fat. Brown fat is not present to any great extent in the adults of most large-bodied species of mammals.⁴ By contrast, brown fat is conspicuous in the adults of most species of placental mammals smaller than about 5 kg. It becomes a particularly prominent tissue in these adults when they are acclimated to cold or acclimatized to winter, as we saw in Chapter 10; and it is a prominent tissue in hibernators, as we will discuss later in this chapter.

Looking back over our discussion of the development of thermoregulation in large and small species, it is striking to observe that in *both* large and small placental mammals, brown fat and nonshivering thermogenesis are the favored means of producing heat for thermoregulation at birth and during the period immediately following birth. Only rudimentary hypotheses are presently available to explain why nonshivering thermogenesis is emphasized while shivering is not. One hypothesis is that skeletal muscles are inherently too immature at birth for shivering to be a viable primary mechanism of thermogenesis in newborns. Another hypothesis stresses that brown fat is often positioned, on average, deeper in the body than the muscles that shiver; possibly,

therefore, natural selection has favored nonshivering thermogenesis in newborns because it delivers heat more effectively to the body core than shivering could. Neither of these hypotheses has been tested, and both make unverified assumptions. Thus the question of why newborn placental mammals so consistently use brown fat and nonshivering thermogenesis to produce heat remains a tantalizing challenge for future research. The fact that we humans rely on brown fat for thermogenesis when we are newly born adds interest to finding an answer.

The Effect of Body Size on Mammals' Lives in Cold Environments: An Overview

A retrospective look at the topics we have discussed so far in this chapter makes clear that body size is a principal determinant of the options available to mammals for thermoregulation. Although both reindeer and white-footed mice are warm in the days following their birth, they are warm for different reasons. Newborn reindeer are so large that they have few options for using protective microhabitats; they cannot burrow underground, and on the tundra they cannot readily find other refuges. Thus newborn reindeer must *physiologically* confront the full harshness of their environment if they are to stay warm. Fortunately, large size—while limiting behavioral options—has physiological advantages; because of their size, newborn reindeer have a surface-to-volume ratio that is favorable for retaining heat in cold environments, and they can have a thick pelage. The interplay between behavior and physiology is almost opposite for small-bodied newborns such as white-footed mice. They are smaller than the little fingers on our hands, and just as naked. Thus, physiologically there is no chance that newborn mice could evolve mechanisms that would allow them to thermoregulate while fully exposed to a cold external environment. Being small, however, they can exist in highly protective microhabitats; their mothers can place them in secluded, benign locations such as underground burrows and can readily ensconce them in an insulating nest. The reasons newborn white-footed mice are warm are principally behavioral: When their mother is present, the newborns are warmed by her; and when she is absent, they benefit from the behavioral provisions she has made for them.

The same trade-offs between physiology and behavior are equally evident in the lives of adult mammals. During winter in Earth's frigid places, small nonhibernating mammals such as lemmings in the Arctic and pikas in the high mountains are able to escape the biting cold and howling winds of the larger environment by living under the snow (see Figure 1.17) or in other protective hideaways. Their ability to escape in this way is fortunate because, physiologically, a mouse- or rat-sized adult could not survive full exposure to the cold of winter in such places. Large mammals, in contrast, are in a far more advantageous position in terms of their physiology of thermoregulation; the body size of an adult reindeer is one of the major reasons it can have a lower-critical temperature below -30°C . The physiological advantage of large size is itself fortunate, because large size limits behavioral options. A large mammal, such as an adult reindeer in the Arctic or a bighorn sheep in the high mountains, cannot escape the severity of the cold season by burrowing under the snow.

The single greatest behavioral option for large-bodied species is migration. In fact, as we saw in Chapter 9 (see Figure 9.8), migra-

⁴Recently, deposits of brown fat "disguised" within white fat have been discovered by use of advanced techniques (e.g., positron emission tomography) in adult humans—after decades in which most specialists had concluded that humans lose brown fat entirely prior to adulthood. The physiological significance of these adult deposits has yet to be determined. Their function may be in body-weight regulation or control of blood glucose rather than thermoregulation. The discovery of these deposits raises the question of whether brown fat will be found to some extent in adults of other large-bodied mammals when the same advanced techniques used in the recent study of people are applied to other species.

tion is energetically more feasible for large species than for small ones. Often, therefore, with the approach of winter, as the small mammals in a place go underground or under the snow, the large ones get out. Bighorn sheep trek to the lowlands, and reindeer often migrate into more-forested areas where they can find windbreaks, as well as better winter feeding grounds.

Because body size is one of an animal's most consequential attributes, it is rewarding to ponder the pros and cons of different sizes. If natural selection starts to favor an increase or decrease in the body size of a species, what are all the implications, and the potential trade-offs, over the full span of an animal's life? We have touched on only some of the highpoints in our discussion here.⁵

Hibernation as a Winter Strategy: New Directions and Discoveries

The hibernating species of placental mammals are noted for retaining brown fat as adults. Indeed, when Conrad Gessner first described brown fat in 1551, he was studying the adults of a hibernating species, the European marmot. For four centuries thereafter, brown fat was observed in the adults of one hibernating species after another. The association of brown fat with hibernation was so consistent, in fact, that—although the function of brown fat was unknown—the tissue was dubbed “the hibernation gland.” The actual function of brown fat—not a gland but a thermogenic tissue—was not discovered until the mid-twentieth century.

Today we know that in adult hibernators, brown fat is the *thermogenic tissue that takes the lead in rewarming during arousal* (emergence from hibernation). Intense thermogenesis by brown fat is activated at the very beginning of the arousal process. Because of the placement of brown fat in the body (some deposits actually surround major arteries), and because of blood flow patterns, heat produced by the activation of brown fat is believed to be delivered particularly to the vital organs such as the heart, lungs, and brain. This focused warming of the vital organs, starting early in arousal, may be important in poising those organs to play their roles (e.g., coordination mediated by the brain) in the overall sequence of events by which homeothermy is gradually restored throughout the body.

As we discuss hibernators further, two species will receive special attention, the Arctic ground squirrel (*Urocitellus parryii*) and the alpine marmot (*Marmota marmota*). The ground squirrel, which weighs 500–800 g, is found widely in the Far North—Alaska, the Yukon, and neighboring parts of Canada. The marmot, which is larger and weighs about 4–5 kg, occurs high in the European Alps. Both species employ hibernation as a strategy to cope with the stresses of winter in some of Earth's most frigid places.

The great majority of hibernators have adult body sizes of 5 kg or less. This means that alpine marmots are near the upper limit of the size range that typifies most hibernators. Typically, species of

mammals larger than 5 kg that occupy frigid environments, such as reindeer, remain active and fully homeothermic through all seasons (although some exhibit nonhibernation hypothermic or hypometabolic states at times). Physiologists have pondered why most large-bodied species have not evolved hibernation. One reason is probably that the energy savings afforded by hibernation decline with body size. As shown in **Figure 11.9**, the weight-specific metabolic rates of hibernators in hibernation are statistically the same regardless of their body size. However, when the animals are not hibernating, small-bodied species have higher weight-specific metabolic rates than large-bodied species. Thus the energy savings achieved by hibernation decrease as body size increases. In the face of this allometric trend, natural selection seems not often to have favored the evolution of hibernation in large-bodied species. Bears stand out as a dramatic exception.

Among species of mammals that weigh 5 kg or less, hibernation is not at all universal. In the Arctic, for example, whereas ground squirrels hibernate, lemmings and flying squirrels do not. We do not understand why species have diverged in these ways. At our present level of understanding, we can only conclude that the two modes of dealing with the cold of winter—hibernating and staying active—must each have pros and cons for small and medium-sized mammals. Neither strategy is so obviously “better” that it has become universal.

As we discuss Arctic ground squirrels, alpine marmots, and other hibernators, it is worth reflecting on the fact that much of what we know about them today is a consequence of a technological revolution that has occurred in the last 40 years in which biologists, engineers, and computer scientists have teamed up to create ever-better technologies for the remote monitoring of physiological traits. At the beginning of this revolution, small radio transmitters were designed that could be implanted in animals and report

FIGURE 11.9 The allometry of energy savings by hibernators Weight-specific resting metabolic rate is shown as a function of body weight in nonhibernating and hibernating mammals, on log–log coordinates. The blue line shows the relation in nonhibernating mammals; this metabolic rate decreases substantially as body weight increases. The red line shows the relation in hibernating mammals; this metabolic rate is statistically the same for animals of all body weights. The nonhibernating metabolic rates are basal rates. Hibernating metabolic rates were measured at ambient temperatures of 2–7°C. In the equations describing the two lines, M is weight-specific metabolic rate ($\text{mL O}_2/\text{g}\cdot\text{h}$); W is body weight (g). (After Heldmaier et al. 2004.)

⁵The basic theme—that large body size tends, overall, to be a physiological advantage, whereas small body size tends overall to be a behavioral advantage—is also evident in desert mammals, as discussed in Chapters 28 and 30 (e.g., see Figure 30.1).

body temperatures by *radiotelemetry*. Today's transmitters are able to operate on their built-in battery power for many continuous months, and the data they transmit are recorded automatically by computers. A more-recent advance is the introduction of *data loggers* to physiological research. These are dedicated microcomputers that have large amounts of internal memory and that periodically log the temperatures they measure into memory.

With these advances in technology, records like that in **Figure 11.10** have become possible—and have revolutionized knowledge of the physiology of hibernation. The record in the figure shows the body temperature of a *free-living* and *undisturbed* Arctic ground squirrel for *8 continuous months*—the full duration of its hibernation season!

Arctic ground squirrels supercool during hibernation and arouse periodically throughout their hibernation season

Although most hibernating species spend the winter in microhabitats where the temperature always stays above freezing, Arctic ground squirrels cannot do so over much of the range where the species occurs. The reason is *permafrost*—soil that never melts throughout the year. At the Arctic Circle, permafrost starts at 0.8–1.0 m below the ground surface. The ground squirrels can burrow only in unfrozen soil, and only the soil above the permafrost thaws in the summer. Accordingly, the animals cannot burrow deeper than about 1 m. At that depth the ambient temperature in the winter can drop to far below freezing, even sometimes to -25°C , within the **hibernacula** (singular *hibernaculum*) of the squirrels—the chambers or cavities where they hibernate.

As mentioned in Chapter 10, essentially all hibernating species periodically undergo temporary arousals during their hibernation season. The animals typically remain in their hibernacula during these arousals. This behavior explains why early naturalists believed that hibernation simply started in the early winter and ended in the spring; hibernating animals disappeared into their hibernacula for the entire period. When automated long-term records of the body temperatures of hibernators were obtained, however, they revealed that periodic arousals almost universally occur. The Arctic ground squirrel in **Figure 11.10** aroused 11 times between October and April before it aroused for the final time and emerged from hibernation. Continuous periods of hypothermia lasted 1–3 weeks. Between those bouts of hibernation, the ground squirrel raised its body temperature to $36\text{--}37^{\circ}\text{C}$ for 12–24 h during each arousal.

A striking aspect of the record in **Figure 11.10** is that, by early December, the ground squirrel's body temperature fell below 0°C during periods of hypothermia! The soil temperature fell as winter progressed, and as the soil temperature fell, the ground squirrel maintained a larger difference between its body temperature during hypothermia and the soil temperature. Nonetheless, the body temperature fell below 0°C , a very unusual state for hibernators. The freezing point of the body fluids of Arctic ground squirrels remains the same during winter as it is in summer: -0.6°C (the typical value for mammals). Yet Arctic ground squirrels sometimes cool during hibernation to body temperatures of -2°C to -3°C . They do not freeze at these times. Instead, they supercool, just as some poikilotherms do in winter (see page 247).

Although supercooling is important, the *principal* way that Arctic ground squirrels cope with the threat of freezing during their hibernation bouts is by *thermoregulating* at body temperatures of -2°C to -3°C ,

FIGURE 11.10 The body temperature of an Arctic ground squirrel during its hibernation season in Alaska. The body temperature was recorded with a data logger. The soil temperature of the ground squirrel's hibernaculum is also shown. (From Boyer and Barnes 1999.)

thereby maintaining their tissues well above the soil temperature when the soil becomes profoundly cold. By midwinter, for example, the ground squirrel in **Figure 11.10** kept its body temperature 10°C above the soil temperature during its bouts of hibernation. To be endothermic in this way, hibernating Arctic ground squirrels must increase their rates of heat production in midwinter to rates above those seen at other times—such as September and October—when the soil is warmer and they can simply let their body temperature approximate soil temperature. The rate of heat production of a hibernating ground squirrel is increased, as needed, by brown-fat thermogenesis (**Figure 11.11**). As noted in Chapter 10, it is common for mammals and birds that are in states of controlled hypothermia to prevent their body temperatures from falling lower than certain levels by elevating metabolic heat production. The increased energy expenditure lowers the energy savings of hibernation, however.

The composition of the lipids consumed before hibernation affects the dynamics of hibernation

As stressed in Chapter 6, the composition of the foods that animals eat is often as significant as the amount of food. A dramatic illustration of the interaction between food composition and physiology has emerged in recent years from studies of hibernators. In addition to brown fat, hibernators often accumulate large stores of white fat with the approach of winter. The white fat is a storage tissue; lipids are deposited in the tissue as fattening occurs and later are mobilized from the tissue to meet metabolic needs (including the need to replenish lipids oxidized in brown fat). The lipids stored are triacylglycerols (see **Figure 6.4c**) and thus meet the chemist's definition of fats and oils. They are accumulated in droplets within specialized cells called *adipocytes*.

Fattening requires time—often many months. Accordingly, it must be set in motion by cues or processes that occur well in advance of winter stresses. In some species, the primary controls of fattening are photoperiodic; the shortening of day length in autumn, for example, may serve as a cue for fattening to begin. In other species,

FIGURE 11.11 Excessively low body temperatures are prevented during hibernation bouts by elevated metabolic heat production The plot—which has a scale for metabolic rate on the left and a scale for body temperature on the right—shows the relations among metabolic rate, body temperature, and ambient temperature in Arctic ground squirrels during bouts of hibernation. As the ambient temperature drops from 0°C to -20°C, the body temperature is held higher and higher above ambient because of ever-accelerating metabolic heat production. The isothermal line is a line of equality between body temperature (T_B) and ambient temperature (T_A). (After Barnes and Buck 2000.)

the timing of fattening is endogenously programmed (see Figure 6.25) under control of a circannual biological clock (see Chapter 15).

The storage lipids of hibernators (and other mammals) reflect in their composition the suites of fatty acids present in the foods the animals eat during fattening. Each triacylglycerol molecule is built from three fatty acid molecules (see Figure 6.4c). The fatty acids fall into three chemical categories (see page 132). *Saturated fatty acids*, also termed *SFAs*, contain no carbon–carbon double bonds. *Monounsaturated fatty acids*—*MUFAs*—contain one carbon–carbon double bond per molecule. Finally, *polyunsaturated*

fatty acids—*PUFAs*—contain two or more such double bonds per molecule. As we discussed in Chapter 6, mammals are incapable of synthesizing most PUFAs from scratch. However, if they eat plants rich in PUFAs, mammals can use those PUFAs directly or employ them as substrates for the synthesis of other PUFAs. Because of this relationship, animals that eat foods rich in PUFAs typically deposit fats that are richer in PUFAs than are the fats deposited by animals eating PUFA-poor foods. Similarly, individuals that eat MUFA-rich diets tend to deposit MUFA-rich fats.

Biochemists postulated years ago that storage fats must be in a physically fluid state to be capable of being mobilized and metabolized. If this is true, fats composed primarily of saturated fatty acids could become useless during hibernation because the body temperatures of hibernators are often low enough to cause SFA-rich fats to solidify (for a mental image, recall the hardness of the SFA-rich fats of beefsteaks at refrigerator temperature). Reasoning from these thoughts, researchers hypothesized that hibernators might hibernate in a more effective manner if they deposit fats rich in PUFAs and MUFAs during their fattening periods. Such fats tend to remain fluid at far colder temperatures than fats composed strictly of SFAs (see page 246).

A great deal of evidence now exists indicating that the lipid composition of the diet of hibernators affects the dynamics of their hibernation! Relatively high levels of PUFAs (and sometimes MUFAs) in the diet, as predicted, improve the effectiveness of hibernation. Laboratory studies using defined diets provide one sort of evidence supporting this conclusion. For example, chipmunks in one study were fed three diets: a particularly PUFA-rich diet, an intermediate diet, and a particularly SFA-rich diet. Those on the PUFA-rich diet, compared with those on the SFA-rich diet, were more likely to hibernate, tolerated lower body temperatures, had lower metabolic rates, and had longer bouts of hibernation (meaning they aroused less frequently) (Table 11.2). For evaluating the predicted relation between diet and hibernation, another sort of approach has been to look at correlations between white-fat composition and hibernation performance in free-living animals in the wild, as we will discuss shortly.

Whereas there are many studies by now that demonstrate a relation between hibernation performance and diet (e.g., Table 11.2), these studies do not in fact demonstrate that lipid fluidity is the *reason* for the relation, as originally postulated. At the present time, a cutting-edge in this area of research is that investigators are starting to do detailed studies to determine the *mechanisms* by which diet—and the fatty-acid composition of an animal's fat—

TABLE 11.2 Hibernation performance in chipmunks (*Eutamias amoenus*) fed three diets

All values are means. All differences between the group on a PUFA-rich diet and the group on a SFA-rich diet are statistically significant.

Diet	Percentage that hibernated (%)	Lowest body temperature that did not provoke arousal (°C)	Rate of O ₂ consumption at an ambient temperature of 2°C (mL O ₂ /g·h)	Length of each continuous hibernation bout at an ambient temperature of 5°C (hours)
PUFA-rich	100	0.6	0.034	138
Intermediate	100	1.2	0.047	110
SFA-rich	75	2.2	0.064	92

Source: After Geiser and Kenagy 1987.

affect hibernation. These studies suggest that, whereas lipid fluidity is a factor, other factors are also important.

There are two major types of PUFAs: the omega-3 and omega-6 fatty acids (see page 132). These differ considerably in structure and conformation, as seen in **Figure 11.12**. Recent research indicates that the type of PUFA deposited in white fat sometimes matters, not just the total amount of all PUFAs.

In free-living populations of alpine marmots, because individuals eat different foods, they differ in the amounts and types of PUFAs in their white fat when they start the hibernation season. Individuals with high percentages of PUFAs tend to be more-effective hibernators; they have lower body temperatures during hibernation and lose less weight during the winter than do individuals with lower percentages of PUFAs—confirming the same sort of conclusion as Table 11.2. Closer analysis reveals, however, that this relation is in fact chemically specific. It depends on the percentages of omega-6 PUFAs rather than omega-3 PUFAs.

To explain the relation between omega-6 PUFAs and hibernation success, a current working hypothesis is that when dietary omega-6 PUFAs are incorporated into membrane phospholipids, they provide a superior membrane lipid matrix for the function at low temperatures of key membrane proteins. One of these, a Ca^{2+} -pumping protein, is critical for heart contraction. According to this hypothesis, therefore, adequate omega-6 PUFAs from an animal's food help ensure stable heart action when the heart is cold.

Although periodic arousals detract from the energy savings of hibernation, their function is unknown

Periodic arousals significantly reduce the energy savings of hibernation. To illustrate, let's look at calculations done by Lawrence Wang for Richardson's ground squirrels (*Urocitellus richardsonii*)

FIGURE 11.12 Structure and conformation of representative omega-3 and omega-6 polyunsaturated fatty acids The particular fatty acids shown are α -linolenic acid (omega-3) and linoleic acid (omega-6); these are the simplest precursors of the two types of PUFAs. Because their structures and conformations are different, the two types of PUFAs, when incorporated into membrane phospholipids, have different effects on the structure of the lipid matrix and create a different context for the function of membrane proteins. (After Ruf and Arnold 2008.)

FIGURE 11.13 The annual cycle of energy use in alpine marmots (red line) Also shown are the cycle of energy use that would exist if the marmots did not hibernate (green line), and the energy costs in winter if the marmots did not undergo periodic arousals during hibernation (black lines). (After Heldmaier 1993.)

hibernating in Alberta, Canada. Suppose that these ground squirrels would use 100 units of energy over the course of their winter hibernation season if they did not hibernate. They actually use 12 units of energy. However, of the 12 units they use during the hibernation season, more than 80% is used for periodic arousals!

A qualitatively similar pattern is exhibited by other species. Alpine marmots, for example, reap great energy rewards by entering hibernation each winter (**Figure 11.13**). However, about two-thirds of their energy expenditure during their hibernation period is for arousals, and thus their winter energy expenditure would be only one-third as great if they did not undergo periodic arousals.

Given that animals pay an energy price for periodic arousals, it seems that the arousals must have important functions. In the early days of research on this topic, a lively hypothesis for periodic arousals was that they allow hibernators to void wastes. Investigators assumed, for instance, that the nitrogenous waste product urea accumulates during bouts of hibernation, and thus animals need to wake up to urinate. One piece of contrary evidence that came to light when researchers tested the hypothesis is that in golden-mantled ground squirrels, blood urea concentration does not increase, but *declines*, during a bout of hibernation! Several other seemingly obvious explanations for periodic arousals have also proved to be far from obvious when studied.

In the last 20 years, multidisciplinary attention has been focused on the question of periodic arousals, and several innovative new hypotheses have been put forward. The first of these was that hibernators are unable to sleep when in hibernation and thus must wake up periodically to catch up on sleep. The “sleep” that hibernators often show after arousal, however, has turned out not to be typical sleep, and studies of brain function have lately suggested that in

fact other brain processes are actually occurring. One postulate that has some experimental support is that brain dendrites tend to be lost—and synapses tend to deteriorate—during hypothermia, and arousal is required to restore dendrites and synapses. An entirely different line of thinking—again with some experimental support—is that normal immune responses may be downregulated or blocked during hypothermia. Periodic arousals, according to this hypothesis, allow periodic function of the immune system and thereby enable hibernators to combat pathogenic organisms during the hibernation season.

The intersection of sociobiology and hibernation physiology

Recent analyses of data from many species have established that hibernation is correlated with increased survival in the wild. For example, one question of interest is whether individuals capable of hibernation enjoy lower odds of death during months when they are hibernating than when they are not. In this regard, the available data provide an emphatic answer. On average, in species of hibernating small mammals, an individual is about five times more likely to die in a month when it is active than when it is hibernating. Hibernation probably has this effect mostly because of avoidance of predators; hibernating animals remain always in their hibernacula, instead of moving around in the larger environment where predators can spot them. Avoidance of predation may, in fact, have been a significant factor in the evolution of hibernation. Because of its effect on odds of survival, hibernation can affect an animal's odds of reproduction.

Many additional, interesting questions arise at the interface of hibernation biology and reproductive biology. For example, are hibernation and pregnancy compatible? Do they occur synchronously in the life of an animal? In 2006, researchers reported for the first time that they had observed full-blown hibernation during pregnancy in a placental mammal. Specifically, they had observed three insectivorous bats (hoary bats, *Lasiurus cinereus*) in advanced pregnancy enter deep hibernation for 3–6 days during cold late-spring weather. The bats later aroused normally and gave birth. Prior to this observation on the bats, scattered pieces of less-conclusive evidence—pointing to occasional hypothermia during pregnancy—had accumulated despite the traditional assumption of biologists that pregnant mothers would not enter hibernation. It is clear that hibernation and other forms of hypothermia are less likely to occur during pregnancy than otherwise. Equally clearly, however, we now know that pregnant mothers do sometimes hibernate. When a pregnant female is hypothermic, growth of her young is slowed. On the other hand, she might use hibernation as a mechanism of surviving to term when confronted with a transitory crisis in her food supply. More research will be needed to understand these elusive phenomena.

Male ground squirrels illustrate another consideration that arises in some cases at the interface of hibernation biology and reproductive biology. In ground squirrel species that have been studied, the testicles are regressed during hibernation; and from what is known, no regrowth is possible while hypothermia continues. **Figure 11.14** shows this phenomenon in male golden-mantled ground squirrels. Testicular development starts only after high body temperatures have been restored following the end of hibernation, and because full development requires several weeks, males are unable to breed

FIGURE 11.14 A constraint of hibernation: Testicular development in ground squirrels requires that hibernation end. Shown are testicular size (weight) and blood testosterone as functions of time before and after the end of hibernation in adult male golden-mantled ground squirrels (*Callospermophilus lateralis*). Error bars show the standard errors. (After Barnes 1996.)

until long after they have terminated hibernation. Why the testicles face these limits is unknown. However, the limits have very real consequences for reproduction. In wild populations of ground squirrels, the males emerge from hibernation many weeks before the females. This early emergence of the males seems necessary for them to prepare to be successful mates.

Social hibernation is another theme of considerable interest. During social hibernation, individuals hibernate together in social groups. Although ground squirrels hibernate as isolated individuals, many of the world's 14 species of marmots undergo social hibernation. Alpine marmots, for example, live throughout the year in social groups. A typical social group of alpine marmots consists of a dominant male and female and an assemblage of related, younger animals of various ages (up to several years old). All these animals hibernate together, in sets that number up to 20 individuals.

Social hibernation in alpine marmots has been shown to increase each individual's probability of overwinter survival, particularly among the young-of-the-year, termed *juveniles*. One reason that survival is aided relates to the fact that these marmots do not allow their body temperatures to go below 3–4°C in winter, yet temperatures in their hibernacula are often lower, meaning that hibernating animals must elevate their metabolic rates to keep their body temperatures from going too low. Animals huddled together in a large cluster are better insulated and require less of an increase in metabolic rate than those hibernating alone or in small groups.

One of the most remarkable revelations in the recent annals of the radiotelemetric study of hibernation is the discovery that adults and subadults in a hibernating group of alpine marmots usually undergo their periodic arousals in close synchrony (**Figure 11.15**). This synchrony lowers their mutual energy costs to arouse. If a single adult were to arouse alone within a hibernating group, it would experience heightened energy costs by being in the group,

FIGURE 11.15 Alpine marmots arouse synchronously Shown are the body temperatures of two adult alpine marmots that were hibernating together. Outside disturbances may have affected arousal of the animals at the two times marked with asterisks (*). (After Arnold 1988.)

because the cold tissues of the other animals in the group, pressed closely against it, would increase the heat production it would require to raise its own body temperature. What actually happens is diametrically opposite. Adults and subadults in a group arouse simultaneously, thereby lowering each other's energy costs to arouse by mutually warming each other. The simultaneity of this arousal is particularly intriguing because all the animals are hibernating and therefore are seemingly comatose when they initiate the process!

Juveniles in a hibernating group often do not initiate their arousals simultaneously with the adults and subadults, but instead lag behind, letting the older animals warm them for a number of hours (or even days). Only after receiving this benefit do the juveniles invest their own energy in the arousal process.

By statistical calculations, an *index of synchrony* can be calculated for arousals in groups of marmots. A high index for a hibernating group means that the individuals monitored with radiotelemeters in the group aroused highly synchronously. Based on data for 14

FIGURE 11.16 Weight loss during hibernation as a function of arousal synchrony in hibernating groups of alpine marmots Each point refers to a distinct group of hibernating marmots and shows both the group's average weight loss during winter and the group's degree of arousal synchrony. High values of the index of synchrony signify high degrees of arousal synchronization among group members. (After Ruf and Arnold 2000.)

hibernating groups, **Figure 11.16** shows the relation between loss of body weight and synchrony. As you can see, individuals in highly synchronized groups lost approximately 20–25% of their body weight during the winter hibernation season, but individuals in some poorly synchronized groups lost about 40–45%—roughly twice as much. Because relatively great loss of body weight lowers animals' likelihood of survival, this analysis reveals that synchrony during periodic arousals has important survival consequences.

Further analysis of the data available also reveals that the presence of juveniles is very important in determining the dynamics of group hibernation. When juveniles are present in a group, they themselves have greater chances of survival than if they lived alone. However, because they tend to diminish arousal synchrony by delaying their own arousals relative to others in their group, they increase the amount of weight lost by adults and subadults in their group, and therefore decrease the odds of survival of the older animals. The interplay between sociobiology and hibernation biology is particularly vivid in this context. For an individual adult to survive the winter, avoidance of all contact with juveniles during hibernation would be an advantage. Without immortality, however, adults require juveniles if they are to pass genes to future generations, even though when they associate with juveniles during hibernation, their own odds of individual survival go down.

Study Questions

1. What are the relative advantages and disadvantages of large and small body size in frigid places? In your explanation, try to go beyond the points mentioned in this chapter.
2. When the composition of the community of rumen microbes in a ruminant changes, there are several possible causes. What are some of them? Could you do experiments to decide what the actual causes are? Explain.
3. Long migrations such as those of reindeer are rare in animals that walk across the land, despite being common in flying birds. In what relevant way are reindeer similar to birds in their energetics of covering distance? (Review Chapter 9 if you are stumped.)
4. List possible hypotheses for the function of periodic arousal, and design experiments to test your hypotheses as rigorously as possible.

Previous page: Purkinje neurons (green) send branching dendrites toward the surface of the cerebellum (top); they receive synaptic input from axons of other neurons (blue). Nuclei of neurons and glial cells are red in this fluorescence micrograph. The cerebellum plays roles in movement coordination and motor learning. A major challenge in physiology is to explain behavioral activities in terms of neural functions and interactions.

Neurons

Locomotion in a squid, whether for capturing a meal or to avoid becoming one, depends on jet propulsion: The contraction of muscles in the squid's outer mantle expels seawater through a moveable siphon, propelling the animal in the opposite direction. As is true in all animals, feeding, escape, and similar behaviors in the squid are controlled by nervous-system signals, which travel rapidly in a point-to-point manner, from one specific cell to another. These signals arise from properties of nerve cells—termed *neurons*—which have long cablelike processes—termed *axons*—that convey electrical signals rapidly and faithfully from place to place in the body, even over long distances. In the squid, sensory neurons such as those in the eyes encode information about the squid's environment and convey signals to the brain. There, the signals are integrated into a decision to attack or retreat. The brain then sends commands to the mantle muscles, in part through a set of large neurons with large (“giant”), rapidly conducting axons.

As you will discover in this chapter, squid giant axons have played an important role in our understanding of neuronal functions. The diameter of these giant axons can be as large as 1 mm (1000 micrometers [μm]), and for more than half a century investigators have taken advantage of this prodigious cellular size to perform noteworthy experiments that have revealed the mechanisms of neuronal signaling. Sir Alan Hodgkin (1914–1998), who received the Nobel Prize in 1963 for his work on squid axons, recalled that a colleague had remarked (not, he thought, with the greatest tact) that it was the squid that really ought to be awarded the prize!

This chapter describes the electrical basis of neuronal function—the ability of neurons to generate electrical signals and propagate them over relatively large distances. The cellular mechanisms of neuronal signaling are similar in all animals, whether we examine neurons of squid, cockroaches, jellyfish, or humans. Before we turn to neuronal function, however, it is important to take a broader look at the challenges of integration and control. Doing so will clarify the range of physiological control processes and the contrasting functions of neuronal and hormonal modes of integration.

The Physiology of Control: Neurons and Endocrine Cells Compared

An animal needs to function like a coherent organism, not like a loose collection of cells and intracellular mechanisms. **Integration** is a general term that refers to processes—such as summation and coordination—that produce coherency and result in harmonious function. *Cellular integration* refers to processes within cells. *Whole-animal integration* refers to the selective combination and processing of sensory, endocrine, and central nervous system (CNS) information in ways that promote the harmonious functioning of the whole organism—including all its cells, tissues, and organs—within its environment. Just as some cells are specialized to produce movements, secrete acid, or carry oxygen, nerve cells and endocrine cells are spe-

Squid axons are important to physiologists—and to the squid

cialized for control and coordination. Whole-animal integration is carried out by the nerve and endocrine cells. The integrative functions carried out by those cells ensure that an animal's responses are smooth and coordinated, rather than clashing or disjointed.

Control systems, initially described in Boxes 1.1 and 10.2, occupy a central place in the achievement of integration. In the abstract, a **control system** is a system that sets the level of a particular variable (temperature, blood pressure, muscle force, and so on) that is being controlled. To do so, it uses information from sensors to determine signals it sends to effectors that can modify the controlled variable. Control systems often (but not always) operate on negative feedback principles (see Box 1.1) and are stabilizing: When the controlled variable deviates from a desired level, the control system activates effectors to reverse the deviation.

The nervous and endocrine systems are also often described as *control systems* because nerve cells and endocrine cells control the ways in which other cells function. This use of the concept of control systems is complementary to the use discussed in the previous paragraph. To see the relations, consider that control systems of the sort discussed in the previous paragraph are present in inanimate objects such as cars and computers, where the physical entities that implement control functions are made of materials such as copper and silicon. In animals, control functions are mostly carried out by nerve cells and endocrine cells.

The nervous system and the endocrine system work in systematically different ways to control and coordinate the cells of an animal. As shown in **Figure 12.1a**, a signal in a neuron travels electrically along a cell process all the way to its target cell; transmission along the cell process is very fast and spatially highly defined (a signal travels only along the cell process in which it was initiated). When the electrical signal arrives at the end of the neuron process, it causes the release of a chemical substance—a neurotransmitter—that diffuses quickly across the minute gap between the neuron process

FIGURE 12.1 Neuronal and hormonal signaling both convey information over long distances. Red dots are signaling molecules: neurotransmitter molecules in (a) and hormone molecules in (b). (a) Neurons have long axons that rapidly propagate action potentials, and also use short-distance chemical neurotransmitter signaling to communicate from cell to cell. (b) Endocrine cells release chemical hormones into circulatory fluids that carry the hormonal message over long distances to activate hormone receptors on other cells.

and the target cell. When this chemical substance arrives at the target cell, it binds (noncovalently) with specific receptor molecules on the cell, activating target-cell responses. In contrast, as shown in **Figure 12.1b**, when an endocrine cell emits a signal, it does so by secreting a chemical substance—termed a **hormone**—into the general blood circulation. The signal travels more slowly than a neuronal signal because it is carried by blood flow, but instead of being spatially highly circumscribed, the signal is transmitted to all cells in the body. The target cells—the cells that respond—are the subset of cells that have receptor proteins for the hormone in their cell membranes. In the ensuing paragraphs, we will discuss the broad features of neural and endocrine control at greater length. Then, in the remainder of this chapter and in Chapters 13–15, we will consider aspects of neural control in detail (neurons, synapses, sensory functions, and the organization of whole systems of neurons). We will discuss endocrine control in detail in Chapter 16.

Neurons transmit electrical signals to target cells

Because neurons are commonly likened to the wires in a telephone or computer network, most people have an intuitive understanding of what these cells do. A **neuron** is a cell that is specially adapted to generate an electrical signal—most often in the form of a brief, self-propagating impulse called an *action potential*—that travels from place to place in the cell. As **Figure 12.2** reveals, a neuron has four parts—dendrites, cell body, axon, and presynaptic terminals—that generally correspond to its four functions—input, integration, conduction, and output—as a controller cell within an animal's body.

A neuron receives input—signals from other neurons or sensory cells—at specialized cell–cell contact points called **synapses**. Usually, the synaptic input occurs along branching *processes* known as **dendrites**, although synapses may occur on the cell body as well. Impulses arriving at a synapse from a *presynaptic* cell cause the release of a chemical substance called a **neurotransmitter** into the synaptic cleft, or space between the cells. The chemical neurotransmitter exerts specific physiological effects on the postsynaptic cell by binding to neurotransmitter receptors. These changes can result in a new electrical impulse in the target neuron. Thus a synapse allows for transmission of information between neurons through conversion of a signal from electrical to chemical to electrical.

The **cell body** (also called the *soma*) is commonly the part of a neuron where signal integration and impulse generation occur. A single neuron may receive thousands of synaptic contacts from other neurons. The neurotransmitters released across some synapses excite the neuron; those released across other synapses inhibit it. From moment to moment, the cell membrane of the cell body combines the inhibitory and excitatory synaptic inputs, and if excitatory inputs surpass inhibitory inputs, the neuron may respond by generating one or more action potentials.

The long slender **axon** is the conduction component of a neuron, serving to propagate action potentials along its length. The axon typically arises from the soma via a conical **axon hillock**, which leads to the **axon initial segment**, a specialized area that is commonly the site of action potential initiation. The microscopic axons from individual neurons sometimes collect together in long macroscopically visible bundles that are called *tracts* in the CNS and *nerves* in the peripheral nervous system.

Where an axon ends, it usually divides into several **presynaptic terminals**, which constitute the places where neuronal output occurs.

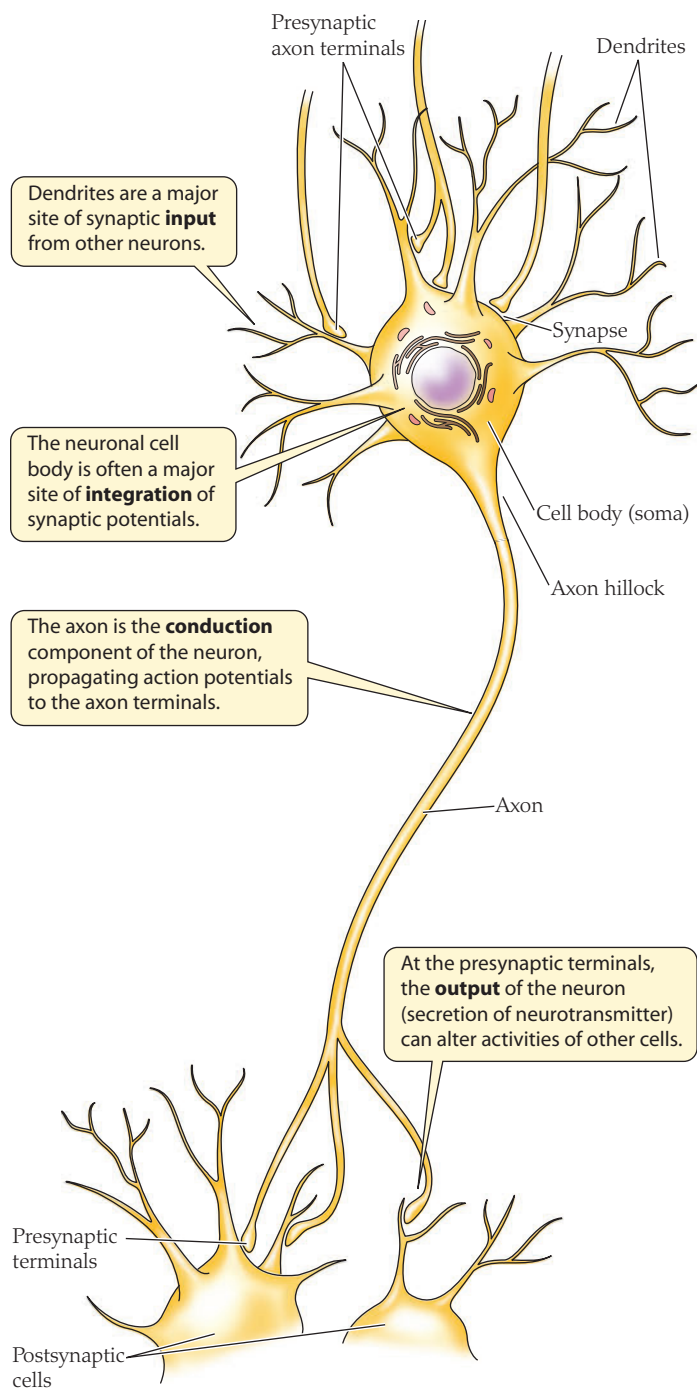

FIGURE 12.2 Neurons have four functional regions that typically correspond to their four major structural regions. The descriptions in the figure provide a functional model of a neuron, showing typical functional properties that it mediates. The labels identify the structural parts of a neuron that are associated with these functions. The correlation between structures and functional properties is imperfect: Synaptic input often occurs at the cell body as well as the dendrites, for example, and some dendrites can generate action potentials. In contrast, some local neurons generate no action potentials at all, and thus lack a separate function of active conduction.

The presynaptic terminals form synapses with other neurons or other types of cells, such as muscle fibers (muscle cells). An action potential arriving at the presynaptic terminals triggers the release of molecules of neurotransmitter across the synapses to exert a specific physiological effect—excitatory or inhibitory—on the target cell. Neurons that form synaptic endings on a cell are said to **innervate** that cell.

The extended networks of neurons in an animal's body (along with supporting cells, described later) constitute its *nervous system*. Neurons perform various roles in the nervous system. Some neurons perform sensory functions by initiating signals in response to physical or chemical stimuli. As we have just described, other neurons integrate signals arriving from other neurons, generate nerve impulses of their own, and transmit these signals over distances that can be very long, at least on a cellular scale. As we will discuss in Chapter 15, animals have a *central nervous system* (CNS) (brain and spinal cord in vertebrates) and a *peripheral nervous system*. Neurons that relay sensory signals to integrative centers of the CNS are called **afferent neurons** (*afferent*, “to bring toward”). Other neurons, called **efferent neurons** (*efferent*, “to carry off”), relay control signals (instructions) from the CNS to target cells that are under nervous control, such as muscle cells or secretory cells. Neurons that are entirely within the CNS are called **interneurons**.

Neural control has two essential features: It is fast and addressed. Neuronal signals are *fast* in that they travel very rapidly and begin and end abruptly. A mammalian neuronal axon, for example, might conduct impulses along its length at 20 to 100 meters per second (m/s), and it might be capable of transmitting 100 or more impulses in a second. The connections of neurons are said to be *addressed* because they provide highly discrete lines of communication (like a letter or a telephone call). A neuron normally must make synaptic contact with another cell to exert control, and it typically innervates multiple, but relatively few, cells that are its potential targets. Neuronal lines of communication therefore provide opportunities for fine control of other cells both *temporally* and *spatially*, sending fast, rapidly changing signals to some potential targets and not to others.

Endocrine cells broadcast hormones

In contrast to the signals of the neurons in nervous systems—which are precisely targeted—the signals produced by the *endocrine system* are broadly distributed throughout the animal's body. Endocrine cells release *hormones* into the blood (or sometimes just into other extracellular fluids). These chemicals are carried throughout the body by the blood, bathing the tissues and organs at large. For a hormone to elicit a specific response from a cell, the cell must possess *receptor proteins* for that hormone (see Chapter 2, page 58). Thus cells of only certain tissues or organs respond to a hormone and are called *target cells*. The responsiveness of target cells is under control of gene expression; that is, the tissues that respond to a hormone are tissues that express the genes encoding its receptor proteins.

Endocrine control has two essential features: It is slow and broadcast. Individual hormonal signals are relatively *slow* because they operate on much longer timescales than individual neuronal signals. Initiation of hormonal effects requires at least several seconds or minutes because a hormone, once released into the blood, must circulate to target tissues and diffuse to effective concentrations within the tissues before it can elicit responses. After a hormone has entered the blood, it may act on targets for a substantial amount of time before metabolic destruction and excretion decrease its concentration to ineffective levels. In the human bloodstream, for example, the hormones vasopressin, cortisol, and thyroxine display half-lives of about 15 minutes (min), 1 hour (h), and nearly 1 week, respectively. Thus a single release of hormone may have protracted effects on target tissues.

Unlike addressed neural control, endocrine control is said to be *broadcast*. Once a hormone is released into the blood, all cells in the body are potentially bathed by it. The specificity of hormone action depends on which cells have receptor molecules for the hormone. Many types of cells may respond to the hormone, perhaps with different types responding in different ways. Alternatively, a hormone may affect only one type of target cell, because only those target cells have the kind of receptor to which the hormone attaches. Although in principle hormones may exert either limited or widespread effects, in practice they commonly affect at least a whole tissue, and often multiple tissues.

Nervous systems and endocrine systems tend to control different processes

Neural lines of communication are capable of much finer control—both temporal and spatial—than is possible for endocrine systems. Not surprisingly, the two systems tend to be used to control different functions in the body. *Whereas the nervous system controls predominantly the fine, rapid movements of discrete muscles, the endocrine system typically controls more widespread, prolonged activities* such as metabolic changes.

Consider, for example, running to catch a fly ball in baseball. It requires rapid computation and very specific control of discrete muscles in split-second time, functions that can be mediated only by the nervous system. In contrast, the control of metabolism or growth requires the modulation of many tissues over a protracted period. In principle, an animal's nervous system *could* carry out a coordination task of this sort. To do so, however, the nervous system would need thousands of discrete axons between integrating centers and controlled cells, and would need to send trains of impulses along all these axons for as long as the modulation is required. In contrast, an endocrine gland can accomplish this task with greater economy, by secreting a single long-lasting chemical into the blood. For this reason, control of metabolism is often under primarily hormonal control, as are other processes (growth, development, reproductive cycles, etc.) that involve many tissues and occur on timescales of days, months, or years.

Most tissues in an animal's body are under dual control of the nervous and endocrine systems. Skeletal muscle illustrates the relationship of this dual control. A typical vertebrate muscle contains thousands of muscle cells (muscle fibers) and is innervated by more than 100 motor neurons. Each motor neuron innervates a separate set of muscle fibers, controlling the contraction of just these fibers. The nervous system can selectively activate a few, many, or all of the motor neurons, to rapidly and precisely control the amount of force the muscle generates. At the same time that the nervous system controls the contractile activity of the muscle cells, the hormone insulin provides endocrine control of their metabolic activity. Insulin facilitates the muscle fibers' uptake of glucose from the blood and their rate of glycogen synthesis. This example emphasizes the spatial and temporal distinctions between the two types of control: The nervous system controls moment-to-moment, differential contractile actions of the muscle cells in a muscle, whereas the endocrine system provides simultaneous long-term metabolic control of all the muscle cells en masse.

Nervous and endocrine systems can exert control over each other, as well as over other targets. *Interaction between the nervous and endocrine systems occurs in both directions.* Nervous systems can

affect the function of endocrine cells, as in innervated endocrine glands. Likewise, hormones can modulate nervous system function; for example, sex steroid hormones affect certain neurons in mammalian brains.

SUMMARY The Physiology of Control: Neurons and Endocrine Cells Compared

- Control by a nervous system involves neurons that send axons to discrete postsynaptic cells. Neurons generate rapidly conducting action potentials to control the specific targets on which they end. They exert fast, specific control by releasing neurotransmitters at synapses.
- Endocrine cells release hormones into the bloodstream to mediate endocrine control. All body cells are potential targets of a hormone, but only those with specific receptors for the hormone actually respond. Hormonal control is slower, longer lasting, and less specific than neural control.

Neurons Are Organized into Functional Circuits in Nervous Systems

The functions of a nervous system depend on “wiring”—the anatomical organization by which neurons are connected into circuits. Any behavioral activity (such as swimming, in the squid with which we opened the chapter) is a property of the neural circuit that mediates it. We will discuss nervous system organization in Chapter 15, but here we provide a simple illustrative example. Suppose you walk into the kitchen and surprise a cockroach. The cockroach jumps, exhibiting a *startle response* in which it turns away from the disturbance and prepares to run. This simple behavioral act is mediated by electrical signals and chemical synapses within the cockroach's nervous system.

The cockroach's jump is a **reflex**, a simple, stereotyped behavioral response to a distinct stimulus. Air currents or airborne sound waves vibrate filiform hairs that act as wind receptors at the cockroach's posterior end (**Figure 12.3, ①**), providing the stimulus that evokes the reflex. This stimulus initiates a brief series of action potentials in sensory neurons **②** located at the bases of the hairs. The action potentials travel along the conducting afferent processes (axons) of the sensory neurons toward the CNS, where the sensory neurons contact other neurons in the CNS. In the cockroach, the sensory axons make synaptic contacts with a few large *interneurons* (neurons that do not extend outside the CNS). These synapses are excitatory, so the barrage of action potentials from the sensory neurons excites the interneurons **③**, which generate their own action potentials.

The interneuron axons extend anteriorly in the ventral nerve cord (part of the CNS). They in turn make synaptic contact with efferent **motor neurons**, whose outgoing axons exit the CNS and innervate a muscle. The interneurons synaptically excite the motor neurons **④**, which in turn excite the extensor muscles of the legs **⑤** that produce the jump. At the same time, the interneurons inhibit motor neurons that excite the antagonist flexor muscles of the cockroach's legs.

As the barrage of action potentials in Figure 12.3 indicates, this startle response happens very quickly: It is less than 150 milliseconds (ms) from stimulus to jump! This rapid and selective activation of

FIGURE 12.3 The neural circuit mediating the startle response in the cockroach *Periplaneta americana* (a) Hairlike wind receptors located on an abdominal cercus trigger this reflex. (b) Nerve and muscle cells in the reflex circuit respond to a controlled puff of air lasting 50 ms. The action potentials in successive neurons in the circuit lead to contraction (tension) in the muscle of the leg. (After Camhi 1984.)

particular muscles to generate a behavioral response is the essential element of neural control.

The Cellular Organization of Neural Tissue

Nervous systems are composed primarily of neural tissue, which in turn is composed of discrete cells: neurons and glial cells (see page 300), as well as connective tissue cells and cells of the circulatory system. The cellular organization of nervous systems is a corollary of the **cell theory**, which states that organisms are composed of cells, that these cells are the structural and functional units of organization of the organism, and that all cells come from preexisting cells as a result of cell division. Matthias Schleiden (1804–1881) and Theodor Schwann (1810–1882) formulated the cell theory in 1839.

The cell theory gained widespread and rather rapid acceptance—except as applied to nervous systems. Instead, the dominant view of the organization of nervous systems in the latter half of the nineteenth century was the **reticular theory**, most strongly argued by Joseph von Gerlach (1820–1896) and Camillo Golgi (1843–1926). The reticular theory held that nervous systems were composed of complex, continuous meshworks of cells and processes in protoplasmic continuity with each other (i.e., the cells ran together without any boundaries).

The reticular theory was supplanted only gradually, over the first third of the twentieth century, by an outgrowth of the cell theory

known as the **neuron doctrine**, which states that neurons are anatomically distinct and are the structural, functional, and developmental units of organization of nervous systems. Santiago Ramón y Cajal (1852–1934), the main champion of the neuron doctrine, used special staining techniques to demonstrate convincingly that neurons are contiguous (in contact with each other) but are not continuous (connected without interruption). However, the debate on contiguity versus continuity persisted until the 1950s, when electron microscopy permitted resolution of cell membranes and rigorously demonstrated the discontinuity of neurons in contact.

Neurons are structurally adapted to transmit action potentials

Neurons, as seen earlier, are cells that are specialized for generating electrical impulses and transmitting those impulses from place to place within the body, sometimes over considerable distances. They have long processes, which relate to their functions—acting, for example, as the conduits for long-distance transmission. As you will recall, a neuron consists of a *cell body*, or *soma* (plural *somata*) (also called the *perikaryon*), which is the region that contains the nucleus, and one or more *processes* arising from it (Figure 12.4).

The cytology of a neuronal soma is broadly similar to that of nonneuronal cells. It contains a nucleus and most of the organelles and cytoskeletal elements familiar to cytologists: mitochondria, Golgi apparatus, smooth endoplasmic reticulum (ER), rough ER, microtubules, neurofilaments, and actin microfilaments. Neurons are very active in protein synthesis and thus have extensive, well-developed rough ER, aggregates of which can be stained to appear in light microscopy as *Nissl substance*.

Neurons can be classified according to the number of processes emanating from the soma. Neurons may be unipolar (having one process), bipolar (two processes), or multipolar (three or more processes). Unipolar neurons predominate in the CNS of most invertebrates, multipolar neurons predominate in the vertebrate CNS, and many sensory neurons are bipolar in various taxa. The neuronal processes themselves exhibit a bewildering geometric variety and complexity. Early anatomists attempted to bring order to this variety by classifying processes as *axons* and *dendrites*. Their classifications were usually based on vertebrate CNS neurons (see Figure 12.4) and are useful for cells resembling vertebrate central

neurons in form. Definitions of dendrites and axons, however, are based on a mixture of functional and morphological criteria that do not always coincide in a single neuron. Functionally (as we noted previously) a *dendrite* is considered to be a *receptive element* of a neuron that conveys information toward the soma (see Figure 12.2). An *axon*, by contrast, is the *output element* of a neuron, carrying information away from the cell body to other cells. This functional classification applies to most, but not all, neurons.

The dendrites of spinal motor neurons are relatively short and branch repeatedly (*dendrite* is Greek for “branch”). Dendrites of most neurons have continuously varying diameters and lack myelin sheaths (which we’ll discuss shortly). In general, the broader dendritic trunks resemble the soma in fine structure; they contain rough ER, mitochondria, microtubules, neurofilaments, and an occasional Golgi apparatus. Thinner dendritic branches may lack Golgi apparatus and rough ER. The dendrites of many vertebrate

neurons bear numerous short, thin protrusions termed *dendritic spines* that, when present, are important sites of synaptic input.

The axon of a neuron is classically single and long, with a relatively constant diameter and few collateral branches. The larger vertebrate axons are surrounded by **myelin** sheaths—multiple wrappings of insulating glial cell membranes (see below) that increase the speed of impulse transmission. Not all axons are myelinated; the smaller axons of vertebrate neurons and nearly all invertebrate axons lack myelin and are termed *unmyelinated*. At the fine structural level, axons contain microtubules, neurofilaments, elongated mitochondria, and sparse smooth endoplasmic reticulum (see Figure 12.4). Axons generally lack rough ER and Golgi apparatuses. Functionally, the axon is usually the portion of the neuron that supports action potentials, which *propagate* or conduct along the axon without decrement, carrying information away from the cell body to the axon terminals.

Glial cells support neurons physically and metabolically

Cells that are referred to collectively as **glial cells** or **neuroglia** (“nerve glue”) surround the neurons (Figure 12.5). Rudolf Virchow (1821–1902) discovered and named the neuroglial cells in 1846 and thought that their primary function was to bind the neurons together and maintain the form and structural organization of the nervous system. The ratio of glial cells to neurons increases with increasing evolutionary complexity, from brains of fish to mammals. Glial cells are estimated to make up half the volume of the mammalian brain and to outnumber neurons by ten to one. These measures suggest that glial cells are important in nervous system function, perhaps in ways that are not yet fully understood.

Different types of glial cells play diverse functional roles in nervous systems. Vertebrate nervous systems have two kinds of ensheathing glial cells, called **Schwann cells** (in the peripheral nervous system, or PNS) and **oligodendrocytes** (in the CNS). Ensheathing glia envelop the axons of neurons (see Figure 12.5). The glial sheath can be a simple encircling of an *unmyelinated* axon or a *myelin sheath* consisting of multiple concentrically wrapped layers of glial membrane that insulate the axon and increase the velocity of nerve-impulse propagation (discussed in detail later in this chapter). Other glial cells called **astrocytes** line

FIGURE 12.4 The cellular structure of neurons

Every neuron has a cell body (soma or perikaryon) and processes usually classified as axons and dendrites. The inset shows the structure of the very end of the axon, the axon terminal. The soma contains organelles, including rough endoplasmic reticulum (ER), Golgi apparatus (not shown), and mitochondria. Stained aggregates of rough ER appear in light microscopy as Nissl substance. Cytoskeletal elements—microtubules and neurofilaments (see inset)—are present in the soma, dendrites, and axon. The axon of this neuron is myelinated, with periodic thickenings of myelin insulation around its axons. (The importance of the myelin sheath for the rate of propagation of nerve impulses is discussed later in this chapter; see page 323.) The axon ends in terminals, where synaptic vesicles (see inset) store molecules of neurotransmitter for synaptic transmission.

FIGURE 12.5 Glial cells There are four types of glial cells in vertebrate nervous systems. Schwann cells ensheath axons (myelinated are shown; unmyelinated are not shown) in the peripheral nervous system. Oligodendrocytes ensheath axons in the CNS. Astrocytes are metabolic support cells in the CNS. Microglial cells are phagocytes related to cells of the immune system.

the outside surfaces of capillaries in the vertebrate CNS and act as metabolic intermediaries between the capillaries and neurons. Astrocytes take up neurotransmitters from extracellular space and help supply metabolic substrates to neurons. They also regulate extracellular ion concentrations and play important roles in nervous system development. *Microglial cells* mediate immune responses in neural tissue and may act as phagocytes, consuming pathogens and cell debris in brain injury.

SUMMARY The Cellular Organization of Neural Tissue

- Neurons are the principal cells of nervous systems. They have long processes (dendrites and axons) that are specialized to receive signals from other neurons (via dendrites) and to generate and propagate action potentials (via axons).
- Glial cells are the support cells of the nervous system. Schwann cells (in the PNS) and oligodendrocytes (in the CNS) form sheaths around neuronal axons, including insulating myelin sheaths around myelinated axons. Astrocytes surround capillaries and act as metabolic intermediaries between neurons and their circulatory supply. Microglial cells serve immune and scavenging functions.

The Ionic Basis of Membrane Potentials

What are the properties of the electrical signals of neurons, and how are these signals generated? Let's begin with a brief review of basic electrical concepts. Protons and electrons have *electrical charge*, and **ions** are atoms or molecules that bear a net charge because they have unequal numbers of protons and electrons. The net movement of charges constitutes an **electric current** (I), which is analogous to the hydraulic current of fluids flowing in a system of pipes. The separation of positive and negative electrical charges constitutes a **voltage**, or electrical *potential difference* (V). This potential difference can do work when charges are allowed to flow as current. Voltage is analogous to a height difference or head of pressure in a hydraulic system, allowing water to flow downhill.

Figure 12.6 shows a simple electrical circuit, that of a flashlight. A battery provides voltage; closing the switch allows current to flow through the electrical circuit. The electric current in the flashlight is the flow of free electrons along metal wires. Current flows through the lightbulb filament, which acts as **resistance** (R) that limits the current flow. Consequently, the filament heats and glows, emitting light.

Electrical circuits in cells are similar to the circuit in a flashlight, but they differ in some important ways. In cells, both the inside and outside media are *aqueous* solutions in which the electrical charges are ions rather than free electrons. Furthermore, all currents in cells are carried by ions, and any voltage or potential difference results from local imbalances of ion charges. Recall from Chapter 5 (see Figure 5.4) that fluids farther than a few nanometers from a membrane are electrically neutral, with equal numbers of positive and negative charges.

Because of this *charge neutrality of bulk solutions*, the only portion of a cell that *directly* determines its electrical properties is its outer-limiting cell membrane. Any electrical activity of a nerve cell is a property of the cell membrane, and the electrical potentials observed are called *transmembrane* potentials. The only immediately important attribute of the rest of the cell is the concentration of ions in solution in the intracellular fluid.

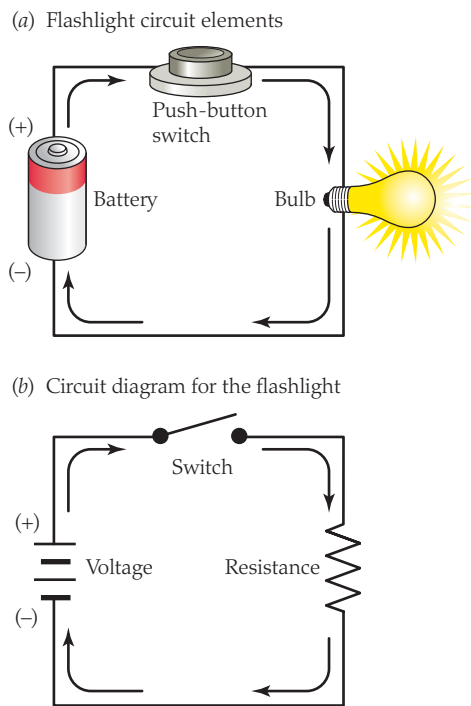

FIGURE 12.6 The simple electrical circuit of a flashlight (a) Elements of the electrical circuit. (b) Circuit diagram. When the switch is closed, electric current flows through the resistance of the lightbulb filament, causing it to glow. Current must flow through the complete circuit. (Note that, by convention, current always flows from plus to minus.)

Cell membranes have passive electrical properties: Resistance and capacitance

All cells respond to electric currents, but not all cells generate action potentials (nerve impulses). The universal responses are *passive* responses (meaning that the cell's electrical properties do not change), but action potentials are active responses in which the properties do change. A cell's passive responses depend on the **passive electrical properties** of the membrane, principally its resistance and capacitance. A membrane exhibits *resistance* (measured in ohms, Ω) resulting from the fact that ions must flow through restrictive ion channels because the membrane's lipid bilayer is impermeable to ions. A membrane exhibits **capacitance** (measured in farads, F) because of the insulating properties of the bilayer. In electrical circuits, a capacitor has two conducting plates separated by an insulating layer; in cells, the conducting fluids on either side of the membrane act as plates, and the lipid bilayer separates and stores oppositely charged ions.

The resistance and capacitance of a cell's membrane depend on membrane area; specific membrane resistance and capacitance are measured per unit of area (e.g., $R_m = 1000 \Omega \times \text{cm}^2$; $C_m = 1 \mu\text{F}/\text{cm}^2$).¹ Whereas the specific membrane capacitance does not change, resistance may or may not change (depending on the behavior of specific populations of ion channels). *When we speak of a cell's passive electrical properties, we mean those conditions in which membrane resistance does not change.* A cell's passive electrical properties govern how voltages change over space and time along neuronal axons. Passive electrical properties do not explain the generation of action potentials (in which

¹The resistance of a whole cell's membrane is usually called its *input resistance*.

FIGURE 12.7 Recording the resting membrane potential of a squid giant axon A section of the squid axon is removed and its ends ligated to seal the axon segment. (a) A voltmeter measures the potential difference between a glass capillary microelectrode (the recording electrode) and a reference electrode in the saline bath around the axon. When the microelectrode is outside the axon, there is no potential difference between the two electrodes. (b) The recording microelectrode has been advanced through the axon membrane, and the resting membrane potential (V_m) is recorded. (c) The output of the voltmeter, recorded on a chart writer or an oscilloscope, demonstrates that the resting membrane potential is inside-negative, a condition true for all cells. (By convention, negative is down for intracellular recording.)

resistances change), but they are important for understanding how neurons generate and propagate action potentials.

We can use a squid giant axon to demonstrate the passive electrical properties of cells. The largest axons of a common squid may be 2 cm long and 700 to 1000 μm in diameter. Because these axons are so large, it is relatively easy to cut out a length of the axon, ligate the ends, and penetrate the isolated axon with a microelectrode (Figure 12.7).

The microelectrode consists of a glass capillary that has been heated and pulled to a fine tip ($<1\ \mu\text{m}$ in diameter) so that it can penetrate the cell membrane without causing damage. The capillary is filled with a solution of strong electrolyte, such as $3\ \text{M}\ \text{KCl}$, to minimize its electrical resistance.

When the tip of the microelectrode is outside the axon (see Figure 12.7a), a voltmeter records no potential difference (voltage) between the recording microelectrode and a neutral (reference) electrode suspended in the surrounding saline bath. Both electrodes are electrically neutral because of the charge neutrality of bulk solutions.

When the recording microelectrode is advanced just past the axon membrane into the cytoplasm (see Figure 12.7b), the voltmeter records a potential difference (see Figure 12.7c). This potential difference across the axon membrane is the **resting membrane potential** (V_m). For all known cells, the polarity of the resting membrane potential is *inside-negative*; that is, the inner membrane surface is negative with respect to the outer membrane surface.² This example also reveals the axon's **membrane resistance** (R_m) to current flow, because without such resistance, ions would freely diffuse across the membrane, and it would not be able to maintain a potential difference.

What would happen to the resting membrane potential if we inserted a second microelectrode into the squid axon and generated a pulse of electric current between it and an extracellular electrode (Figure 12.8)? The current pulse would either depolarize or hyperpolarize the membrane, depending on the direction of the current. **Depolarization** is a *decrease* in the absolute value of the membrane potential toward zero (becoming less negative inside the cell). **Hyperpolarization** is an *increase* in the absolute value of the membrane potential away from zero (becoming more negative inside the cell).

In the example of Figure 12.8, we apply a current that flows outward across the membrane to cause a depolarization of the membrane potential, perhaps from -65 to $-55\ \text{mV}$. (Remember that we are not considering action potentials yet, so assume that this depolarization is too small to trigger an action potential.) According to **Ohm's law**, the current should change the membrane potential by an amount proportional to the resistance to current flow:

$$\Delta V = IR \quad (12.1)$$

where ΔV is the change in potential (termed a **graded potential**), I is the current (in amperes), and R is the resistance (in ohms). If the membrane exhibited only resistance, the change in membrane potential would occur instantaneously, as shown by the "theoretical" line in Figure 12.8b. However, the actual change in membrane potential occurs more gradually, reaching a plateau after a short delay, as shown by the "observed" line in Figure 12.8b.

²By convention, the membrane potential is given as the inside value, with the outside considered zero.

FIGURE 12.8 Changes in the membrane potential: the membrane time constant
 (a) Here a second current microelectrode is advanced into the squid axon shown in Figure 12.7. (b) The redistribution of charges during the current pulse (I) occurs more slowly than would be expected if the membrane acted as a pure resistance (dashed line), indicating that the membrane also has capacitive properties (see inset in [a]). (c) A neuronal membrane exhibits resistance (R) and capacitance (C) in parallel. The membrane **time constant** (τ) is the time it takes for membrane potential to reach 0.63 of its final value. In many neurons, τ is 2 to 20 ms.

(a) A current pulse changes membrane potential

(b) Time course of voltage and current changes

The time constant τ is the time required for the observed ΔV to reach 0.63 of the asymptote (maximum ΔV).

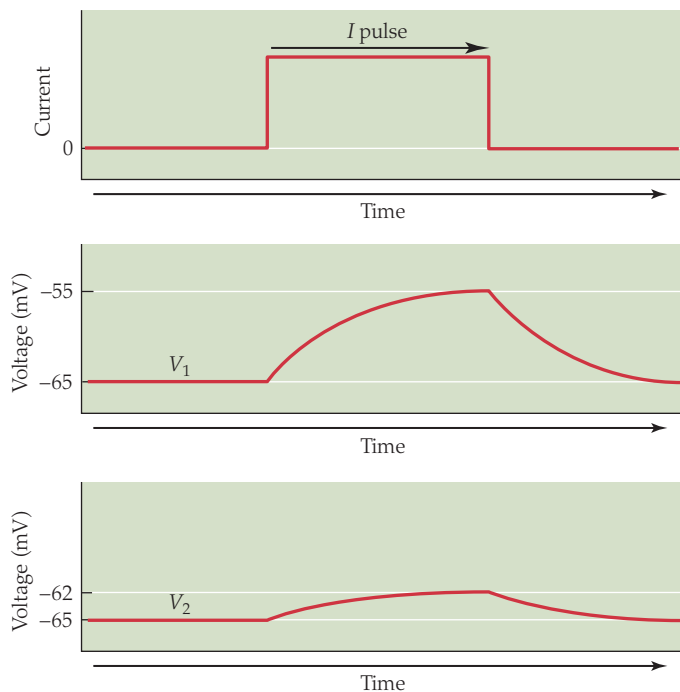

(c) Membrane resistance and capacitance

(a) Recording the spread of a potential

(b) Passive potentials spread decrementally

(c) The membrane length constant describes the exponential decrement

Because most of the current flows through shorter paths of lower resistance, less and less current is available to change the membrane potential at greater distances from the source.

PASSIVE ELECTRICAL PROPERTIES RETARD MEMBRANE VOLTAGE CHANGES The delay in depolarizing (or hyperpolarizing) a cell membrane occurs because the membrane behaves electrically like a resistor and a capacitor in parallel (see Figure 12.8c). On the one hand, the lipid bilayer of a cell membrane behaves like a *capacitor*: The bilayer blocks the exchange of ions between the extracellular fluid and the intracellular fluid, and its insulative properties enable oppositely charged ions to accumulate along the inner and outer surfaces of the membrane. On the other hand, the membrane-spanning ion channels behave like *resistors*: They allow ions to flow across the membrane at a rate governed by the structure of the channels and the potential difference between the inside and outside of the membrane. Current first redistributes the charges on the membrane capacitance (capacitive current) and then flows through the membrane resistance (resistive or ionic current). This redistribution of charges slows (retards) the change in voltage on the membrane, by a factor that increases if the resistance or capacitance is increased.³

The exponential time course of the voltage change shown in Figure 12.8b is described by the **time constant**, τ (tau), the time it takes the voltage change to reach 63% of its final value. The time constant of a cell depends on the resistance and capacitance of its membrane:

$$\tau = RC \tag{12.2}$$

where R is the cell's resistance (input resistance) and C is capacitance. For many cells, τ is in the range of 2 to 20 ms.

PASSIVE ELECTRICAL PROPERTIES LIMIT THE SPREAD OF GRADED POTENTIALS How does a change in voltage spread over *distance* in a membrane? (Remember that we are considering only the *passive* electrical properties of a membrane.) Suppose we insert yet another electrode into the squid axon, this one farther away from the other two (Figure 12.9a). The V_2 electrode will record a smaller voltage displacement in response to a current pulse than the nearer V_1 electrode (Figure 12.9b). The voltage change (ΔV) will decrease exponentially with distance from the source producing

³To understand this, it is helpful to realize that *capacitance* (expressed in farads) is the amount of charge stored per unit of voltage ($C = Q/V$). The greater the capacitance, the more ions the membrane can separate and store for a given potential difference, and therefore the more time it takes for ions to be redistributed in response to a pulse in current.

FIGURE 12.9 Graded potentials decrease exponentially with distance The amplitude of a voltage change decreases with distance along the axon. (a) A third electrode (V_2) is added to the setup diagrammed in Figure 12.8 and is used to measure the potential change at some distance from the source of current (I). (b) The voltage change measured at V_2 is smaller than that at V_1 , which is closer to the source of current. This decremental spread of graded potentials is referred to as *electrotonic conduction*. (c) The decrement in voltage change is exponential with distance from I . Arrows show the local paths of current flow that depolarize the membrane. (Capacitances are ignored.) The membrane *length constant* (λ) describes the exponential decay of a change in voltage (ΔV) with distance.

it, a property called **passive spread (decremental spread)** or **electrotonic conduction**. The steepness of this decrease with distance is described by the membrane **length constant**, λ (lambda), which represents the distance at which the decaying voltage change (ΔV_m) is 37% of its value at the origin (Figure 12.9c).

The reason for this decrease with distance is that as current flows along the inside of the axon, some of it leaks out through ion channels. For simplicity we ignore the slowing effects of membrane capacitance, and we lump the resistive pathways as R_m (the resistance to current flow out across the membrane ion channels in a segment) and R_i (the resistance to current continuing down the axon to the next segment). An axon (or dendrite) with a high R_m value and a low R_i value will have a large λ value. We will consider the membrane length constant again later, when we discuss action-potential propagation.

The electrical properties of membrane resistance (R_m), membrane capacitance (C_m), and resting membrane potential (V_m), and the related time constant (τ) and length constant (λ), adequately describe the passive electrical properties of a neuron or any other cell. Because the passive electrical properties of axons are similar to those of underwater telephone cables, these passive electrical properties are often called *cable properties*. For the same reason, the equations describing the length constant and time constant of neuronal membranes are called *cable equations*.

Resting membrane potentials depend on selective permeability to ions: The Nernst equation

Our model of the passive electrical properties of cells describes the inside-negative resting membrane potential maintained by all living cells. A cell membrane's permeability to different kinds of ions is the mechanism that establishes and maintains this voltage. Dissolved ions have charges and attract polar water molecules around them. The charged ions cannot mix with the nonpolar tails of the lipid molecules in the center of the membrane bilayer, so the ions cannot pass through the bilayer (see Chapter 5). Instead, ions must pass (if they pass at all) by way of the protein ion channels that span the bilayer. There are many kinds of ion channels, each kind *selectively permeable* to specific ions. Moreover, some ion channels can open and close, which means that *membrane permeability to specific ions is a controlled condition*.

How does a membrane's selective permeability to ions produce a membrane potential? Consider a simplified cell (Figure 12.10) that contains a solution of potassium ions (K^+) and nonpermeating anions (represented by A^-), such as charged proteins. (The identity of A^- is unimportant; all we're concerned with is its charge.) The cell is in a bath of two nonpermeating ions (Na^+ and A^-); we stipulate that the cell membrane is permeable only to K^+ . When the cell is placed in the bath, K^+ tends to diffuse out of the cell, down its concentration gradient. Because charge neutrality is always maintained in bulk solution, A^- would tend to follow the K^+ across the membrane; however, the membrane is not permeable to A^- . Therefore, A^- tends to accumulate at the inner surface of the membrane, while K^+ tends to accumulate at the outer surface (because of charge attraction). Thus a net charge separation develops, but only at the membrane.

The net negative charge on the inner surface of the membrane and net positive charge outside tend to move K^+ ions back into the cell, by forces of charge attraction and repulsion. Eventually this system reaches *electrochemical equilibrium* (see Chapter 5, page

FIGURE 12.10 Selective permeability of a membrane gives rise to a membrane potential A simplified, theoretical cell containing a solution of K^+ and A^- is bathed by a solution of Na^+ and A^- . The cell membrane is permeable only to K^+ . At the membrane, K^+ ions tend to diffuse out, down their concentration gradient. A^- ions attempt to follow (to maintain charge neutrality), but the membrane is not permeable to them, so they cannot pass through it. The resulting charge separation produces a membrane potential.

105), in which there is no *net* movement of ions and no work is done. In Figure 12.10, equilibrium is reached when the tendency for K^+ ions to diffuse out of the cell (down the concentration gradient) is exactly balanced by their tendency to move in (down the electrical gradient of the membrane potential). That is, when the concentration–diffusion force just equals the opposing electrical force, there is no *net* flow of K^+ ions. *For this system to come to equilibrium, there must be an electrical force (i.e., a membrane potential) across the membrane.* This simple example shows that any cell that has a transmembrane concentration difference of a permeating ion tends to generate a membrane potential. It is a good starting point for visualizing a cell's resting potential because cells at rest are more permeable to K^+ than to other ions.

It is important to grasp that the resting membrane potential results from relatively few ion charges sitting on the membrane, and to remember as well that the charge separation producing the membrane potential is an extraordinarily local phenomenon. Charge neutrality always prevails in the bulk solutions that make up the intracellular and extracellular fluids. For example, there are approximately 110,000 cations and 110,000 anions in a $1\ \mu\text{m} \times 1\ \mu\text{m} \times 0.001\ \mu\text{m}$ “slice” of the fluid compartments on either side of the cell membrane of a mammalian muscle fiber (Figure 12.11). Of these portions, approximately six pairs of ions sit along the $1\ \mu\text{m} \times 0.001\ \mu\text{m}$ area of membrane, and these six pairs are responsible for the charge imbalance that amounts to a robust -90-mV resting membrane potential! Thus the movement of only a few ions in a region can establish (or change) a membrane potential without disrupting the overall charge neutrality of the intracellular and extracellular fluids.

FIGURE 12.11 The membrane potential results from relatively few charges sitting on the membrane. A small patch of membrane ($1 \mu\text{m} \times 0.001 \mu\text{m}$ in area) from a mammalian muscle fiber, with a small volume ($1 \mu\text{m} \times 1 \mu\text{m} \times 0.001 \mu\text{m}$) of adjacent cytoplasm and extracellular fluid. As in Figure 12.10, assume that the membrane is most permeable to K^+ . Of the 110,000 cations and 110,000 anions in each fluid compartment, only *six* pairs of ions need to sit on the membrane and charge its capacitance to produce a membrane potential of -90 mV . (After Schmidt 1985.)

Although living cells are not at electrochemical equilibrium, we can describe the contribution of a permeating ion species to membrane potential by asking how large the membrane potential *would be* at equilibrium. The relation between the concentration difference of a permeating ion across a membrane and the membrane potential at equilibrium is given by the **Nernst equation**:

$$E = \frac{RT}{zF} \ln \frac{C_{\text{out}}}{C_{\text{in}}} \quad (12.3)$$

in which E is the membrane potential (E stands for *electromotive force*, an older term for voltage), R is the gas constant, T is absolute temperature, z is the valence of the ion species (charge for the kind of ion), F is Faraday's constant (charge per mole of ions), and C_{out} and C_{in} are the ion concentrations on the two sides of the membrane. Notice that *the larger the concentration difference across the membrane, the larger the membrane potential* at which the ion species is in equilibrium. The reason for this relation is that increasing the concentration difference increases the concentration gradient of the ion species and thus increases the electrical force necessary to oppose it.

We can simplify the Nernst equation by calculating R/F , converting to \log_{10} , and considering an ion of a given valence at a given temperature. For K^+ , a monovalent cation, at 18°C (British room temperature),

$$E(\text{in mV}) = 58 \log_{10} \frac{C_{\text{out}}}{C_{\text{in}}} \quad (12.4)$$

For a mammal at 37°C ,

$$E(\text{in mV}) = 61 \log_{10} \frac{C_{\text{out}}}{C_{\text{in}}} \quad (12.5)$$

Thus, for our simplified cell permeable only to K^+ , if the internal K^+ concentration is, say, 100 mM and the external concentration

is 10 mM , at 18°C , $E = 58 \log_{10} (0.1) = -58 \text{ mV}$. (By convention, the minus sign means that the inside of the membrane is negative relative to the outside.)

The value of -58 mV is the **equilibrium potential** for potassium (E_K) in our system as we have defined it—that is, the value of the membrane potential at which K^+ ions are at electrochemical equilibrium and the internal K^+ concentration is ten times the external concentration. In other words, the electrical force holding K^+ inside the cell is just balanced by the chemical (concentration) force for K^+ diffusion out of the cell. There is an equilibrium potential for each ion species (E_{Na^+} , E_{Cl^-} , etc.).

The Nernst equation relates membrane potential to the concentration ratio of only one ion species. For this and other reasons, the generation of membrane potentials in real cells is considerably more complex than in this simplified model.

Ion concentration differences result from active ion transport and from passive diffusion

All cells maintain higher concentrations of potassium and lower concentrations of sodium and chloride in the intracellular fluids than are present in the surrounding extracellular fluid (Figure 12.12a). The concentrations of these ions differ from organism to organism, as shown in Table 12.1. Despite quantitative differences, the *concentration ratios* of ions in all cells are similar to those represented in the table. The difference in ion concentrations between the intracellular and extracellular fluids results from a combination of two processes: (1) the active transport of some ions and (2) the passive distribution of other ions.

Examine Figure 12.12a and consider the Nernst equation. It is impossible for both Na^+ and K^+ ions to be in passive equilibrium, because the ratios of their concentrations differ. Whereas K^+ would require an inside-negative membrane potential to be in equilibrium, Na^+ would require an inside-positive potential (to counteract inward Na^+ diffusion). In fact, *neither* ion species is in passive equilibrium in cells, because both ions are maintained at nonequilibrium levels by *pumps*—that is, by active ion transport that requires the input of energy from hydrolysis of ATP.

The most important pump is the $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ pump (see Chapter 5, page 110), which actively transports Na^+ out of the cell and K^+ into it. For most cells, Na^+ ions slowly leak into the cell and K^+ ions slowly leak out. (The channels through which these leaks occur are normally open and are called *leakage channels*.) The $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ pump counteracts these leaks, using ATP energy to pump Na^+ out as fast as it leaks in, and to pump K^+ in as fast as it leaks out (Figure 12.12b). The function of the $\text{Na}^+ - \text{K}^+ - \text{ATPase}$ pump is analogous to a bilge pump in a boat, bailing water out as fast as it leaks in. Another good analogy for the pump is a battery charger, which can work in the background to prevent the “batteries” of Na^+ and K^+ concentration distributions from running down. For known $\text{Na}^+ - \text{K}^+$ exchange pumps, the ratio of Na^+ and K^+ pumped is 3:2. (We will consider a secondary consequence of the 3:2 ratio shortly.)

However, a permeating ion species may have very different concentrations inside and outside a cell *without* being pumped. Consider the Cl^- ions in Figure 12.12a. Because cells have large intracellular concentrations of nonpermeating anions, permeating ions such as Cl^- must become distributed unequally across the membrane. The A^- ions that limit the tendency of K^+ ions to diffuse out of the cell (see Figure 12.10) also limit the tendency of Cl^- ions

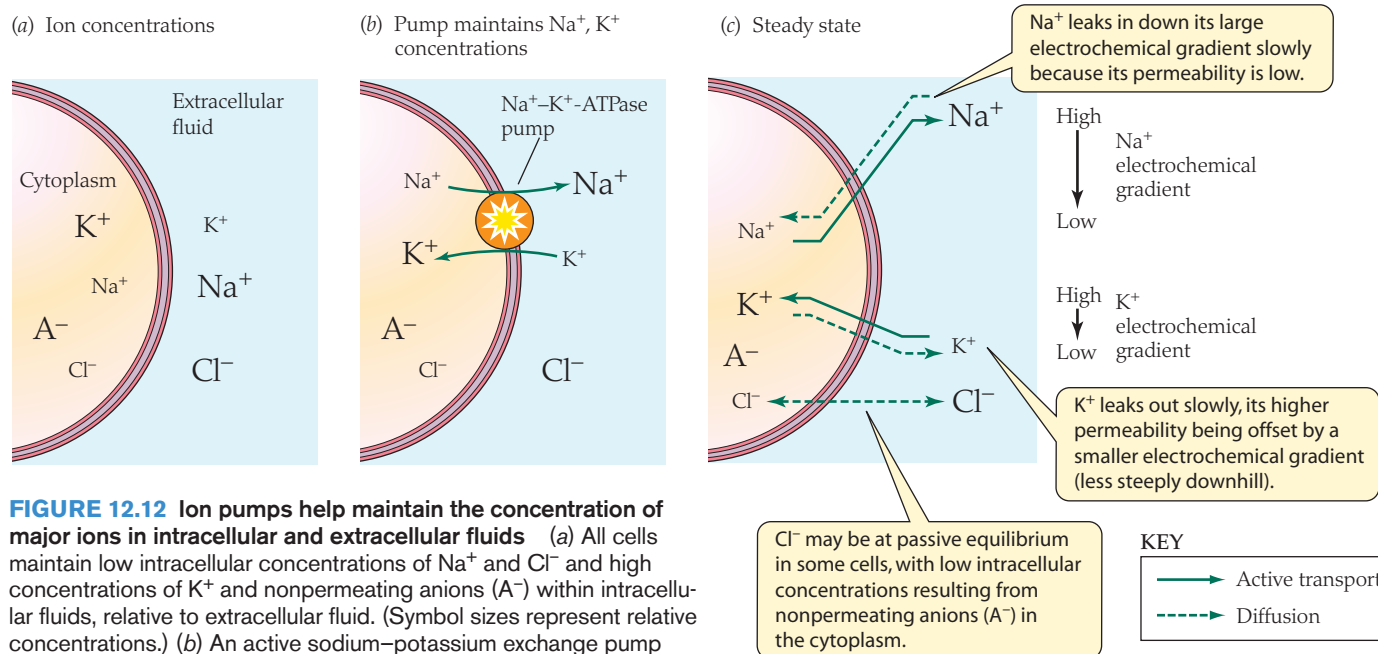

FIGURE 12.12 Ion pumps help maintain the concentration of major ions in intracellular and extracellular fluids (a) All cells maintain low intracellular concentrations of Na^+ and Cl^- and high concentrations of K^+ and nonpermeating anions (A^-) within intracellular fluids, relative to extracellular fluid. (Symbol sizes represent relative concentrations.) (b) An active sodium–potassium exchange pump transports Na^+ out and K^+ in, counteracting the tendency of Na^+ to diffuse in and K^+ to diffuse out. (c) Here the Na^+ and K^+ concentrations are maintained in a steady state across the membrane. The slow, passive leaks of Na^+ and K^+ (dashed arrows) are counteracted by active transport by the Na^+ – K^+ exchange pump (solid arrows). Chloride, in contrast, can be at passive equilibrium in some cells.

to diffuse in. As described by the Nernst equation, the membrane potential counteracts the tendency of Cl^- ions to diffuse from their high extracellular concentration to the lower intracellular concentration (see Figure 12.12c). In many cells, Cl^- ions are in passive equilibrium despite strikingly unequal concentrations inside and outside the cell. This equilibrium, sometimes called a *Donnan equilibrium* or *Gibbs–Donnan equilibrium*, explains how nonpermeating anions inside the cell can lead to unequal concentrations across the membrane of permeating ions such as Cl^- .

Donnan-type phenomena are one way in which inequalities of ions such as Cl^- are maintained in living cells. The nonpermeating anions (A^-) in cells are a mixture of relatively small organic anions such as amino acids, along with proteins and other large molecules that bear net negative charges. Chloride ions appear to be passively distributed across the membranes of many cells, even though the ratio of outside to inside Cl^- concentrations may be quite large, as it is, for example, in mammalian muscle (see Table

12.1). Neurons of the vertebrate CNS, however, actively transport Cl^- out, so the ratio of $[Cl^-]_{out}$ to $[Cl^-]_{in}$ is larger than that predicted by Donnan equilibrium, and E_{Cl} is more negative than V_m .

Now we are in a position to explain ion concentration distributions of living cells. Neither Na^+ nor K^+ is at equilibrium in Figure 12.12, so passive diffusion alone produces net movement of Na^+ and K^+ . (This disequilibrium results from the pump having changed Na^+ and K^+ concentrations from their equilibrium levels.) Na^+ especially is far out of equilibrium because both the concentration–diffusion gradient and the electrical gradient of the inside-negative membrane potential drive Na^+ inward. Because the membrane is only slightly permeable to Na^+ at rest, Na^+ enters only slowly and is pumped out as fast as it diffuses in. K^+ is closer to equilibrium but not at it. The cell loses K^+ passively at a slow rate because although permeability to K^+ is large, the driving force for K^+ flow ($V_m - E_K$) is small. The slow passive loss of K^+ is also counteracted by the sodium–potassium exchange pump. Thus the cation concentrations are maintained in a *steady state* in which passive-transport leaks are counteracted by active-transport pumps. Metabolic energy is required to maintain ions at concentrations different from the concentrations at equilibrium.

Figure 12.12c summarizes the roles of active and passive transport in maintaining the steady-state concentrations of Na^+ and K^+ ions in intracellular and extracellular fluids: Passive leaks of Na^+ into the cell and of K^+ out of the cell are counteracted by active ion transport. Chloride ions are passively distributed in this cell. The balance of active and passive transport that controls concentrations of different ions is important because, as we will see, the steady-state concentrations of K^+ , Na^+ , and Cl^- ions all contribute to membrane potentials in animal cells.

TABLE 12.1 Concentrations of major ions in intracellular fluid (cytoplasm) and extracellular fluid

Ion type	Squid axon			Mammalian muscle		
	Out (mM)	In (mM)	Out/In	Out (mM)	In (mM)	Out/In
Na^+	440	50	8.8	145	12	12.1
K^+	20	400	0.05	4	155	0.03
Cl^-	560	60	9.3	120	3.8	31.6
A^- (organic anions)	—	270	—	—	—	—

Membrane potentials depend on the permeabilities to and concentration gradients of several ion species: The Goldman equation

The ion concentrations of living cells are in a steady state in which the ions are unequally distributed across the cell membrane and many are out of equilibrium. *The resting membrane potential is largely determined by K^+ concentrations because the cell membrane is more permeable to K^+ than to other ions.* If the membrane were permeable only to K^+ , then the membrane potential would be exactly equal to the K^+ equilibrium potential (i.e., $V_m = E_K$), as predicted by the Nernst equation employing the K^+ concentrations across the membrane. Because the membrane is somewhat permeable to other ions, however, they also contribute to the membrane potential.

The contribution of each ion is weighted by its ability to permeate the membrane, with the more-permeating ions having more effect. The value of the membrane potential (V_m) produced by the contributions of several permeating ion species can be determined by the **Goldman equation**:

$$V_m = \frac{RT}{F} \ln \frac{P_K [K^+]_o + P_{Na} [Na^+]_o + P_{Cl} [Cl^-]_i}{P_K [K^+]_i + P_{Na} [Na^+]_i + P_{Cl} [Cl^-]_o} \quad (12.6)$$

in which P_K , P_{Na} , and P_{Cl} are relative permeability values for potassium, sodium, and chloride ions, respectively. (The chloride term in the equation is inverted to reflect its negative charge.) In principle, it is necessary to add a term in the Goldman equation for every permeating ion species, but in practice it is necessary to include terms only for Na^+ , K^+ , and Cl^- . The contributions of other ion species can be neglected, by reason of either low permeability of the membrane to those ions (e.g., HCO_3^-) or low concentrations of those ions (e.g., $[H^+] = 10^{-7} M$).⁴

In fact, for some purposes it is useful to consider sodium and potassium only, ignoring chloride. In such a simplification of the Goldman equation (Figure 12.13), we can view the membrane potential as a result of the membrane's relative permeabilities to sodium and potassium ions, visualized with a sliding voltage scale, rather like a thermometer but in units of voltage. Consider a squid axon with the following ion concentrations:

$$\begin{aligned} [K^+]_{out} &= 20 \text{ mM} & [Na^+]_{out} &= 440 \text{ mM} \\ [K^+]_{in} &= 400 \text{ mM} & [Na^+]_{in} &= 44 \text{ mM} \\ [K^+]_{out} : [K^+]_{in} &= 0.05 & [Na^+]_{out} : [Na^+]_{in} &= 10 \\ E_K &= 58 \log 0.05 = -75 \text{ mV (inside-negative)} \\ E_{Na} &= 58 \log 10 = +58 \text{ mV (inside-positive)} \end{aligned}$$

If the cell were permeable only to K^+ , then V_m would equal E_K , or -75 mV ; and if it were permeable only to Na^+ , then V_m would equal E_{Na} , or $+58 \text{ mV}$. The actual membrane potential can be anywhere between these values and is governed by the ratio of membrane permeabilities to Na^+ and K^+ . The “voltage thermometer” shows that

FIGURE 12.13 The Goldman equation and the “voltage thermometer” A simplified Goldman equation describes membrane potential in terms of relative permeabilities (P) of the membrane to K^+ and Na^+ . The voltage scale graphs the membrane potential determined by these permeabilities. For the resting membrane, $P_K \gg P_{Na}$, so E_m is close to E_K . If P_{Na} increases to become greater than P_K , E_m will approach E_{Na} . Each arrow relates the dominant term in the equation to the value of E_m toward which it drives the membrane.

when permeability to potassium is much greater than permeability to sodium, the membrane potential approaches E_K (see Figure 12.13):

$$\text{If } P_K = 10 \times P_{Na}$$

$$\text{then } V_m = 58 \log_{10} \frac{10[20] + 1[440]}{10[400] + 1[44]} = 58 \log (644/4044) = -46.3 \text{ mV}$$

In contrast, when permeability to sodium is much higher than permeability to potassium, the membrane potential approaches E_{Na} . This visualization of membrane potential in terms of the Goldman equation will be important for our consideration of action potentials later in this chapter.

Electrogenic pumps also have a small direct effect on V_m

Our explanation to this point of the generation of membrane potentials has been termed the ionic hypothesis. The **ionic hypothesis** argues that the concentrations of ions inside and outside a cell are maintained in a *steady state* by a mixture of active-transport processes (ATPase pumps) and passive-transport processes (diffusion and Donnan effects). The ionic hypothesis further asserts that the concentrations of ions inside and outside the cell, and the permeability of the cell membrane to these ions, determine the resting membrane potential (V_m) as described by the Goldman equation. The ionic hypothesis is substantially accurate, and provides a useful description of the factors giving rise to membrane potentials in living cells. A more complete explanation of the causes of membrane potentials, however, must include the fact that some ion pumps are electrogenic.

There are two kinds of active ion-transport mechanisms: electroneutral pumps and electrogenic pumps. An **electroneutral pump** transports equal quantities of charge inward and outward across a membrane and thus changes ion concentrations without generating an electric current. An **electrogenic pump** transports unequal quantities of charges inward and outward across the membrane. As noted already, the Na^+K^+ exchange pump has a 3:2 ratio, transporting 3 Na^+ ions out for each 2 K^+ ions transported into the cell.

Any ion pump that is not 1:1 generates a net current (net movement of charge) across the membrane. This current, acting across the cell's membrane resistance, directly generates a potential, via Ohm's law. The potential resulting from pump current changes V_m from the value predicted by the Goldman equation. Thus an

⁴Strictly speaking, the ion concentration values in the Nernst equation and the Goldman equation should be those for *free* (unbound) ions rather than total concentrations. The **activity** of an ion is the concentration of the ion in its dissociated, freely diffusible form. Monovalent ions dissociate relatively completely in cytoplasm and extracellular fluids, so not much correction is needed for ion activities. Divalent ions such as Ca^{2+} , however, are predominantly bound in cytoplasm, so corrections for their activity are important.

electrogenic pump has two functional properties: It changes concentrations to offset passive leaks (its major function), and it alters V_m directly via the pump current (a smaller, secondary function).

The 3:2 sodium–potassium pump generates an outward ionic current (outward movement of positive charge) that hyperpolarizes the cell to a level more inside-negative than is predicted by the Goldman equation. Because sodium–potassium exchange pumps can be selectively poisoned with toxins such as *ouabain*, their electrogenic contribution to resting membrane potentials can be measured as the initial change in V_m before concentrations change. (Inactivation of the pump will also [more slowly] lead to changes in ion concentrations, and thus have an additional, indirect effect on membrane potential.) In many neurons the direct contribution of an electrogenic pump accounts for only a few millivolts of the resting membrane potential, although electrogenicity can make a larger contribution in small axons and in some invertebrate neurons.

SUMMARY The Ionic Basis of Membrane Potentials

- Cell membranes have properties of electrical resistance and capacitance, which allow them to maintain a voltage (membrane potential) and regulate current flow across the membrane. Cells have inside-negative resting membrane potentials. The passive electrical properties of membranes determine how membrane potentials change with time (the time constant, τ) and with distance (the length constant, λ).
- Membrane potentials depend on selective permeability to ions. Any ion species to which the membrane is permeable will tend to drive the membrane potential toward the equilibrium potential for that ion. The Nernst equation calculates the equilibrium potential of a single ion species in terms of its concentrations on both sides of the membrane.
- All cells have higher concentrations of K^+ inside than outside, higher concentrations of Na^+ outside than inside, and higher concentrations of Cl^- outside than inside. Ion concentrations inside and outside cells are maintained by active ion pumps, as well as by passive Donnan-equilibrium effects.
- Membrane potentials depend on the permeabilities to and concentration gradients of several ion species: The resting membrane is dominated by permeability to K^+ , so the resting membrane potential is near E_K . The Goldman equation describes how changing the membrane permeability of an ion species changes the membrane potential.
- In addition to their major role of maintaining the nonequilibrium concentrations of ions, electrogenic ion pumps generate a current that makes a small, direct contribution to V_m . In addition, only those ions that are freely diffusible contribute to V_m , so corrections for bound ions may be necessary.

The Action Potential

Excitable cells such as neurons, muscle fibers, and a few others have the ability to generate electrical signals. The hallmark electrical signal of an excitable cell is the *action potential*. Action potentials (which in neurons may also be called *nerve impulses*) are one of the most important kinds of electrical signals underlying the integrative activity of nervous systems. Some kinds of neurons do not gener-

ate action potentials, however, so the association of neurons with action potentials is not universal.

Action potentials are voltage-dependent, all-or-none electrical signals

Action potentials result from *voltage-dependent* changes in membrane permeabilities to ions because the ion channels that produce action potentials are *voltage-gated*—that is, their opening depends on the membrane potential (see Figure 5.5). An action potential is initiated by a change in the resting membrane potential, specifically by a depolarization sufficiently strong to open the voltage-gated channels. The voltage dependence of ion permeabilities is a critical feature of action potentials, and it makes action potentials fundamentally different from resting potentials or from graded potentials.

Action potentials have characteristic features. An **action potential** is a momentary reversal of membrane potential from about -65 mV (inside-negative) to about $+40$ mV (inside-positive)—a voltage change of about 100 mV, lasting about 1 ms, followed by restoration of the original membrane potential (Figure 12.14a). The action potential is triggered by any depolarization of the membrane that reaches a critical value of depolarization, the **voltage threshold**. After the suprathreshold (above threshold) depolarization, the action potential has a rapid *rising phase* that reaches a peak more positive than zero potential (*overshoot*) followed by a rapid repolarization (the *falling phase*). In the squid axon and in many other neurons, the action potential is followed by an *undershoot*, a transient after-hyperpolarization lasting a few milliseconds.

To illustrate the voltage-dependent properties of action potentials, let's perform a hypothetical experiment using a squid giant axon (Figure 12.14b). As we did in Figure 12.8, we penetrate the axon with two glass capillary microelectrodes—one to apply current pulses and one to record voltage. The first three inward-flowing current pulses hyperpolarize the membrane in the vicinity of V_i ; the amount of hyperpolarization is proportional to the strength of each current pulse (Figure 12.14c). This relation follows from Ohm's law and (ignoring the time constant) indicates that with hyperpolarization the membrane resistance does not change. Thus, hyperpolarization can't induce action potentials, because it doesn't change the permeabilities of membrane ion channels. Weak, outward-flowing current pulses in the opposite direction (pulses 4 and 5 in Figure 12.14c) elicit small depolarizations that approximately mirror the preceding hyperpolarizations, again indicating no significant change in membrane resistance.

Stronger depolarizing currents (pulses 6 to 8 in Figure 12.14c) that exceed the voltage threshold produce action potentials. However, a stronger depolarizing current (beyond threshold) does not produce a larger action potential (compare the responses to pulses 6 and 7). Instead, action potentials are **all-or-none** phenomena; that is, a depolarization below threshold elicits no impulse, but all suprathreshold depolarizations produce complete impulses substantially alike in amplitude and duration.

Immediately following an action potential, another action potential cannot be generated for at least 1 ms (the **absolute refractory period**) and is harder to generate for a few milliseconds longer (the **relative refractory period**). We will discuss the membrane properties that impose these refractory periods later in this chapter. Because of the all-or-none property of the action potential and the succeeding refractory period, impulses cannot summate. Instead, a prolonged

(a) An action potential

(b) Stimulating and recording action potentials

(c) Subthreshold responses and action potentials

1 Current pulses flowing inward across the membrane capacitance hyperpolarize the membrane (pulses 1–3).

2 Small pulses of outward current (4, 5) elicit depolarizations that are nearly the mirror image of the corresponding hyperpolarizations...

3 ...but as a critical voltage threshold is reached (6), the depolarization triggers an action potential.

4 A larger pulse of depolarizing current (7) produces an identical action potential to that produced by a smaller pulse (6), but a prolonged suprathreshold current (8) elicits a train of action potentials.

FIGURE 12.14 General features of action potentials (a) An action potential is a brief voltage change characterized by a rising phase that overshoots zero and a falling phase (repolarization) that may be followed by an after-hyperpolarization, or undershoot. (b) Recording action potentials in a squid giant axon, using a stimulating electrode (I) and a recording electrode (V_1). (c) Responses of the axon to stimulating current pulses.

suprathreshold depolarizing current (pulse 8 in Figure 12.14c) can elicit a *train* of discrete action potentials. For many neurons, the frequency of impulses in a train increases with increasing strength of depolarizing current (within limits).

An action potential, once initiated, *propagates* along the axon without a decrease in amplitude and at a constant velocity that depends on the diameter of the axon (among other factors). If in Figures 12.14b and c a remote electrode measured voltage at the end of the axon (not shown), it would record each action potential that the local electrode (V_1) records, with no decrease in amplitude. Each impulse recorded remotely follows the impulse at V_1 by a short latency that represents the time required for the impulse to propagate along the axon between the two electrodes. The distant V_2 electrode would not record the subthreshold depolarizations and hyperpolarizations, because they are not propagated; instead they spread decrementally and so are weakened before reaching V_2 (compare Figure 12.9).

In summary, action potentials are all-or-none electrical signals in excitable cells that propagate rapidly and without degradation over long distances. This ability to send signals over long distances rapidly and without distortion was presumably an important factor allowing the evolution of large animals whose complex physiology and behavior require extensive neural coordination.

Action potentials result from changes in membrane permeabilities to ions

The permeability terms in the Goldman equation (Equation 12.6) show that any factor that changes the permeability of the membrane to one or more ion species will change the value of the membrane potential. *An action potential results from intense, localized increases in permeabilities to specific ions*—increases that are both voltage- and time-dependent. What's more, the permeability increases are selective for specific ions: first sodium and then potassium.

PERMEABILITIES AND ION CHANNELS Let's follow the rise and fall of one action potential to see when and how these changes in the membrane's permeability to sodium and potassium ions occur. At the resting membrane potential of -65 mV, the membrane is most permeable to K^+ ions (Figure 12.15a). Neurons contain some K^+ channels that are normally open and are not voltage-gated. These *leakage channels* allow K^+ to diffuse across the membrane following the electrochemical gradient. The K^+ leak channels remain open throughout an action potential, but the more numerous voltage-gated channels swamp their effects.

The rising phase of the action potential (depolarization and polarity reversal) begins when a stimulus depolarizes the membrane past threshold. Voltage-gated Na^+ channels open in response to the depolarization, vastly increasing the membrane's permeability to sodium ions (Figure 12.15b). Because of the much higher

FIGURE 12.15 Membrane permeability changes that produce an action potential

(a) At rest the membrane is most permeable to K^+ , as represented here by leak channels that are always open. The box in the graph on the right indicates the membrane potential at this stage, described by the “voltage thermometer” (see Figure 12.13). (b) During the rising phase of the action potential, voltage-gated Na^+ channels open, and the high permeability to Na^+ dominates, driving the membrane potential toward E_{Na} . (c) Na^+ channels are inactivated soon after they open, and voltage-gated K^+ channels begin to open. Thus, during the falling phase permeability to K^+ again dominates, driving the membrane toward E_K . (d) K^+ channels remain open for a short time after an action potential, producing an undershoot in some cells. Na^+ channels recover from inactivation and again become ready to be opened by depolarization. (Leak channels remain open throughout, but their effects are swamped by the more numerous voltage-gated channels.) (After Bear, Connors, and Paradiso 2001.)

concentration of Na^+ outside the cell, Na^+ rushes in, driving the membrane potential toward E_{Na} (which is inside-positive). The inward-rushing sodium current is the cause of depolarization and polarity reversal at the rising phase of the action potential. Just as a dominant permeability to K^+ at rest makes the resting membrane potential inside-negative, the inflow of Na^+ during the rising phase of the action potential makes the membrane momentarily inside-positive.

The falling phase of the action potential results from two changes in the membrane’s permeability to ions (Figure 12.15c). First, the opening of the voltage-gated sodium channels is rapidly terminated by a process called Na^+ channel **inactivation**, which abruptly decreases permeability to Na^+ . Second, after a slight delay, voltage-gated potassium channels open, greatly increasing permeability to K^+ . Potassium ions flow out and drive the membrane toward E_K .

At the conclusion of an action potential, the membrane remains highly permeable to K^+ for a brief period (Figure 12.15d). Voltage-gated potassium channels remain open for a few milliseconds, producing a characteristic undershoot (after-hyperpolarization) in many neurons. The voltage-gated sodium channels recover from inactivation and again become ready to be opened by depolarization.

In summary, the action potential results from three overlapping permeability changes:

1. Increased permeability to Na^+ , caused by the rapid opening of voltage-gated Na^+ channels
2. Decreased permeability to Na^+ , caused by the inactivation of Na^+ channels

(a) Resting membrane potential

(b) Rising phase

(c) Falling phase

(d) Recovery

3. Increased permeability to K^+ , caused by the slower opening of voltage-gated K^+ channels

All three permeability changes are initiated by depolarization of the membrane and thus are characterized as *voltage-dependent* permeability changes. The voltage dependence of neuronal membrane permeabilities permits action potentials and gives the action potentials their unique all-or-none property.

THE HODGKIN CYCLE EXPLAINS THE RISING PHASE OF THE ACTION POTENTIAL To see how voltage dependence makes an action potential all-or-none, let’s examine the increase in permeabil-

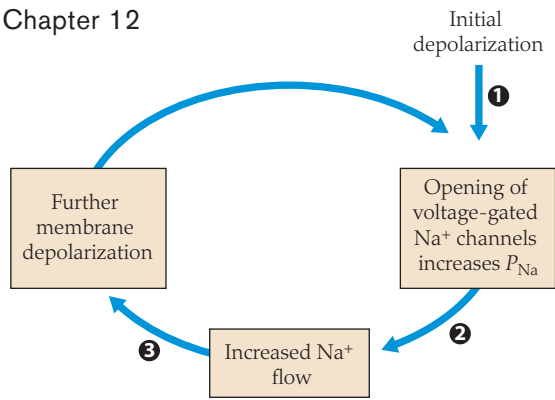

FIGURE 12.16 The Hodgkin cycle produces the rising phase of the action potential The critical feature of the cycle is that permeability to Na^+ is *voltage-dependent*. ① An initial depolarization increases P_{Na} by opening voltage-gated Na^+ channels. ② The increased permeability to Na^+ allows inflow of Na^+ down its electrochemical gradient, which further depolarizes the membrane ③. The cycle intensifies as each depolarization step opens additional Na^+ channels.

ity to sodium that underlies the rising phase of the action potential. We have discussed how increased permeability to and inflow of Na^+ depolarizes the membrane. *The critical feature of action-potential generation is that the permeability to Na^+ that produces depolarization itself depends on depolarization.* The **Hodgkin cycle** describes the effects of depolarizing an excitable membrane in which the permeability to sodium (P_{Na}) is voltage-dependent. (The cycle is named after Sir Alan Hodgkin, who was a corecipient of the Nobel Prize for his work clarifying the ionic mechanism of action potentials.) The cycle (**Figure 12.16**) consists of three processes that feed back on each other in a cyclic manner.

The Hodgkin cycle describes a positive feedback loop that starts with depolarization: Changing V_m changes P_{Na} , and (as predicted by the Goldman equation) changing P_{Na} changes V_m . At rest, the membrane is 20 to 50 times as permeable to K^+ as to Na^+ , so the resting V_m is near E_{K} . Subthreshold depolarizations open some voltage-gated Na^+ channels, but not enough to overcome the effects of the higher resting permeability to K^+ . At threshold, the current carried by Na^+ inflow just equals the K^+ current, and at any depolarization above threshold the Hodgkin cycle “wins.” The regenerative increase in P_{Na} in the Hodgkin cycle makes the membrane transiently much more permeable to Na^+ than to K^+ , so V_m approaches E_{Na} (+40 to +55 mV inside-positive).

The Hodgkin cycle explains only the rising phase of the action potential, since if the cycle alone were operating, the membrane potential would remain near E_{Na} indefinitely. Instead, the polarity reversal lasts only about 1 ms because the sodium channels become inactivated and voltage-gated potassium channels open, causing the membrane to repolarize rapidly.

SINGLE-CHANNEL CURRENT RECORDING FROM ION CHANNELS
The changes in membrane permeability that cause action potentials can be visualized as the actions of individual ion channels. (They can also be seen as whole-cell ionic currents, which we discuss next.) Evidence at the level of single ion channels comes from **single-channel current recording**, also termed **patch-clamp recording**.

In this procedure, a patch of membrane containing (with a little luck) a single Na^+ ion channel is sealed by suction onto the smoothed tip of a fine glass micropipette electrode, so that any current must

flow through a channel in the isolated patch (**Figure 12.17a**). The electrode records the opening and closing of the membrane ion channel by recording the ionic current that flows through the single channel when it is open. In this configuration, the experimenter has access only to the outside of the patch in the extracellular medium inside the micropipette. It is also possible, however, to rapidly pull a patch away from a cell and maintain the tight seal. In the inside-out arrangement of this detached patch, the inside of the electrode is equivalent of the outside of the cell and the bathing fluid is equivalent to the inside of the cell. In response to a depolarization (caused by setting the voltage across the membrane patch to a less negative value) (**Figure 12.17b**), the channel opens, allowing Na^+ ions to flow out of the electrode and into the bathing medium

FIGURE 12.17 Patch-clamp recording of single-channel currents (a) A fine, fire-polished glass electrode is fused to the membrane with suction, making what is known as a *gigaohm seal*, and the patch of membrane is pulled away from the cell. The electrode will then record current flowing through the channel when it opens. (b) A voltage-gated Na^+ channel is closed at resting potential (-70 mV), and no current flows through it. When the membrane patch is depolarized, the channel opens transiently, allowing an inward current carried by Na^+ ions. (Note that “inward” is toward the cytoplasmic side, not relative to the pipette, and that ion concentrations of the solutions in the bath and inside the electrode on either side of the patch are similar to the respective concentrations inside and outside the cell before detachment.) pA = picoampere (a measure of electric current).

(remember, the bathing medium is now acting as the *inside* of the cell). This inward-flowing current lasts for about 1 ms before the channel closes again (conventionally, an inward-flowing current is shown downward and an outward-flowing current is upward). By providing data about the opening and closing of single channels, patch-clamp recording allows direct visualization of the permeability changes underlying action potentials. This technique has resulted in such major advances in our understanding of single channel function in neurons (as well as other cell types) that its developers were awarded the Nobel Prize, in 1991.

To show a more complete picture of the ion currents flowing in and out of a neuron during an action potential, let's consider three responses of voltage-gated Na^+ channels and three responses of voltage-gated K^+ channels to a depolarization that is similar to the depolarization in an action potential (Figure 12.18). Recordings of the voltage-gated Na^+ channels and voltage-gated K^+ channels reveal conspicuous differences in latency and action of each type of channel. The channels are normally closed at resting potential, and depolarization increases the *probability* that they will open.

The voltage-gated Na^+ channels have a short latency and open first, but rapidly become inactivated and remain so until membrane potential returns near baseline (see Figure 12.18a). The K^+ channels

open with a slightly longer latency but do not become inactivated, and tend to stay open until the depolarization ends (see Figure 12.18b). The six individual single-channel currents illustrate the three effects of depolarization on Na^+ and K^+ channels: (1) Na^+ channels open first in response to the depolarization, (2) they are then inactivated during depolarization, and (3) K^+ channels open slightly later than the Na^+ channels but do not become inactivated.

VOLTAGE-CLAMP EXPERIMENTS SHOW WHOLE-CELL IONIC CURRENTS

Before the development of single-channel current recording, researchers used a whole-cell current-measuring technique called a *voltage clamp* in experiments to study action-potential generation, and these experiments became a cornerstone of the physiological investigation of action potentials. A **voltage clamp** is an electronic device that allows the experimenter to measure whole-cell ionic currents, by setting membrane potential very rapidly to a predetermined value, delivering whatever current is necessary to keep it there, and measuring the imposed current.

Recall that we described the Hodgkin cycle as a positive feedback loop in which a change in membrane potential changes the permeability to sodium ions, and vice versa. As the Hodgkin cycle exemplifies, any ion flow through the membrane constitutes an ionic current that tends to change the membrane potential. Clamping the membrane potential uncouples the feedback loop of the Hodgkin cycle. To keep the potential constant, the clamp circuit must generate an opposing (bucking) current that is exactly opposite to the net ionic current (current carried by ion flows through ion channels). *By measuring the bucking current, the experimenter has an accurate measure of the amplitude and time course of the net ionic current, because the two must be equal and opposite to each other.* Hence a voltage clamp uncouples the feedback loop of the Hodgkin cycle (at step 3 in Figure 12.16) so that ionic currents resulting from permeability changes are prevented from changing the membrane potential.

In 1952, Alan Hodgkin and Andrew Huxley published a series of landmark papers in which they used voltage-clamped squid axons to demonstrate and quantify the voltage-dependent permeability changes underlying the action potential. Figure 12.19 shows the most fundamental result of such a voltage-clamp experiment. When the membrane potential is clamped to a hyperpolarized value (see Figure 12.19a), the current-measuring circuit shows only a brief blip of capacitive current required to set the membrane potential to a new

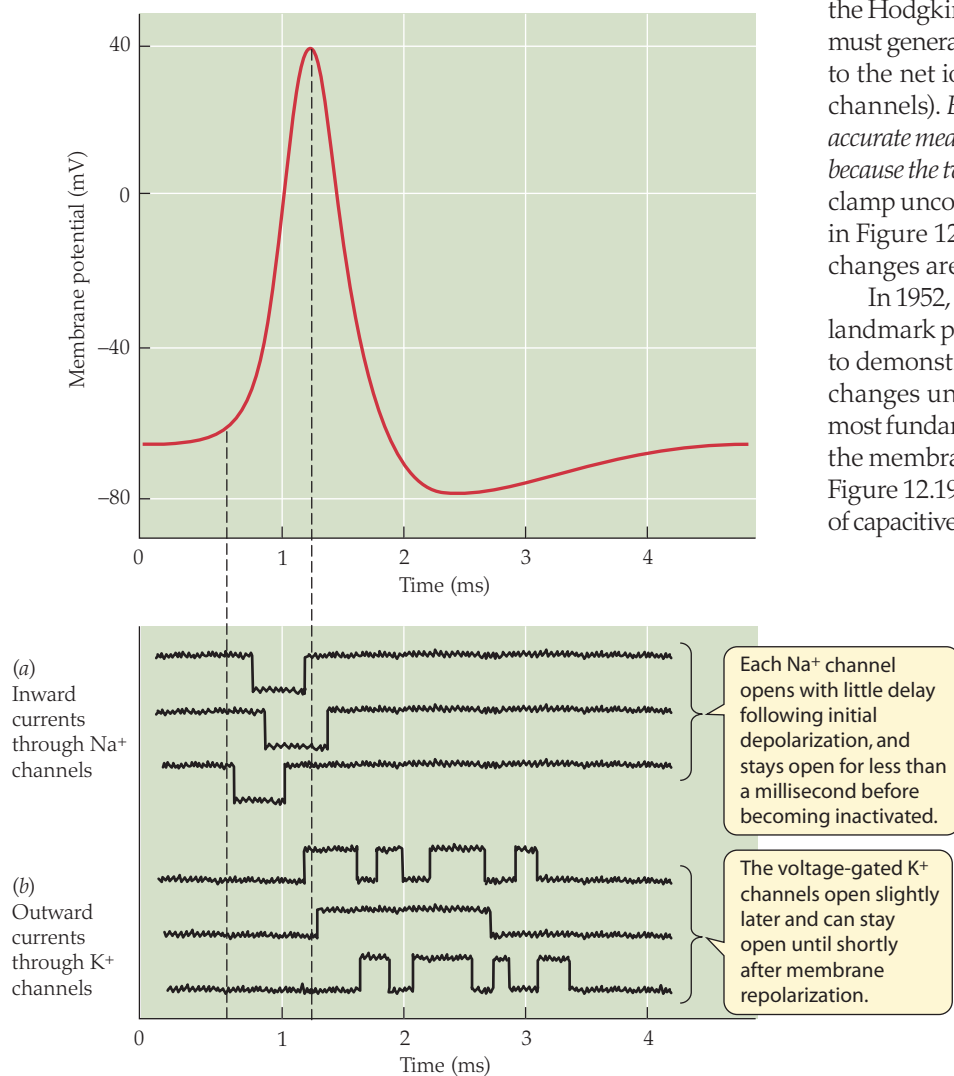

FIGURE 12.18 Patch-clamp recording of single-channel currents underlying an action potential

These diagrams illustrate simulated patch-clamp recordings of inward currents through three representative voltage-gated Na^+ channels (a), and outward currents through three representative voltage-gated K^+ channels (b) of the hundreds that produce the action potential. Note that the voltage-gated Na^+ channels open in a narrow time window that corresponds to the rising phase of the action potential. The extended permeability to K^+ can lead to an after-hyperpolarization of the membrane. (See Figure 12.14a for a description of the different phases of the action potential diagrammed at the top of this illustration.) (After Bear, Connors, and Paradiso 2001.)

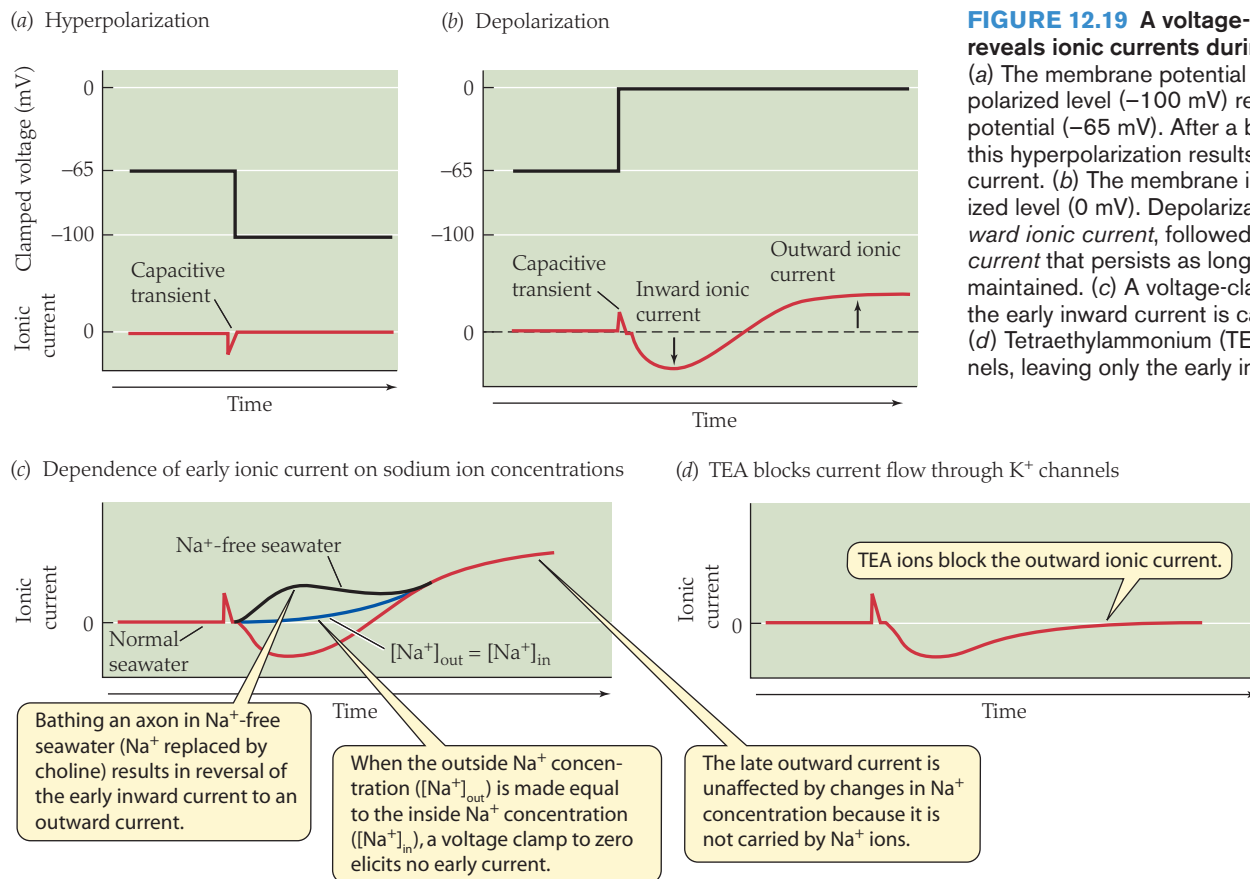

FIGURE 12.19 A voltage-clamp experiment reveals ionic currents during the action potential (a) The membrane potential is clamped at a hyperpolarized level (-100 mV) relative to the resting potential (-65 mV). After a brief capacitive transient, this hyperpolarization results in no significant ionic current. (b) The membrane is clamped at a depolarized level (0 mV). Depolarization induces an early *inward ionic current*, followed by a later *outward ionic current* that persists as long as the depolarization is maintained. (c) A voltage-clamp demonstration that the early inward current is carried by sodium ions. (d) Tetraethylammonium (TEA) ions block K^+ channels, leaving only the early inward (Na^+) current.

level (changing the charge stored by the membrane capacitance). The capacitive transient is not ionic current (i.e., not current flowing through ion channels), but just a shift in accumulated charges on either side of the membrane. Following the capacitive transient there is only a slight leakage current resulting from holding the membrane at a hyperpolarized level (too small to appear within the scale of the current record shown in Figure 12.19a). Hyperpolarization thus leads to no significant flow of ionic current because it doesn't increase permeability to any ions.

In contrast, clamping the membrane potential to a value more *depolarized* than the resting potential produces quite different effects (see Figure 12.19b). Following the initial capacitive transient, bucking current is required to hold the membrane at the set value. The bucking current (which is not shown) flows first outward and then inward. Because the bucking current is equal and opposite to the net ionic current, this pattern shows that there is an *early inward ionic current* that is reversed in 1 to 2 ms to a *later outward ionic current*. Depolarization of the membrane thus induces permeability changes that (if the currents are carried by cations) result in first an inward movement of cations and then an outward movement of cations. If the membrane were not clamped, these ionic currents would produce first a depolarization and then a repolarization of the membrane, as in an action potential.

Hodgkin and Huxley proposed that the early inward ionic current (which generates the rising phase of the action potential in unclamped axons) is an influx of Na^+ ions. How could this prediction be tested? Hodgkin and Huxley replaced the Na^+ in the seawater with which they bathed the axon with choline, a nonpermeating cation. In the absence of extracellular Na^+ , the early inward cur-

rent was replaced by an early outward current (see Figure 12.19c). That is, depolarization induced an increase in permeability to Na^+ , which, in the absence of extracellular Na^+ , resulted in Na^+ diffusion *outward* down its concentration gradient.

This interpretation predicts that if the Na^+ concentration is equal on both sides of the membrane, there will be no Na^+ concentration gradient and no early Na^+ current in either direction. Hodgkin and Huxley replaced about 90% of the extracellular Na^+ with nonpermeating ions so that $[Na^+]_{in} = [Na^+]_{out}$. When the membrane was clamped to 0 mV (so that there was no voltage gradient), there was no early current (see Figure 12.19c).

Further evidence that the early inward current is carried by Na^+ was provided by experiments in which a squid axon in normal artificial seawater was clamped to the sodium equilibrium potential ($E_{Na} = +50$ mV). There was no resultant early current because there was no driving force on Na^+ ions at E_{Na} . Clamping the membrane at a level beyond E_{Na} (more inside-positive than E_{Na}) resulted in an early outward current, representing Na^+ efflux toward E_{Na} . These experiments demonstrate that Na^+ ions carry the early inward current during a voltage clamp, but not the later outward current, which is unchanged by changing Na^+ concentrations. Other experiments demonstrate that the late current is a K^+ efflux.

Pharmacological agents used in conjunction with a voltage clamp confirm that sodium and potassium currents flow through separate ion channels. Certain drugs can selectively block Na^+ and K^+ channels when they are applied to the membrane. For example, tetrodotoxin (TTX), an extremely poisonous substance found in puffer fish, selectively blocks voltage-dependent Na^+ channels. If a squid axon is bathed in seawater containing TTX and is voltage-

clamped to a depolarized level such as 0 mV, the early inward Na^+ current is blocked. The delayed outward (K^+) current, however, is completely unaffected. However, tetraethylammonium (TEA) ions selectively block the delayed outward current flowing through K^+ channels (see Figure 12.19d). TEA ions have no effect on the early inward current flowing through Na^+ channels.

From their voltage-clamp experiments, Hodgkin and Huxley were able to quantify the voltage dependence and time course of the changes in permeability to Na^+ and K^+ .⁵ They developed a set of equations by which they showed that the magnitudes and time courses of these three voltage-dependent processes are sufficient to describe the behavior of action potentials in unclamped squid giant axons. These studies remain critical for our understanding of the physiology of excitable membranes.

ION MOVEMENTS IN ACTION POTENTIALS DO NOT SIGNIFICANTLY CHANGE BULK ION CONCENTRATIONS In the generation of an action potential, a neuron gains a small amount of Na^+ and loses a small amount of K^+ . These amounts have been calculated to be 3×10^{-12} to 4×10^{-12} mol/cm² of membrane per impulse. As with the slow passive leaks of Na^+ in and K^+ out across the resting membrane, the ions crossing the membrane during an impulse must be pumped back again by the Na^+ - K^+ exchange pump. It is important to realize that the pumping process is *slow* relative to the time course of the action potential, and serves only to keep the

⁵Permeabilities are often measured in electrical units of **conductance**, the inverse of resistance ($g = 1/R$). *Conductance* and *permeability* are not synonymous, because increasing ion concentrations increases conductance but not permeability.

ion concentrations constant over minutes, hours, and days. The Na^+ - K^+ exchange pump does not contribute directly to the generation of action potentials, and the ion movements underlying impulse generation are very small relative to the quantities of ions inside and outside the axon.

If the Na^+ - K^+ exchange pump of a squid giant axon is poisoned, the axon can still generate about 100,000 impulses before the internal Na^+ concentration is increased by 10%! Smaller axons, however, have a greater ratio of membrane surface to internal volume, so the concentration changes produced by impulses are greater. Therefore, the smallest axons (0.1 μm in diameter) presumably cannot generate impulses at a rate that greatly exceeds the moment-to-moment ability of the Na^+ - K^+ exchange pump to maintain normal ion concentrations.

The molecular structure of the voltage-dependent ion channels reveals their functional properties

The voltage-gated Na^+ channel protein changes its tertiary structure in response to membrane depolarization, to achieve three conformations: closed, open, and inactivated. Molecular analysis of the voltage-gated Na^+ channel suggests which parts of the protein mediate specific aspects of its function.

The major (α) protein of the voltage-gated Na^+ channel forms the channel itself. It consists of a single polypeptide chain (Figure 12.20; see also Figure 2.4). (There are two smaller, variable β -peptide subunits that interact with and modify the single α protein. However, the α protein alone is sufficient to produce voltage-gated Na^+ currents, and we will consider it only.) The Na^+ channel α polypeptide

FIGURE 12.20 The molecular structure of voltage-gated Na^+ channels (a) The predicted structure of the principal (α) subunit of the voltage-gated Na^+ channel. This subunit makes up the pore-forming channel itself and is a single polypeptide chain, with four homologous domains labeled I, II, III, and IV. Each domain has six membrane-spanning α -helical segments (labeled 1 through 6). (b) A hypothetical surface view of the Na^+ channel. The P (for pore) loops between segments 5 and 6 of each domain are thought to line the pore and determine ion selectivity. Other segments (not shown) mediate channel inactivation, intracellular regulation, and association with other channel subunits. (c) A hypothetical three-dimensional structure of the channel, showing closed and open conformations. The four domains surround a central pore. The segment-4 voltage sensors are thought to rotate and slide upward in response to depolarization, leading to channel opening.

chain has four *domains* or regions, each domain consisting of amino acid sequences very similar to the other three. Thus there is said to be extensive *sequence homology* among the four domains, suggesting that they evolved from a common ancestral peptide. Each of the four domains contains six *membrane-spanning segments*, regions of the polypeptide that contain predominantly hydrophobic amino acid side chains that can form α -helices and cross the lipid bilayer of the membrane. The four domains of the voltage-gated Na^+ channel α protein surround an aqueous channel pore, through which Na^+ ions can diffuse in response to depolarization (see Figure 12.20*b*).

Particular structural regions of the channel protein impart to it particular functional properties. For example, the region of the protein that responds to voltage is membrane-spanning segment 4 of each domain (see Figures 12.20*a* and *b*). The voltage-sensor region of the channel must be charged, but it must also be in or close to the membrane in order to detect changes in the transmembrane electric field, and segment 4 has a collection of positively charged amino acids appropriate to act as the voltage-sensor region. Moreover, mutations affecting segment 4 selectively alter the voltage sensitivity of the channel. The channel's voltage-sensor segments are thought to move outward in response to depolarization, leading to an overall conformational change in the channel from closed to open (see Figure 12.20*c*).

(a) Na^+ channel(b) Ca^{2+} channel(c) K^+ channel

Another structural correlate of a critical channel function is the P loop connecting segments 5 and 6 of each domain. This loop lines the pore of the ion channel (see Figure 12.20*b*) and helps mediate ion *selectivity*. Mutations in the P-loop region alter ion selectivity in ways consistent with this idea. Finally, the cytoplasmic loop between domains III and IV appears to mediate inactivation of the Na^+ channel; it is thought to act like a “ball on a string” that can block the (open) channel from the cytoplasmic side (see Figure 12.15*c*).

Other voltage-gated channels are structurally similar to the voltage-gated Na^+ channel (Figure 12.21). Channels showing such similarity include the K^+ channels that repolarize the membrane in an action potential, as well as Ca^{2+} channels involved in neurotransmitter release. (Like the Na^+ channels, these channels have modulatory polypeptides, but only the principal α protein of each is considered here.) Na^+ , Ca^{2+} , and K^+ channels are similar in overall structure and have extensive homology in amino acid sequence. The sequence homology is greatest in certain regions (conserved regions), such as the voltage-sensor region of membrane-spanning segment 4. Their homology suggests that the various ion channels are evolutionarily related, and therefore they are referred to as the **voltage-gated channel superfamily** of membrane proteins.

The Na^+ and Ca^{2+} channels are most similar in structure (see Figures 12.21*a* and *b*). The K^+ channels (see Figure 12.21*c*) consist of four identical subunits that resemble one of the four domains of a Na^+ channel. Evidently, four K^+ channel proteins interact as subunits to form a channel, aligning like the four domains of a Na^+ channel protein around a central pore. There are several subtypes of each kind of ion channel, with an especially large number of K^+ channel subtypes. Box 12.1 discusses the evolution of the voltage-gated channel superfamily and the molecular bases of their actions.

There are variations in the ionic mechanisms of excitable cells

How universal are the ionic mechanisms of action potentials? Studies have shown that the basic aspects of impulse generation elucidated in squid axons apply to most excitable cells. The action potentials of vertebrate and invertebrate unmyelinated axons, amphibian myelinated axons, and vertebrate skeletal twitch muscle fibers have ionic mechanisms qualitatively similar to those of squid axons. In fact, even ion channels from algae have been shown to function in mammalian neurons (Box 12.2).

FIGURE 12.21 The voltage-gated channel superfamily All the voltage-gated channels have principal subunits with extensive sequence homology and thus are evolutionarily related. Voltage-gated Na^+ channels (a) and Ca^{2+} channels (b) have four domains, each with six α -helical membrane-spanning segments and a P loop (P). (c) The voltage-gated K^+ channel, in contrast, has only a single domain of six α -helices and the P loop, homologous to one domain of a Na^+ channel. Four separate subunits interact to form a complete K^+ channel. (After Kandel, Schwartz, and Jessell 1995.)

BOX 12.1 EVOLUTION AND MOLECULAR FUNCTION OF VOLTAGE-GATED CHANNELS

Voltage-gated channels are amazing molecular mechanisms that make possible the functions of nervous systems. Recent molecular studies have suggested a sequence of steps in the evolution of voltage-gated channels, and have largely clarified the structural basis of their action. **Box Extension 12.1** shows how voltage-gated channels are thought to have evolved, and how their critical features—ion selectivity and voltage gating—work at the molecular level.

There are, however, variations on the theme: Some neurons may lack some voltage-gated channels or may possess additional channels. Studies reveal a wide range of ion channels in excitable membranes, each identified by its unique current signature (Table 12.2). The variations on action potential-generating mechanisms may endow the cell with special features, such as the ability to generate spontaneous action potentials or bursts of action potentials. Here we consider two examples of variations on the usual action-potential theme.

GRADED POTENTIALS IN NONSPIKING NEURONS Not all nerve cells generate action potentials. Researchers report increasingly numerous examples of **nonspiking neurons** (neurons that do not

generate the sharp “spikes” of action potentials). Nonspiking neurons produce only *graded* membrane-potential changes in response to a stimulus or synaptic input because they substantially lack voltage-gated sodium channels.

Figure 12.22 compares signal transmission in spiking and nonspiking neurons. The input of both neurons (sensory stimulation or synaptic input) is graded in amplitude, and so is their output (neurotransmitter release). Spiking neurons encode the graded input signals into trains of action potentials for long-range transmission; the action potentials are recoded at the terminal to control graded release of neurotransmitter. Nonspiking neurons, in contrast, are typically compact cells with short axons or no axons, so a graded potential change at one part of the cell can spread passively (electrotonically) to the terminal without major decrement.

The inputs and outputs of spiking and nonspiking neurons are the same, but the short-axon nonspiking neuron does not require spike encoding to carry the signal over large distances. Examples of nonspiking neurons include the photoreceptors, bipolar cells, and horizontal cells of the vertebrate retina (see Chapter 14), granule cells of the olfactory bulb, and many arthropod interneurons.

PACEMAKER POTENTIALS OF SPONTANEOUSLY ACTIVE CELLS

Many neurons are spontaneously active, generating action potentials at rather regular intervals without an external source of depolarization. The somata of some molluscan neurons, for example, generate action potentials in regular trains, or even in repetitive bursts, in the absence of synaptic input. Vertebrate cardiac muscle fibers and some other excitable cells are also spontaneously active.

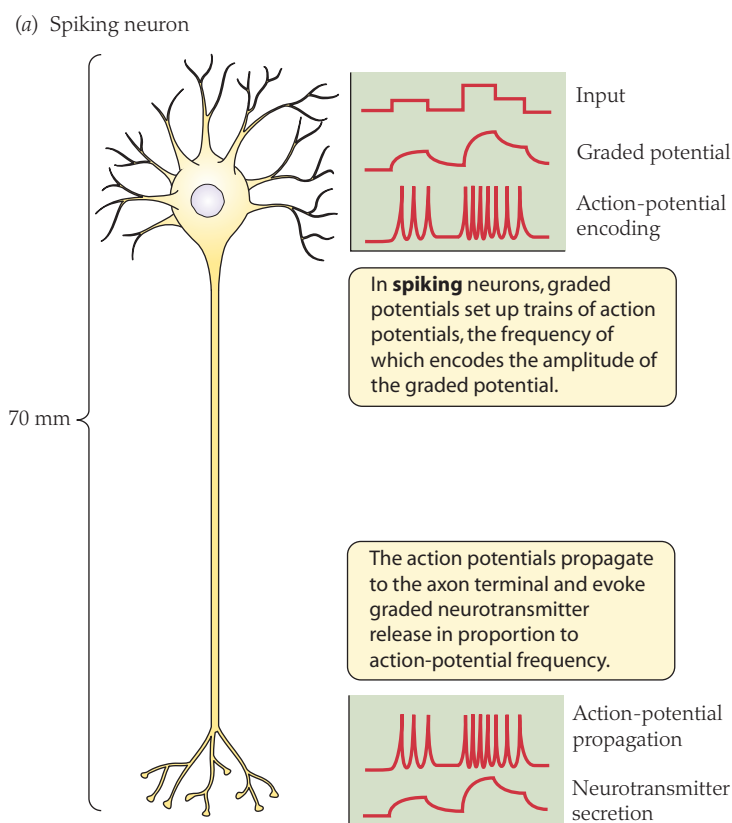

FIGURE 12.22 Nonspiking neurons do not generate action potentials

Information transmission in an ordinary, spiking neuron (a) is contrasted with that in a nonspiking neuron (b). (a) Input to the spiking neuron is graded in amplitude and evokes graded potentials in the dendrites and soma of the neuron. (The input could be an external stimulus for a sensory neuron, or synaptic input for a nonsensory neuron.) (b) Nonspiking neurons do not encode graded potentials into action potentials; instead the graded potentials spread electrotonically to the axon terminal. If the axon is short relative to its membrane length constant, the amplitude of the graded potential will be sufficient to evoke graded neurotransmitter release. Action-potential generation, then, may be an adaptation for signal transmission in long-axon neurons that is unnecessary in short-axon neurons.

BOX 12.2 OPTOGENETICS: CONTROLLING CELLS WITH LIGHT Matthew S. Kayser

The human brain is a remarkably complex organ, with billions of neurons and trillions of synapses communicating through precisely timed electrical signals. A major limitation in understanding how our brains work is that researchers have been unable to manipulate the system on the same millisecond time scale on which it normally operates. To learn how every movement, thought, and experience we have results from groups of neurons talking to each other, don't we need a way to speak to neurons on the same time scale they use when communicating with each other? The field of "optogenetics" has begun to accomplish just this by combining optics (the use of light) with manipulation of genes (thus, *opto* + *genetics*). Specifically, scientists have figured out how to put genes into cells that make those cells responsive to pulses

of light. Unexpectedly, this technology is possible because of light-sensitive transporter proteins and ion-channel proteins first discovered in microorganisms a few decades ago. **Optogenetics** involves taking the genes encoding these light-sensitive transporter and channel proteins, inserting them into target cells, and then delivering light to those cells as a way of controlling their functions. For example, neurons in the mammalian brain can be targeted to express the light-sensitive channels. Then, by delivering light to those neurons (see figure), investigators are able to exert millisecond control over neuronal firing patterns, shedding light—literally—on mysteries of neuroscience in the process.

Box Extension 12.2 describes how optogenetics was developed and its many potential applications.

A mouse prepared for an optogenetic experiment

TABLE 12.2 Neuronal ionic currents

Current	Description	Function
Na⁺ currents		
$I_{Na,t}$	Transient; rapidly activating and inactivating	Mediates action-potential rising phase
$I_{Na,p}$	Persistent; noninactivating	Enhances depolarization; allows sustained firing
Ca²⁺ currents		
I_T , low threshold	Transient; rapidly inactivating; threshold negative to -65 mV	Underlies rhythmic burst firing
I_L , high threshold	Long-lasting; slowly inactivating; threshold about -20 mV	Underlies Ca ²⁺ spikes of dendrites; involved in synaptic transmitter release
I_N	Rapidly inactivating; threshold about -20 mV	Underlies Ca ²⁺ spikes of dendrites; involved in synaptic transmitter release
I_P	Purkinje cells; threshold about -50 mV	
K⁺ currents		
I_K	Activated by strong depolarization	Mediates action-potential repolarization
I_C	Activated by increase in $[Ca^{2+}]_i$	Mediates action-potential repolarization and interspike interval
I_{AHP}	Slow after-hyperpolarization; sensitive to increase in $[Ca^{2+}]_i$	Slow adaptation of action-potential discharge; block by neuromodulators enhances excitability
I_A	Transient; inactivating	Delays onset of firing; lengthens interspike interval
I_M	Muscarine-sensitive; activated by depolarization; noninactivating	Contributes to spike frequency adaptation; block by neuromodulators enhances excitability
I_h	Depolarizing (mixed cation) current that is activated by hyperpolarization	Contributes to rhythmic spiking and rhythmic burst activity
$I_{K,leak}$	Contributes to neuronal resting potential	Block by neuromodulators changes V_m

Source: From McCormick 1999.

The membrane potential of a spontaneously active cell, instead of maintaining a fixed resting value, undergoes a continuous upslope of depolarization between action potentials, until it reaches threshold for the generation of the next action potential. The repolarizing phase of an action potential restores the membrane to a relatively hyperpolarized level, from which the next ramp of depolarization begins. These ramp depolarizations are termed **pacemaker potentials** because they determine the rate of impulse generation by the cell. For example, in a cardiac muscle cell in the pacemaker region of a vertebrate heart, the greater the rate of depolarization during the ramp phase, the sooner the cell reaches threshold for the next action potential and, thus, the faster the heart rate. For vertebrate cardiac muscle fibers, norepinephrine increases the rate of depolarization during the ramp phase, whereas acetylcholine decreases it. (See Chapter 25 for discussion of heart rate control.)

The ionic basis of pacemaker potentials can be complex and may vary somewhat among cells. Spontaneously active cardiac muscle fibers have a slow inward cationic current (termed I_h) that is activated by hyperpolarization rather than by depolarization. This current is carried by both Na^+ and K^+ because the channels that open to produce it are not very selective among cations. I_h is activated at potentials more negative than -40 mV. The unique features of this current—that it is inward and activated by hyperpolarization—give it pacemaker properties. I_h produces a ramp depolarization that triggers an action potential and then is inactivated at -40 mV. After the action potential, the repolarizing potassium current (I_K , flowing through voltage-gated K^+ channels) restores the membrane to a value near E_K . The hyperpolarization turns off I_K and turns on I_h for the next ramp depolarization.

CARDIAC MUSCLE ACTION POTENTIALS The action potentials of heart muscle fibers demonstrate a significant departure from the mechanisms of action-potential generation seen in squid axons. In contrast to most action potentials, which last about 0.4 to 3 ms, vertebrate cardiac muscle fibers have action potentials with typical durations of 100 to 500 ms (Figure 12.23a). The long duration of cardiac muscle action potentials is functionally important because action-potential depolarization is the necessary stimulus for myocardial contraction, and because cardiac muscle must contract for about 100 ms to pump blood effectively. A cardiac muscle fiber action potential has a rapid upstroke and a rapid initial recovery to near 0 mV, but it remains depolarized near zero for many milliseconds. This prolonged depolarization, the *plateau* of the action potential, gradually decreases and is followed by a relatively slow repolarization.

Two separate inward currents underlie the cardiac action potential. The first is a fast current resulting from increased permeability to Na^+ (P_{Na}) (Figure 12.23b), very similar to the squid axon's permeability to Na^+ . The fast Na^+ current produces the rapid upstroke of the cardiac action potential and is inactivated within a few milliseconds. A second, slow inward current results mainly from increased permeability to Ca^{2+} (P_{Ca}) and helps produce the plateau. The Ca^{2+} channels take at least 20 ms to open, and their slow inward current is much weaker than the fast Na^+ current.

The other factor sustaining the plateau is a *decrease* during the plateau in permeability to K^+ (P_K) from the resting level (in contrast to the increased permeability to K^+ that occurs in axons). Thus the plateau represents a balance between two small currents, a slow inward

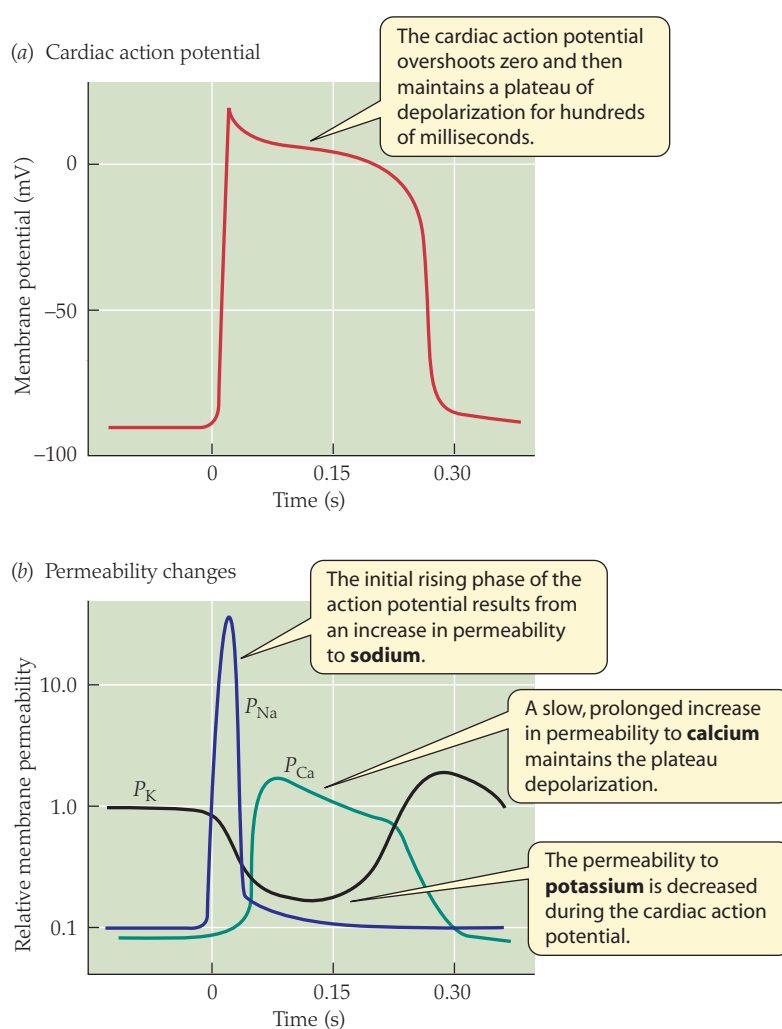

FIGURE 12.23 The cardiac muscle fiber action potential (a) An action potential in a vertebrate cardiac muscle fiber has a long duration. (b) Permeability changes underlie the cardiac action potential. Eventually, increased $[\text{Ca}^{2+}]$ opens Ca^{2+} -activated K^+ channels, leading to repolarization.

Ca^{2+} current and a diminishing outward K^+ current. Repolarization depends on two factors: (1) the Ca^{2+} channels gradually become inactivated during the plateau depolarization, and (2) permeability to K^+ gradually increases. Some of the K^+ channels are activated by intracellular Ca^{2+} ions (see Box 12.1 and Table 12.2), which accumulate during the plateau and eventually open the K^+ channels.

The complex ionic basis of cardiac action potentials increases their energetic efficiency. Recall that in a 1-ms action potential of a typical neuron, only the in-rushing fast sodium current sustains the brief depolarization. A cardiac muscle cell would be flooded with Na^+ if the fast current alone had to sustain a 100-ms action potential, and metabolically expensive ion-exchange pumps would be needed to clear the Na^+ ions from the cytoplasm. During a cardiac action potential, however, the duration of the fast sodium current is about the same as that of a standard action potential. Instead, *depolarization is sustained by the slow Ca^{2+} current and by the decreased membrane permeability to K^+ .* Thus a cardiac muscle fiber can generate a protracted action potential with only a relatively modest exchange of ions across its membrane.

SUMMARY The Action Potential

- An action potential is a voltage change—a brief, transient reversal of membrane potential from inside-negative to inside-positive. Action potentials are all-or-none responses to any depolarization beyond a voltage threshold and are each followed by a brief refractory period.
- Action potentials result from voltage-dependent changes in membrane permeability to ions. Depolarization first opens voltage-gated Na^+ channels, allowing Na^+ ions to flow in and further depolarize the membrane toward E_{Na^+} . The voltage-gated Na^+ channels rapidly become inactivated to terminate the rising phase of the action potential; then voltage-gated K^+ channels open to repolarize the membrane.
- The effects of depolarization on membrane permeability to ions can be studied at the level of single channels by patch clamp, and at the whole-cell level by voltage clamp.
- Ongoing investigations are clarifying the molecular structures of voltage-gated channels. The principal protein subunit of a K^+ channel is a single chain with six transmembrane regions; a K^+ channel consists of four of these protein subunits around a central pore. Na^+ and Ca^{2+} channels consist of a single polypeptide chain with four similar domains; each domain corresponds to one of the four subunits of the K^+ channel. Functional attributes of the channels can be localized to particular regions of the proteins.
- Nonspiking neurons do not generate action potentials, and the ionic mechanisms of action potentials in excitable cells can vary. Calcium ions can make substantial contributions to action potentials in cardiac muscle cells and in some neurons. Other varieties of voltage-gated channels modify the excitable properties of neurons.

The Propagation of Action Potentials

Consider that in large animals, single axons—such as those that control wiggling of your toes—can be at least 1 m long. Now recall that an electrotonic voltage change at one point on a membrane decreases exponentially with distance. Indeed, with passive or electrotonic spread, the amplitude of a voltage change typically decreases to a third of its starting value in a fraction of a millimeter! Because of this decrement, passive electrotonic spread of a voltage change cannot serve as an electrical signal over long distances. Instead, there must be a mechanism to amplify or refresh the electrical signal.

We have seen that an action potential is all-or-none because the voltage-dependent, regenerative permeability increases bring the membrane potential toward a limiting value, which is the sodium equilibrium potential (E_{Na^+}). *Nondecremental propagation of the action potential is possible because the action potential at one location on an axon can itself initiate an action potential at a neighboring location, and the induced action potential will have the same all-or-none amplitude as the original action potential.* By repeating this process, a signal can travel 1 m along an axon without any decrease in amplitude.

Local circuits of current propagate an action potential

An action potential at one locus on an axon depolarizes an adjacent locus by setting up local circuits of current flow (Figure 12.24). A complete local circuit is composed of a series of ionic and capaci-

tive currents, which can be broken down into four components as shown in Figure 12.24b:

- ① At the locus of the action potential, an ionic current begins with the inflow of sodium ions through open Na^+ channels into the intracellular fluid (cytosol).
- ② Ions flow in intracellular fluid, carrying the current to more distant parts of the membrane (see Figure 12.9).
- ③ At the membrane the ion movements change the distribution of charges on the membrane capacitance (see Figure 12.24c): Cations accumulate along the membrane interior, displacing negative charges and repelling an equivalent number of cations from the membrane exterior. Although ions do not physically cross the membrane at this point, the movements of ions onto and off the membrane surface constitute a capacitive current.
- ④ An (extracellular) ionic current completes the local circuit as cations move toward the locus of the action potential and anions move away.

During an action potential, local circuits of current such as the one described here spread the depolarization passively (electrotonically) along the surface of the membrane. *The action potential propagates to an adjacent portion of the axon because the capacitive depolarization produced by the local current lowers the membrane potential to threshold.* When this happens, the Hodgkin cycle takes over; the region of the membrane that reaches threshold undergoes a regenerative increase in permeability to Na^+ and generates its own action potential. In this way the nerve impulse passes along the entire length of the axon without any decrease in amplitude.

Membrane refractory periods prevent bidirectional propagation

An axon can conduct impulses equally well in either direction. For example, an action potential that is triggered via an electrode placed in the middle of an axon will be propagated in both directions from that point. Normally, however, impulses start at or near one end of an axon and travel along the axon in one direction. As an impulse is propagated, its local currents depolarize the membrane behind it, as well as the membrane ahead of it. Why don't these local currents initiate reverse-traveling impulses going the other way? The membrane behind a traveling impulse is not reexcited by the local currents because the membrane is still in its refractory period (Figure 12.25).

Three aspects of the ionic mechanisms of action potentials produce the absolute and relative refractory periods following an impulse, and thereby prevent reexcitation and bidirectional propagation:

1. The inactivation of sodium channels (which turns off the voltage-dependent increase in permeability to Na^+) persists until the membrane potential returns near its negative resting state, which means that inactivation lasts for at least 1 ms after an impulse passes a region of the membrane. Na^+ channel inactivation prevents the channels from entering the Hodgkin cycle until the action potential is far enough away to minimize local depolarization. This is the primary basis of the absolute refractory period.

FIGURE 12.24 Propagation of an action potential An action potential is diagrammed here at an instant in time, while propagating from right to left. (a) The action potential induces local circuits of current flow along the axon, ahead of the advancing action potential and behind it. (b) The local circuit ahead of the action potential can be divided into four components, as shown. These components are described in the text. (c) This diagram illustrates how the capacitive current on the left in (b) depolar-

izes the membrane ahead of the advancing action potential, by adding cations and removing anions at the inner side of the membrane, and adding anions and removing cations on the extracellular side. These changes in the distribution of charges on the membrane depolarize it, without any ions crossing the membrane. The depolarization resulting from the local currents opens voltage-gated sodium channels, leading (via the Hodgkin cycle) to an action potential at the new location.

2. The increased permeability to potassium (the slowest of the three voltage-dependent processes in onset) does not decrease to resting levels until after repolarization. The lingering P_K increase after an impulse may hyperpolarize the membrane toward E_K for a few milliseconds after the impulse. Thus (for those neurons whose action potentials have an undershoot) a region of membrane that has just generated an impulse is hyperpolarized *away* from its voltage threshold for new impulse generation.
3. The increase in P_K also renders a membrane refractory because it represents a decreased

membrane resistance. The decreased resistance means that by Ohm's law ($V = IR$), local currents will cause a smaller voltage change, so more current is needed to depolarize the membrane to threshold.

FIGURE 12.25 Inactivation of voltage-gated Na^+ channels prevents reverse propagation of an action potential An action potential is shown propagating from right to left; local currents depolarize the axon membrane ahead of the advancing action potential and behind it. The axon membrane behind the advancing action potential is refractory because its sodium channels are still inactivated. This refractory period prevents self-excitation by the trailing local currents.

Sodium-channel inactivation causes the absolute refractory period, and the effects of residual P_K increase are largely responsible for the relative refractory period. During the absolute refractory period (>1 ms), the membrane's voltage threshold is infinite because no amount of depolarization can open the inactivated Na^+ channels. During the relative refractory period the voltage threshold, membrane potential, and membrane resistance gradually return to resting levels within a few milliseconds. The refractory periods outlast the backward spread of local currents, thus preventing reverse propagation of the action potential.

The conduction velocity of an action potential depends on axon diameter, myelination, and temperature

Several factors can affect the velocity of propagation of an action potential along an axon. In general, these factors affect either or both of two conduction parameters: (1) the spatial parameter and (2) the temporal parameter. Spatially, the farther that local currents can spread along an axon, the farther they can (directly) depolarize the membrane to threshold, and the sooner an action potential will result. Therefore, any factor that increases the spread of local currents (i.e., increases the membrane length constant, λ) tends to increase the conduction velocity of an action potential. Both large axon diameter and myelination increase the spatial spread of local currents.

With respect to the temporal parameter, the less time it takes the membrane to reach threshold, the faster the conduction velocity. Intrinsic membrane properties such as differences in the density of sodium channels may have minor effects on conduction velocity by influencing the spatial and temporal parameters. The three major evolutionary variables that influence conduction velocities are axon diameter, myelination, and temperature.

AXON DIAMETER AND CONDUCTION VELOCITY

Large-diameter axons tend to conduct action potentials more rapidly than small-diameter axons. Many animal groups have evolved rapidly conducting neuronal giant axons (Box 12.3). Conduction velocity increases with axon diameter because larger-diameter axons have longer length constants and thus more distant spread of local currents. The length constant depends principally on two types of resistance (see Figure 12.9c): the resistance across the membrane (R_m) and the axoplasmic resistance (R_i) to current flow along the length of the axon (the cytoplasm inside the axon is called *axoplasm*). (The external longitudinal resistance is usually small and is ignored.) A slightly simplified equation for the length constant (λ) is

$$\lambda = K \left[\frac{R_m}{R_i} \right]^{1/2} \quad (12.7)$$

where K is a constant.

BOX 12.3 GIANT AXONS

Because an increase in axon diameter increases the conduction velocity of an action potential and because animals often face circumstances in which a rapid response is advantageous for survival, **giant axons** have evolved in several animal groups. No particular diameter qualifies an axon as *giant*. Rather, the term is relative: A giant axon is of exceptional diameter compared with other axons in the same animal. Some axons are truly giant in cellular dimensions, such as the third-order giant axons in the squid, which may be 1 mm (1000 μm) in diameter. At the other extreme, the giant axons in the fruit fly *Drosophila* are only about 4 μm in diameter, but they are still an order of magnitude larger than other nearby axons. **Box Extension 12.3** describes the structure and function of giant axons in squid and in some other invertebrates.

The membrane surface area increases proportionally with increasing axon diameter, which lowers R_m by adding resistances in parallel. However, R_i decreases in proportion to an increase in cross-sectional area of the axoplasm—that is, in proportion to the square of the diameter. The net effect is that the ratio R_m/R_i increases linearly with increasing diameter. If other factors are equal, the length constant and the conduction velocity should increase with the square root of the diameter. This would make the conduction velocity an allometric function of diameter: $V \propto D^b$, with $b = 0.5$ (see Appendix F).

Figure 12.26 shows that conduction velocity empirically increases with increasing axon diameters. The data are plotted on log-log coordinates. On these coordinates, the allometric relation $V \propto D^b$

FIGURE 12.26 The velocity of nerve-impulse conduction increases with increasing axon diameter in both myelinated and unmyelinated axons. Points not connected by lines are axons of different types. (After Bullock and Horridge 1965.)

will plot as a straight line regardless of the value of b (see Appendix F). The two lines forming a V at the center show the slopes for $V \propto D^1$ (simple proportionality) and $V \propto D^{0.5}$. As you can see, the empirical plots (red lines) have slopes between these extremes. For some unmyelinated axons, V and D follow the square-root relationship ($V \propto D^{0.5}$), but many myelinated axons have a more nearly proportional relationship of velocity to diameter ($V \propto D^1$). That the relation of velocity and diameter differs for different kinds of axons implies that other factors, including intrinsic membrane differences, are also involved.

MYELINATION INCREASES CONDUCTION VELOCITY Myelinated axons of vertebrates represent a tremendous evolutionary advance because they allow very high conduction velocities with relatively small axon diameters. A **myelinated axon** (Figure 12.27) is wrapped with 200 or more concentric layers of glial membrane (the membrane of Schwann cells in peripheral nervous systems and of oligodendrocytes in CNSs; see Figure 12.5). The glial cytoplasm is extruded from between the glial membrane layers so that the whole wrapping serves as an insulating layer. This multiply-wrapped insulating layer, termed *myelin*, stops at intervals of 1 mm or so along the length of the axon. The gaps at which the glial wrappings are absent (Nodes A, B, and C in Figure 12.27) are called the **nodes of Ranvier**.

Myelin electrically insulates the major part of the axon (the regions between nodes, or **internodes**) nearly completely, leaving only the nodes of Ranvier as loci of ion flow across the axon membrane (see Figure 12.27). *In myelinated axons, action potentials occur only at the nodes of Ranvier*, in contrast to the continuous sweep of action potentials over an unmyelinated axon. Myelinated axons

are therefore said to exhibit **saltatory conduction**, in which the action potential jumps (saltates) from node to node without active propagation in the internode. Action potentials are typically initiated at the axon initial segment, and then saltate from node to node because these are the only regions with high concentrations of voltage-gated Na^+ channels (Figure 12.28).

The principal effect of myelin is to increase the membrane resistance of myelinated axon regions by 1000- to 10,000-fold over the resistance at the nodes of Ranvier. When a node of Ranvier undergoes an action potential, the local currents cannot leak out through the high membrane resistance of the adjacent internode, but instead must flow farther to the next node of Ranvier (see Figure 12.27). Thus myelination greatly increases the spatial spread of local currents (i.e., the axon length constant) by this resistance effect.

A second, equally important function of myelin is to decrease membrane capacitance. If myelin only increased membrane resistance (without decreasing capacitance), its effect on the axon length constant would be largely offset by an increase in the membrane time constant, τ . (Recall that the time constant is equal to the product of membrane resistance and membrane capacitance, $R_m C_m$.) An increase in the time constant would tend to *slow* conduction velocity because it would take more time for a current to depolarize a patch of membrane to threshold. Capacitance is inversely proportional to the distance separating the charges on the “plates” of a capacitor, which in this case is the distance between the axoplasm and the extracellular fluid. Myelin increases this distance in proportion to the number of glial membrane wrappings, so that capacitance is decreased about 1000-fold. Thus the increase in R_m of myelinated regions is offset by a decrease in C_m , and the membrane time constant is nearly unaffected.

Myelination, then, greatly increases conduction velocity by increasing the axon length constant without increasing the time constant.

Currents from an action potential at one node must travel to the next node before crossing the membrane, and the currents are not slowed by having to displace much charge in the intervening myelinated internode.

Myelinated axons permit vertebrates to have neural coordinating and control systems with small-diameter axons that nonetheless conduct rapidly. A frog myelinated axon 12 μm in diameter has a conduction velocity of 25 m/s at 20°C. An unmyelinated squid giant axon must be about 500 μm in diameter to achieve the same 25-m/s velocity at 20°C! Thus myelination allows the same velocity to

FIGURE 12.27 Myelinated axons speed the propagation of an action potential

(a) Each segment of an axon in the peripheral nervous system is myelinated by a Schwann cell. The Schwann cell wraps around the axon segment, providing many layers of Schwann cell membrane without intervening cytoplasm. (b) An action potential at one node of Ranvier (Node A) sets up local currents that flow along the axon, as in Figure 12.25. Currents cannot cross the membrane in the internode, which has very high resistance and low capacitance. Therefore, transmembrane current flow is restricted to the nodes, and the membrane length constant is much longer. Below, depolarization of Node B opens Na^+ channels, generating the action potential and setting up local currents that spread to Node C. Note that some local current can flow past the nearest node to contribute to the depolarization of more distant nodes. Action-potential propagation in myelinated axons is saltatory, jumping from node to node.

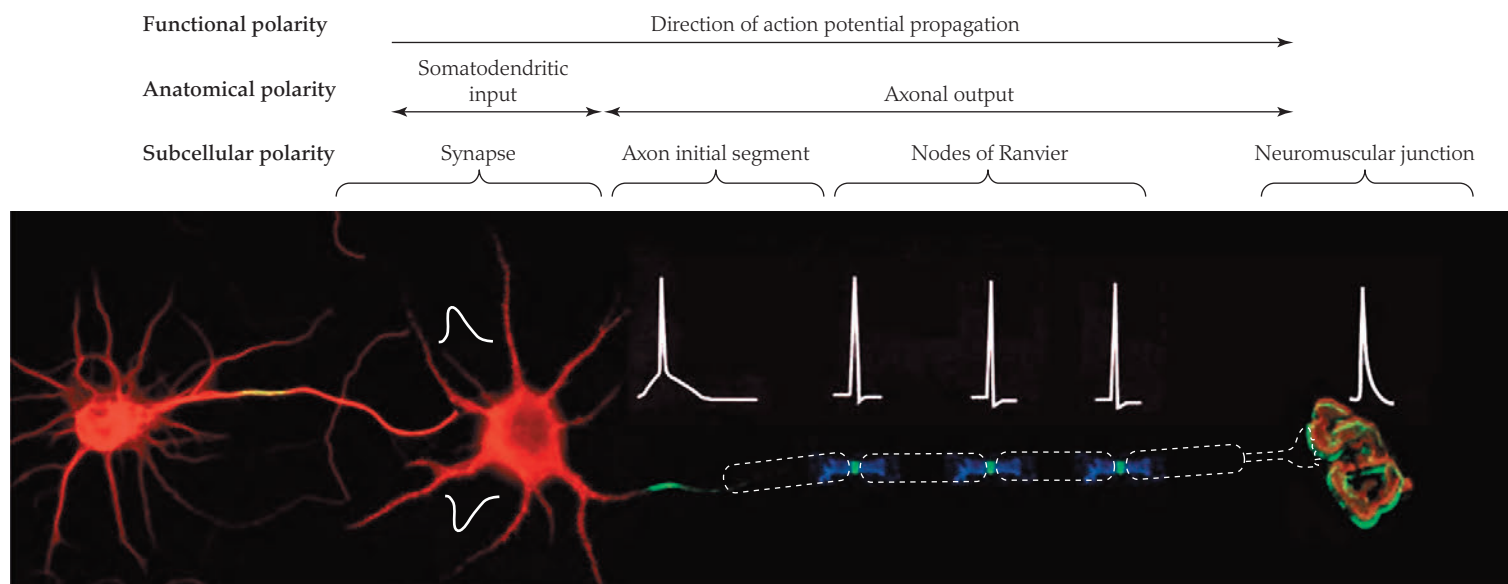

FIGURE 12.28 Spatial distribution of voltage-gated channels at the surface of a myelinated neuron This composite fluorescence micrograph depicts the locations of high concentrations of voltage-gated Na^+ channels (green, yellow) and K^+ channels (blue). The Na^+ channels are localized at the axon initial segment (site of action-potential initiation) and at the nodes of Ranvier. K^+ channels are localized at paranodal regions just next to the nodes. (From Rasband 2010.)

be achieved with a 40-fold reduction in diameter and a 1600-fold reduction in axon cross-sectional area and volume. *With a reduction in axon dimensions, many more axons can be incorporated into a nervous system of a given size.*

Although myelin is usually considered to have evolved exclusively in vertebrates, some crustaceans have axons with analogous sheaths of glial wrappings that exhibit increased conduction velocities similar to those for vertebrate compact myelin. The 30- μm myelinated axons of a shrimp conduct at 20 m/s at 17°C, a velocity comparable to that of a 350- μm squid axon. Other myelinated shrimp axons 100 to 120 μm in diameter conduct at velocities exceeding 90 m/s at 20°C, rivaling the fastest mammalian myelinated axons. In contrast, unmyelinated lobster axons of the same 100- to 120- μm diameter have conduction velocities of only 8 m/s. Vertebrates, however, remain the only group with substantial numbers of myelinated neurons. Crustacean myelinated neurons are rare, specialized adaptations in high-velocity escape systems, but myelinated neurons are ubiquitous features of vertebrate nervous systems.

TEMPERATURE The gating of the voltage-dependent ion channels, and thus the time course of membrane depolarization to threshold, is temperature-dependent. Consequently, an increase of 10°C tends to nearly double conduction velocity (the value of Q_{10} is approximately 1.8; see Chapter 10, page 236) in both myelinated and unmyelinated axons. A frog myelinated axon 12 to 14 μm in diameter conducts at 25 m/s at 20°C, but a cat myelinated axon of only 3.5 to 4 μm conducts at the same 25 m/s at 37°C. Thus the evolution of homeothermy in birds and mammals—along with myelination—has allowed further axon miniaturization and higher conduction velocities.

Finally, the propagation of action potentials merely ensures that a neuron's electrical signals reach the end of the axon undiminished. For a neuron's signals to affect other cells, another process—synaptic transmission (the topic of Chapter 13)—is required.

SUMMARY The Propagation of Action Potentials

- Action potentials propagate because the membrane's underlying permeabilities to ions are voltage-dependent. Local circuits of current flow spread the depolarization along the axon, depolarizing a new region to threshold. Behind an advancing action potential, Na^+ channels remain inactivated long enough to prevent reexcitation by the local currents.
- The conduction velocity of an action potential depends on axon diameter, myelination, and temperature. Larger-diameter axons have higher conduction velocities because their length constants are longer, so local currents spread farther along the axon. Myelin greatly increases conduction velocity by increasing R_m (increasing the length constant) while decreasing C_m (preventing an increase in the time constant). Increasing temperature speeds the gating of channels so that the membrane responds faster to the local currents.

Study Questions

1. Suppose that the cell shown in Figure 12.12a is permeable to Na^+ , K^+ , and Cl^- but not to A^- . In the absence of ion pumps, Na^+ and Cl^- will diffuse in, the cell will become out of osmotic balance, and water will enter. Explain why a cell cannot be in thermodynamic equilibrium and also be in osmotic balance, unless there is a nonpermeating ion in the extracellular fluid (as would be the case if Na^+ were nonpermeating). What does this suggest about the evolutionary origin of the Na^+ - K^+ exchange pump?
2. Unmyelinated axons conduct action potentials without decrement, but when myelinated axons lose myelin in demyelinating diseases such as multiple sclerosis, conduction of action potentials is blocked. Why?

3. Using Figure 12.26, compare and explain the difference (a) between the velocity of action-potential propagation in lamprey axons and frog myelinated axons of equal diameter, (b) between squid axons and frog myelinated axons of equal velocity, and (c) between frog and mammalian myelinated axons.
4. The ion flows across neuronal membranes at rest and during an action potential do not significantly change bulk ion concentrations, except for that of Ca^{2+} ions. Resting Ca^{2+} ion concentrations in cells are usually about $10^{-7} M$, and Ca^{2+} ions exert physiological effects at concentrations of perhaps $10^{-5} M$. Explain why relative changes of intracellular $[\text{Ca}^{2+}]$ are much greater than for, say $[\text{Na}^+]$ (12–50 mM).
5. For the ion concentrations in Table 12.1, calculate the equilibrium potentials for each ion species in squid axons and in mammalian muscle fibers.
6. Using the values in question 5, determine what ions are in passive equilibrium at a membrane potential of -60 mV in the squid at 18°C , and at -91 mV in mammalian muscle fibers at 37°C .
7. Suppose you voltage-clamp a squid axon from a resting membrane potential of -60 mV to a clamped value of $+55 \text{ mV}$. Describe the early ionic current (say, at 0.5 ms after clamping). Use ionic concentrations from Table 12.1.
8. Suppose a squid axon at rest is 20 times as permeable to K^+ as to Na^+ . Using the simplified version of the Goldman equation in Figure 12.13, calculate the resting membrane potential. If during the rising phase of an action potential the permeability to Na^+ increases to 100 times the permeability to K^+ , at what value will the action potential peak?
9. Suppose you stimulate an axon so that you generate an action potential at both ends at the same instant. Describe the propagation of these action potentials. What happens when they meet?
10. With increased neuronal electrical activity in a brain area, the rates of glucose uptake, O_2 consumption, and blood flow increase. (These changes are the basis of activity imaging such as functional magnetic resonance imaging [fMRI], which is illustrated in Figure 15.7.) Why does neuronal activity increase local metabolic rate?
11. Toxins such as tetrodotoxin (from puffer fish and newts) and saxitoxin (from red-tide dinoflagellates) block voltage-gated Na^+ channels selectively. What effect would they have on currents in a voltage clamp to 0 mV ? How do you suppose they evolved?
12. Part of the evidence for a “ball-and-string” model of Na^+ channel inactivation is that the proteolytic enzyme pronase can selectively disable channel inactivation when perfused into the axoplasm of a squid axon. Where would you expect pronase to cleave the Na^+ channel protein?

Synapses

A synapse, as we have noted, is a specialized site of contact of a neuron with another neuron or with an effector. It is the locus where one cell (the *presynaptic* neuron) influences the function of another cell (the *postsynaptic* neuron or effector). Neurons—except in the special case of those having electrical synapses—are discontinuous with each other; even at synapses, they are typically separated by a 20- to 30-nanometer (nm) space called the *synaptic cleft*. Essentially all influences that neurons have on each other and on effectors are exerted at synapses. The green neuron shown here receives synaptic input from axon terminals of other neurons, which exhibit red fluorescence. Each yellow spot is a synapse at which the red presynaptic terminal overlaps with the bright green postsynaptic membrane, producing a combined yellow fluorescence.

You often hear the analogy that the brain is like a computer. Like all analogies, this one is imperfect, but it is useful here. Inasmuch as the brain is like a computer, the neuronal axons (which transmit action potentials long distances without degradation) are analogous to the wires in the computer, and the synapses are analogous to logical junctions by which signals in one element affect others. It is the connections and properties of the logical junctions (the synapses) that determine the performance—and improvement in performance—of the brain computer, more than the properties of the wires.

The *Doogie* mouse introduces two sorts of synaptic function that illustrate the range of ways in which a synapse can work: *synaptic transmission* and *synaptic plasticity*. In **synaptic transmission**, a presynaptic signal—usually an action potential—has an effect on a postsynaptic cell. The effect is rapid and transient, and it can be excitatory or inhibitory. This transmission of a signal across the synapse is the simplest kind of synaptic action. We introduce this fast-transmission function of synapses by examining a neuromuscular junction: the synapse between a neuron and a muscle fiber. Neuromuscular synaptic transmission causes muscle fibers to contract, allowing, for example, a mouse to jump. The second sort of synaptic function is **synaptic plasticity**: the ability to change the functional properties of synapses. Synaptic actions can change the synapse itself to make it stronger or weaker, and they can also produce long-lasting changes in the postsynaptic cell. This modulation of synaptic processes is the basis of

The *Doogie* mouse This genetically engineered mouse is synaptically smarter than the average mouse. Mouse brains contain neurons that receive synaptic input; the neuron shown here has a postsynaptic protein labeled with a green fluorescent dye, with the presynaptic terminals of other neurons labeled with a red fluorescent dye. Each synapse is a yellow spot of overlap of the red presynaptic ending and the green postsynaptic membrane in a yellow mix of both red and green fluorescence. Changes in synaptic strength underlie learning and memory. (Neuron photograph courtesy of Mary B. Kennedy, Division of Biology, Caltech.)

TABLE 13.1 Kinds of synapses

Characteristic	Chemical synapse		Electrical synapse
	Ionotropic	Metabotropic	
Mechanism and time course	Fast	Slow	Instantaneous current flow
Function	Signal transmission	Signal transmission, neuronal modulation	Electrical transmission
Effect	Excitation (fast EPSP), inhibition (fast IPSP) ^a	Excitation (slow EPSP), inhibition (slow IPSP), other (cytoplasmic and genetic effects)	Electrical coupling

^aEPSP = excitatory postsynaptic potential; IPSP = inhibitory postsynaptic potential.

much functional change in the nervous system, both in development and in learning and memory.

Synapses have diverse actions, as befits their functional importance. A synapse can work chemically or electrically. It can excite the postsynaptic cell or inhibit it. A synaptic potential can result from a permeability increase or a permeability decrease. Synaptic action can be fast or slow, and it can *mediate* transmission or *modulate* the plastic properties of the synapse itself. Synapses can act immediately and directly on the membrane potential of the postsynaptic cell, or they can have indirect and longer-lasting effects. Some of these diverse actions are functionally linked, but others are not. In this chapter, we first consider electrical transmission and then give an overview of the more widespread chemical transmission. Later in the chapter we examine the presynaptic and postsynaptic mechanisms of chemical synapses and study the distinction between *ionotropic* synaptic action (which is fast and produces direct changes in ion permeability and thus membrane potential) and *metabotropic* synaptic action (which is slow and produces chemical signal transduction changes in the postsynaptic cell). Only after considering these kinds of synaptic mechanisms can we try to explain (with the help of the *Doogie* mouse) the synaptic changes that may form much of the basis of learning and memory.

Synaptic Transmission Is Usually Chemical but Can Be Electrical

At the most fundamental level, there are two kinds of synapses: electrical and chemical (Figure 13.1). Both kinds can rapidly change the membrane potential of a postsynaptic cell. Electrical and chemical synapses play different functional roles, so both kinds are adaptive in nervous systems. We discuss electrical transmission first, setting the stage for treatment of the more common and more complex chemical transmission process. Table 13.1 classifies the different types of synapses.

Fast synaptic transmission—in contrast to slow synaptic effects, which we will discuss later—works in milliseconds: An action potential in a presynaptic neuron leads to a rapid postsynaptic voltage change, with a typical delay of less than a millisecond. The mechanism of this fast synaptic action was a subject of much debate in the first half of the twentieth century. One group (the “sparks”) argued that synaptic transmission was by direct electrical means. The other group (the “soups”) postulated that transmission was by a chemical mechanism: Depolarization of the presynaptic terminal caused it to release a chemical neurotransmitter, which diffused across the synaptic cleft to affect the postsynaptic cell. It is now clear that both kinds of synaptic transmission can occur:

FIGURE 13.1 **Electrical and chemical synapses** Both kinds of synapses play roles in neural communication, but they work in fundamentally different ways. (a) Electrical synapses have low-resistance pathways that allow currents to flow directly between neurons. Current flow through the low-resistance pathways of gap junctions electrically couples the neurons. If current is injected into one neuron, the depo-

larization (or hyperpolarization) spreads to another electrically coupled neuron, and the depolarization of one cell produces a smaller depolarization of the adjacent cell. (b) In chemical synapses, the currents escape between neurons and do not enter the postsynaptic neuron. Instead, released molecules of neurotransmitter (not shown) carry the signal across the synaptic cleft.

Most synaptic transmission is chemical, whereas direct electrical transmission occurs uncommonly.

Electrical synapses transmit signals instantaneously

In an **electrical synapse**, electric currents from one cell flow directly into the next cell, changing its membrane potential (see Figure 13.1a). Because this current flow is instantaneous, an electrical synapse has essentially no delay. Moreover, such current flow can usually be in either direction, so electrical synapses are often not polarized. Because of their instantaneous transmission of signals and their synchronizing ability, electrical synapses are found in nervous systems where speed is most important, and where synchronous activity of several cells is an advantage.

The major structural specialization for electrical transmission is the **gap junction**. A gap junction (as introduced in Chapter 2; see page 39) is a specialized locus where protein channels bridge the gap between two cells, directly connecting their cytoplasm. Gap junctions provide a low-resistance path for current flow, electrically coupling the cells that they join. Thus any electrical change in one cell is recorded in the other, with some weakening but with negligible delay.

Figure 13.1a shows the typical effects of this electrical coupling. Depolarization or hyperpolarization of one cell produces a weaker corresponding change in the other cell. The voltage change is always accompanied by some decrease because every gap junction has some resistance, but the amount of the decrease varies. Thus electrical synapses differ in strength: The larger the gap-junction area, the lower the resistance between cells and the stronger the coupling.

Electrical synapses can act as short-latency synaptic relays, in which each presynaptic action potential triggers a postsynaptic action potential. In other cases, with weaker electrical coupling or high-impulse thresholds, a presynaptic action potential may produce only subthreshold depolarization of the postsynaptic cell. Most electrical synapses are bidirectional, transmitting voltage changes roughly symmetrically in both directions. However, in the electrical synapse between the lateral giant axon and the giant motor neuron of crayfish, the electrical synapse is rectifying; that is, it allows current flow preferentially in one direction. Thus an action potential in the lateral giant axon excites the giant motor neuron, but excitation of the motor neuron by other pathways cannot “backfire” to the lateral giant axon.

The structure of vertebrate gap junctions has been examined by electron microscopy and X-ray diffraction studies. Gap junctions narrow the space between adjacent cells, holding the pre- and postsynaptic membranes only about 3.5 nm apart (instead of the 20–30 nm that usually separates neighboring cells). In the region of close membrane apposition, the narrow gap separating the membranes is bridged by a regular array of channel structures termed **connexons** (Figure 13.2).

Each connexon is composed of hexamers of the protein *connexin* surrounding a 2-nm pore. Connexons are hemichannels; each connexon of one cell pairs with a connexon of the adjacent cell to form a channel that connects the cytoplasm of the cells. The channels of all the connexons are the low-resistance pathways that allow electric current to flow between the cells. They are large enough to allow the passage of most ions, as well as dye and tracer molecules smaller than about 1000 daltons. Connexon

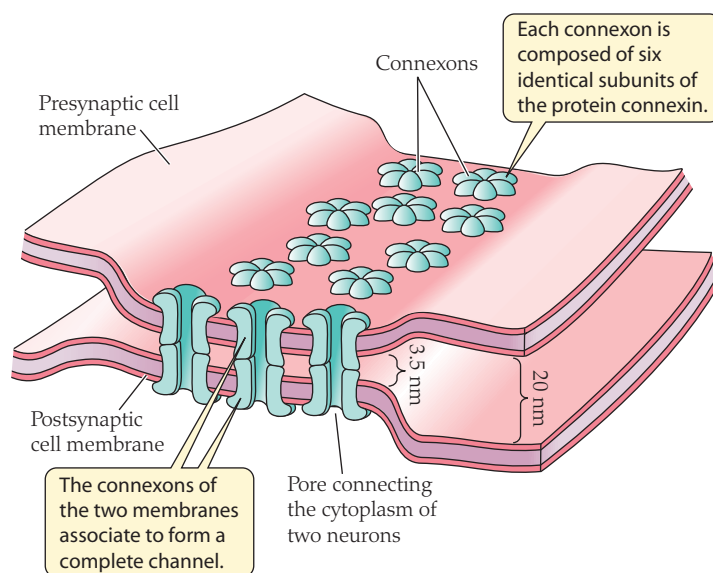

FIGURE 13.2 The molecular structure of gap junctions A gap junction is a localized patch of close membrane apposition where protein hexamers called connexons provide channels that electrically connect the cytoplasm of the cells.

channels are thought to be open normally, but they can close in response to electrical or chemical changes in the cells. Gap junctions in invertebrate protostomes have similar structures, called *innexons*, which are composed of subunits of the protein *innexin*. Innexin proteins are analogous but not homologous to the connexin proteins of vertebrates.

Where in nervous systems has natural selection favored the evolution of electrical synapses? In most cases it is where speed or synchronization is paramount. We noted that electrical synapses can act as fast intercellular relays, in which action potentials are instantaneously transmitted from cell to cell. Such relay electrical synapses are found in escape systems—for example, in crayfish (Figure 13.3) and fish. In such fast escape responses, every millisecond saved by an electrical synapse can produce a selective advantage of not being eaten. Electrical synapses are also advantageous for groups of neurons that normally fire synchronously, such as the neurons controlling electric-organ discharge in electric fish.

Chemical synapses can modify and amplify signals

Unlike electrical synapses, **chemical synapses** have a discontinuity between the cells because the 20- to 30-nm synaptic cleft of a chemical synapse is a barrier to direct electrical communication (see Figure 13.1b). The presynaptic electrical signal is first transduced into a chemical signal: the release of neurotransmitter molecules from the presynaptic terminals. The molecules of neurotransmitter rapidly diffuse to the postsynaptic membrane, where they bind to receptor molecules that are specialized to generate an electrical or chemical change in response to the neurotransmitter binding.

Viewed with an electron microscope, chemical synapses exhibit a distinctive structure (Figure 13.4). The axon terminal of the presynaptic neuron contains neurotransmitter molecules stored in **synaptic vesicles**, with several thousand molecules per vesicle. At the synaptic cleft, both the pre- and postsynaptic membranes appear

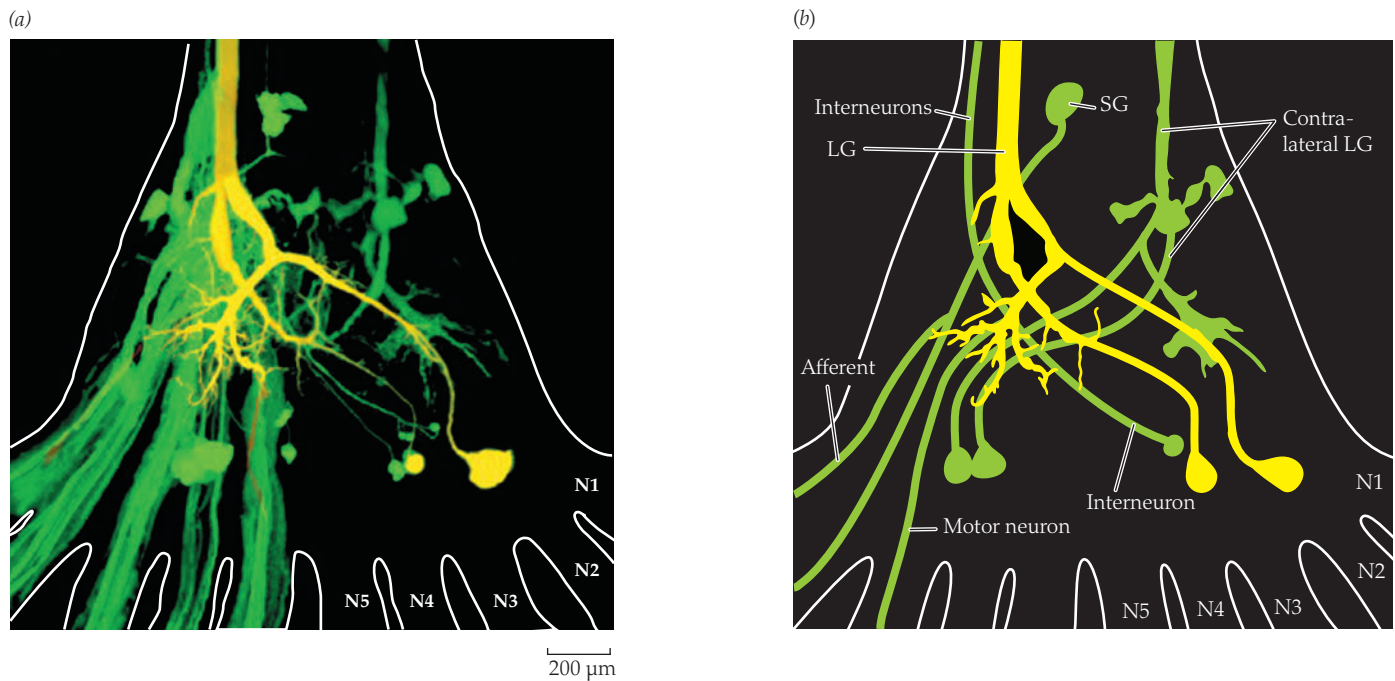

FIGURE 13.3 Electrical synapses in the crayfish escape circuit. Neurons electrically connected by gap junctions are said to be dye-coupled, because low-molecular-weight dyes pass through the gap junctions to the coupled cells. (a) A fluorescence micrograph and (b) diagram show the coupling of cells in the last abdominal ganglion of a crayfish. The lateral giant neuron (LG, yellow) has been injected with two fluorescent dyes: a small dye molecule that fluoresces green and a larger dye molecule that fluoresces red. The smaller, green-fluorescing molecule passes through gap junctions, so the green images are all neurons that are dye-coupled, and electrically coupled, to the lateral giant

neuron. The red-fluorescing molecule is too large to pass through gap junctions and thus stays in the LG. The LG is yellow because it contains both the red- and green-fluorescing dyes. Neurons that are electrically coupled to LG include sensory neurons from tactile hairs on the crayfish's tail (diffuse green in nerves N1–N5), sensory interneurons, motor neurons to tail muscles (bright green cell bodies and axons in N1–N5), the segmental giant neuron (SG), and the contralateral LG. Electrically mediated synaptic transmission through many elements of this neural circuit allows for a very rapid, short-latency escape tail flip in response to threatening stimuli. (a from Antonsen and Edwards 2003.)

denser and thicker than elsewhere because of local aggregations of proteins at these membranes. Dark tufts of electron-dense material on the cytoplasmic side of the presynaptic membrane mark **active zones** at which synaptic vesicles release their neurotransmitter. Other dense aggregates at the postsynaptic membrane are called **postsynaptic densities**, and reflect accumulation of neurotransmitter receptors as well as **scaffolding proteins** that help organize these receptors and other proteins at the synapse.

The vast majority of excitatory synaptic inputs in the central nervous system (CNS) occur on neuronal dendrites, and specifically on small mushroom-shaped protrusions known as dendritic spines (Figure 13.5). As we will discuss later, these dendritic spines remain malleable even in the mature CNS: Their size and shape appear to change in the intact brain of living mice in response to alterations of external stimuli!

A presynaptic neuron releases neurotransmitter molecules in response to an arriving action potential (Figure 13.6). Neurotransmit-

ter is synthesized in the presynaptic neuron and stored in synaptic vesicles until release. Neurotransmitter is released by calcium-dependent exocytosis—fusion of the synaptic vesicles to the presynaptic membrane (see Figure 13.6b). The released neurotransmitter molecules bind to receptor proteins embedded in the postsynaptic membrane. Neurotransmitter receptors are transmembrane proteins that are effectors for change in the postsynaptic cell, usually producing a change in postsynaptic membrane potential.

FIGURE 13.4 The structure of a chemical synapse. Electron microscopy reveals distinctive features of chemical synapses. Presynaptic terminals (here colored yellow) contain mitochondria (red) and numerous synaptic vesicles (green), some of which are clustered at dense release sites called active zones (presynaptic densities; purple). Opposite the active zones across the synaptic cleft (pink), postsynaptic densities (also purple) line the postsynaptic membrane. The densities represent proteins involved in neurotransmitter release (presynaptically) and in clustering of neurotransmitter receptors (postsynaptically).

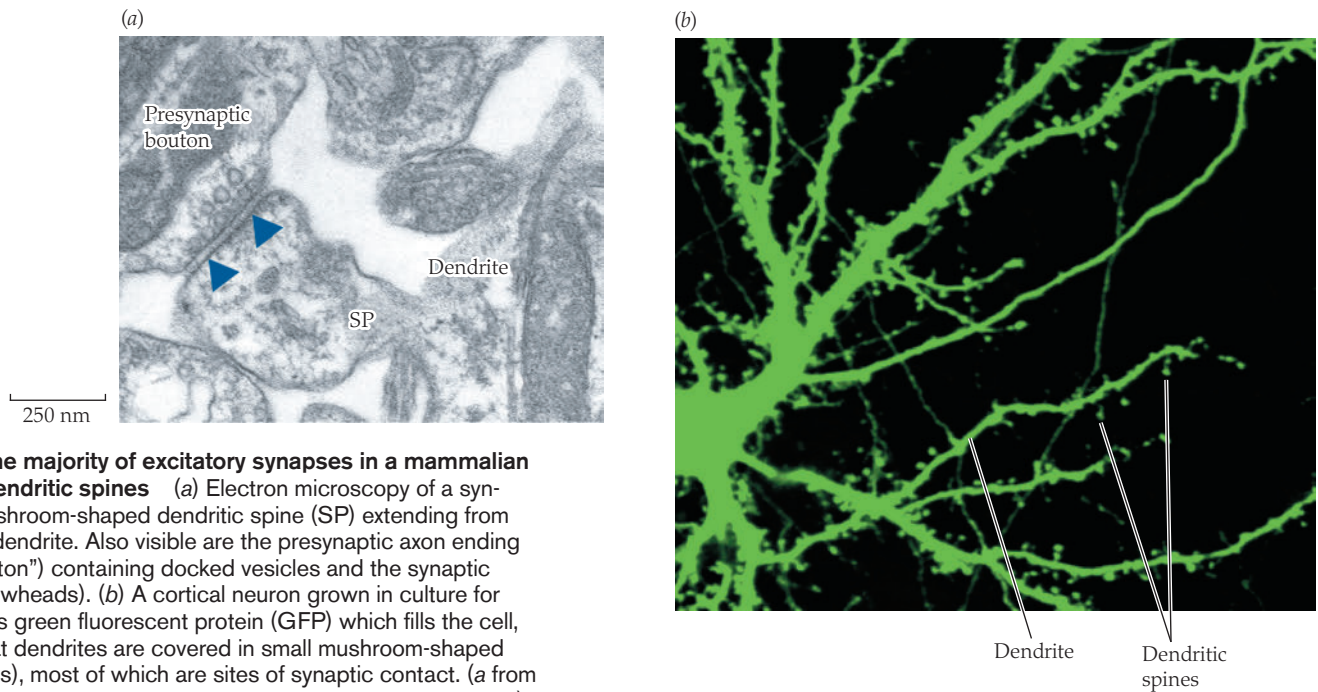

FIGURE 13.5 The majority of excitatory synapses in a mammalian brain occur on dendritic spines (a) Electron microscopy of a synapse shows a mushroom-shaped dendritic spine (SP) extending from the postsynaptic dendrite. Also visible are the presynaptic axon ending (“presynaptic bouton”) containing docked vesicles and the synaptic junction (blue arrowheads). (b) A cortical neuron grown in culture for 21 days expresses green fluorescent protein (GFP) which fills the cell, demonstrating that dendrites are covered in small mushroom-shaped protrusions (spines), most of which are sites of synaptic contact. (a from Waites et al. 2005; b courtesy of Matthew Kayser and Matthew Dalva.)

Neurotransmitter receptors work in one of two ways. They can produce *fast* changes in membrane potential (depolarization or hyperpolarization) by directly increasing permeability to ions (see Figure 13.6c). When such receptors bind their neurotransmitter, they open to allow ion flow. In this case, a single molecule constitutes both the receptor and the ion channel. Receptors working in this

way are termed **ionotropic receptors** because they directly alter permeability to ions. Other receptors (see Figure 13.6d) trigger a signaling cascade of second messengers in the postsynaptic cell and are called **metabotropic receptors**. Metabotropic receptors often have relatively *slow*, long-lasting modulatory effects on synaptic processes, as we will discuss later in this chapter.

FIGURE 13.6 The function of a chemical synapse (a) A presynaptic action potential depolarizes the axon terminal and opens voltage-gated Ca^{2+} channels located near active zones. (b) Ca^{2+} ions enter the terminal and induce vesicles at the active zones (indicated by triangles on the membrane) to fuse with the presynaptic membrane and release neurotransmitter by exocytosis. Neurotransmitter molecules diffuse across the synaptic cleft and bind to postsynaptic receptor proteins.

(c) Ionotropic neurotransmitter receptors open ion channels, creating an ionic current that changes the postsynaptic cell's membrane potential. In this example, Na^+ influx would cause depolarization. (d) Metabotropic receptors activate a metabolic cascade in the postsynaptic cell. Metabotropic receptors are G protein-coupled receptors (GPCRs) that activate G proteins to produce a second messenger such as cyclic AMP (cAMP).

Transmission at chemical synapses is necessarily slower than transmission at electrical synapses because the steps of transmitter release and receptor action take more time than the instantaneous spread of electric current. Fast ionotropic chemical synapses typically have a *synaptic delay* of 0.3 to 3 milliseconds (ms), depending on species and temperature. Even though these delays are short, there must be countervailing adaptive advantages of chemical synapses that explain their prevalence. Several advantages can be recognized:

- Chemical synapses can amplify current flow. A presynaptic action potential can lead to the release of a few or many synaptic vesicles. Each vesicle contains a few thousand molecules of transmitter. Depending on the number of active zones and the size of the presynaptic terminal, the amount of transmitter released can open many channels and amplify the postsynaptic current.
- Chemical synapses can be either excitatory or inhibitory, unlike electrical synapses, which are nearly always excitatory.
- Chemical synapses are one-way; a presynaptic neuron excites or inhibits a postsynaptic cell, but not vice versa. Most electrical synapses are two-way.
- Chemical synapses are much more modifiable in their properties than electrical synapses are. Use and circumstance can make them stronger, and disuse can make them weaker. This plasticity is important for nervous system development and for learning.

SUMMARY Synaptic Transmission Is Usually Chemical but Can Be Electrical

- Most synapses are chemical; some are electrical. Electrical synapses are very fast and usually are bidirectional. Gap junctions are the anatomical basis of electrical synapses; they contain connexons that allow current to flow directly between the cells, electrically coupling them.
- Chemical synapses are unidirectional, with a presynaptic neuron that releases neurotransmitter when stimulated, and a postsynaptic neuron (or effector) that bears receptor molecules to which the neurotransmitter binds.
- Neurotransmitter receptors may directly open their own ion channels; or they may act indirectly through a signal transduction cascade that involves second messengers, to open, close, or change ion channels that are separate molecules.
- Electrical synapses mediate fast, synchronizing actions of neurons. Chemical synapses integrate neuronal functions, by fast (ionotropic) excitation and inhibition, or by slow (metabotropic) modulation of neuronal and synaptic properties.

Synaptic Potentials Control Neuronal Excitability

The primary function of synaptic transmission is to control the excitability of the postsynaptic cell. When a burst of neurotransmitter diffuses across a synapse, it generates a **synaptic potential**—a tran-

sitory, graded change in the resting membrane potential—in the postsynaptic cell. A synaptic potential that tends to *depolarize* the cell membrane is excitatory, and one that tends to *hyperpolarize* the cell membrane is inhibitory. **Excitation** is an increase in the probability that a cell will generate an impulse (an action potential), or if the cell is already generating impulses, excitation causes an increase in the impulse frequency. **Inhibition**, by contrast, is a decrease in the probability of impulse generation or a decrease in impulse frequency. Excitatory and inhibitory synapses summate their voltage effects to control action-potential generation of the postsynaptic cell.

Synapses onto a spinal motor neuron exemplify functions of fast synaptic potentials

We can witness the excitatory and inhibitory effects of synaptic potentials by stimulating the peripheral nerves containing axons that synapse on a cat spinal motor neuron, while recording the changes in the motor neuron's membrane potential (**Figure 13.7**). In **Figure 13.7b**, stimulation of certain peripheral nerves (sensory pathway A or B) produces synaptic potentials that are graded depolarizations in the motor neuron, each with a brief rising phase and an exponential decay over a time course of 10 to 20 ms. These depolarizations are **excitatory postsynaptic potentials (EPSPs)**. Each excitatory synapse usually produces a very small EPSP, one that depolarizes the membrane by less than 1 millivolt (mV).

EPSPs can be combined in two ways. If peripheral nerve A is stimulated repeatedly and rapidly, the resultant EPSPs combine in a process called **temporal summation**. Simultaneously occurring EPSPs produced by different nerves (Stimulus A + B in **Figure 13.7b**) also combine, in a process called **spatial summation**. With sufficient presynaptic stimulation, EPSPs can summate temporally and spatially to the voltage threshold and cause the motor neuron to generate one or more action potentials.

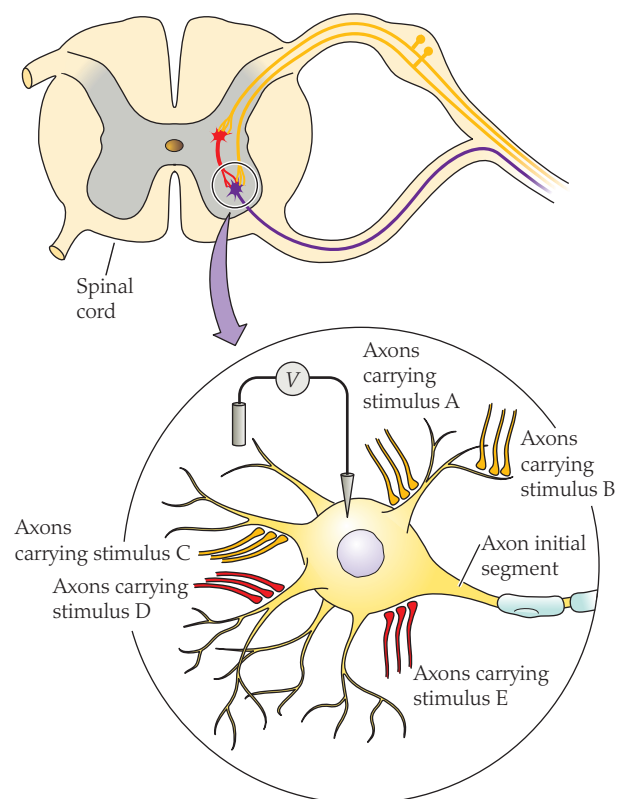

Inhibitory synapses produce similar, but countervailing, effects on the membrane potential of a motor neuron. In the example in **Figure 13.7c**, stimulating peripheral nerve D or E evokes synaptic potentials that briefly hyperpolarize the motor-neuron cell membrane. Because they drive the membrane potential away from threshold, these synaptic potentials are called **inhibitory postsynaptic potentials (IPSPs)**.

As **Figure 13.7c** demonstrates, IPSPs also produce temporal and spatial summation effects. What's more, EPSPs and IPSPs that occur simultaneously can summate spatially, reducing or canceling their respective excitatory and inhibitory effects on the postsynaptic neuron's membrane potential. A typical cat motor neuron receives input from about 10,000 synaptic terminals, and the moment-to-moment balance of EPSPs and IPSPs determines whether the motor neuron generates impulses or remains quiescent.

Synapses excite or inhibit a neuron by depolarization or hyperpolarization at the site of impulse initiation

Because most neurons receive thousands of synaptic endings, the output of a neuron—its temporal sequence of action potentials—is a complex function of its synaptic input. Thus a neuron's output is not the same as its input, but is instead an integral function of that input, a property called **neuronal integration**. The major process underlying neuronal integration is the spatial and temporal summation of EPSPs and IPSPs. However, this process is more complex than the simple algebraic summation of postsynaptic potentials.

(a) Motor neurons and synapses

(b) Excitatory postsynaptic potentials (EPSPs)

(c) Inhibitory postsynaptic potentials (IPSPs)

**FIGURE 13.7 Excitatory and inhibitory postsynaptic potentials**

(a) Clusters of synapses onto a spinal motor neuron of a cat. Yellow presynaptic terminals are excitatory; red presynaptic terminals are inhibitory. The axon initial segment is the site of action-potential initiation. (b) Stimulation of excitatory presynaptic neurons elicits excitatory postsynaptic potentials (EPSPs), graded depolarizations that depolarize V_m (membrane potential) toward threshold (indicated by the red arrow). (c) Inhibitory postsynaptic potentials (IPSPs) are hyperpolarizing, moving V_m away from threshold. Both EPSPs and IPSPs can summate with other postsynaptic potentials of the same pathway (temporal summation) or a different pathway (spatial summation).

Neuronal integration also is a function of the spatial relationships of excitatory and inhibitory synapses to one another, as well as their relative proximity to the site of impulse initiation. For spinal motor neurons, this site is the initial segment of the axon, adjacent to the axon hillock.

Because postsynaptic potentials are *graded potentials*, their spread is governed by the cable properties of the postsynaptic cell membrane (see Chapter 12; page 304). Consequently, the functional effect of a synapse depends in part on where it is located on a neuron. A synapse on the soma or cell body (called an **axosomatic synapse**) is only a short electrotonic distance from the axon initial segment; that is, the amplitudes of postsynaptic potentials are decreased a small amount in their passive spread from the soma to the impulse initiation site.

A synapse onto a dendrite (**axodendritic synapse**), however, may be as much as 200 micrometers (μm) away from the axon hillock. The electrotonic length of motor neuron dendrites is estimated to be 1 to 2λ (one or two times the membrane length constant [symbolized by the Greek letter lambda]; see p. 305), so a synaptic potential at the dendrite tip is decreased to 14–37% of its initial amplitude in its spread to the axon hillock. Although other factors may partially compensate for this decrease with distance, synapses that are closer to the axon hillock usually have more effect on the output of the postsynaptic cell than do synapses on the distal ends of dendrites. Thus the summation of synaptic input is weighted by the electrotonic distance of the synapses from the axon hillock.

SUMMARY Synaptic Potentials Control Neuronal Excitability

- Most synapses in nervous systems are chemical synapses that mediate fast excitation and inhibition. Neurotransmitters act at receptors to open ion channels, to depolarize (EPSP) or hyperpolarize (IPSP) the postsynaptic neuron.
- EPSPs and IPSPs summate, so the membrane potential of the postsynaptic neuron is a moment-to-moment integral of synaptic input.
- Postsynaptic potentials are graded and spread passively to the axon initial segment (the site of action-potential initiation). Therefore, more-distant synapses may have smaller effects on the neuron's output.

Fast Chemical Synaptic Actions Are Exemplified by the Vertebrate Neuromuscular Junction

We turn now to the mechanisms of action of fast chemical synapses, the sort that gave rise to the synaptic potentials in the preceding section. Such synapses are called *fast* because they produce postsynaptic potentials within a few milliseconds of a presynaptic action potential. Fast synaptic action is the conceptual model that has dominated scientific thinking about how nervous systems work.

In fact, until about 25 years ago, fast synaptic transmission was the only kind known, or even suspected. All synapses were thought to work by producing fast EPSPs and IPSPs such as those shown in Figure 13.7. Although investigators now know that synapses can also work in other ways, fast chemical transmission is still considered the “workhorse” of synaptic mechanisms, the basis of most neuronal interaction in nervous systems.

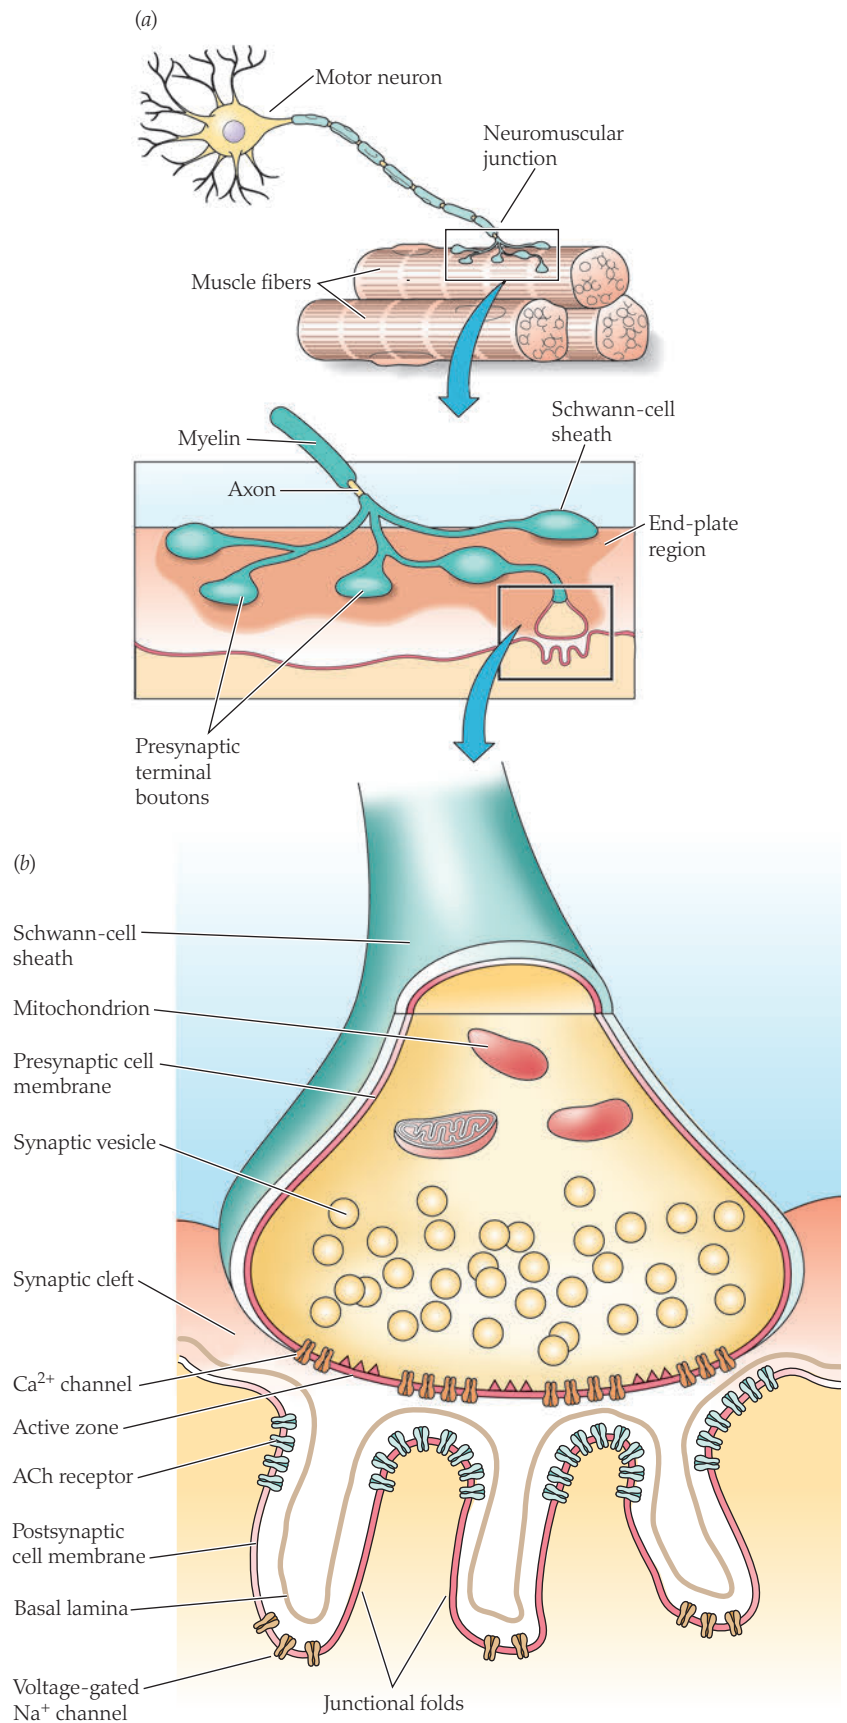

To show the *function* of fast chemical synapses, in the previous section we considered synapses onto motor neurons in the CNS. Much of what we know about synaptic *mechanisms*, however, has been learned through the study of *peripheral* synapses. For technical reasons it is hard to study synaptic mechanisms in the CNS. Synapses in the vertebrate CNS are buried inside a large mass of tissue. They usually cannot be seen through a microscope, nor can their immediate environment be changed readily. Moreover, a single vertebrate CNS neuron may have tens of thousands of synapses from other neurons ending on it, each neuron producing its own synaptic effects. Hence, researchers have turned to simpler *model systems*, in which detailed investigations of synaptic transmission are easier, and have later applied their findings to the more complex CNS. This strategy is analogous to studying squid giant axons to clarify the mechanisms by which action potentials are generated (see Chapter 12).

The vertebrate skeletal **neuromuscular junction** (also called the *motor end-plate*) is the model system for chemical synaptic transmission from which much of our basic knowledge of synaptic physiology is derived (Figure 13.8). For most vertebrate skeletal muscles, each muscle fiber is innervated by only one motor neuron. (Hundreds of motor neurons may innervate the whole muscle, but only one innervates a given fiber.) The neuromuscular junction functions as a *relay synapse*: Each action potential in the motor neuron evokes a large EPSP in the muscle fiber, which reaches threshold and elicits an action potential in the muscle fiber. The muscle fiber action potential propagates to all parts of the muscle fiber, depolarizing its membrane and triggering its contraction (muscle contraction will be discussed in Chapter 20).

The vertebrate neuromuscular junction has several advantages as a model synapse. In addition to its anatomical simplicity and large synaptic response, the neuromuscular junction is accessible and microscopically visible at the muscle surface. A researcher can impale a muscle fiber with an electrode under visual control and can readily change the fluid bathing the junction.

FIGURE 13.8 A vertebrate neuromuscular junction

(a) The neuromuscular junction consists of a single presynaptic motor neuron contacting a single postsynaptic skeletal muscle fiber. Presynaptic vesicles fill part of the terminal and cluster near active zones. (b) The postsynaptic muscle fiber membrane is deeply infolded, and these junctional folds contain ligand-gated acetylcholine (ACh) receptors at the upper parts of the fold. Voltage-gated channels are absent at the tops of the folds but are present deep in the folds and at the nonjunctional membrane. A basal lamina of extracellular, secreted proteins covers the muscle fiber. (After Kandel et al. 2000.)

FIGURE 13.9 Summary of events in chemical synaptic transmission at the vertebrate neuromuscular junction ① An action potential depolarizes the axon terminal of the motor neuron. ② The depolarization opens voltage-gated Ca^{2+} channels. ③ Depolarization of the terminal triggers vesicle exocytosis at an active zone, releasing acetylcholine (ACh). ④ ACh diffuses rapidly across the synaptic cleft and binds to acetylcholine receptors at the postsynaptic membrane. ⑤ The receptor channel opens to allow Na^+ and K^+ ion flow, producing a depolarizing excitatory postsynaptic potential (EPSP). The EPSP spreads to depolarize nearby regions to threshold and triggers a muscle fiber action potential. ⑥ The action potential propagates to all parts of the muscle fiber, eliciting contraction. ⑦ Acetylcholinesterase hydrolyzes the acetylcholine into acetate and choline. ⑧ Choline is actively transported back into the motor axon terminal to be resynthesized into acetylcholine.

Chemical synapses work by releasing and responding to neurotransmitters

The sequence of events of synaptic transmission at the vertebrate skeletal neuromuscular junction is summarized in **Figure 13.9**. Many of these steps and their sequence are characteristic of most synapses, as previously introduced in **Figure 13.6**. At the neuromuscular junction the neurotransmitter is acetylcholine (ACh), so when an action potential depolarizes the presynaptic terminal and opens voltage-gated Ca^{2+} channels (step ① in **Figure 13.9**), the Ca^{2+} entry (step ②) triggers vesicle fusion to release ACh into the synaptic cleft (step ③). Diffusion of neurotransmitter molecules across the synaptic cleft to the postsynaptic membrane is rapid (20–50 microseconds [μs]) because the diffusion path is so short (50 nm at the neuromuscular junction, 20–30 nm at CNS synapses).

At the postsynaptic membrane, neurotransmitter molecules bind to specific receptor proteins (step ④). At the neuromuscular junction, ACh receptor molecules are ligand-gated channels that are opened by the binding of transmitter. The channel opening allows ion flow, producing an *excitatory postsynaptic potential that spreads decrementally* (step ⑤).

At the neuromuscular junction (unlike most synapses) the excitatory postsynaptic potential is large enough to depolarize the muscle fiber membrane to its threshold and initiate a muscle fiber action potential (step ⑥). The muscle fiber action potential is generated by voltage-gated channels and propagates to the ends of the fiber, depolarizing the entire membrane and thereby initiating contraction of the fiber (see Chapter 20).

The action of the neurotransmitter at most synapses is terminated by enzymatic degradation or by reuptake (step ⑦). At the neuromuscular junction, ACh is destroyed by acetylcholinesterase, an enzyme synthesized by the postsynaptic muscle fibers and located in the extracellular matrix (basal lamina) within the synaptic cleft. A choline transporter (step ⑧) retrieves choline into the presynaptic terminal for ACh resynthesis.

Postsynaptic potentials result from permeability changes that are neurotransmitter-dependent and voltage-independent

In Chapter 12 we learned that the permeability changes that produce an action potential are voltage-dependent, resulting from depolarization of the membrane. In contrast, the permeability (P) changes that produce a synaptic potential depend on neurotransmitter and not on voltage. As noted above, the molecules that control permeability changes at fast synapses are ligand-gated channels (see Chapter 2, page 58, for review). Ligand-gated channels open as a result of binding neurotransmitter, not in response to depolarization. (Ligand-gated channel structure will be considered in a later section.)

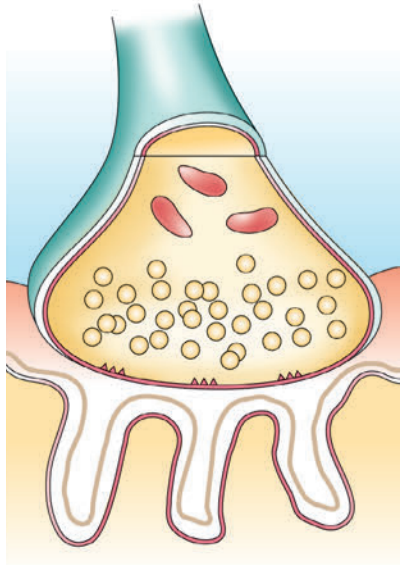

AN EPSP RESULTS FROM A SIMULTANEOUS INCREASE IN THE POSTSYNAPTIC MEMBRANE'S PERMEABILITY TO Na^+ AND K^+

When the channel of an acetylcholine receptor opens, it becomes permeable to both Na^+ and K^+ ions. Therefore, during an EPSP, P_{Na} and P_{K} increase *simultaneously*, rather than sequentially as in generation of the action potential. The ion flows through all the channels that open in response to release of neurotransmitter constitute the **synaptic current**, which produces the depolarization that is the rising phase of an EPSP. Although the channels' permeabilities to Na^+ and K^+ are similar, most of the synaptic current underlying an EPSP is carried by Na^+ entry, because the two ions have different driving forces. The membrane potential of the muscle fiber is very far from the sodium equilibrium potential (E_{Na} ; see Chapter 12), so there is a large driving force for sodium entry ($E_m - E_{\text{Na}}$). In contrast, the resting membrane potential is closer to the potassium equilibrium potential (E_{K}), so the driving force for potassium entry ($E_m - E_{\text{K}}$) is smaller.

Because both Na^+ and K^+ contribute to the synaptic current, they drive the membrane toward a potential near zero. Suppose for a minute that neurotransmitter molecules opened ion channels that allowed only Na^+ ions to flow into the cell. If this were so, then the EPSP would always displace V_m (membrane potential) toward E_{Na} . This is not the case, however. If a muscle fiber is voltage clamped to different values and the synaptic current is measured, the current always drives the membrane toward a value near zero, intermediate between E_{Na} and E_{K} (rather than toward E_{Na}). This value is the **reversal potential** of the EPSP (E_{EPSP}), the value of V_m beyond which an EPSP would reverse its polarity. Typical values of E_{EPSP} are between 0 and -15 mV in different cells.

EPSPs between neurons resemble neuromuscular EPSPs but are smaller

Fast EPSPs between neurons in the CNS are generally similar to those at the neuromuscular junction, but they also exhibit some differences (Figure 13.10). They are similar in waveform, with a fast rise of 1 to 2 ms and an exponential return typically lasting 10 to 20 ms. The underlying ionic mechanisms of these postsynaptic potentials are also similar. At both synapses, neurotransmitter molecules bind to postsynaptic receptors to increase the permeability of the membrane to both Na^+ and K^+ ions. Neuronal EPSPs have reversal potentials near zero, similar to the reversal potentials of neuromuscular EPSPs. Because of their similarities in mechanism and ionic basis, we use the same term, *EPSP*, to refer to both neuronal EPSPs and neuromuscular EPSPs.¹

¹Neuromuscular EPSPs are sometimes called end-plate potentials (EPPs), named after the motor end-plate.

FIGURE 13.10 A neuromuscular synapse, a CNS excitatory synapse, and a CNS inhibitory synapse (a) As shown in these fluorescence micrographs, CNS synapses (three on the right) are far smaller than neuromuscular junction synapses (on the left). In both images, the presynaptic axon terminal is green, postsynaptic receptor clusters are red, and the synapse (overlap of pre- and postsynaptic terminals) is yellow. The mechanism of an excitatory synapse at a neuromuscular junction (b) and in the central nervous system (c) is similar, but the EPSP is smaller in the CNS because the presynaptic neuron terminal is much smaller and releases fewer vesicles. The ionic basis of the EPSP is the same in both the neuromuscular and the CNS synapses, although the neurotransmitter is different. (d) A CNS inhibitory synapse produces an inhibitory postsynaptic potential (IPSP) by opening chloride channels, driving the postsynaptic membrane toward the chloride equilibrium potential (E_{Cl}). Thus E_{Cl} is the reversal potential for the IPSP, or E_{IPSP} . Note that CNS excitatory synapses often have a different appearance (Type 1) in electron micrographs from CNS inhibitory synapses (Type 2). (a from Sanes and Lichtman 2001, courtesy of Josh Sanes.)

However, there are two major differences between neuronal and neuromuscular EPSPs. First, in the CNS of vertebrates, the common neurotransmitter mediating fast EPSPs is *glutamate*, rather than acetylcholine (see Figure 13.10c). Thus some glutamate receptors have the same effect as the ACh receptors at the neuromuscular junction: rapidly increasing permeability to Na^+ and K^+ ions when they bind their neurotransmitter.

The second major difference between neuromuscular and neuronal EPSPs is their size. At a neuromuscular junction, a single presynaptic action potential liberates enough neurotransmitter to produce an EPSP that depolarizes the muscle fiber by 25 to 60 mV, more than enough to exceed the voltage threshold for a muscle fiber action potential. In the CNS, the EPSP resulting from a single presynaptic action potential is typically a small fraction of a millivolt in amplitude. The major cause of this difference is that a neuromuscular junction is large (see Figure 13.10a,b) and contains many active zones so the axon terminal releases many vesicles of neurotransmitter per action potential. In contrast, at synapses in the CNS, each presynaptic action potential leads to the release of only one or a few vesicles. The smaller the quantity of neurotransmitter released, the fewer the receptors activated and the smaller the synaptic current generated.

The difference in size and amount of neurotransmitter release at neuromuscular and CNS neuronal synapses is an adaptation

that largely determines the functional properties of the synapses. Recall that the vertebrate skeletal neuromuscular junction is a relay synapse, at which each presynaptic action potential produces a postsynaptic action potential. In contrast, CNS synapses are usually integrating synapses, in which each of many presynaptic neurons has only a rather small effect on the postsynaptic neuron, and excitatory input from 20 to 50 neurons may have to be summated to depolarize the integrating neuron past its voltage threshold (see Figure 13.7).

Fast IPSPs can result from an increase in permeability to chloride

What about IPSPs? IPSPs are the major mechanism of synaptic inhibition in central nervous systems. The waveform of a fast IPSP resembles that of an EPSP but is typically hyperpolarizing rather than depolarizing. Most fast IPSPs result from an increase in permeability to Cl^- ions and are mediated by one of two neurotransmitters: gamma-aminobutyric acid (GABA) or glycine. We will consider IPSPs mediated by GABA as our example because most inhibitory synapses in mammalian brains use GABA as their neurotransmitter (see Figure 13.10*d*).

The common mechanism for GABA-mediated synaptic inhibition is as follows: As with other synapses, an action potential in the presynaptic, GABA-containing neuron causes vesicle fusion and GABA release. GABA diffuses to the postsynaptic membrane and binds to GABA receptors that open to allow selective permeability to Cl^- ions. In most mammalian neurons, Cl^- is pumped out of the cell, so E_{Cl} is at a hyperpolarized value relative to E_m . Then when the permeability to Cl^- increases, Cl^- diffuses in, down its concentration gradient, hyperpolarizing the cell by driving E_m toward E_{Cl} (see Figure 13.10*d*). In other neurons, Cl^- is not pumped, so E_{Cl} and E_m are equal. Nevertheless, inhibitory synapses that increase permeability to Cl^- are still effective in inhibition because they “lock” the membrane potential at a value more hyperpolarized than the threshold voltage.

Excitatory and inhibitory synapses in the mammalian CNS have different characteristic appearances in electron micrographs (as shown schematically in Figure 13.10*c, d*). Type 1 synapses are usually excitatory and have a relatively wide synaptic cleft with a relatively large area of prominent density under the postsynaptic membrane. Synaptic vesicles are round. Type 2 synapses are usually inhibitory and have a narrower cleft with smaller areas of membrane density that are more symmetrically distributed at the pre- and postsynaptic membranes. The vesicles appear flattened after aldehyde fixation for electron microscopy. This classification can be valuable in identifying which synapses in a micrograph are inhibitory and which are excitatory. The classification is not completely reliable, however, because the correlation of structural type with function is imperfect, and not all synapses fit the two types.

Overall, then, we see that at fast chemical synapses, neurotransmitters bind receptors and increase permeability to ions, leading to a postsynaptic potential. Whether the postsynaptic potential is excitatory or inhibitory depends on what kinds of ions flow through the ion channels when the channels open. Different neurotransmitters act at different receptors; they may produce different effects (e.g., glutamate \rightarrow EPSP, GABA \rightarrow IPSP) or similar effects (e.g., glutamate \rightarrow EPSP, ACh \rightarrow EPSP).

Note that, in addition, a single neurotransmitter substance can have several different functions because it can act on different kinds of transmitter receptors. For example, ACh produces fast EPSPs at neuromuscular junctions (by acting on one kind of ACh receptor), but the same neurotransmitter produces IPSPs to inhibit the heart, by acting on a different kind of ACh receptor. We will consider this important principle in more depth later.

SUMMARY Fast Chemical Synaptic Actions Are Exemplified by the Vertebrate Neuromuscular Junction

- At the vertebrate skeletal neuromuscular junction, the neurotransmitter is acetylcholine. When stimulated, the presynaptic axon terminal releases acetylcholine, which diffuses to postsynaptic receptors.
- Acetylcholine binding to its receptors opens ion channels to increase permeability to both Na^+ and K^+ ions. The resulting Na^+ and K^+ currents drive the membrane toward a value (E_{EPSP}) that is more depolarized than the threshold of the muscle fiber. At the neuromuscular junction, the amplitude of the EPSP is sufficient to exceed threshold and triggers a muscle fiber action potential.
- The EPSP itself is a nonregenerative, nonpropagated local response because the neurotransmitter-dependent permeability changes are not voltage-dependent.
- Fast excitatory synapses in central nervous systems work by mechanisms similar to those at neuromuscular junctions. Neurotransmitter-gated ion channels increase membrane permeability to Na^+ and K^+ ions to produce depolarizing EPSPs.
- Neuronal EPSPs are much smaller than neuromuscular EPSPs because at neural synapses the postsynaptic membrane encompasses a small area that has a small number of receptor molecules, and the presynaptic axon releases less neurotransmitter, activating fewer postsynaptic receptors.
- Fast synaptic inhibition results from the opening of ion channels to increase permeability to chloride. E_{Cl} is commonly at a hyperpolarized value relative to the resting potential, leading to a hyperpolarizing IPSP.
- CNS excitatory and inhibitory synapses often have characteristic differences in their appearance in electron micrographs of the vertebrate CNS.

Presynaptic Neurons Release Neurotransmitter Molecules in Quantal Packets

Neurotransmitter molecules are synthesized and stored in the presynaptic terminal and are released by presynaptic impulses. Much of our knowledge of the mechanisms of neurotransmitter release comes from the vertebrate neuromuscular junction, and because acetylcholine is the neurotransmitter at this synapse, we will consider primarily cholinergic (acetylcholine-mediated) transmission here. However, because mechanisms of neurotransmitter release are thought to be similar for different neurotransmitters, much of this information is general.

FIGURE 13.11 Acetylcholine synthesis and breakdown

Acetylcholine is synthesized in the cytoplasm of the presynaptic terminal and then taken up into synaptic vesicles. Many vesicles are stored away from active-zone release sites; vesicles move from the storage compartment to release sites and dock to the presynaptic membrane at active zones. Acetylcholine is released by exocytosis of vesicles; the enzyme acetylcholinesterase (AChE) in the synaptic cleft terminates its action, hydrolyzing it to choline and acetate. A high-affinity transporter reabsorbs choline into the presynaptic terminal.

Acetylcholine is synthesized and stored in the presynaptic terminal

Acetylcholine (ACh) is synthesized from choline and acetyl coenzyme A in the cytoplasm of the presynaptic terminal (Figure 13.11). The reaction is catalyzed by the specific enzyme choline acetyltransferase. After synthesis in the cytoplasm, ACh is taken up into vesicles by a specific vesicular transporter molecule. Like all other proteins, choline acetyltransferase is synthesized in the cell body and must be transported the length of the axon. Nevertheless, the availability of choline is the limiting factor in the rate of ACh synthesis. Choline is supplied via the blood and by choline uptake transporters at the presynaptic membrane, but as the available choline in the terminal is converted to ACh, synthesis slows and eventually ceases.

Acetylcholine in an axon terminal is stored in various compartments. Some vesicles are “docked” at release sites and constitute the rapidly releasable compartment of ACh. Other vesicles are anchored to the cytoskeleton distant from release sites in the interior of the terminal; these constitute the storage compartment of ACh.

Neurotransmitter release requires voltage-dependent Ca^{2+} influx

Under normal circumstances, neurotransmitter release requires both presynaptic depolarization and Ca^{2+} ions. The normal stimulus for neurotransmitter release is the depolarization of the presynaptic terminal by an action potential. Experiments indicate that the amount of neurotransmitter release increases with increasing depolarization over the physiological range. The release of ACh into the synaptic

cleft depends on an influx of Ca^{2+} ions into the presynaptic terminal. If a neuromuscular junction is bathed in a saline solution free of Ca^{2+} ions, then a depolarization of the presynaptic membrane does not elicit an EPSP, because exocytosis does not occur.

All neurotransmitter release appears to be Ca^{2+} -dependent. Depolarization of the presynaptic membrane opens voltage-gated Ca^{2+} channels, allowing Ca^{2+} to enter and trigger neurotransmitter release. Because the intracellular concentration of Ca^{2+} is much lower than the extracellular concentration, there is a strong inward driving force on Ca^{2+} ions; Ca^{2+} entry locally increases the Ca^{2+} concentration near the channels. In preparations of the squid giant synapse (between second-order and third-order giant axons in the stellate ganglion; see Box 12.3), the presynaptic terminal is large enough to impale with a micropipette. Experimenters have injected the presynaptic terminal with aequorin, a protein that emits light in the presence of Ca^{2+} . Depolarization of the presynaptic terminal induces aequorin luminescence, experimentally confirming that presynaptic depolarization leads to local Ca^{2+} entry. In fact, *the only role of presynaptic depolarization is to trigger Ca^{2+} entry*. In the squid giant synapse, investigators can inject Ca^{2+} directly into the presynaptic terminal with a microelectrode. Pulsed Ca^{2+} injection triggers postsynaptic EPSPs, indicating that Ca^{2+} entry is sufficient to release neurotransmitter.

Neurotransmitter release is quantal and vesicular

Acetylcholine is not released from the presynaptic membrane of a neuromuscular junction a molecule at a time; rather, it is released in multimolecular “packets” called **quanta** (singular *quantum*), units of about 5000 molecules each. Experimental evidence has demonstrated that each quantum is the equivalent of the contents of one synaptic vesicle.

The original evidence for quantal release comes from the vertebrate neuromuscular junction. If we impale a muscle fiber near the neuromuscular junction with an intracellular microelectrode (Figure 13.12), we can record a series of small depolarizations in the absence of any stimulation. These depolarizations have the same shape as a neuromuscular EPSP but are about 1/50th the amplitude; thus they are termed spontaneous **miniature EPSPs (mEPSPs)**.

Each mEPSP is the postsynaptic response to a quantum. Miniature EPSPs typically have amplitudes of about 0.4 mV and occur nearly randomly over time (see Figure 13.12b). They do not represent responses to individual molecules of acetylcholine, because several thousand ACh molecules are required to produce a depolarization of 0.4 mV. The presence of spontaneous mEPSPs indicates that in the absence of presynaptic stimulation, there is a spontaneous, low-frequency release of ACh quanta—that is, about 5000 molecules at a time.

Can we show that the release of ACh evoked by presynaptic depolarization is also quantal? The neuromuscular EPSP evoked by a presynaptic impulse has an amplitude of 20 to 40 mV and would require the nearly simultaneous discharge of 100 to 300 quanta. This number is too large to determine whether the release is quantal or not, since the difference between the response to, say, 200 and 201 quanta is not detectable.

Researchers solve this problem by *decreasing the number of quanta* released with an applied stimulus, so that only 1 or 2 quanta are released at a time into the synaptic cleft, rather than hundreds. To achieve this, they lower the Ca^{2+} concentration in the bath surrounding the

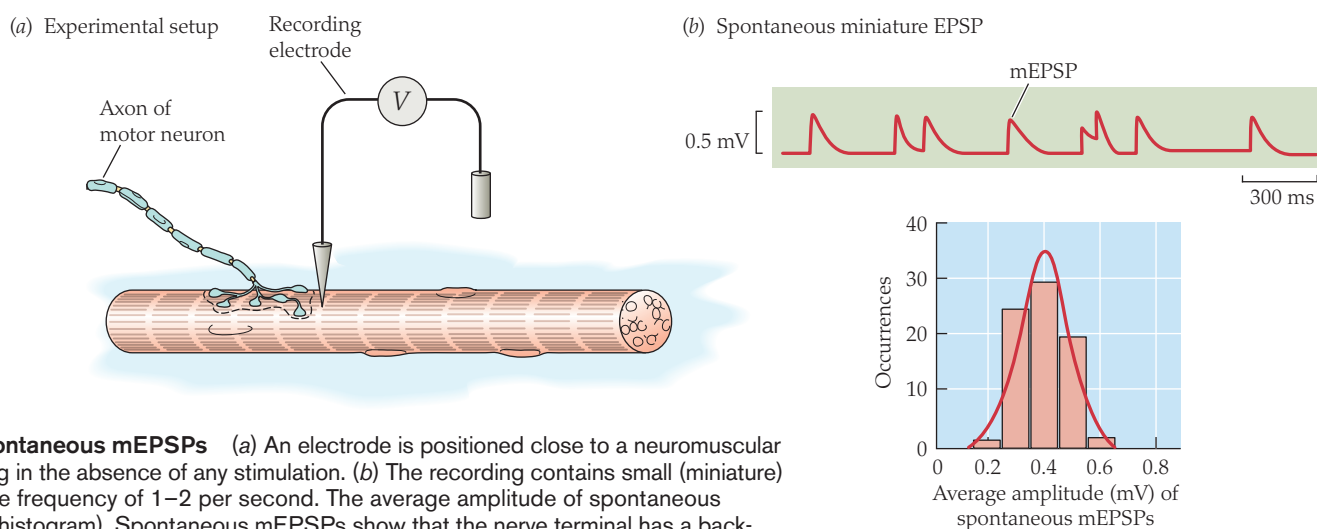

FIGURE 13.12 Spontaneous mEPSPs (a) An electrode is positioned close to a neuromuscular synapse for recording in the absence of any stimulation. (b) The recording contains small (miniature) EPSPs at an average frequency of 1–2 per second. The average amplitude of spontaneous mEPSPs is 0.4 mV (histogram). Spontaneous mEPSPs show that the nerve terminal has a background low level of transmitter release in the absence of stimulation. The transmitter is released in multimolecular quantal packets, each quantum eliciting a mEPSP at the postsynaptic membrane.

muscle fiber, and they raise the bath concentration of Mg^{2+} , an ion that competitively inhibits the action of the Ca^{2+} . Are the resultant *evoked mEPSPs* quantal? As **Figure 13.13** shows, evoked mEPSPs fall into amplitude classes that are multiples of the amplitudes of spontaneous mEPSPs. That is, each presynaptic stimulus evokes the release of 0, 1, 2, or 3 quanta (but never 1.5 quanta).

The experiment in **Figure 13.13** illustrates that neurotransmitter release evoked by a presynaptic impulse is quantal. Similar results occur with other types of synapses, and in some of these cases quantal release can be demonstrated without manipulating extracellular ion concentrations. It is thought, then, that quantal release is the general rule for all chemical synapses.

Research has shown that cholinergic vesicles contain 10^3 to 10^4 molecules of acetylcholine, and that neurotransmitter is released in quanta of 10^3 to 10^4 molecules; thus the conclusion seems inescapable that a quantum corresponds to a synaptic vesicle. The synaptic vesicles fuse with the presynaptic membrane and discharge their content of neurotransmitter by exocytosis. The fusion of vesicles

with the presynaptic membrane is sporadic in the resting terminal, producing spontaneous mEPSPs. Depolarization of the terminal by the presynaptic action potential greatly increases the *probability* of release of each of many vesicles, so that at a neuromuscular junction 150 to 300 synaptic vesicles discharge in a millisecond and produce a neuromuscular EPSP.

Synaptic vesicles are cycled at nerve terminals in distinct steps

The idea that quantal release of neurotransmitter corresponds to vesicular exocytosis is termed the *vesicular release hypothesis*, which is now widely accepted as explaining how neurotransmitter is released at all chemical synapses. The vesicular release hypothesis suggests that fusing exocytotic vesicles should be seen in electron micrographs, and that vesicular membranes must be recycled (to prevent vesicle depletion and expansion of the postsynaptic membrane with release). Exocytosis occurs rapidly, and it is difficult to show it directly in routinely fixed electron micrographs. However,

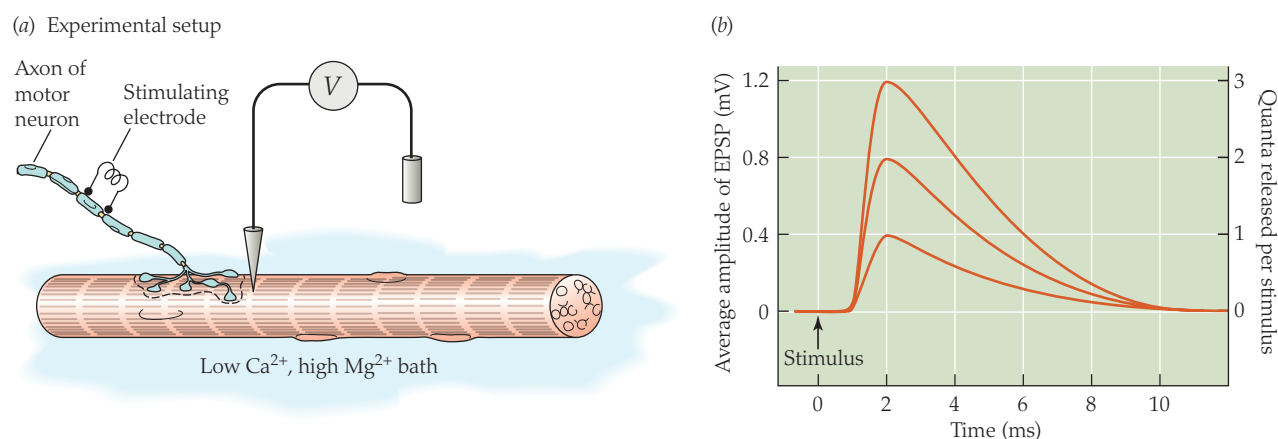

FIGURE 13.13 Evoked miniature EPSPs (a) A stimulating electrode evokes presynaptic action potentials in the motor axon, but because of the low Ca^{2+} , high Mg^{2+} bath, each action potential releases only a few quanta of neurotransmitter. (b) The amplitudes of the resultant EPSPs cluster around the size classes shown in the graph, indicating

that the amplitude of each response results from the release of 0, 1, 2, or 3 quanta. (There are no recorded responses of 0.2 mV, for example, which would be half a quantum.) Therefore, stimulus-evoked release of neurotransmitter, like spontaneous release, is quantal.

(a) Overview of vesicle recycling

(b) Retrieval of the vesicular membrane

electron micrographs of neuromuscular junctions stimulated at modest rates can show a temporary depletion of synaptic vesicles, but within minutes the vesicular membranes are pinched off and returned to the inside of the terminal by endocytosis.

The recycling of vesicular membranes allows synaptic vesicles to re-form and prevents the plasma membrane from expanding by the addition of vesicular membrane from exocytotic fusion. **Figure 13.14** summarizes the processes of recycling vesicular membranes. Synaptic vesicles first are mobilized or targeted to move to release sites (step 1 in **Figure 13.14a**), where they dock and are primed until Ca^{2+} ions trigger fusion of the vesicular and presynaptic membranes (steps 2–4).

There appear to be at least two modes of fusion and subsequent retrieval of vesicular membranes: classical and kiss-and-run. In *classical* exocytosis, the vesicular membrane merges with the terminal membrane and a new vesicle is later retrieved by endocytosis, a pinching off from the terminal membrane (step 5). Classical endocytosis selectively retrieves vesicular membranes with the aid of two proteins: *clathrin* and *dynamin*. In *kiss-and-run* fusion, the docked vesicle opens a fusion pore to release transmitter into the synaptic cleft, without completely becoming integrated into the terminal membrane; the vesicle is then reinternalized without requiring clathrin-mediated pinching off. The kiss-and-run pathway is faster and may predominate at lower rates of neurotransmitter release, whereas the classical exocytotic–endocytotic pathway is slower and may predominate at higher rates of release. Interestingly, recent work has demonstrated that the size of the fusion pore and the mode of vesicle recovery are not necessarily correlated: Kiss-and-run

FIGURE 13.14 Synaptic vesicle recycling at the neuromuscular junction (a) Synaptic vesicles cycle through several steps: 1 mobilization (also called targeting); 2 docking; 3 priming; 4 exocytotic fusion; and 5 endocytosis. Endocytotic vesicles may have to fuse with an inner membrane compartment, the endosome, before budding off as synaptic vesicles again. (b) After synaptic vesicles fuse with the presynaptic membrane and undergo exocytosis, at least two different sorts of pathways can retrieve the vesicular membrane. In the *classical* pathway, after complete fusion with the presynaptic membrane, the vesicular membrane is retrieved by endocytosis of clathrin-coated pits into endocytotic vesicles. This process selectively aggregates specific vesicle components and occurs away from the active zone. In the *kiss-and-run* pathway, synaptic vesicles fuse transiently to the presynaptic membrane. They discharge their transmitter at a fusion pore and then are retrieved without having been fully integrated into the presynaptic membrane.

can occur after formation of a large fusion pore, and does not always follow formation of a small fusion pore.

Several proteins play roles in vesicular release and recycling

The molecular mechanism of the exocytotic release of neurotransmitters is a topic of active investigation. Researchers have identified the proteins of vesicular membranes and other proteins with which they interact. Interestingly, these proteins are similar to those of exocytotic release in other cells, including yeast cells. These similarities suggest that a common mechanism of exocytotic secretion evolved in early eukaryotic cells, and although neurotransmitter release is much faster than other exocytotic secretion, the basic mechanism has been largely conserved.

Various proteins play roles in the several stages of vesicular release and recycling (**Figure 13.15**). The first stage is vesicular *mobilization* or *targeting*. At any time, many of the vesicles in a presynaptic terminal are located away from active zones in the storage compartment. Before these vesicles can release their contents, they must be mobilized to move up to release sites at the active zones. At rest, the protein *synapsin* attaches vesicles to the actin cytoskeleton, and in mobilization this attachment is released when synapsin is phosphorylated, permitting the vesicle to migrate to an active zone. A vesicle may *attach* or *tether* reversibly to the terminal membrane, followed by *docking* (which is irreversible) (see **Figure 13.15a,b**).

Docking involves the interaction of proteins called *SNAREs*; vesicular v-SNAREs intertwine with terminal-membrane t-SNAREs to hold the docked vesicle at the active zone. A major v-SNARE is called *vesicle-associated membrane protein* (*VAMP*, also called *synaptobrevin*). It connects with the t-SNAREs *syntaxin* and *SNAP*. Docked vesicles are primed by proteins, including Munc18 and complexin, readying the vesicles for rapid release (see **Figure 13.15b**).

Depolarization triggers Ca^{2+} entry through voltage-gated Ca^{2+} channels, and the Ca^{2+} ions bind to the vesicle protein *synaptotagmin*, triggering formation of a fusion pore that may lead to complete exocytotic fusion of the docked vesicle and the presynaptic membrane (**Figure 13.15c, d**). Another protein, *rab3*, is active in vesicular mobilization and recycling, and may inhibit excessive fusion and release. Cytoplasmic proteins may disassemble the SNARE complex after fusion. The protein *dynamin* promotes the pinching-off of vesicles, through an ATP-dependent mechanism, and as noted above, vesicular endocytosis is associated with the protein *clathrin*.

FIGURE 13.15 Vesicular docking and fusion release neurotransmitters Several proteins function in transmitter release from synaptic vesicles. Proteins called v-SNAREs are associated with the vesicular membrane; others, t-SNAREs, are attached to the terminal membrane. **1** Targeted vesicles move to active zones where they tether, attaching reversibly. **2** *Docking* is mediated by the formation of a SNARE complex, the v-SNAREs and t-SNAREs interacting to hold the vesicle at the release site. **3** Following priming, Ca²⁺ entry through voltage-gated Ca²⁺ channels triggers **4** *fusion* by the binding of Ca²⁺ to the vesicular protein synaptotagmin. The Ca²⁺-synaptotagmin complex changes conformation to fuse the vesicular and terminal membranes.

SUMMARY Presynaptic Neurons Release Neurotransmitter Molecules in Quantal Packets

- Small-molecule neurotransmitters are synthesized predominantly at axon terminals and are transported into synaptic vesicles.
- Neurotransmitters are released by presynaptic depolarization, which opens voltage-gated Ca²⁺ channels at active zones. Calcium ions trigger neurotransmitter release.
- Neurotransmitter is released in quantal packets, several thousand molecules at a time. Each quantum corresponds to a synaptic vesicle.
- Synaptic vesicles fuse with the presynaptic membrane to release their transmitter contents by exocytosis. Vesicular membranes are retrieved, refilled with transmitter, and recycled.
- Specific proteins associated with synaptic vesicles play different roles in vesicular targeting, docking, fusion, and retrieval.

Neurotransmitters Are of Two General Kinds

Several dozen chemical compounds have been identified as possible neurotransmitters, and the list of such compounds continues to increase. There are two major kinds of neurotransmitters: *small-molecule neurotransmitters* (mostly amines and amino acids) and *neuropeptides* (Table 13.2). Some neurotransmitters are well known; others are still being discovered.

Our knowledge of different neurotransmitter systems bears little relation to their physiological prevalence. *Cholinergic* synapses (defined previously as synapses in which the neurotransmitter is acetylcholine) are best known because the neuromuscular junction is an easily studied model. Synapses in which the neurotransmitter is norepinephrine, or noradrenaline (termed *noradrenergic* or *adrenergic* synapses), are the next best known, because there are peripheral noradrenergic synapses in the sympathetic nervous system. It is estimated, however, that fewer than 10% of the synapses in the vertebrate CNS are cholinergic and fewer than 1% employ catecholamines such as norepinephrine. Neurotransmitter identity is not always known, but amino acids appear to be the most abundant and widespread central neurotransmitters. This section discusses selected aspects of neurotransmitter function; it is beyond our scope to survey the subject comprehensively. The references at the end of the chapter and the back of the book (see Additional References) provide more extensive information.

TABLE 13.2 Some neurotransmitters, key synthetic enzymes, and receptors of vertebrate central nervous systems^a

Neurotransmitter	Enzyme	Receptor	Receptor type	Common mode of action
Amines				
Acetylcholine	Choline acetyltransferase	Nicotinic	Ionotropic	EPSP
		Muscarinic M ₁ –M ₅	Metabotropic	G protein → IPSP
Dopamine	Tyrosine hydroxylase (TH)	d ₁	Metabotropic	
		d ₂	Metabotropic	
		d ₃	Metabotropic	
Norepinephrine	TH and dopamine β-hydroxylase	α _{1,2,3}	Metabotropic	
Serotonin	Tryptophan hydroxylase	β _{1,2}	Metabotropic	
		5HT ₁	Metabotropic	
		5HT ₂	Metabotropic	
		5HT ₃	Ionotropic	
Amino acids				
Glutamate	(General metabolism)	AMPA	Ionotropic	EPSP
		NMDA	Ionotropic	Ca ²⁺ second messenger
		Metabotropic	Metabotropic	DAG/IP ₃
GABA	Glutamic acid decarboxylase	GABA _A	Ionotropic	IPSP
		GABA _B	Metabotropic	G protein → IPSP
Glycine	(General metabolism)		Ionotropic	IPSP
Peptides	(Protein synthesis)	Various	Metabotropic	G protein–coupled (some tyrosine kinase)

^aThis table is not exhaustive; there are more transmitters, and more receptors for each transmitter.

Neurons have one or more characteristic neurotransmitters

Neurons are metabolically specialized to synthesize and release a particular neurotransmitter or combination of neurotransmitters. A cholinergic neuron, then, expresses the genes for proteins that synthesize and transport acetylcholine. A neuron, however, may contain and release more than one kind of neurotransmitter; such multiple neurotransmitters released by single neurons are termed **cotransmitters**. Many neurons, for example, contain and apparently release a small-molecule neurotransmitter and one or more neuropeptides.

Even a single neurotransmitter may produce a variety of postsynaptic effects, as we will discuss shortly. Moreover, a postsynaptic neuron typically receives synapses from many kinds of presynaptic neurons, and each kind may release a different neurotransmitter. Thus, although it is relatively sound to characterize a neuron in terms of the neurotransmitter it releases (e.g., as a cholinergic neuron), it is usually unsound to characterize it as responding to a particular neurotransmitter (e.g., as a cholinergic neuron), because any neuron may respond to several different neurotransmitters.

An agent is identified as a neurotransmitter if it meets several criteria

There is general agreement on the experimental criteria for identifying the neurotransmitter at a synapse:

- The candidate neurotransmitter must be *present in the presynaptic terminal*, along with its synthetic machinery (enzymes, precursors, transporters).
- The candidate neurotransmitter is *released upon presynaptic stimulation*, in amounts sufficient to exert a postsynaptic action.
- When the candidate neurotransmitter is added to extracellular fluid in moderate concentrations, it should *mimic the effects of presynaptic stimulation*. For example, it should induce the same changes in permeability to ions as the synaptic action does.
- A *mechanism for removal* of the candidate neurotransmitter should exist. This removal mechanism can be by enzymatic inactivation or by reuptake into cells. (We should point out, however, that many peptide neurotransmitters may have no specific removal mechanism.)
- The *effects of drugs* on transmission at a synapse may help identify its neurotransmitter and receptors. For example, curare is an ACh receptor antagonist that blocks neuromuscular transmission, and it also blocks the effect of ACh experimentally applied through a micropipette.

Note that these criteria were developed at a time when only fast, direct synaptic transmission was known. Some criteria are more

essential than others, and some may be modified as our views of synaptic processes expand.

It is difficult to demonstrate all of these criteria at a particular synapse, especially in the CNS. For example, the demonstration of release of a candidate neurotransmitter requires that it be collected in sufficient quantity to be assayed, and further requires demonstration that the released neurotransmitter came from the presynaptic terminal. Such demonstration is rarely possible in the brain, where neurotransmitter identification is often inferred solely from chemical evidence of neurotransmitter presence. Rigorous tests employing the full spectrum of criteria are important where possible, to prevent uncritical acceptance of every synaptically active agent as a presumed neurotransmitter. Because these criteria are so difficult to satisfy experimentally, we have a long list of *possible* and *probable* neurotransmitters and a shorter list of cases in which the neurotransmitter at a particular synapse is convincingly demonstrated.

Vertebrate neurotransmitters have several general modes of action

The principal synaptic neurotransmitters of vertebrates are summarized in Table 13.2. The table could be much longer, because there are other small-molecule neurotransmitters and perhaps 90 neuroactive peptides. It is difficult to generalize about neurotransmitter functions because all neurotransmitters work in different ways and mediate different functional effects at different synapses. Nevertheless, here are some very broad generalizations about functional classes of neurotransmitters and synapses in the CNS of vertebrates:

- Most synapses (numerically) in the CNS use amino acid neurotransmitters. Most fast EPSPs result from glutamate; most fast IPSPs result from GABA or glycine.
- Biogenic amines (acetylcholine, norepinephrine, dopamine, serotonin) are found in relatively few neurons, but these neurons have widely projecting endings that appear to release transmitter over broader areas than discrete synapses (termed *volume transmission*). Many receptors for these neurotransmitters have slow actions that modulate neuronal activities, rather than mediating fast excitation or inhibition.
- Peptides are present in substantial numbers of CNS neurons. A neuroactive peptide may be co-released with one or more small-molecule neurotransmitters and may function as a cotransmitter with slow synaptic effects.

Rather than surveying the metabolism and action of specific neurotransmitters, let's discuss a few neurotransmitter-related concepts that are important for understanding general synaptic functions.

MULTIPLE RECEPTORS Many neurotransmitters can mediate different postsynaptic actions at different postsynaptic cells. For example, acetylcholine excites skeletal muscle via EPSPs but inhibits vertebrate heart muscle via hyperpolarizing IPSPs. These effects involve different permeability changes in the different postsynaptic cells (P_{Na} and P_K in skeletal muscle; P_K in heart muscle). Completely different postsynaptic receptors mediate these different effects: one a ligand-gated channel and one a *G protein-coupled*

receptor. The two different kinds of acetylcholine receptors were first characterized many years ago by their pharmacology (i.e., the effects of drugs on them). The ACh receptor of skeletal muscle is stimulated by nicotine and hence is termed **nicotinic**. As noted on the previous page, a nicotinic ACh receptor is blocked by curare. The ACh receptor of heart muscle is stimulated by muscarine and hence is termed **muscarinic**; it is blocked by atropine. Muscarinic ACh receptors are the end-receptors of parasympathetic signals in the autonomic nervous system (see Chapter 15).

Most neurotransmitters affect more than one kind of neurotransmitter receptor, and these may be of different classes (e.g., ligand-gated channels and G protein-coupled receptors). The different receptor classes that respond to a particular neurotransmitter were originally characterized by pharmacology, as with nicotinic and muscarinic acetylcholine receptors. More recently, researchers have cloned the genes for neurotransmitter receptors, enabling them to associate dozens of receptors with a particular neurotransmitter. Some well-studied neurotransmitter receptors are listed in Table 13.2.

TERMINATION OF NEUROTRANSMITTER ACTION: ENZYMES AND REUPTAKE

Neurotransmitters are generally active for only a short time. Neurotransmitter release, diffusion, and receptor binding occur within a few milliseconds. For normal synaptic function, neurotransmitter molecules must be cleared from the synaptic cleft. The temporal and spatial effects of neurotransmitter action are limited in two ways: by *enzymatic destruction* of the neurotransmitter molecules and by *reuptake* (using active transport to retrieve the neurotransmitter or its products).

At the neuromuscular junction, ACh is enzymatically digested by the enzyme acetylcholinesterase (AChE), located in the synaptic cleft (see Figure 13.11). AChE acts very rapidly; the entire sequence of ACh release, diffusion, binding to ACh receptors, and digestion requires about 5 ms. Some ACh molecules are destroyed even before they can bind to receptors. The products of ACh breakdown are choline and acetate. Choline is transported back into the presynaptic terminal by a specific high-affinity transporter in the terminal membrane. Thus the action of AChE both terminates the postsynaptic effects of ACh and (via the transporter) provides choline, the rate-limiting substrate for resynthesis of ACh in the presynaptic terminal.

The termination of neurotransmitter action by a localized enzyme is not a feature of all chemical synapses. For many neurotransmitters (catecholamines, amino acids), the termination and reuptake processes are combined. For example, the neurotransmitter norepinephrine (noradrenaline) is itself actively transported back into the presynaptic cell by a high-affinity transporter. Although enzymes that catabolize norepinephrine are present, they act more slowly than the reuptake system. Thus the synaptic action of norepinephrine is terminated by reuptake of the neurotransmitter rather than by enzymatic destruction. Glial cells can also actively take up neurotransmitters. Reuptake transporters are linked to Na^+ , using Na^+ entry down its electrochemical gradient to drive transmitter uptake against a concentration gradient.

The “recycling” of neurotransmitter molecules—with or without enzymatic conversion—is a process distinct from the recycling of vesicular membranes discussed earlier. Whereas vesicular recycling involves endocytotic pinching off of *organelles* (multimolecular

pieces of vesicular membrane), in neurotransmitter recycling a transporter actively transports *molecules* of neurotransmitter or neurotransmitter metabolite across the membrane against a concentration gradient. The two processes occur independently of each other.

PEPTIDE NEUROTRANSMITTERS DIFFER FROM SMALL-MOLECULE NEUROTRANSMITTERS IN SYNTHESIS, RELEASE, AND TERMINATION

Peptide neurotransmitters are chains of amino acids, typically 3 to 55 amino acids long. Unlike small-molecule neurotransmitters, which are synthesized in the axon terminals, peptide neurotransmitters are synthesized in the cell body of a neuron and must be transported down the axon for release. All peptides are synthesized on ribosomes of the rough endoplasmic reticulum; the neuronal axon lacks ribosomes and performs no protein synthesis.

Peptide neurotransmitters are synthesized as part of a larger precursor polypeptide, called a *propeptide*. A propeptide typically contains several copies of the peptide neurotransmitter within its amino acid sequence. After synthesis, the propeptide molecules are packed into secretory vesicles called *large dense-cored vesicles*, which are distinct from the smaller vesicles of small-molecule transmitters. The large dense-cored vesicles are transported down the axon, and in the vesicle the propeptide is cleaved enzymatically into smaller pieces that may include several copies of the active peptide.

Release of peptide neurotransmitters is by processes similar to the release of small-molecule neurotransmitters, but with some differences. Exocytosis of large dense-cored vesicles is not at active zones, and thus is not as near to the sites of Ca^{2+} entry. Probably for this reason, the release of peptide neurotransmitters requires a higher frequency of presynaptic action potentials than does the release of small-molecule transmitters, presumably allowing more Ca^{2+} entry and buildup of Ca^{2+} concentration over a larger area.

Peptide neurotransmitters are not retrieved once they have been released; eventually they are digested by nonspecific extracellular peptidases. Peptide neurotransmitters may become depleted as a result of the “long supply chain” for their synthesis, as well as the absence of their recycling. In contrast, for small-molecule neurotransmitters, resupply can usually keep up with release because the neurotransmitter can be locally retrieved or rapidly resynthesized in the axon terminal.

Table 13.3 compares several key differences between small-molecule and peptide neurotransmitters.

Neurotransmitter systems have been conserved in evolution

Most neurotransmitters that act at vertebrate synapses are also present in the nervous systems of the major invertebrate groups. For example, evidence supports neurotransmitter roles for acetylcholine, GABA, glutamate, dopamine, and serotonin (also called *5-hydroxytryptamine*, or *5-HT*) among coelenterates, nematodes, annelids, arthropods, and molluscs. Genomic studies reinforce the evolutionary similarities of neurotransmitter systems in different phyla; for example, the genomes of the nematode worm

TABLE 13.3 Comparison of small-molecule and peptide neurotransmitters

	Small molecule neurotransmitters	Neuropeptides
Synthesis site	Axonal terminal or varicosity	Nucleus/ER as propeptide
Vesicles	Small clear vesicles	Large dense-cored vesicles
Release	Low-frequency stimulation	High-frequency stimulation
Inactivation	Reuptake or specific enzymes	Extracellular peptidases

Caenorhabditis and of *Drosophila* and other insects have been completely sequenced, so their entire collections of neurotransmitter enzymes and receptors are known. They have nicotinic ACh receptors, GABA receptors, excitatory glutamate receptors, and many G protein–coupled receptors related to their vertebrate counterparts.

The same neurotransmitters, however, may be employed in different roles in different phyla. For example, most evidence indicates that in arthropods, glutamate is the major excitatory neuromuscular transmitter and acetylcholine is the major sensory neurotransmitter, whereas their roles are reversed in the vertebrates.

These observations suggest that the evolution of neurotransmitter systems has been conservative; the same or related neurotransmitters and receptors are conserved across many phyla. Even the peptide neurotransmitters, which might be expected to show greater differences among phyla than the small-molecule amino acids and amines, are organized in protein families that indicate their evolutionary relationship across phyla.

SUMMARY Neurotransmitters Are of Two General Kinds

- Neurotransmitters can be small molecules or peptides. Perhaps a dozen small-molecule neurotransmitters and several dozen peptide neurotransmitters have been identified.
- A neuron can be identified by its characteristic neurotransmitter, but a single neuron may produce and release more than one neurotransmitter.
- For any neurotransmitter there are several receptors. Different kinds of receptors for a transmitter may coexist in the same organism and the same neuron.
- Most fast synapses in central nervous systems employ glutamate for EPSPs and GABA or glycine for IPSPs.
- Many receptors for small-molecule neurotransmitters, and probably for all peptides, act metabotroically and mediate slow synaptic potentials and modulatory responses.
- Peptides are synthesized in the neuronal cell body and transported down the axon packed in vesicles, unlike small-molecule transmitters, which are synthesized locally in axon terminals.
- The synaptic action of small-molecule neurotransmitters is terminated by reuptake or by enzymatic destruction.

Postsynaptic Receptors for Fast Ionotropic Actions: Ligand-Gated Channels

As we noted earlier, physiologists classify the postsynaptic neurotransmitter receptors into two broad categories, depending on their mechanism of action. *Ionotropic receptors* produce their effects *directly*; the neurotransmitter binds to the active site of the receptor protein, which is a *ligand-gated channel* (see Figure 2.27a). The receptor–channel opens in response to the binding to allow ions to pass into and out of the postsynaptic cell. *Metabotropic receptors* are not channels; instead they produce their effects *indirectly*. Neurotransmitter molecules bind to and activate a metabotropic receptor, which in turn initiates a cascade of signal transduction messenger molecules that may eventually modulate an ion channel in the postsynaptic membrane. Because an ionotropic receptor is a single macromolecular unit, it works rapidly and produces fast PSPs. Because a metabotropic receptor produces a cascade of reactions of separate proteins, its effects are slower and longer-lasting. **Table 13.4** compares some of the key structural, functional, and mechanistic differences between ionotropic and metabotropic receptors.

ACh receptors are ligand-gated channels that function as ionotropic receptors

The best-known examples of ionotropic receptors are the nicotinic acetylcholine (ACh) receptors (discussed earlier) that produce EPSPs

at the vertebrate neuromuscular junction. Molecular biologists first isolated nicotinic ACh receptors in the electric organs of marine fish such as skates and rays (see Box 20.1), which consist almost entirely of modified neuromuscular junctions with dense concentrations of ACh receptors. These nicotinic ACh receptors are strikingly similar to those of other vertebrate neuromuscular junctions. A nicotinic ACh receptor is a glycoprotein composed of five subunits, including two α subunits (**Figure 13.16a**). Each subunit has four helical, membrane-spanning hydrophobic segments: M1 through M4 (**Figure 13.16b,c**). The polar M2 domains face the interior of the protein to form the central ion channel. The different subunits of the ACh receptor share considerable sequence homology and presumably evolved from a common ancestor.

Each of the two α subunits has an ACh-binding site on its extracellular side (**Figure 13.16d,e**). When the receptor binds two ACh molecules, the five subunits change their conformations to open a central channel large enough for Na^+ and K^+ ions to pass through it. The channel binds ACh and remains open only for a short time (about 1 ms). In fact, the channel may flicker open and closed during this brief interval. With prolonged exposure to ACh (e.g., if acetylcholinesterase is inhibited), the ACh receptor enters a third, *desensitized* state in which ACh is bound but the channel is closed. Desensitized receptors remain desensitized until the ACh molecules dissociate from the receptor.

The current flowing through a single ACh receptor, and the additive nature of the currents flowing through more than one

FIGURE 13.16 The molecular structure and function of a ligand-gated channel, the nicotinic acetylcholine receptor (a) The receptor has five protein subunits; the two α subunits each contain an ACh-binding site. (b) The five subunits surround a central ion channel, and each subunit has a similar structure, with four membrane-spanning segments (M1–M4). The M2 segments line the pore. (c) Each subunit is a single polypeptide chain. (d) When ACh is not bound to the receptor, its inner channel, which narrows in the region of the lipid bilayer, is closed. (e) The binding of an ACh molecule to each of the two α subunit-binding sites leads to a conformation change that opens the channel to a diameter of 0.6 nm, allowing Na^+ and K^+ ions to flow through.

TABLE 13.4 Ionotropic and metabotropic receptors: Structural, functional, and mechanistic differences

Characteristic	Ionotropic receptors	Metabotropic receptors
Receptor molecule	Ligand-gated channel receptor	G protein-coupled receptor
Molecular structure	Four or five subunits around an ion channel	Protein with seven transmembrane segments; no channel
Molecular action	Open ion channel	Activate G protein; metabolic cascade
Second messenger	No	Yes (usually)
Gating of ion channels	Direct	Indirect (or none)
Type of synaptic effect	Fast EPSP or IPSP	Slow PSPs; modulatory changes (in channel properties, cell metabolism, or gene expression)

channel, can be demonstrated by patch clamp. The patch-clamp technique (described in Chapter 12; page 312) records single-channel currents, as shown in **Figure 13.17**. By slowly increasing the ACh concentration inside the pipette (which in this inside-out patch is equivalent to the synaptic cleft), we control the probability that a channel will open. At a low ACh concentration, only one channel opens at a time (top recording in **Figure 13.17b**). Increasing the ACh concentration slightly causes each channel to open more frequently (center recording in **Figure 13.17b**), and increasing the ACh concentration still further causes both channels to open simultaneously for intermittent periods (bottom recording in **Figure 13.17b**).

To summarize, the patch-clamp experiment demonstrates four characteristics of ligand-gated channel receptors and the ionic currents they produce once they are activated:

1. The opening of a ligand-gated channel is an all-or-none phenomenon.
2. The probability that a channel will open depends on the concentration of neurotransmitter at the receptor.
3. The net ionic current through the open channel provides that channel's contribution to a synaptic potential.
4. The currents through all open channels can be summated and constitute the synaptic current.

The properties of ACh receptors as ligand-gated channels can be compared to those of voltage-gated channels that underlie the action potential. The major difference is in the control of permeability changes of the molecules. In the voltage-gated Na⁺ channel, permeability depends directly on the membrane

potential (see **Figures 12.16** and **12.17**). Permeability of the ACh receptor is essentially voltage-independent and depends instead on the binding of the neurotransmitter ACh. As noted previously, this difference in the control of permeability to ions of the two molecules results in the difference in properties of the potentials they produce: Action potentials are all-or-none and propagated; synaptic potentials are graded in amplitude and spread decrementally.

(a) Patch clamp of ACh receptor channels

(b) Effect on single-channel currents of increasing ACh

At low concentrations of acetylcholine, channel openings are infrequent.

At higher concentrations, sometimes both channels are open at once, and the individual currents summate.

FIGURE 13.17 Patch-clamp recordings of acetylcholine receptor-channel currents (a) A fine glass electrode is sealed to the membrane with suction, and the patch of membrane is pulled free of the rest of the cell. In this example, the patch contains two nicotinic acetylcholine receptors. Opening of a receptor-channel allows current to flow, as shown in the recordings in (b). (b) Each opening results in an inward current, shown as a downward deflection. The frequency of opening increases with increasing ACh concentration.

Many, but not all, ligand-gated channel receptors have evolved from a common ancestor

We have discussed nicotinic acetylcholine receptors in some detail, as examples of receptor proteins mediating direct, fast action of neurotransmitters. Studies have clarified the molecular structures of other neurotransmitter receptors that act as ligand-gated channels. Most of these structures are strikingly similar to the structure of the ACh receptors of neuromuscular junctions. The many ligand-gated channels that mediate PSPs in response to GABA, glycine, or serotonin (see Table 13.2) are composed of five subunits, each with four membrane-spanning segments, with considerable sequence homology to the ACh receptor. Therefore, these receptors appear to have evolved from a common ancestor and are termed the **ligand-gated channel superfamily**, comparable to the voltage-gated channel superfamily discussed in Chapter 12 (see page 315).

In contrast, ionotropic receptors for the excitatory amino acid glutamate appear evolutionarily unrelated to the ligand-gated channel superfamily. Ionotropic glutamate receptors each contain four relatively large subunits that have three membrane-spanning segments. The glutamate receptor subunits share little or no sequence homology with members of the ligand-gated channel superfamily, and doubtless evolved independently. Functions of glutamate receptors are discussed in the section “Synaptic Plasticity: Synapses Change Properties with Time and Activity” (see page 350).

SUMMARY Postsynaptic Receptors for Fast Ionotropic Actions: Ligand-Gated Channels

- The receptors that produce fast PSPs are ligand-gated channels. They are receptor–channels because the same molecule is both the receptor and the ion channel.
- The nicotinic acetylcholine receptor of the neuromuscular junction is the model ligand-gated channel. It contains five homologous subunits that surround a central ion channel that opens to allow Na^+ and K^+ ions to flow across the membrane.
- A ligand-gated channel opens briefly in response to binding two molecules of neurotransmitter, contributing to the synaptic current that produces a PSP.

Postsynaptic Receptors for Slow, Metabotropic Actions: G Protein–Coupled Receptors

Our discussion of synaptic action so far has largely considered only fast synapses such as vertebrate neuromuscular junctions and synapses onto spinal motor neurons. In these synapses, neurotransmitter produces an EPSP or IPSP by means of a brief increase in permeabilities to ions. Until the 1980s such fast, direct synaptic transmission was thought to be *the* mechanism of synaptic action. Several lines of investigation led to a broader view of synaptic function that included much longer time courses and wider synaptic actions than those of fast PSPs. Researchers discovered (1) second messenger–mediated cell signaling (see Chapter 2; pages 61–64) in nonneural and neural cells, (2) slower synaptic actions such as

synaptic potentials mediated by *decreased* permeability (to be discussed shortly), and (3) peptide neurotransmitters and cotransmitters that did not seem to produce classical fast PSPs.

Physiologists now understand that fast PSPs represent *one* kind of synaptic mechanism, not the only kind, and that synapses can also produce long-lasting metabolic effects. Metabotropic receptors can alter permeability to ions to change membrane potential indirectly (termed *indirect gating* of ion channels) but can also induce other metabolic changes that don’t gate ion channels at all.

G protein–coupled receptors initiate signal transduction cascades

The major group of receptors that mediate metabotropic synaptic actions are **G protein–coupled receptors (GPCRs)**, so called because they activate other membrane proteins termed G proteins. A GPCR is not an ion channel, and so is unlike a ligand-gated channel. All GPCRs have similar overall protein structures and have considerable sequence homology with each other. Thus GPCRs constitute an evolutionary superfamily, like the superfamilies of voltage-gated channels and ligand-gated channels. Because GPCRs have seven transmembrane segments (**Figure 13.18**), they are sometimes termed the *7-TM superfamily*. For many 7-TM neurotransmitter receptors, ligands bind near the extracellular ends of some transmembrane domains, whereas several cytoplasmic domains (adjacent to TM5, TM6, TM7, and perhaps TM4) mediate G protein binding.

GPCRs are widespread initiators of signal transduction cascades, some activated by neurotransmitters and others by other signals. Receptors for peptide hormones (see Chapter 16) and some sensory receptor molecules (see Chapter 14) are also members of the GPCR superfamily. Clearly this mechanism of cellular response to extracellular signals arose early in evolutionary history and has been exploited for many functions.

Metabotropic receptors act via second messengers

Metabotropic receptors typically act to increase the concentration of an intracellular second messenger. Recall from Chapter 2 that

FIGURE 13.18 G protein–coupled receptors share a common structure A GPCR has seven membrane-spanning segments (TM1–7) (shown pictorially on the left and lined up on the right). Several of the intracellular loops can interact with G proteins. Neurotransmitter-binding sites are part of the membrane-spanning segments of the receptors for most small-molecule transmitters.

a **second messenger** is an intracellular signaling molecule that carries the signal to the interior of the cell, altering some activity of the cell in response to activation of a surface membrane receptor (see Figure 2.30). The best-known second messenger is the cyclic nucleotide **3'-5'-cyclic adenosine monophosphate (cyclic AMP, or cAMP)**.

Let's consider a specific example of how a neurotransmitter receptor acts via a second messenger to influence cellular metabolism (Figure 13.19). Consider a synapse at which the presynaptic neuron releases the neurotransmitter norepinephrine (noradrenaline). Norepinephrine acts on a GPCR, which, when activated by binding neurotransmitter, activates a membrane protein called a **G protein**. G proteins are so named because they bind guanosine nucleotides, which regulate their activity. Both the GPCR and the G protein can diffuse laterally in the fluid mosaic membrane of the postsynaptic neuron, so when the GPCR is activated, it can bump into the G protein and activate it (step ① in Figure 13.19). The G protein is bound to the inner leaflet of the plasma membrane. It consists of α , β , and γ subunits. In their inactive form, the G-protein subunits are bound together, and the α subunit is bound to a molecule of *guanosine diphosphate (GDP)*. When the G protein is activated by a GPCR, the α subunit releases its GDP and acquires a molecule of *guanosine triphosphate (GTP)* (step ②); then the G protein dissociates from the GPCR, and the α subunit dissociates from the β and γ subunits, which remain joined to each other (step ③).

Once it has been activated by the receptor, the G protein can activate another class of membrane protein termed an *intracellular*

effector. In the case illustrated in Figure 13.19, the intracellular effector is an enzyme, adenylyl cyclase. Adenylyl cyclase (once activated by the active G protein) catalyzes the cytoplasmic conversion of ATP to cAMP. (Usually the dissociated α subunit is the active form of the G protein; the β and γ subunits remain together and play regulatory roles. In some cases, however, the linked β and γ subunits can activate an effector; see Figure 13.20.) The α subunit has GTPase activity, so eventually the GTP bound to it is degraded to GDP. When this occurs, the α subunit deactivates and reassociates with the regulatory β and γ subunits.

Intracellular second messengers such as cAMP can exert widespread metabolic effects, by activating a **protein kinase** (step ④), an enzyme that phosphorylates proteins. An increase in intracellular cAMP concentration leads to increased activation of cAMP-dependent protein kinase. (cAMP action is eventually terminated by the enzyme phosphodiesterase, which converts the cAMP molecules to 5'-AMP.) Activated cAMP-dependent protein kinase phosphorylates proteins (steps ⑤–⑦), altering their structure and activity. Thus stimulation of a neurotransmitter-dependent adenylyl cyclase leads to protein phosphorylation.

In postsynaptic neurons, the proteins phosphorylated often include membrane ion channels; phosphorylation alters their gating to change the membrane's permeability to ions and thereby change membrane potential (step ⑤). This indirect gating of ion channels is one way in which metabotropic receptors function, but it is not the only way! Cyclic AMP-dependent protein kinase can also phosphorylate cytoplasmic proteins involved in control of cellular

FIGURE 13.19 Metabotropic receptors: cAMP as a second messenger Some neurotransmitters act via GPCRs to alter cellular metabolism, rather than via ligand-gated channels. In this example, norepinephrine binds to a GPCR ① to activate a G protein ②. The G protein has three subunits; when the protein is inactive, the α subunit binds GDP. The G protein is activated when it encounters an activated receptor; it exchanges the GDP for a GTP, and the α subunit dissociates from the joined β and γ subunits. The α subunit in turn activates the enzyme

adenylyl cyclase ③. Adenylyl cyclase catalyzes the conversion of ATP to the second messenger cAMP. Cyclic AMP activates a protein kinase ④, which phosphorylates proteins to activate or inactivate them. ⑤ Cyclic AMP-dependent protein kinase can phosphorylate membrane proteins, which can indirectly gate them open or closed. The kinase can also phosphorylate cytoplasmic proteins (such as metabolic enzymes) ⑥ and nuclear proteins that regulate gene expression ⑦. Thus neurotransmitter binding can have widespread, long-lasting effects on postsynaptic cells.

metabolism (step ⑥), and even nuclear proteins that regulate gene expression (step ⑦). Uncovering the fact that synaptic actions can control cellular metabolism and gene expression is one of the most important advances in our understanding of synaptic physiology in the last 25 years.

Cell signaling initiated by GPCRs underlies the action of many other controls of cellular activities, as discussed in Chapters 2 and 16. Both at metabotropic synapses and elsewhere, GPCRs can act via a variety of mechanisms in addition to the production of cAMP diagrammed in Figure 13.19. As one example, other GPCRs can activate a different G protein that *inhibits* adenylyl cyclase, decreasing rather than increasing the concentration of cAMP in the cell.

Other mechanisms of G protein-mediated activity

Some G proteins can activate ion channels directly without employing a second messenger. This direct G-protein action is present in cholinergic synapses on cardiac muscle tissue, which, unlike skeletal muscle, is inhibited by acetylcholine. The inhibitory action of ACh is mediated by muscarinic ACh receptors, which are GPCRs. In mammalian cardiac muscle fibers, the GTP-bound α subunit dissociates from the activated G protein, and the β and γ subunits bind directly to K^+ channels, opening them to produce IPSPs (Figure 13.20). This mechanism demonstrates three significant features of synaptic function:

1. A particular neurotransmitter can mediate very different effects by activating different kinds of receptors.
2. G proteins can act on channels directly without an intervening second messenger (although this is not their usual mechanism).
3. Channels can be gated by signals other than voltage or direct neurotransmitter binding.

GPCRs can act via second-messenger systems other than cyclic AMP. The number of known systems is small, although different kinds of cell-signaling mechanisms are still being discovered. One other second messenger is *cyclic GMP* (cyclic guanosine monophosphate),

the production of which is similar to that of its adenosine analog cAMP. That is, some neurotransmitter receptors act via a G protein to activate a guanylyl cyclase to produce cyclic GMP, which activates a cGMP-dependent protein kinase, leading to protein phosphorylation.

Another way GPCRs can act is via second-messenger systems involving products of membrane lipid metabolism and Ca^{2+} ions. Most lipids in membranes are phospholipids (see Chapter 2; page 33), in which one of the fatty acids in a neutral fat is replaced by a phosphate to which is bound a small organic residue. One common membrane phospholipid is phosphatidylinositol 4,5-bisphosphate (PIP_2). Neurotransmitters can act via GPCRs to lead to the production of second messengers from PIP_2 (Figure 13.21). For example, norepinephrine can activate a GPCR, activating a G protein so that its α subunit activates a membrane-bound enzyme, *phospholipase C*. Phospholipase C catalyzes the hydrolysis of PIP_2 into **inositol trisphosphate (IP_3)** and **diacylglycerol (DAG)**.

Both IP_3 and DAG act as second messengers, via different paths that reflect their structures. IP_3 , which had formed the polar head of the phospholipid, is a polar molecule that freely diffuses through the cytoplasm. Its major action is to release Ca^{2+} ions from intracellular stores such as the endoplasmic reticulum. DAG, in contrast, is nonpolar and is constrained to the membrane lipid bilayer. It diffuses through the bilayer to activate *protein kinase C*. Thus DAG as a second messenger leads to protein phosphorylation, as does cAMP. The Ca^{2+} released by action of IP_3 can enhance the activation of protein kinase C, as well as activating **calmodulin (CaM)**, which with Ca^{2+} activates *calcium/calmodulin-dependent protein kinase*, or *CaM kinase*.

The ability of neurotransmitters to stimulate the production of second messengers is important, in part because it provides one possible mechanism whereby synaptic transmission can mediate relatively slow and long-lasting effects. The direct action of neurotransmitters on ion channels in membranes has a time course of milliseconds. The time course of effects mediated by second messengers may be less than a second (e.g., in slow PSPs mediated by decreased permeabilities to ions, discussed later in this section). At the other extreme, second-messenger actions may underlie synaptic changes involved in learning and memory, with a time course of days or years, as we will see.

FIGURE 13.20 G proteins can themselves activate ion channels, without a second messenger In this example of acetylcholine-mediated inhibition of vertebrate heart muscle fibers, a muscarinic acetylcholine receptor (a GPCR) activates a G protein, which can itself gate

a potassium (K^+) channel open without involving a second messenger. In this case the joined β and γ subunits activate the channel, rather than the more common activation by an α subunit.

FIGURE 13.21 Diacylglycerol and inositol trisphosphate are other second messengers Another pathway of cellular regulation via GPCRs is activation (via a G protein) of the enzyme phospholipase C, which cleaves the membrane phospholipid phosphatidylinositol 4,5-bisphosphate (PIP_2) into two second messengers: diacylglycerol (DAG) and inositol trisphosphate (IP_3). DAG activates a protein kinase (kinase C), and IP_3 mobilizes Ca^{2+} ions from intracellular stores. Both pathways play important regulatory roles in cell metabolism.

G protein-coupled receptors mediate permeability-decrease synaptic potentials and presynaptic inhibition

GPCRs mediate a variety of synaptic effects, as we have indicated. They may lead to indirect opening of ion channels, but they can also act to close ion channels or act on postsynaptic targets that are not ion channels. Here we consider two of these alternative possibilities: permeability-decrease synaptic potentials that are mediated by ion-channel closing, and presynaptic inhibition.

Permeability-decrease synaptic potentials were first studied at synapses in vertebrate sympathetic ganglia. It should be clear from the Goldman equation (Equation 12.6) that any changes in a postsynaptic cell's permeability to ions—decreases as well as increases—change the membrane potential. Thus a neurotransmitter receptor that leads to a *decrease* in permeability to an ion species also produces a synaptic potential. Postsynaptic neurons in bullfrog sympathetic ganglia characteristically have two distinct phases of synaptic response to stimulation of preganglionic axons: a fast EPSP lasting about 30 ms, and a slow EPSP lasting several seconds. The fast EPSP results from ACh acting at nicotinic receptors (ligand-gated channels) to increase permeability to ions; the slow EPSP results from a permeability *decrease*, due to the closing of a type of K^+ channel, moving the membrane potential away from E_{K} . In the latter case the ACh released by the presynaptic neurons acts on muscarinic GPCRs to indirectly gate the closing of the K^+ channels.

Presynaptic inhibition (PSI) is a specific inhibitory interaction in which one axon terminal ends on another axon terminal (a configuration called an *axo-axonal synapse*) and causes a *decrease* in the amount of neurotransmitter that the second terminal releases per action potential. Presynaptic inhibition is more specific than the more common postsynaptic (or just synaptic) inhibition, since it opposes only those excitatory synapses on which the PSI neuron ends. In many cases GPCRs mediate PSI, sometimes by decreasing the amplitude or duration of the action potential in the inhibited presynaptic terminal, and sometimes by decreasing the amount of Ca^{2+} entry and neurotransmitter release in response to the depolarization.

SUMMARY Postsynaptic Receptors for Slow, Metabotropic Actions: G Protein-Coupled Receptors

- Many neurotransmitter receptors act via second messengers, triggering metabolic cascades in postsynaptic neurons. These metabotropic receptor effects are often slow and long-lasting.
- G protein-coupled receptors (GPCRs) are the major receptors of metabotropic synapses. All GPCRs have seven membrane-spanning segments, and all are evolutionarily related.
- GPCRs act via G proteins. A G protein has three subunits; normally the α subunit becomes activated when it dissociates from the regulatory β and γ subunits.
- An activated G protein activates an intracellular effector, usually to produce an intercellular second messenger.
- Second messengers of importance in metabotropic synapses include cyclic AMP, the membrane phospholipid derivatives DAG and IP_3 , and Ca^{2+} ions.
- Most second messengers activate protein kinases, which phosphorylate proteins such as ion channels and change their activity.
- G proteins can activate ion channels directly.
- Metabotropic receptors play roles in slow synaptic potentials in which permeability to ions decreases, and in presynaptic inhibition.

Synaptic Plasticity: Synapses Change Properties with Time and Activity

The parameters of each step of synaptic transmission may change quantitatively over time. Presynaptically, neurotransmitter can be synthesized, stored, and released at different rates, and postsynaptic sensitivity to the neurotransmitter may be increased or decreased in different circumstances. Even electrically mediated transmission can be altered by changes in pH and in Ca^{2+} concentration that can

close gap-junction channels. Changes in the parameters of synaptic transmission are important both for homeostatic regulation of transmitter metabolism and for *synaptic plasticity*—changes in synaptic strength over time. Because synaptic functions are more labile than other aspects of neuronal function, such as axonal conduction, it is widely supposed that synaptic plasticity is the mechanism that underlies how nervous system function changes over time. Thus the synaptic bases of nervous system development, and of learning and memory, are subjects of active current investigation. We cannot survey the entire burgeoning field, but we will present examples that illustrate some of the major themes.

Neurotransmitter metabolism is regulated homeostatically

The metabolism of neurotransmitters must be regulated just as other aspects of metabolism are regulated. Consider the following example: A stimulated superior cervical ganglion releases 10% of its acetylcholine (ACh) content per minute, yet the total ACh content of the ganglion is not diminished. How can this be, when the rate of stimulated release is 50 times greater than the resting release rate? Clearly, the rate of synthesis of ACh following stimulated release must also increase 50-fold if there is no depletion of ACh.

Although not all the mechanisms controlling the increased synthesis of ACh are known, the increased availability of free choline plays a major role, since choline is normally the rate-limiting substrate in ACh synthesis. When more ACh is released into the synaptic cleft, more choline is produced by acetylcholinesterase. Thus more choline is taken up by the choline transporter at the presynaptic terminal and is available for resynthesis of ACh by choline acetyltransferase (see Figure 13.11). At other synapses, control of the synthesis and action of neurotransmitters may be more complex than in this simple example.

Several important advances in the pharmacological treatment of psychiatric conditions have focused on manipulation of neurotransmitter synthesis or reuptake pathways. For instance, selective serotonin reuptake inhibitors (SSRIs) function—as the name would suggest—to reduce the amount of the neurotransmitter serotonin that is taken up after release into the synaptic cleft. The resulting increased availability of serotonin to postsynaptic receptors has proven to be a strikingly effective treatment for depression and other mood disorders.

Learning and memory may be based on synaptic plasticity

Synaptic potentials have time courses of milliseconds to seconds—long enough to have a transient effect on the excitability of postsynaptic cells. However, if synapses are involved in the long-term behavioral changes of learning and memory (an assertion for which there is increasing evidence), then neurons should demonstrate changes in synaptic strength—synaptic plasticity—that have a suitably long time course of minutes, days, or weeks. Synaptic strength is usually measured as the amplitude of a postsynaptic potential in response to a presynaptic action potential.

In many synapses, the amplitudes of individual postsynaptic potentials are not constant over time. **Synaptic facilitation** is an increase in amplitude of postsynaptic potentials in response to successive presynaptic impulses (Figure 13.22a). A decrease in amplitude of postsynaptic potentials with successive presynaptic

FIGURE 13.22 Synaptic facilitation and antifacilitation

impulses is termed **synaptic antifacilitation**, or *synaptic depression* (Figure 13.22b). Both *synaptic facilitation* and *antifacilitation* result from changes in the amount of neurotransmitter liberated per presynaptic impulse. These changes are known to be calcium-dependent, but their mechanisms are otherwise incompletely understood.

Facilitation of synaptic transmission is often especially pronounced after *tetanic* stimulation of presynaptic neurons—that is, stimulation by trains of stimuli at a rate of about 10 to 100 per second for several seconds. The response to a single presynaptic impulse may be elevated severalfold after tetanic stimulation, and although the effect diminishes over time, it may persist for hours. This extended enhancement of synaptic response is termed **posttetanic potentiation**. Posttetanic potentiation indicates that synaptic efficacy can change with use, and these changes can be long-lasting. Particularly long-term potentiation changes have been reported in the hippocampus and cerebral cortex of the vertebrate brain, regions that are implicated in learning and memory functions. We will discuss these changes after considering the anatomically simpler example of the marine mollusc *Aplysia*.

Habituation and sensitization in *Aplysia*

Habituation and sensitization are two simple forms of behavior that occur in nearly all kinds of animals. **Habituation** is defined as the decrease in intensity of a reflex response to a stimulus when the stimulus is presented repeatedly. **Sensitization** is the prolonged enhancement of a reflex response to a stimulus, which results from the presentation of a second stimulus that is novel or noxious. Habituation and sensitization are considered simple forms of learning—that is, of modification of behavior with experience.

Reflexive gill withdrawal in *Aplysia* is a behavioral response that is subject to habituation and sensitization and is amenable to study of its synaptic basis. The gill of *Aplysia* withdraws in response to mechanical stimulation of the animal's siphon or mantle shelf (Figure 13.23a). The amplitude of gill withdrawal decreases with repeated low-frequency stimulation; that is, the response habituates. After a shock to the head, the response to siphon stimulation is again large; that is, it is *sensitized* by the head shock (Figure 13.23b).

Eric Kandel, a Nobel Prize-winning American neurobiologist, together with his colleagues, mapped the neural circuit of the gill-withdrawal reflex and determined the synaptic locus of the habituation and sensitization. Habituation of the gill-withdrawal response results from a waning of synaptic excitation of gill motor neurons by sensory neurons, and the time course of the decrease

in sensory-to-motor EPSPs closely parallels the time course of behavioral habituation (Figure 13.23c). This decrease of EPSP amplitude results not from any postsynaptic change, but rather from a decrease in the number of quanta of neurotransmitter released by the sensory nerve endings. Thus the synaptic basis of habituation in *Aplysia* is *antifacilitation* of the sensory synaptic terminals.

Sensitization of the gill-withdrawal response by head shock also occurs at the sensory-to-motor synapses (see Figure 13.23c). In contrast to habituation, a sensitizing stimulus increases the amount of neurotransmitter released per impulse at the sensory-neuron

terminal. This facilitation apparently results from activation of synaptic endings of sensitizing interneurons that end on the sensory terminals in axo-axonal synapses. Thus presynaptic *facilitation* is the synaptic basis of behavioral sensitization.

How is the amount of neurotransmitter release diminished during habituation and increased by sensitization? Evidence indicates that the Ca^{2+} current entering the presynaptic terminal during an impulse is depressed during habituation. This finding suggests that there is a progressive, long-lasting inactivation of Ca^{2+} channels with habituation, allowing less Ca^{2+} to enter and to trigger neurotransmitter release. The presynaptic facilitation underlying sensitization is caused by an increased Ca^{2+} influx.

Some facilitating interneurons release 5-HT (serotonin), which acts to increase the amount of cAMP in the sensory terminals (Figure 13.24). The cAMP acts via a cAMP-dependent protein kinase to phosphorylate K^+ channels in the terminal, and thereby to decrease the K^+ current that normally terminates the action potential. This K^+ channel inactivation prolongs the action potential, leading to an increase in the Ca^{2+} influx and in resultant neurotransmitter release. Cyclic AMP-dependent protein kinase can also phosphorylate other proteins (e.g., to increase the mobilization of stored neurotransmitter to the release sites), and serotonin can also act at the synapse through other serotonin receptors and other second messengers, such as diacylglycerol (DAG).

The studies on *Aplysia* outlined here have determined the anatomical location of two forms of behavioral plasticity in specific, identifiable synapses and have made considerable progress in defining the synaptic mechanisms producing these changes. Short-term sensitization in *Aplysia* lasts about an hour, but with repeated training sessions sensitization may persist for more than 3 weeks. This long-term sensitization depends on changes in the same sensory-to-motor synapses, but it requires new protein synthesis. Long-term sensitization is driven by persistent serotonin-dependent elevation of cAMP, leading to the movement of cAMP-dependent protein kinase to the nucleus, where the kinase activates gene transcription via cAMP-dependent transcriptional regulatory proteins such as CREB (cAMP response element-binding protein).

Investigators have also demonstrated *classical conditioning* of the *Aplysia* gill-withdrawal response: a learned association between

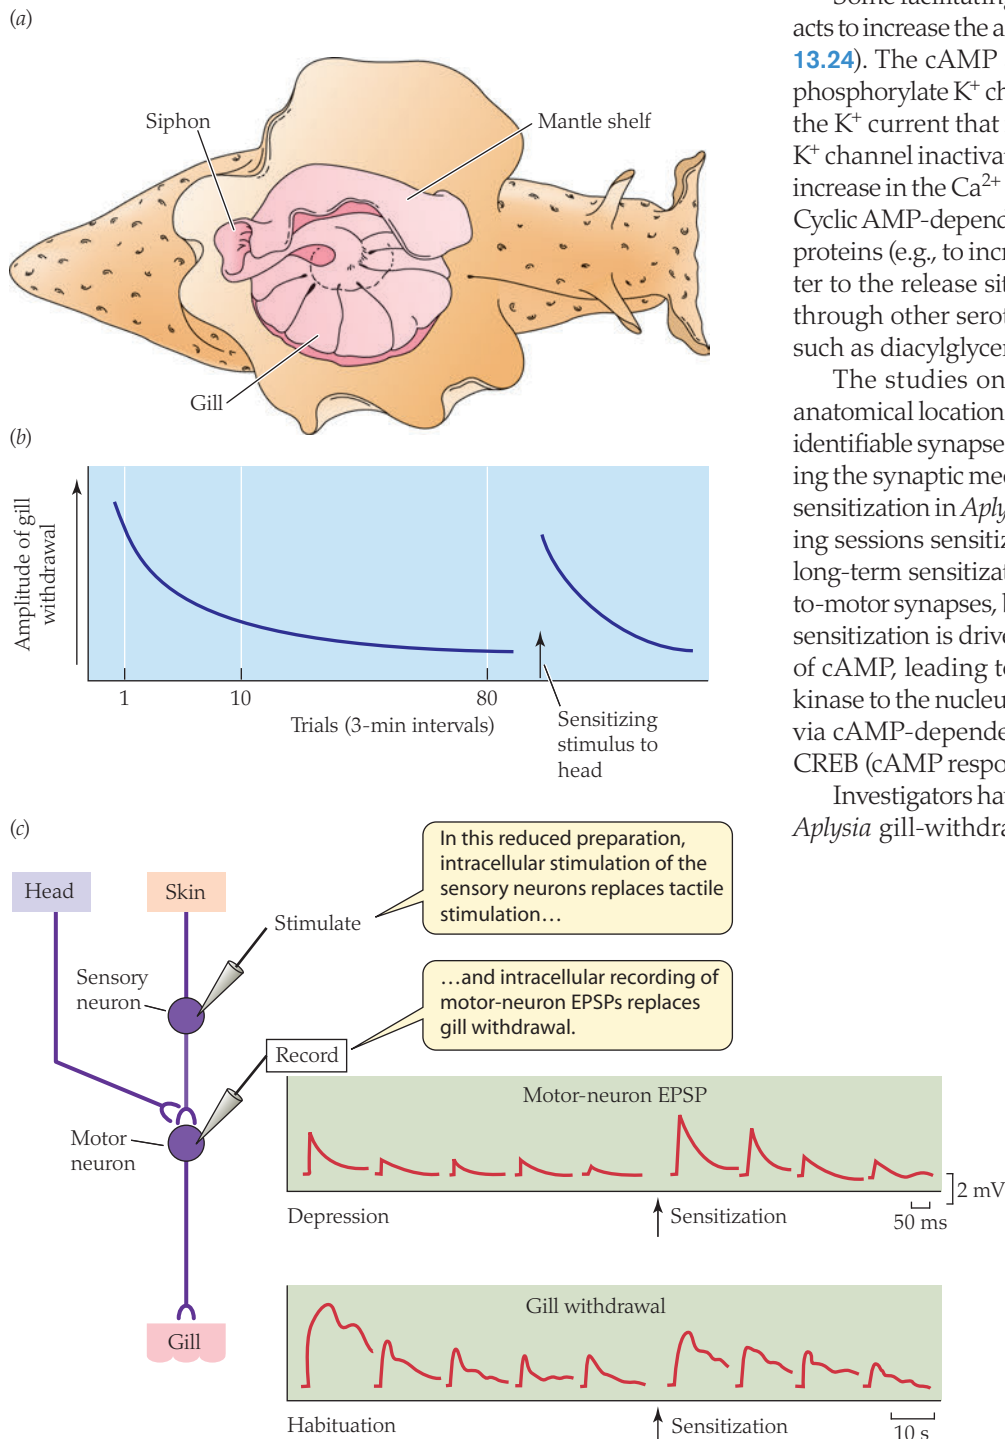

FIGURE 13.23 Habituation and sensitization in *Aplysia* gill withdrawal (a) The gill-withdrawal reflex of *Aplysia* is a response to stimulation of the siphon or the mantle shelf. The animal retracts the gill. (b) The gill-withdrawal reflex habituates with repeated stimulation and is recovered following a sensitizing stimulus to the head. (c) Changes in synaptic activity of a reduced preparation (diagrammed) are comparable to habituation and sensitization responses of the whole animal. Stimulation of a nerve from the head replaces head shock. The decrement and enhancement of the motor-neuron EPSPs mirror the behavioral habituation and sensitization, respectively, of gill withdrawal. This result suggests that the sensory-to-motor neuron synapse is the primary site of the behavioral plasticity. (Note the longer time course of the behavioral responses.)

FIGURE 13.24 A model of *Aplysia* sensitization Transmitter release in the sensory terminals decreases with habituation and increases with sensitization. With habituation, fewer Ca^{2+} channels open in response to action potentials in the sensory terminal. The resulting decrease in Ca^{2+} influx decreases transmitter release. Serotonergic neurons promote sensitization ①. Serotonin acts ② to activate an adenylyl cyclase in the terminals, which stimulates the synthesis of cAMP ③. Cyclic AMP in turn acts on a cAMP-dependent protein kinase ④ to phosphorylate proteins, including a K^+ channel ⑤; this leads to a decrease in the repolarizing K^+ current and a broadening of the action potential. The increase in the duration of the action potential increases the time during which Ca^{2+} channels can open ⑥, leading to a greater influx of Ca^{2+} and increased release. The kinase also acts on Ca^{2+} channels and on mobilization of neurotransmitter vesicles ⑦. Other serotonin effects are not shown. (After Kandel et al. 1995.)

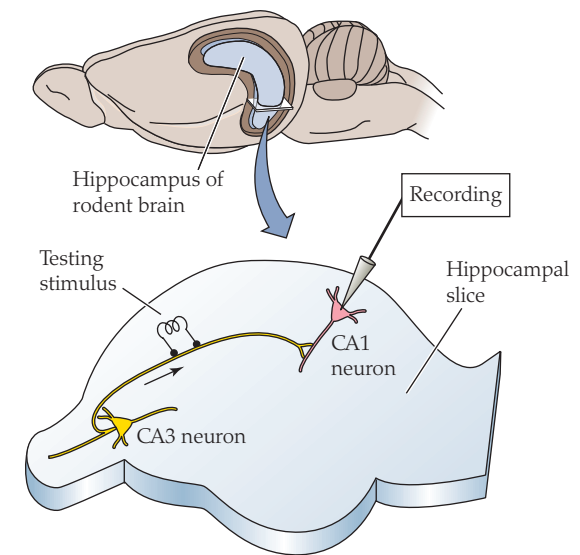

two stimuli. The synaptic basis of classical conditioning is more complex than that of sensitization. In part it depends on similar presynaptic mechanisms of enhanced neurotransmitter release, but there is also a postsynaptic component that involves NMDA-type glutamate receptors (see page 354).² The details of these mechanisms are complicated, but the major point is that synaptic mechanisms similar to those that underlie sensitization and habituation can also be employed to explain classical conditioning in *Aplysia*.

Long-term potentiation in the hippocampus

Synaptic changes in mammalian brains that are long-lasting have been explored extensively during the last 30 years, most notably in the hippocampus. The hippocampus is a deep forebrain structure that is strongly implicated in spatial learning (such as maze learning) and in memory formation. The circuitry of the hippocampus is well characterized, and because it is largely restricted to two dimensions, it can be studied in hippocampal slices that allow stable, long-term recordings from visible neurons (Figure 13.25a). Circuits in the hippocampus (and elsewhere in the brain) undergo prolonged changes when strongly stimulated, and some of these changes are associative; that is, they are specific to the pathways that are stimulated together.

We will examine associative long-term potentiation in a particular region (CA1) of the hippocampus. **Long-term potentiation (LTP)** is a long-lasting enhancement of synaptic transmission following intense stimulation (Figure 13.25b); it resembles posttetanic potentiation but is more prolonged. Associative LTP is specific to the activated pathway and requires the cooperative interaction of

(a) Experimental setup

(b) Long-term potentiation

FIGURE 13.25 Long-term potentiation in the hippocampus Synapses in the hippocampus and in other brain areas exhibit long-term potentiation (LTP), a long-lasting increase in EPSP amplitude after a tetanic (strong, repeated train) stimulus. (a) The hippocampus of mammalian brains contains several synaptic pathways and types of neurons. Here we consider synapses (of CA3 neurons) onto CA1 neurons. For simplicity, only one neuron of each type is shown in the diagram. (b) Long-term potentiation may persist for many hours.

² D. G. Glanzman and coworkers have shown that longer-term sensitization in *Aplysia* also has a postsynaptic component that depends on NMDA receptors.

many presynaptic neurons to depolarize the postsynaptic CA1 cell adequately.

LONG-TERM POTENTIATION IN THE BRAIN INVOLVES CHANGES IN SYNAPSE STRENGTH As first pointed out by Donald Hebb, learning could depend on “successful” synapses getting stronger, with a “successful” synapse meaning one in which the presynaptic and postsynaptic neurons have been active or depolarized at the same time: “Neurons that fire together wire together.” A synapse that undergoes a long-term change in strength as a result of coincident activation of the pre- and postsynaptic neurons is called a *Hebbian synapse*. The synapses that undergo LTP in the CA1 region of the hippocampus are Hebbian because potentiation depends on the associated activity of presynaptic and postsynaptic cells. A critical feature of LTP is that any synapse that is active while the postsynaptic cell is strongly depolarized will be potentiated, for a period that can last hours in hippocampal slices and weeks in intact animals. Interestingly, some of the mechanisms controlling synaptic plasticity in the mature nervous system may function similarly to those that control synapse formation in neural development (**Box 13.1**).

Establishment of hippocampal LTP (**Figure 13.26**) depends on two related glutamate receptors: NMDA receptors (so named because they also are activated by the drug *N*-methyl-D-aspartate) and other ionotropic glutamate receptors, most notably AMPA receptors (activated by the drug α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid). AMPA receptors produce fast EPSPs. NMDA receptors also produce EPSPs, but they have an important functional property: They work only when the postsynaptic cell is depolarized. As **Figure 13.26a** shows, an NMDA receptor is activated by glutamate, but at resting membrane potential the ion channel is blocked by a bound Mg^{2+} ion, so few or no ions flow through it. The EPSP produced under these conditions depends on AMPA receptors. In contrast, when the postsynaptic cell is substantially depolarized, the bound Mg^{2+} ion is released; with glutamate binding to NMDA receptors, a considerable number of Na^+ and Ca^{2+} ions can enter the cell through the unblocked channels (see **Figure 13.26b**). In this way, an NMDA receptor functions as a molecular coincidence detector: Both postsynaptic depolarization and presynaptic stimulation must occur at the same time for NMDA receptor-mediated ion flux to occur.

The Ca^{2+} ions entering the postsynaptic cell act as second messengers, activating Ca^{2+} -dependent signaling molecules such as Ca^{2+} /calmodulin-dependent kinase II (CaMKII) and protein kinase C (see **Figure 13.26b, c**). Thus two features of NMDA receptors are important for the establishment of LTP: (1) Their full activation requires a Hebbian simultaneous depolarization of the presynaptic and postsynaptic cells; and (2) they have indirect, long-lasting effects mediated by second messengers.

Whereas long-lasting changes in synapse strength are clearly induced by postsynaptic activation of NMDA receptors, what mechanisms actually underlie the increased synaptic strength observed in LTP? For more than a decade, there was a hearty scientific debate on whether LTP is a reflection of changes in neurotransmitter release or neurotransmitter receptor properties (in other words, presynaptic or postsynaptic alterations). It now seems clear that a major mechanism for enduring changes in synapse strength involves modulation of the postsynaptic AMPA-type ionotropic glutamate receptors touched

on above. Ca^{2+} flux through NMDA receptors triggers a series of downstream events leading to phosphorylation and subsequent insertion of new AMPA receptors into the postsynaptic cell membrane (see **Figure 13.26b**). The increased number of postsynaptic AMPA receptors results in increased amplitude of synaptic responses. In addition, alteration in the biophysical properties of these channels contributes to the observed potentiation.

Of course, one might imagine that our brains would not work optimally if synaptic contacts were only able to get stronger. As it turns out, certain stimuli result in a *long-term depression (LTD)* of synaptic responses. At least some forms of LTD are also NMDA receptor-dependent, which raises the question of how both LTP and LTD could rely on NMDA receptor activity and the resultant Ca^{2+} influx. Although the answers are not totally clear, it is thought that high postsynaptic levels of Ca^{2+} over a short period result in LTP, whereas lower levels of Ca^{2+} over a prolonged period result in LTD. Stimuli known to result in LTD set into motion a cascade of events leading to removal of AMPA receptors from the postsynaptic membrane and, in turn, reduced amplitude of postsynaptic responses. Because the insertion or removal (processes known as trafficking) of AMPA receptors is a key event in the modification of synaptic strength, one could ask what happens if the signals controlling AMPA receptor trafficking are perturbed. Researchers recently asked this very question using mutant mice with single amino acid changes to specific phosphorylation sites on their AMPA receptors. These mutations interfere with the normal phosphorylation and dephosphorylation—and thus the trafficking—of the AMPA receptor proteins. The researchers found that the mutant mice have abnormal LTP and LTD, as well as memory defects in spatial learning tasks. Thus LTP and LTD not only reflect the dynamic nature of synaptic contacts, but also highlight the fact that synapse strength can be both increased and decreased and is involved in memory formation.

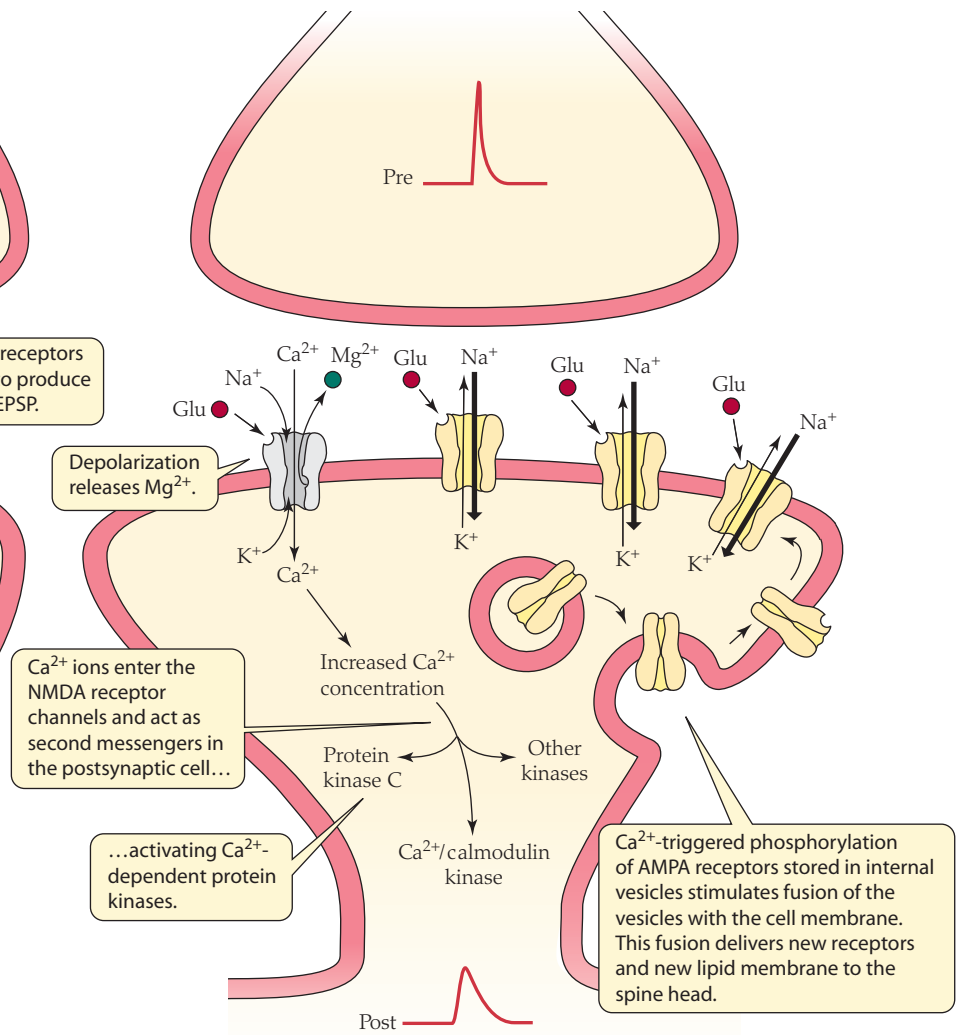

LONG-TERM MEMORIES CAN INVOLVE CHANGES TO THE PHYSICAL STRUCTURE OF NEURONS The establishment of LTP (or LTD) requires NMDA receptor-mediated Ca^{2+} flux and AMPA receptor insertion (or removal), but some memories, as they say, last a lifetime. How are more permanent changes to synapses accomplished? The answer appears to have at least two components. First, the so-called late phase of LTP (persistent changes lasting hours to even weeks) requires the synthesis of new proteins as well as gene transcription. Inhibition of protein synthesis at the time an animal is being trained in a new task does not affect the animal’s ability to learn, but it prevents the consolidation (“conversion”) of the new memory into a long-term one. Some of the new required proteins can be made locally at a synapse. However, some signals ultimately activate processes in the nucleus. In the nucleus, transcription factors such as CREB are known to be of particular importance in turning on the transcription of genes encoding proteins that are critical in maintaining memories. What is the character of these proteins and how are they transported to the correct synapse where the signal began? These are significant questions for the next generation of neuroscientists!

The second manner in which changes to synaptic transmission are made more permanent involves structural alterations to synapses themselves. Excitatory synapses usually occur on the stereotyped morphologic protrusions known as dendritic spines (see **Figure 13.5**). Stimuli resulting in LTP, or even the experimental

(a) Normal synaptic transmission

(b) LTP induction

(c)

focal release of glutamate right next to a spine, have an interesting effect: The head of the affected spine gets larger (see Figure 13.26c). So in concert with the prolonged increase in response amplitude described above comes an increase in the volume of the dendritic spines on which the LTP-inducing stimuli occurred. Investigators hypothesize that the same vesicles that supply new AMPA receptors to the postsynaptic density also deliver fresh lipid materials to allow expansion of the postsynaptic membrane (see Figure 13.26b). The enlargement of individual spines also requires activation of NMDA receptors and CaMKII, indicating that spine

FIGURE 13.26 Induction and maintenance of LTP in the hippocampus Induction of long-term potentiation (LTP) is postsynaptic. (a) At the unpotentiated synapse, glutamate neurotransmitter is released and acts at various kinds of glutamate receptors, principally AMPA receptors. NMDA receptors are blocked by Mg^{2+} . (b) Tetanic stimulation depolarizes the postsynaptic cell substantially, releasing the Mg^{2+} block and allowing glutamate to activate the NMDA receptors, leading to Ca^{2+} entry. The resultant phosphorylation events lead to an enhanced postsynaptic response via insertion of internal AMPA receptors into the postsynaptic membrane, extensive downstream signaling, and synaptic growth. (c) The fluorescence micrographs in this time series show the effect of increased glutamate on a single dendritic spine (the green spot to the left of the vertical green dendrite). Localized release of glutamate (at the white triangle) increases the CaMKII activity (red, peaking at 12s) and then increases the volume of only the dendritic spine immediately adjacent to the glutamate release. (c from Lee et al. 2009.)

growth likely is a structural basis of LTP. Moreover, changes in dendritic spine morphology are synapse-specific—another important property of LTP. Neighboring, unstimulated spines or portions of the dendrite are unaffected. In this way, only the “successful” synapses are strengthened, without nonspecifically reinforcing other, unpaired contacts.

BOX 13.1 SYNAPSE FORMATION: COMPETING PHILOSOPHIES

Matthew S. Kayser

How does the nervous system form synapses during development? Much of what we know comes from the model system of the vertebrate neuromuscular junction (NMJ). The neuromuscular synapse is a reliable relay, so that an action potential traveling in a motor axon will consistently result in contraction of the muscle fiber it innervates. Interestingly, during development, multiple motor axons can innervate a muscle fiber initially (see figure), but at a mature NMJ just one axon innervates one muscle fiber. How is it decided which motor axon will innervate a given muscle fiber? The outcome is more analogous to Darwinian natural selection than Calvinist predestination: Motor

axons engage in a competition for space on a muscle fiber.

Single mature neurons in the central nervous system (CNS)—in sharp contrast to single mature muscle fibers at the NMJ—receive thousands of inputs. That is, the dendrites of a single neuron may make synaptic contact with axons of thousands of other neurons. This raises the question of how the brain can possibly become wired properly. A leading hypothesis suggests molecular matchmaking occurs, wherein the appropriate axons and dendrites recognize cues on one another.

Box Extension 13.1 describes more about how synapses form during development in the brain and at neuromuscular junctions.

A neuromuscular junction with multiple innervation

Multiple axons can innervate each muscle fiber at immature NMJs in mice In this image (on day 8 of postnatal development) some neurons have been labeled blue and others green. The postsynaptic receptors are red. The muscle fibers themselves are not visible.

of new synapses and actually reshape the *physical* structure of dendrites in a mouse's brain.

Remember, however, the elegance of brain circuitry: Nothing lasts forever, as the next mind-altering experience is just around the bend.

Long-term potentiation is a necessary component of learning

LTP was originally studied as a long-lasting synaptic change that might underlie learning and memory, a molecular *correlate* of the changes needed for long-term behavioral changes to have a synaptic basis. The existence of LTP does not prove that it is involved in learning and memory—only that it could be. Is there direct evidence that LTP is a necessary component of learning? The answer is yes. Studies that knock out (block the expression of) particular genes show that the absence of NMDA receptors, of CaM kinase, or of other kinases disrupts both LTP and spatial learning of a mouse trying to negotiate a water maze (see page 497). As described above, the same holds true for manipulations that disrupt AMPA receptor insertion into the postsynaptic membrane.

One of the most compelling studies correlating NMDA receptors, LTP, and learning and memory is that of *Doogie* mice, introduced at the beginning of the chapter. Joe Tsien and coworkers genetically engineered mice to overexpress a particular subunit of their NMDA receptors. This subunit is normally abundant in developing mice but less so in adults. An important functional difference is

So far we have covered the mechanisms by which individual synapses and spines respond to plasticity-inducing stimuli. But in addition to spine expansion, changes in experience can also result in the growth of new dendritic spines altogether. Karel Svoboda and colleagues have characterized how dendritic spines behave in functioning cortical circuits of awake animals. Svoboda's group made cranial viewing windows in the skulls of mice and repeatedly (even over the course of months) imaged portions of dendrites closest to the surface of the brain, coming from neurons that were made to fluoresce bright green. The type of neurons chosen were those from barrel cortex, the somatosensory area of the rodent brain receiving input from the animal's whiskers (Figure 13.27). By trimming the whiskers of a mouse in a particular pattern, Svoboda and colleagues were able to alter the animal's sensory experience, and found that the changing sensory input drove the formation of new dendritic spines and synaptic contacts, while eliminating others. In other words, alterations in external stimuli allow formation

that NMDA receptors containing the juvenile subunit remain open longer than NMDA receptors containing only adult subunit types. Mice of the *Doogie* strain (with more NMDA receptors containing the juvenile subunit) have more potent hippocampal LTP when their brains are tested, presumably because more Ca^{2+} enters through the longer-opening NMDA receptors during LTP induction. The mice also perform better than average mice on several sorts of learning tasks, and they remember novel stimuli longer. These studies show that manipulation of the molecular substrates of LTP can enhance learning and memory, as well as disrupt it. Interestingly in this regard, a recent study has shown that in the CA2 region of the hippocampus that does not normally show LTP, a protein regulator of G protein signaling termed RGS14 normally suppresses LTP in mice. Knockout of the gene for RGS14 leads both to LTP in CA2 neurons and to enhanced spatial learning and memory! Both this study and the earlier experiments with *Doogie* mice show strong correlations of LTP with learning.

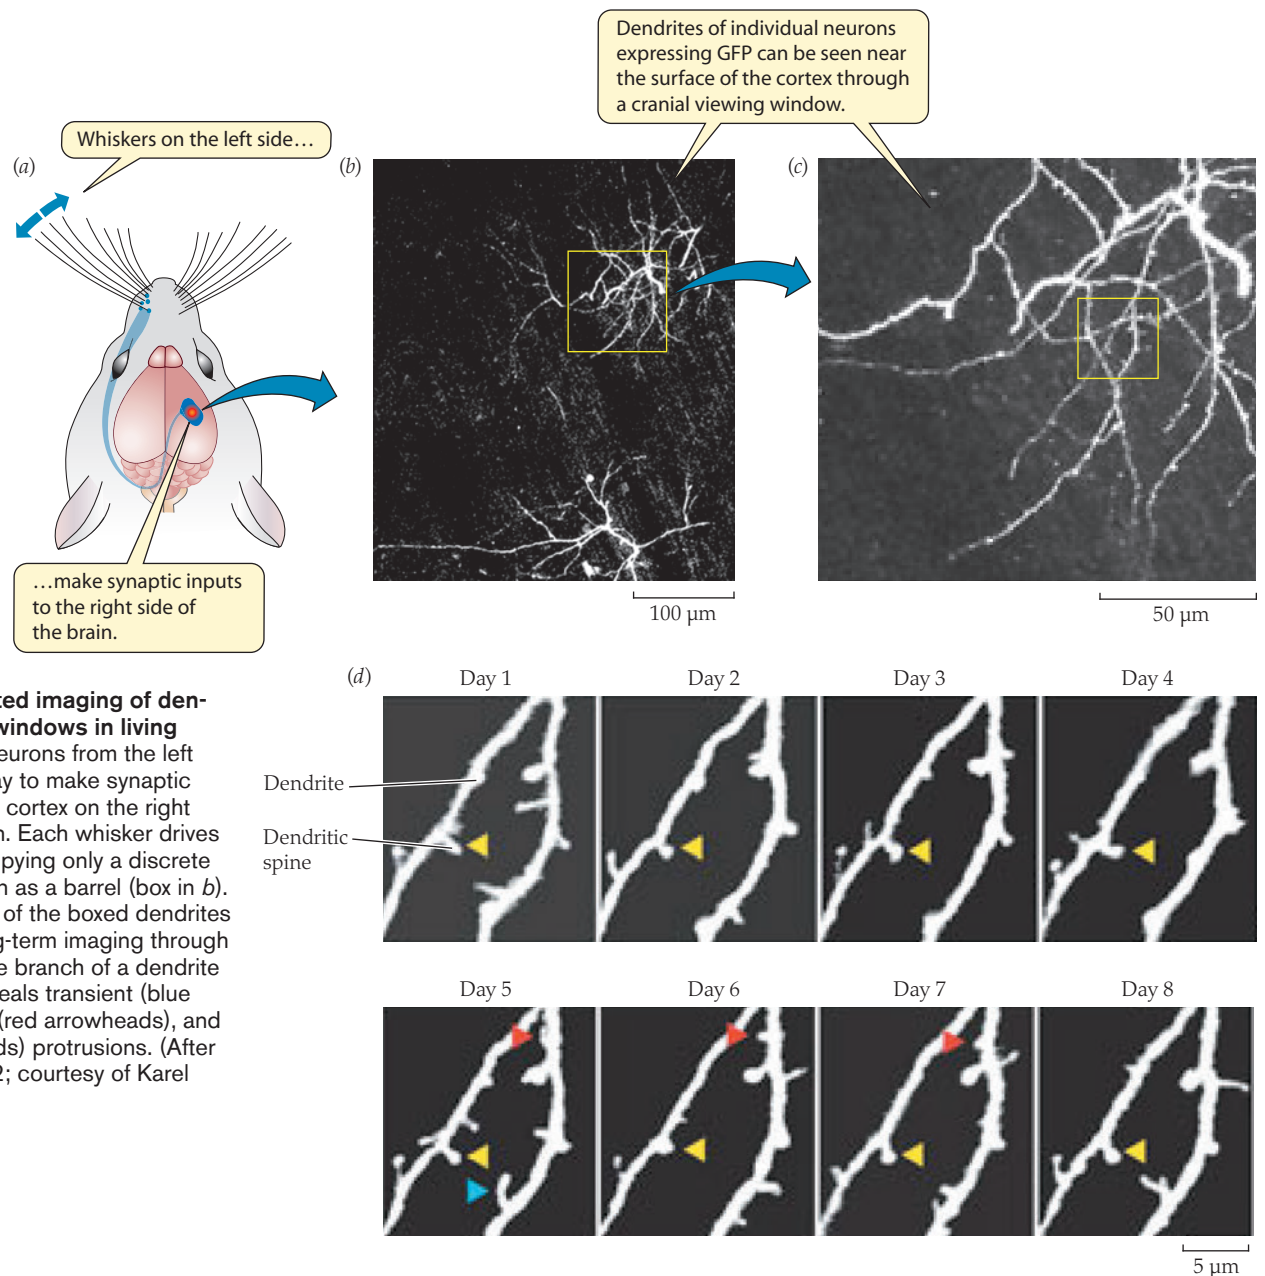

FIGURE 13.27 Repeated imaging of dendrites through cranial windows in living rodents (a) Sensory neurons from the left whiskers of a rodent relay to make synaptic inputs in somatosensory cortex on the right side of the animal's brain. Each whisker drives input onto neurons occupying only a discrete area of the cortex, known as a barrel (box in b). (c) Higher magnification of the boxed dendrites in (b). (d) Repeated long-term imaging through the cranial window of the branch of a dendrite (the area boxed in c) reveals transient (blue arrowhead), semistable (red arrowheads), and stable (yellow arrowheads) protrusions. (After Trachtenberg et al. 2002; courtesy of Karel Svoboda.)

Beyond these correlational studies, is there also direct evidence that learning induces LTP in the brain? Mark Bear and colleagues have finally confirmed this 30-year-old conjecture. While putting mice through a training protocol in which the mice learned to avoid a mild shock, the investigators used multielectrode arrays to record from multiple areas of hippocampus area CA1 at once, since it is not known where in CA1 LTP might occur with this particular task. They found in awake and behaving animals that the process of learning the task results in long-term potentiation of synaptic responses using the same signaling pathways as electrophysiologically induced LTP. This work provides the most definitive evidence yet that LTP really is a molecular basis for learning and memory.

The extent of synaptic plasticity even in adult nervous systems represents a staggering expansion of our understanding of the range of mechanisms and functions of synaptic physiology. Synapses transmit signals, by both rapid and prolonged mechanisms. But synapses also modulate properties—of synapses, of neurons, and of behavior.

SUMMARY Synaptic Plasticity: Synapses Change Properties with Time and Activity

- Neuronal stimulation that increases the rate of neurotransmitter release also increases rates of neurotransmitter resynthesis. The homeostatic mechanisms of this regulation involve both substrate availability and more complex mechanisms.
- With a train of presynaptic action potentials, the amplitudes of the resultant postsynaptic potentials may increase (facilitation) or decrease (antifacilitation). Thus the synaptic transfer of information depends on its history.
- The synaptic bases of behavioral habituation, sensitization, and classical conditioning in *Aplysia* depend on second messenger-mediated control of the amount of neurotransmitter released at CNS synapses.

- Hippocampal long-term potentiation (LTP) is a long-lasting change in synaptic properties related to learning and memory. The induction of LTP depends on NMDA receptors that respond to both glutamate neurotransmitter and postsynaptic depolarization, to allow Ca^{2+} entry into the postsynaptic cell.
- LTP is maintained by means of Ca^{2+} -dependent second-messenger pathways that make the postsynaptic cell more sensitive to glutamate neurotransmitter. Insertion of AMPA receptors into the postsynaptic membrane increases the amplitude of the postsynaptic response, and occurs along with expansion of the area of dendritic spines.
- Studies that manipulate the expression of critical genes in the LTP metabolic pathway significantly affect learning and memory in mice.

Study Questions

1. What are the functional advantages and disadvantages of electrical synapses?
2. What adaptive advantage do synapses provide in nervous systems (i.e., why isn't the nervous system just a mesh of cells cytoplasmically connected through gap junctions)?
3. Why is it difficult to show vesicular release of neurotransmitter molecules by electron microscopy?
4. In his book *Ionic Channels of Excitable Membranes*, Bertil Hille characterized the importance of calcium ions: "Calcium channels ... serve as the only link to transduce depolarization into all the nonelectrical activities controlled by excitation. Without Ca^{2+} channels our nervous system would have no outputs." Discuss this statement with reference to synaptic function.
5. What are the criteria for identification of the neurotransmitter at a particular synapse? Which two criteria are *sufficient* to conclude that a candidate is the neurotransmitter?
6. Why (in evolutionary terms) do you think there are so many kinds of neurotransmitters?
7. Why are there multiple receptor subtypes for each neurotransmitter? Why not a few receptors and lots of neurotransmitters acting on each receptor?
8. Discuss the functional differences between ionotropic and metabotropic receptors.
9. Would you classify NMDA receptors as ionotropic or metabotropic? Why?
10. Do you think there is one cellular mechanism of learning and memory or several? Cite studies in *Aplysia* and in the mammalian hippocampus to support your answer.

Sensory Processes

Sensory systems provide animals with essentially all of the information they have about their external environment—as well as most of the information they have about their internal environment. For example, consider the nocturnal encounter between a hunting bat and a moth in the accompanying photo. The bat finds its prey by echolocation: It emits ultrasonic cries (sounds at frequencies above the limit of human hearing) and hears the echoes of its cries that bounce off objects in the environment, rather like human detection of submarines by sonar. Moths, however, have evolved auditory organs that are very sensitive to bat cries. A moth will fly away from faint bat cries (at distances beyond the range of the bat's echodetection), but in response to louder cries (when the bat is close enough to get clear echoes) the moth will either take erratic and apparently random evasive action or power-dive to the ground.

Clearly it is of selective advantage for bats to have evolved auditory systems that allow them to use echolocation to detect and capture insects in the dark, while also detecting and avoiding obstacles. Likewise it is of selective advantage for moths to detect and evade hunting bats. We will examine aspects of auditory sensory systems in both bats and moths later in this chapter, along with other sensory systems that provide animals with information about their environments.

Sensory systems of all kinds depend on specialized sensory receptor cells that respond to stimuli, either environmental stimuli or stimuli arising inside the body. Different sensory cells respond to different stimuli, and they vary greatly in **sensitivity** (the ability to distinguish among stimuli of different intensity) and **specificity** (the ability to distinguish among stimuli of different types). Auditory reception in bats and moths is both sensitive and specific, having been shaped by long periods of natural selection. But all cells are somewhat responsive to aspects of their environment and thus subserve some functions that can be considered sensory. For example, bacteria and protists respond to light and to chemical gradients. Cellular responses of this kind presumably preceded the evolution of specialized sensory neurons. A **sensory receptor cell** is a cell that is specialized to transform the energy of a stimulus into an electrical signal. The kind of stimulus that excites different receptor cells may be chemical, mechanical, or electromagnetic. A **stimulus** is a form of external energy (external to the cell) to which a sensory receptor cell can respond.

Humans have studied sensory functions since the ancient Greeks, and currently new experimental approaches are revolutionizing our understanding of how sensory systems work. Recording techniques such as patch-clamp recording (see Figure 12.17) have greatly increased the ease of registering the responses of sensory cells. Imaging methods have allowed the examination of activity of many neurons at once. Molecular techniques

A nocturnal encounter between a moth and a hunting bat
Bats echolocate to orient and to capture insects, and moths have evolved auditory systems that help them evade bat predators. In this case a moth hears the bat's cries and is able to evade the bat by diving toward the ground. Sensory systems may be energetically expensive, but the information they provide is often crucial for survival.

have also been important, both for identifying the genes and proteins responsible for sensory detection and for manipulating the expression of sensory genes (see Chapter 3, pages 76–79) to clarify their functions.

Organization of Sensory Systems

Sensory receptor cells normally function as parts of a larger system, rather than in isolation. They are commonly clustered together in **sense organs**, anatomical structures that are specialized for the reception of particular kinds of stimuli. Usually a sense organ contains many similar receptor cells, as well as several kinds of nonneural tissues. For example, the vertebrate eye is a sense organ that contains photoreceptor cells, as well as nonneural tissues such as those that make up the cornea and iris. We can also speak of **sensory systems**, defined as sense organs and all of their associated central processing areas. For example, the vertebrate visual system includes the eyes and the central areas in the brain that are primarily concerned with processing visual information.

The basic function of a sensory receptor cell is to convert stimulus energy into an electrical signal, a process known as **sensory transduction**. Sensory transduction requires specialized molecules called **sensory receptor molecules** (or simply **receptor molecules**), which are particularly sensitive to a sensory stimulus. Sensory receptor molecules initiate the transduction of the stimulus to produce an electrical response called a *receptor potential*. The receptor potential may lead to action potentials carried to the central nervous system (CNS), where sensory information is processed. Different kinds of sensory receptor cells have different receptor molecules that make them sensitive to different stimuli. The receptor molecules are all membrane proteins. Receptor cells often have modified cell membranes to increase surface area and thus receptor number and resultant sensitivity. The two common ways in which receptor cells increase their outer membrane surface area are via cilia and microvilli (microscopic fingerlike projections; see page 37).

Sensory receptor cells can be classified in four different ways

The oldest way of classifying sensory receptor cells is by **sensory modality**—the subjective nature of the sensory stimulus. Aristotle distinguished five primary senses: vision, hearing, touch, smell, and taste. As **Table 14.1** shows, however, animals perceive many other stimuli besides these classical five senses. Humans are aware of additional sensory modalities such as balance and temperature, and there are many other modalities that do not normally enter our consciousness (such as muscle length and blood oxygen partial pressure). In addition, many animals appear to possess receptor cells sensitive to modalities and qualities of stimuli not sensed by humans. These include electric and magnetic fields and ultraviolet radiation.

A second classification is based on the *form of stimulus energy* that excites sensory receptor cells at the receptor surface (see **Table 14.1**). Photoreceptors, electroreceptors, and magnetoreceptors all respond to different forms of electromagnetic energy; auditory receptors, mechanoreceptors, and vestibular receptors (for balance) are all

FIGURE 14.1 Two kinds of sensory transduction mechanisms
Sensory stimuli activate sensory receptor molecules in one of two ways. (a) Stimulus-gated ion channels open directly in response to an applied stimulus, constituting an ionotropic mechanism. (b) Stimulus energy activates a metabotropic G protein–coupled receptor (GPCR), triggering a metabolic cascade (see **Figure 13.6d**) that results in activation of the sensory cell. The examples shown are chemoreceptor proteins, but the two types of transduction apply to all kinds of sensory receptors.

excited by mechanical energy. Olfactory (smell) and taste receptors are chemoreceptor cells that respond to chemical energy: They have receptor proteins that bind specific chemicals, and the change in free energy associated with this binding triggers a conformational change in the protein to induce a response.¹

A third classification of sensory receptor cells is according to their *mechanism of transduction*. Recall from Chapter 13 that the synaptic neurotransmitter receptor molecules are of two types (see **Figure 13.6**): *ionotropic receptors* or *ligand-gated channels*, in which the same molecule binds neurotransmitter and acts as the ion channel; and *metabotropic* or *G protein–coupled receptors (GPCRs)*, in which binding of neurotransmitter activates a G protein, leading to a metabolic cascade that ultimately opens membrane channels. Sensory receptor molecules bear striking similarities to neurotransmitter receptors and divide into the same two classes of mechanism (see **Table 14.1** and **Figure 14.1**). In **ionotropic transduction** (see **Figure 14.1a**), the sensory stimulus is received and then transduced into an electrical signal, a depolarization produced by Na⁺ entry into the cell. The same receptor molecule produces both the reception and the transduction. All forms of mechanoreception, including hearing, seem to be ionotropic. Thermoreception, electroreception, and some forms of taste reception also use ionotropic transduction. Other sensory systems use **metabotropic transduction**, meaning the sensory receptor molecule acts like a neurotransmitter- or hormone-activated GPCR in activating a metabotropic cascade (see **Figures 2.27, 13.19, and 14.1b**). The receptor molecule activates

¹The definition of a stimulus as a form of energy that stimulates a receptor cell can be difficult to grasp, particularly for chemoreceptors. Thinking of mechanical, photic, and thermal stimuli as energy is fairly intuitive, but the energy in a chemical stimulus is less clear. Chemoreceptor proteins bind chemical molecules in the same way that enzymes bind substrates, using weak bonds rather than covalent bonds (see Chapter 2). There is a change in free energy associated with this binding, and this change in free energy leads to a conformational change in the bound receptor protein that initiates the cell's response to the stimulus. This energy change is quite different from the energy transformations in a molecule (e.g., a glucose molecule) when it is metabolized and the energy from breaking its covalent bonds is released.

TABLE 14.1 Sensory receptor cells differ in the kind of stimulus that excites them and in their mechanism of transduction

Receptor type	Stimulus perceived	Mechanism of transduction
Mechanoreceptors	Touch, pressure, proprioception	Ionotropic
Vestibular receptors	Balance; body position and movement	Ionotropic
Osmoreceptors	Osmotic pressure	Ionotropic
Auditory receptors	Sound	Ionotropic
Thermoreceptors	Heating and cooling	Ionotropic
Electroreceptors	Electric fields in water	Ionotropic
Some taste chemoreceptors	Salty and sour in vertebrates; insects?	Ionotropic
Some taste chemoreceptors	Sweet, bitter, and umami (proteinaceous) in vertebrates	Metabotropic
Olfactory chemoreceptors	Chemicals generally from a distance	Metabotropic in vertebrates; ionotropic or mixed (insect)
Photoreceptors	Light	Metabotropic
Magnetoreceptors	Position or change of magnetic field	Unknown

a G protein, which in turn activates an effector molecule to alter the concentration of a second messenger that triggers events leading to the cell's response. Vision, vertebrate olfaction, and some forms of taste reception use metabotropic transduction. Both ionotropic and metabotropic sensory receptor molecules are membrane proteins, as earlier noted.

Finally, receptor cells can be classified according to the *location* of the source of the stimulus energy relative to the body. **Exteroceptors** are sensory cells that respond to stimuli outside the body, such as light or sound. **Interoceptors** respond to internal stimuli, such as the pH or osmotic concentration of the blood.

Sensory receptor cells transduce and encode sensory information

Sensory receptor cells have two functional roles. First, as we noted above, a sensory receptor cell *transduces* some form of stimulus energy, converting it to an electrical signal termed a *receptor potential*. The receptor potential is usually a depolarization of the sensory cell, which (if it reaches threshold) can trigger action potentials that propagate to the CNS. (Some sensory receptor cells do not have axons, but instead synaptically excite separate sensory neurons to generate action potentials, as shown, for example, in Figures 14.7 and 14.15.) Second, a sensory receptor cell *encodes* information about a stimulus; this information is carried via trains of action potentials that are transmitted to the CNS. It is worth pointing out that the only information that the CNS receives to tell an animal what is happening in the external environment comes from the encoded signals of the animal's peripheral sensory receptor cells. Thus the encoding of sensory signals must allow the CNS to get all necessary information: What's out there? Where? How much? How is it changing over time?

A key part of the encoding of sensory information is "keeping the wiring straight," by maintaining within the CNS an orderly segregation of axons from different sensory receptor cells that

project to different specific CNS locations. Visual afferent axons project to different areas of the brain than do auditory afferent axons, skin touch receptors, and so on. This observation leads to an important generalization: *The sensory modality or quality of sensation associated with a stimulus depends solely on which receptor cells are stimulated, rather than on how they are stimulated.* **Figure 14.2** illustrates this generalization, known as the principle of **labeled lines**. Most sensory receptor cells are quite specific in the kind of stimulus to which they respond, but any form of stimulus energy may excite a receptor cell if there is enough of it. For example, any stimulus that excites photoreceptors is perceived as light, whether the stimulus is actually light, a poke in the eye ("seeing stars"), or electrical stimulation of the optic nerve. Another key aspect of "keeping the wiring straight" is that for each kind of receptor cell, the afferent axons typically maintain a geometric arrangement within the CNS that mirrors the geometric arrangement of the receptor cells, so that the axons project onto orderly maps in the CNS. This pattern facilitates central decoding of where each stimulus comes from.

The rest of this chapter will review our present understanding of several of the most important and well-studied sensory organs. We will consider both transduction and selected examples of sensory coding of information, emphasizing the five common senses that have been the most thoroughly investigated. We will choose our examples primarily from arthropods and mammals, since the molecular techniques available for *Drosophila* and mice, for example, have made the sensory organs in these organisms the most attractive for current research. We will describe ionotropic sensory receptors first, beginning with touch and proceeding to the vestibular sense and hearing. Then, with taste in the middle (since it exhibits transduction mechanisms of both kinds), we will continue on to metabotropic sensory receptors, for olfaction and finally for vision. Sensory reception of polarized light and of magnetic stimuli are discussed in Chapter 18.

(a) The labeled-lines principle

(b) Regions of the cerebral cortex that process different sensory qualities

SUMMARY Organization of Sensory Systems

- Sensory receptor cells respond to stimulation by a form of energy. Most sensory cells are specialized to respond to one form of stimulus energy.
- Sense organs contain clusters of similar receptor cells as well as nonneural cells.
- Receptor cells transduce stimulus energy into an electrical response, usually a depolarizing receptor potential. The transduction depends on specific receptor molecules and can be ionotropic (directly opening ion channels) or metabotropic (triggering a metabolic cascade via a G protein–coupled receptor, or GPCR).
- The receptor potential in a sensory neuron can trigger action potentials that propagate to the central nervous system.
- Sensory receptor cells often have cilia or microvilli that increase the area of the membrane surface.

FIGURE 14.2 The principle of labeled lines in sensory systems

(a) In the peripheral nervous system (PNS), receptor cells sensitive to different kinds of stimuli send similar kinds of signals (action potentials) to the central nervous system (CNS). The CNS interpretation of the sensory modality depends on which lines (axons) convey the signals. Note that the sensory receptor cells for touch and smell are neurons with axons that enter the CNS, whereas the sensory cells that detect sound and taste have no axons but instead synaptically excite sensory neurons. (b) In the CNS, different sensory pathways ultimately project to different regions of the cerebral cortex, providing the anatomical basis for the principle of labeled lines.

Mechanoreception and Touch

All cells are somewhat responsive to mechanical stimulation, but **mechanoreceptors** are specialized to respond to different types of mechanical stimuli. Various mechanoreceptors mediate the senses of touch, pressure, equilibrium, and hearing, as well as certain types of osmotic stimulation. Some of these are treated separately later in this chapter. Here we introduce general features of sensory receptor function, using an insect mechanoreceptor.

Insect bristle sensilla exemplify mechanoreceptor responses

Insects have a hard exoskeleton covered with sensory bristles or hairs, each of which is a miniature sense organ called a **sensillum** (plural *sensilla*). Many sensilla are mechanosensory, whereas others are predominantly chemosensory (but may also contain a mechanoreceptor). Mechanosensory bristles are hollow and contain sensory neuron endings. The structure of a bristle sensillum is shown in **Figure 14.3a**. A bristle shaft or hair extends from the body of the insect as a part of its exoskeleton. The very tip of the mechanoreceptor cell's dendrite is attached to the inside of the bristle shaft at its base. When the bristle is moved, it deforms the membrane at the distal tip of the mechanoreceptor dendrite and opens *stretch-activated channels*. These channels open in response to stretch and allow cations to flow through the channel. The net inward current carried by cations produces a **receptor potential**, defined as the primary electrical response of a sensory receptor cell to stimulation, the output of sensory transduction. In bristle mechanoreceptor neurons, and in most sensory cells, the receptor potential is a depolarization (the membrane potential becoming less inside-negative, typically toward zero) (**Figure 14.3b**). The stretch-activated channels in the bristle mechanoreceptor membrane are nonselective cation channels, permeable to both Na^+ and K^+ . Thus the ionic basis of the receptor potential is similar to the ionic basis of fast excitatory postsynaptic potentials (EPSPs), and like fast EPSPs, the receptor potential has a reversal potential near zero (see page 335).

The receptor potential, if suprathreshold, depolarizes the sensory neuron enough to generate action potentials, which then propagate to the CNS. The magnitude of the stimulus is *encoded* by the sensory receptor cell. **Figure 14.3b** shows that the stronger the stimulus deflecting the bristle, the greater the receptor potential depolarization and the higher the frequency of action potentials in the sensory neuron. The CNS, then, receives a coded message which it decodes from the train of action potentials (as well as from the identity of the cell that is activated). The frequency of the action potentials denotes the strength of the stimulus, and the cell's

(a) An insect mechanosensory bristle

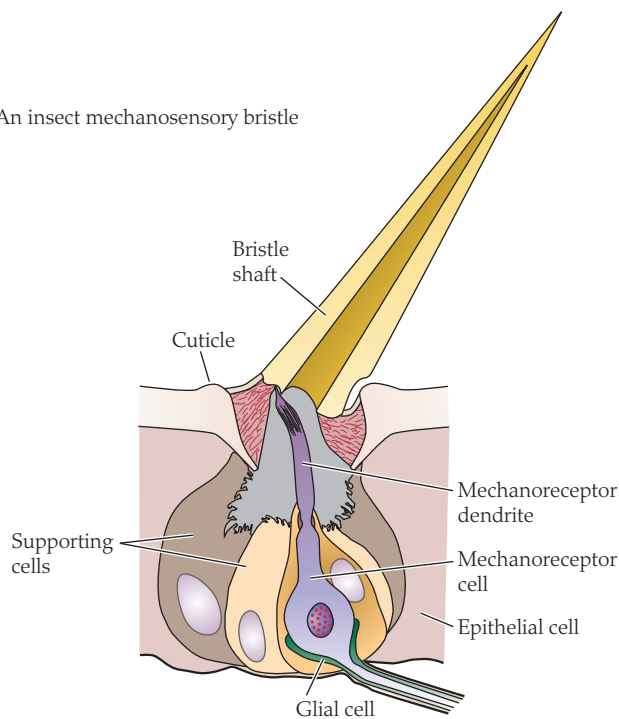

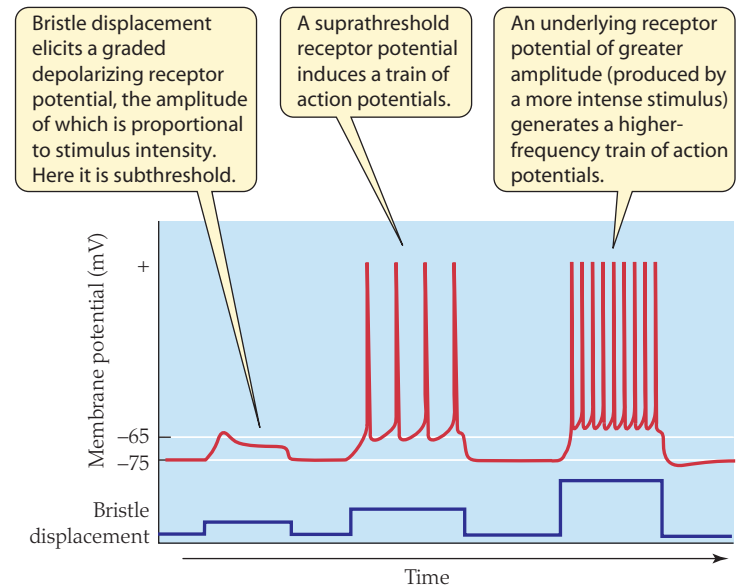

FIGURE 14.3 Insect cuticular mechanoreception (a) An insect mechanosensory bristle (bristle sensillum) contains a bipolar sensory neuron, the dendrite of which is distorted by movement of the bristle shaft, leading to activation of the neuron. (b) The general response of a receptor cell to stimulation, illustrated here with an insect sensillum, is

(b) Mechanoreceptor responses to bristle displacement

to produce a graded, depolarizing receptor potential, the amplitude of which is proportional to the intensity of the stimulus. The receptor potential induces a train of action potentials, the frequency of which is a code for stimulus intensity. (a after Thurm 1964, Bullock and Horridge 1965, and Keil 1997.)

identity denotes that the stimulus is a mechanical deflection of a bristle at a certain position on the insect's body.

What is the nature of the stretch-activated ion channels that respond to mechanical stimuli to generate a receptor potential? Ion

channels sensitive to membrane stretch and pressure are actually rather widespread in cells, as was discovered after the invention of the patch-clamp technique. In the experiment depicted in **Figure 14.4a**, a patch-clamp electrode was sealed onto an embryonic

(a) Opening of a stretch-activated channel shown by patch-clamp recording

(b) The structure of the NOMPC mechanosensory ion channel

FIGURE 14.4 Stretch-activated channels (a) Patch-clamp recording from a patch of membrane isolated from a mammalian muscle fiber (see Figure 12.17). An increasing pressure difference across the patch (shown as millimeters of mercury [mm Hg]) distorts the membrane patch and opens the stretch-activated channel (single-channel currents shown in picoamps [pA], see Figure 12.17). (b) Protein subunit of the NOMPC ion channel of *Drosophila* (see page 364), which transduces mechanical deformation into an electrical receptor potential (see Figure 14.3). The protein is related to a voltage-gated K⁺ channel protein (see Figure 12.21) but without the voltage sensitivity; instead its ankyrin (ANK) repeats attach the protein to cytoskeletal components to provide mechanical sensitivity. Like the voltage-gated K⁺ channel protein, the NOMPC ion channel has six transmembrane α -helices (S1–S6) and a P loop. (Note: The structure of the mammalian channel shown in [a] may differ from that of the *Drosophila* channel shown in [b].) (a after Hamill 2006.)

skeletal muscle cell and then removed to form an isolated patch, much as we described earlier for voltage-gated Na⁺ channels (see Figure 12.17). When pressure was applied directly to the membrane patch by sucking the patch farther into the electrode and stretching the membrane, a channel opened. The greater the negative pressure (indicated by millimeters of mercury), the more often and longer the channel opened. In a patch of membrane that has been pulled away from the cell, the opening of the channel must result directly from the stretch, rather than indirectly from a metabotropic cascade (since any second messenger would be washed away by the bathing solution).

Further information about stretch-activated channels underlying mechanoreception comes from molecular genetic studies. The ion channel responsible for the bristle mechanoreceptor response was identified by screening for mutations in *Drosophila*. These experiments identified a channel called NOMPC (for *no mechanoreceptor potential C*), the gene for which was then cloned. The channel protein's structure is shown in Figure 14.4b. The structure is somewhat similar to that of a voltage-gated K⁺ channel or one of the domains of a voltage-gated Na⁺ channel (see Figure 12.21), with six transmembrane sequences and a P loop that lines the channel pore. The NOMPC channel is not a voltage-gated channel, however; it is a member of a different but related channel family, called the **TRP (transient receptor potential) channel** family. As we will see, TRP channels are central to transduction in many kinds of sensory receptor cells, including receptors for touch, taste, smell, temperature, and some visual systems. Table 14.2 summarizes our present knowledge of the major transduction ion channels in sensory receptor cells. The TRP channels in mechanoreceptors tend to have many *ankyrin repeats* (see Figure 14.4b), a protein structural motif used to link the protein to elements of the cytoskeleton. This linkage allows the channels to open in response to stretch, enabling cations to flow through the channels to produce a depolarizing receptor potential.

Touch receptors in the skin of mammals have specialized endings

The organs mediating touch in the skin of mammals have been much studied, although the channels responsible for transduction have not yet been identified. Touch receptor cells in mammalian skin involve an association of epithelial cells with the distal endings of neurons that have their cell bodies in the dorsal root ganglia adjacent to the spinal cord (see Figure 15.3). These sensory neurons, called **dorsal root ganglion (DRG)** cells, send their distal processes into the skin and their central axons into the dorsal or sensory part of the spinal cord. The distal processes of the DRG cells form four kinds of specialized endings with epithelial cells, illustrated for the non-hairy skin of mammals in Figure 14.5. The most important of these specialized endings for the tactile sensing of form and texture is the *Merkel disc* just below the skin epidermis, formed by the association of a Merkel cell with a nerve ending. A single DRG cell sends its distal process into many fine branches, which end in association with several Merkel cells. The nerve endings respond directly or indirectly to indentation of the skin. It is not clear whether transduction occurs in the nerve endings or in the associated epithelial Merkel cells. The Merkel cells appear to contain and release neurotransmitters, and mutant mice that lack Merkel cells lack the sensitivity to light touch that is characteristic of the Merkel disc response. Adjacent to the Merkel discs are the *Meissner corpuscles*, formed from two to six sensory neuron endings associated with Schwann cells and collagen (not shown). Deeper within the skin are two more elaborate types of organs sensitive to pressure, called *Ruffini endings* and *Pacinian corpuscles*. There are also sensory endings located around mammalian hair follicles, as well as free nerve endings that mediate pain and temperature sensation.

For most sensory receptors, the frequency of action potentials in response to a continuous and constant stimulation decreases over time, a process termed sensory **adaptation**. When recordings are

TABLE 14.2 Major transduction ion channels in sensory receptor cells

Sense	Type of animal	Kind of channel	Direct, ionotropic activation of channel by:	Indirect, G protein-coupled receptor activation of channel via:
Touch	Insect	TRP ^a	Stretch	—
	Vertebrate	TRP	Stretch, temperature	—
Hearing	Insect	TRP	Stretch	—

Taste	Insect	?	?	?
	Vertebrate	TRP (sweet, umami, bitter) ENaC (salt)	— Na ⁺	PLC → IP ₃ → Ca ⁺⁺ —
Smell	Insect	OR _x /OR83b?	Odorant binding to OR _x ?	?
	Vertebrate	CNG (MOE)	—	cAMP
		TRP (VNO)	—	PLC → DAG/IP ₃
Vision	Insect	TRP	—	PLC → DAG/IP ₃
	Vertebrate	CNG	—	cGMP

^aAbbreviations: cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; CNG, cyclic nucleotide-gated channel; DAG, diacylglycerol; ENaC, epithelial sodium channel; IP₃, inositol trisphosphate; MOE, main olfactory epithelium; OR_x/OR83b, different odorant receptor proteins may dimerize with OR83b to form or modulate a channel; PLC, phospholipase C; TRP, transient-receptor-potential channel; VNO, vomeronasal organ.

FIGURE 14.5 Mechanoreceptor cells in mammalian skin A small area of skin contains many mechanosensory endings of sensory neurons, the cell bodies of which are located in dorsal root ganglia (see Figure 15.3). The sensory endings have four kinds of specialized endings with epithelial cells. Merkel discs and Meissner corpuscles are superficial, just beneath the epidermis. Pacinian corpuscles and Ruffini endings are larger and more deeply located. All respond to mechanical stimulation. Free nerve endings respond to other stimuli.

made from the axons of DRG cells, two basic types of responses can be recorded, called **tonic** (slowly adapting) and **phasic** (rapidly adapting). Typical examples are given in Figure 14.6. Tonic responses decrease slowly in frequency and generally continue for as long as the stimulus is present. The DRG sensory endings associated with the Merkel discs and Ruffini endings give tonic responses. Phasic responses, because they adapt rapidly, generally signal *changes* in touch or pressure. Meissner corpuscles have phasic responses, giving a burst of action potentials as the stimulus is applied but ceasing during a maintained stimulus. Pacinian corpuscles deep within the skin adapt so rapidly that they normally give only a single action potential at the onset or offset of a prolonged stimulus. Thus they are sensitive only to sudden indentation of the skin or to vibration (which changes rapidly). The sensory ending of a Pacinian corpuscle is encased in a bulb formed by multiple layers of thin, concentric accessory cells called *lamellae*. These lamellae are mostly responsible for the phasic nature of the response, since when they are removed, the sensory ending of the Pacinian corpuscle responds more like a tonic receptor. The multiple layers of the lamellae apparently absorb the energy of the mechanical stimulus, so that only rapid changes in pressure are communicated deep within the lamellar wrappings to the sensory ending. Many sensory systems contain separate tonic and phasic receptor cells, but their mechanisms of sensory adaptation may differ. The Pacinian corpuscle depends on accessory structures to provide its phasic property, but other phasic sensory receptors do not have analogous accessory structures, and their phasic responses to a prolonged stimulus appear to depend on properties of the transduction channels or on other elements of the neuronal membrane.

Proprioceptors monitor internal mechanical stimuli

In addition to exteroceptive mechanoreceptors sensitive to external touch and pressure, most animals also have interoceptive mechanoreceptors, which monitor movement, position, mechanical stress,

and tension within the body. Such internal mechanoreceptors are termed **proprioceptors** (from the Latin *proprius*, “one’s own”). Strictly speaking, proprioceptors are mechanoreceptors associated with the musculoskeletal system. They provide most of the information available to the brain about muscle contraction, position, and movement of parts of the body, although other receptors, such as skin mechanoreceptors and vision, may make secondary contributions.

The best-understood proprioceptive organ in vertebrates is the **muscle spindle** organ, which monitors the length of a skeletal muscle. We discuss this sense organ in Chapter 19, along with consideration of its physiological roles.

FIGURE 14.6 Tonic and phasic receptors (a) Tonic (slowly adapting) receptor cells have a slow and incomplete decrease in impulse frequency. A Merkel disc is a tonic receptor. (b) A Ruffini ending is also tonic in its response. (c) Phasic (rapidly adapting) receptor cells have a rapid, complete decrease in impulse frequency and thus convey information about *change* in stimulus intensity. A Meissner corpuscle is a phasic receptor. (d) A Pacinian corpuscle is extremely phasic, normally generating only a single action potential at the beginning and end of a sudden stimulus.

SUMMARY Mechanoreception and Touch

- Mechanoreceptors have many behavioral uses. In addition to surface mechanoreceptors that convey information about environmental touch and pressure, mechanoreceptors can serve as proprioceptors that monitor body and limb position and muscle length and force. (They can also serve as equilibrium and auditory receptors, as we will see in the next section.)
- Mechanoreceptors have stretch-activated ion channels that mediate ionotropic transduction.
- Many sensory receptors produce a response that diminishes over time and are said to adapt to sustained stimulation. Tonic (slowly adapting) receptors signal the intensity and duration of a stimulus, whereas phasic (rapidly adapting) receptors signal changes in stimulus intensity.

Vestibular Organs and Hearing

Most animals have mechanoreceptor organs for orientation to gravity and for sound detection. Even a simple animal like a jellyfish has an organ for orientation with respect to gravity, called a **statocyst**, some version of which is present in members of all animal phyla. A statocyst contains grains of sand or a secretion of calcium carbonate. This relatively dense mineral material sinks within the statocyst and stimulates receptor cells beneath it by bending their cilia. In this way an uncomplicated structure can provide reliable information about orientation relative to gravity, as well as movement and acceleration of the animal. Many kinds of animals also use mechanoreceptors to detect sound, by a variety of mechanisms.

Insects hear with tympanal organs

Sound consists of waves of compression of air or water, which propagate away from a vibrating source. Suppose we have a loudspeaker, whose cone or membrane is vibrating in and out. When the membrane pushes out, it compresses air molecules, momentarily increasing the air pressure. When the membrane vibrates back into the speaker, there is a momentary rarefaction of air molecules (the same number of molecules occupies more volume) and the pressure decreases. Therefore, the vibrating speaker cone causes a repeating pressure wave in the air, the frequency of which is identical to the frequency of movement of the speaker cone. This wave of sound pressure propagates away from the speaker cone at the speed of sound, with a frequency that is a function of the rate of repetition of the pressure wave. Auditory organs are specialized to detect such waves of sound pressure and sometimes to measure their frequencies.

In insects the most common form of auditory organ is the **tympanal organ**, in which a thin cuticular tympanum (eardrum) is displaced by sound waves. Mechanosensory cells are attached to the tympanum and are stimulated by its movement, much like the receptor cell of the bristle sensillum. Tympanal organs may occur at any of several locations on an insect's body, including the thorax (noctuid moths), abdomen (locusts, cicadas), legs (crickets, katydids), or labial palps (sphingid moths). Auditory organs seem to have evolved repeatedly in different insect groups, at different locations on the body.

One of the simplest and best-studied tympanal organs is that of noctuid moths such as the moth at the beginning of this chapter. Each of the paired thoracic tympanal organs contains only two neurons that respond to sound. The frequency sensitivity ranges from 3 to 150 kilohertz (kHz), with maximum sensitivity at 50 to 70 kHz. Most of this range is *ultrasonic*—above the frequency range of sound audible to humans (20 Hz–20 kHz)—but it matches the frequency range of ultrasonic cries of echolocating bats (see Box 14.1). The two auditory cells of a moth's tympanic organ (called A_1 and A_2) respond similarly to ultrasonic pulses, but the threshold (lowest detectable sound intensity) of A_2 is 100 times higher than that of A_1 . The cells convey no information about sound frequency. Sound intensity is coded by the impulse frequency in each receptor cell, by a shorter response latency with increasing intensity, and by recruitment of the high-threshold A_2 cell.

The behavioral significance and neurophysiology of auditory responses in moths have been well studied. Moth tympanal organs provide good directional information about the source of ultrasound. If a bat emits ultrasonic pulses to the left of a moth, the response of the moth's left "ear" (tympanal organ) will be greater. The left A_1 cell will respond with a shorter latency and a higher frequency than the right A_1 cell. Using this asymmetric response, the moth can turn away from the sound source and fly away. This response is effective for predator avoidance if the bat is distant, but because bats are stronger fliers, it is ineffective if the bat is close enough to detect echoes from the moth. A nearby bat emits an ultrasonic cry loud enough to stimulate one or both A_2 cells, and triggers a very different response from the moth. Instead of turning away, the moth flies erratically or dives to the ground—responses presumably more evolutionarily adaptive than an attempt to "outrun" the bat once detected. In addition, some moths such as the toxic dogbane tiger moth (*Cycnia tenera*) emit ultrasonic clicks, using a separate thoracic sound-producing tymbal organ, in response to attacking bat cries. These clicks may confuse or "jam" the bat's sonar system and may also serve to advertise the moth's unpalatability.

Most insect tympanal organs are similar to those of moths, in that they are sensitive detectors and encoders of sound intensity over a certain range of frequencies but are poor at detecting frequency differences. Some insects, however, have a limited ability to discriminate sound frequencies, and others have specialized tympanal organs with which they can localize relatively low-frequency sounds. There is some evidence in *Drosophila* that the ion channels responsible for hearing are TRP channels related to the NOMPC channels of bristle sensilla, but characterization of auditory transduction in insects is not yet complete.

Vertebrate hair cells are used in hearing and vestibular sense

Hair cells are the sensory mechanoreceptor cells in the vertebrate acoustico-lateralis system, which includes the vestibular organs (for balance and detection of acceleration), the lateral line system of surface receptors in fish and amphibians (which detect water flow as well as other stimuli), and the mammalian *cochlea*, an auditory organ that we'll discuss shortly. A vertebrate **hair cell** (Figure 14.7) is an epithelial cell, and like all epithelial cells, it has an apical surface that faces an overlying lumen and a basal surface that faces underlying tissues. A hair cell has at its apical end a tuft of microvilli. These microvilli are collectively called a **hair bundle**

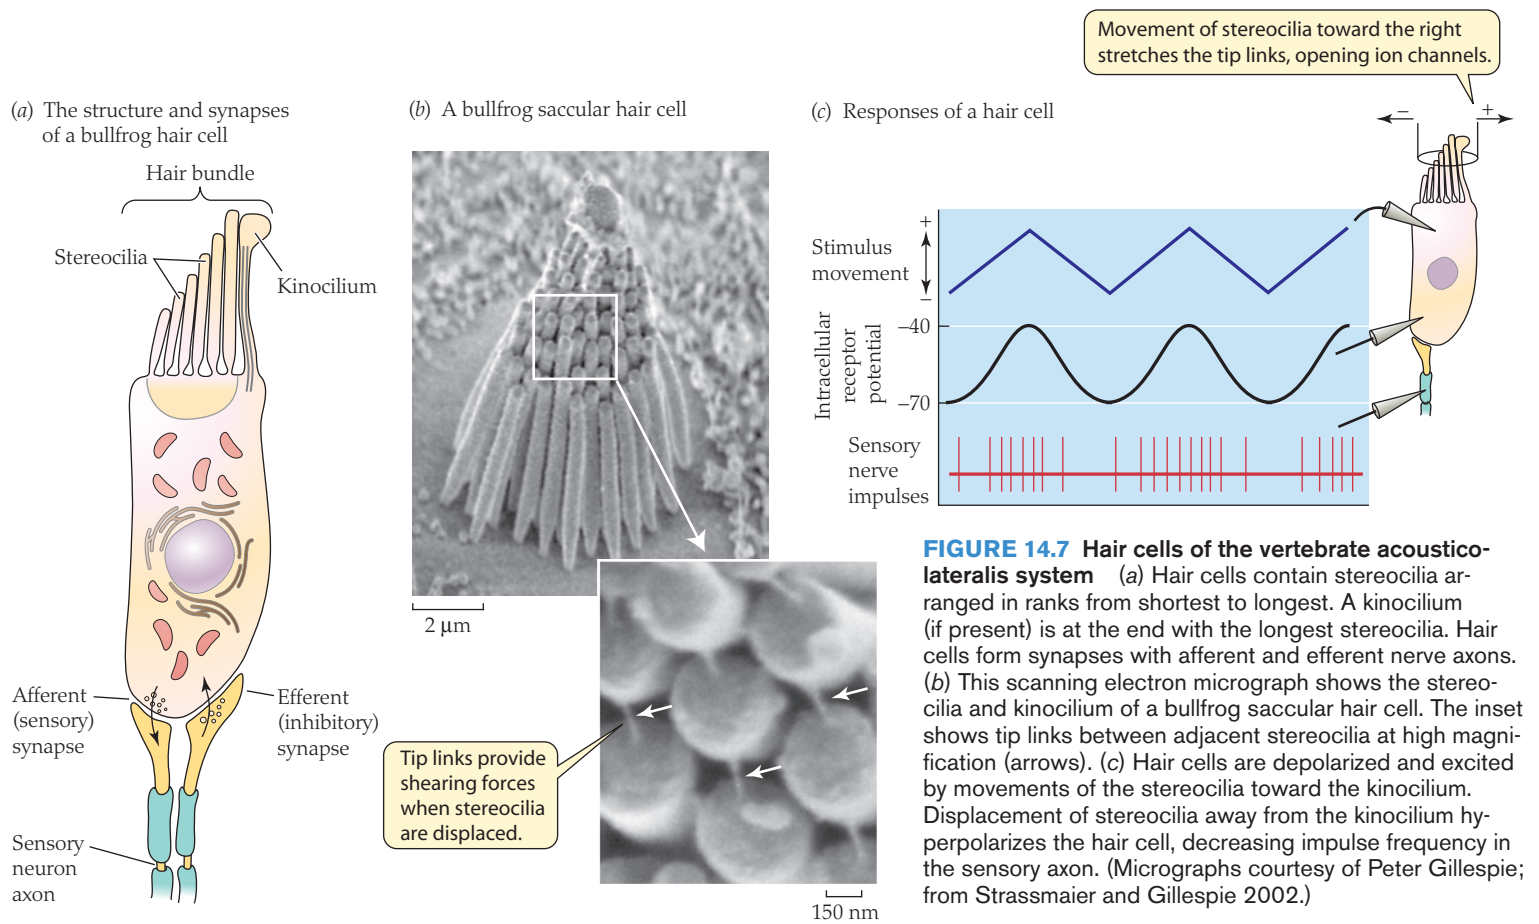

FIGURE 14.7 Hair cells of the vertebrate acoustico-lateralis system (a) Hair cells contain stereocilia arranged in ranks from shortest to longest. A kinocilium (if present) is at the end with the longest stereocilia. Hair cells form synapses with afferent and efferent nerve axons. (b) This scanning electron micrograph shows the stereocilia and kinocilium of a bullfrog saccular hair cell. The inset shows tip links between adjacent stereocilia at high magnification (arrows). (c) Hair cells are depolarized and excited by movements of the stereocilia toward the kinocilium. Displacement of stereocilia away from the kinocilium hyperpolarizes the hair cell, decreasing impulse frequency in the sensory axon. (Micrographs courtesy of Peter Gillespie; from Strassmaier and Gillespie 2002.)

because they resemble microscopic hairs. The individual microvilli have the unfortunate name of *stereocilia* (singular *stereocilium*)—unfortunate since they are most definitely not cilia but instead are true microvilli, containing numerous actin fibers that make them rigid. Hair cells do not possess axons and do not generate action potentials. Instead, they release neurotransmitter substance onto afferent neurons that conduct action potentials into the central nervous system (CNS).

The hair cells of the acoustico-lateralis system all work in the same basic way: The bending of the stereocilia is transduced into a receptor potential. The stereocilia of a hair bundle are arranged in order of increasing height (see Figure 14.7a). Hair cells of some species may also have a single true cilium, called a *kinocilium*, as shown in Figure 14.7a for the vestibular hair cells of a bullfrog. Mammalian auditory hair cells, however, do not have kinocilia, and even in the bullfrog the kinocilium can be removed with no loss of function. The actin in a stereocilium makes it rigid, and the diameter of each stereocilium narrows at its junction with the rest of the hair cell, as shown in the scanning micrograph of Figure 14.7b. When pushed to the side, the stereocilia pivot at their bases. The pivoting of the displaced stereocilia produces a shearing force between neighboring stereocilia that is transduced into a change in membrane potential. Hair cells are directionally sensitive, as shown in Figure 14.7c. Displacement of the hair bundle toward the tallest of the stereocilia depolarizes the hair cell and increases the amount of neurotransmitter it releases (from a resting level). The

increased release of neurotransmitter onto postsynaptic cranial sensory neurons increases the frequency of action potentials they produce. Displacement toward the shortest of the stereocilia hyperpolarizes the cell, decreases the transmitter released from the resting tonic level, and decreases cranial sensory neuron activity.

The stereocilia are joined to their neighbors by filamentous *tip links* (see arrows in Figure 14.7b inset), which are directly involved in producing the hair-cell response. When hair cells are exposed to a solution with a very low Ca^{2+} concentration (say $1 \mu\text{M}$), the tip links break and the voltage response of the hair cell is abolished. Over a period of about 24 hours in normal levels of Ca^{2+} , the tip links reform, and the hair-cell response returns with approximately the same time course. Movement of the stereocilia in one direction presumably stretches the tip links and opens cation channels near the outer ends of the stereocilia, permitting ion fluxes that depolarize the cell. Movement in the opposite direction causes the channels to close. The channels open within microseconds of displacement, permitting the receptor potentials of auditory hair cells to follow sound frequencies of several kilohertz. Because of this extraordinarily fast response, investigators believe that the forces exerted by the attached tip links directly gate the channel opening. The channels themselves are nonselective cation channels, and there appear to be only a small number in each hair cell—perhaps no more than one or two at the end of each tip link. The molecular identity of the channels is not yet known, in part because of the small number of channels per cell.

Vertebrate vestibular organs sense acceleration and gravity

Vertebrate **vestibular organs**, by definition, subserve sensory functions of acceleration and balance. The paired vestibular organs lie adjacent to the auditory organs in the *inner ear* and use similar hair cells. They are called vestibular because their hair cells project into fluid-filled chambers reminiscent of tiny rooms. Because of their complex geometry, the vestibular chambers and the neighboring chambers of the cochlea are collectively termed the *labyrinth*. **Figure 14.8a** shows the structure of the human ear. The outer ear consists of the pinna, concha, and air-filled external auditory canal. The eardrum separates the *external ear* from the *middle ear*, which is also air-filled and contains the bones that transmit sound vibrations from the eardrum to the inner ear. We return later to these structures in the section on hearing. **Figure 14.8b** shows the mammalian inner ear, including the vestibular organs and cochlea, in greater detail. Each vestibular organ comprises three **semicircular canals**, which detect angular acceleration of the head and body, and two **otolith organs**, called the **sacculus** and **utricle**, which detect linear movement and acceleration. The cochlea is involved in hearing. All of these chambers are filled with fluid, and many are continuous with each other.

The three semicircular canals on one side of the head are oriented at approximately right angles to one another, with one canal in each of the x , y , and z planes (**Figure 14.8c**). This conformation allows detection of angular movement in all three axes in space. At the base of each canal, a region called the *ampulla* contains a cluster of hair cells in a structure called the *crista ampullaris* (**Figure 14.8d**). Acceleration of the head causes fluid (endolymph) in the ampulla to slosh against the hair bundles of the hair cells, like water sloshing in a bowl when the bowl is suddenly moved. This movement of fluid pushes against the crista ampullaris and deflects the bundles of the hair cells, opening or closing mechanoreceptive channels as in the bullfrog hair cells. Because for each of the three major geometrical planes (x , y , z) there are two semicircular canals, one on each side of the head, rotational movement in any plane produces sloshing of fluid in one direction on the right side of the head and in the other direction on the left side. As a result, the hair cells are depolarized on one side and hyperpolarized on the other. This information, carried into the CNS by axons of afferent neurons, makes possible a determination of the direction of head movement.

The utricle and sacculus also contain hair cells. The hair cells in these structures are contained in a region called the **macula** (plural *maculae*). The macula is oriented approximately horizontally for the utricle and vertically for the sacculus. The hair

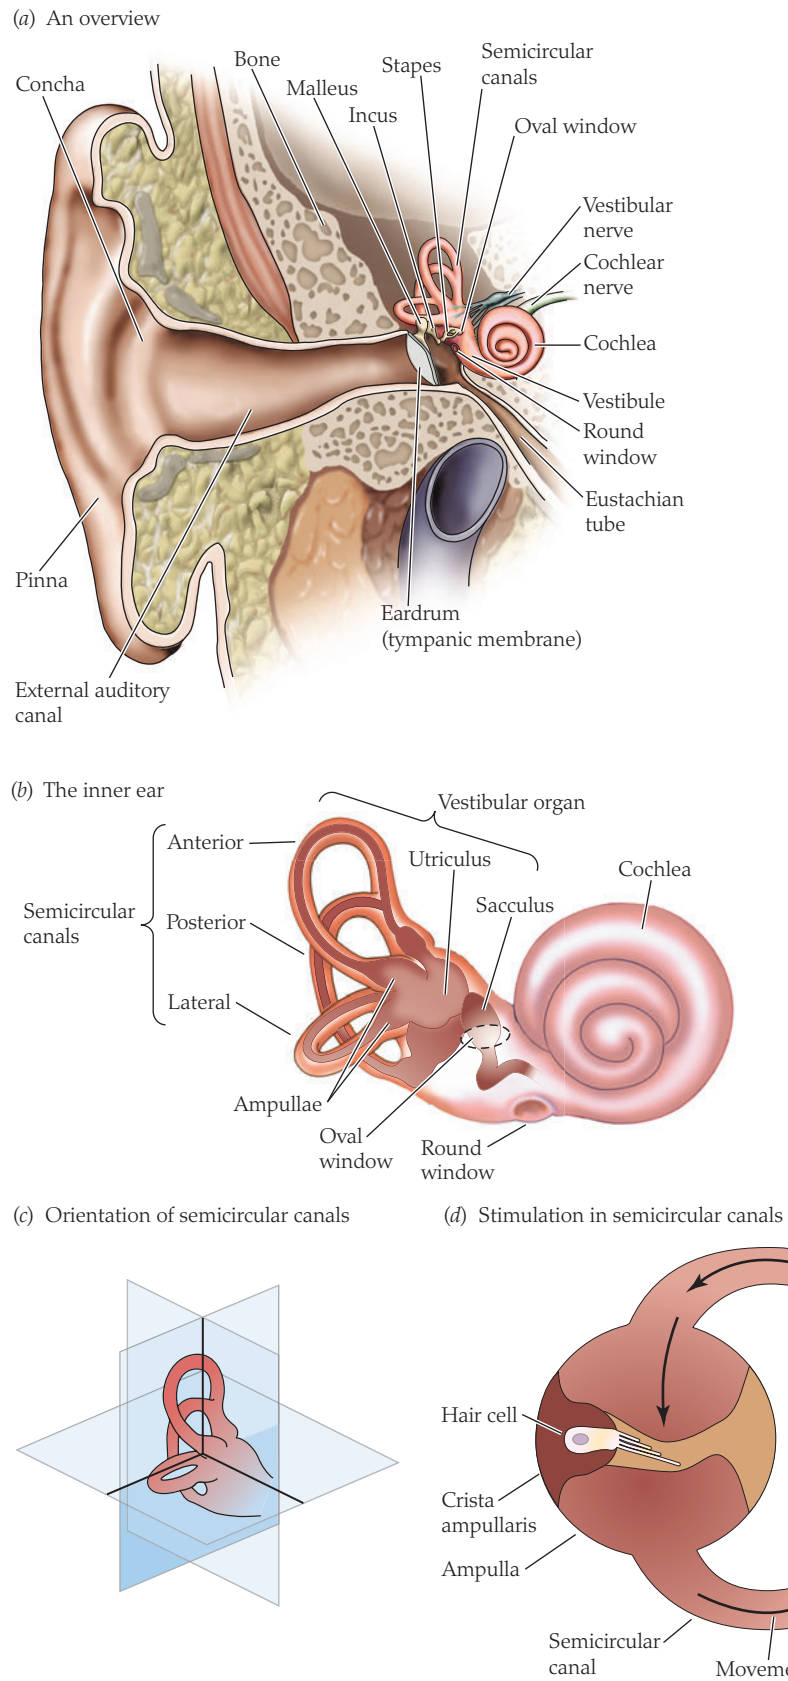

FIGURE 14.8 Anatomy of the mammalian ear (a) Structure of the human ear. (b) Components of the inner ear. The semicircular canal receptors are stimulated by head rotation. The utricle and sacculus contain macular hair cells that are stimulated by linear motion of the head and by gravity. The cochlea contains auditory receptors. (c) The three semicircular canals of the inner ear are at approximately right angles to each other, so that any angular movement of the head stimulates at least one of them. (d) With rotation of the head, fluid movement in the canal stimulates the hair cells.

cells are covered by a gelatinous mass called the *otolithic membrane* into which the hair bundles protrude. A dense network of crystals of calcium carbonate lies on top of the otolithic membrane. The maculae are sensitive to orientation with respect to gravity as well as head movements. When the head moves, these crystals (collectively called an *otolith*) tend to lag behind as an inertial mass, causing the otolithic membrane to slide against the hair bundle. This deflects the hair bundle and produces a change in hair cell membrane potential.

Sound stimuli create movements in the vertebrate cochlea that excite auditory hair cells

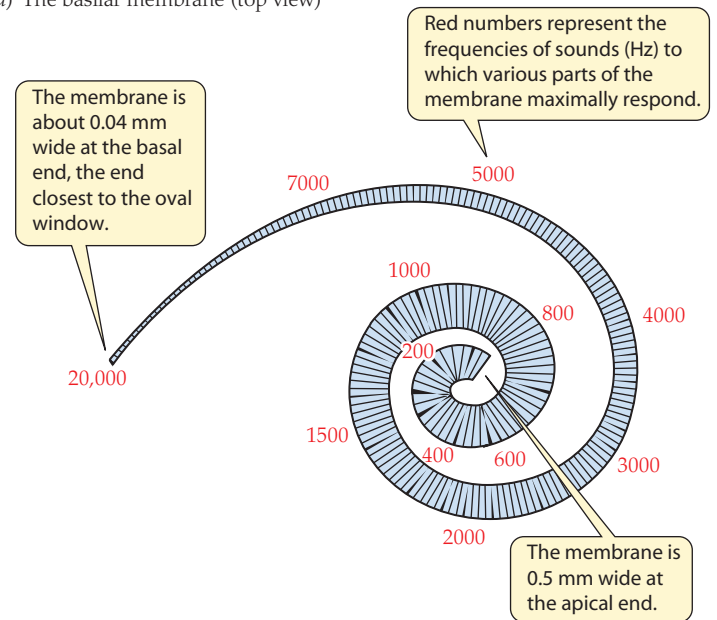

The mammalian ear is adapted to receive and amplify sound-pressure waves, in order to detect both the amplitude and frequency of sound. High-frequency waves produce *high-pitch* sounds, and low-frequency waves produce *low-pitch* sounds. The *intensity* (loudness) of a sound depends on the amplitude of the sound waves, which correlates with how far a sound source, such as a speaker cone, pushes in and out.

The mammalian ear consists of three parts: an **external ear** distal to the eardrum, an air-filled **middle ear**, and a liquid-filled **inner ear**, which consists, in part, of the **cochlea** (see Figure 14.8a). Sound-pressure waves vibrate the eardrum (tympanic membrane), and this vibration is transmitted to the membranous *oval window* of the inner ear (see Figure 14.8b) by three middle-ear ossicles: the *malleus*, *incus*, and *stapes*. Two middle-ear muscles, the tensor tympani (associated with the eardrum) and the stapedius (associated with the stapes), can contract to damp the movements of the ossicles, protecting the auditory membranes from damage by loud sounds. The eustachian tube connects the middle ear with the pharynx, equalizing pressure in the middle ear with environmental pressure.

The major function of the middle-ear ossicles is to transfer sound energy from air to the liquid of the inner ear. Airborne sound striking a liquid surface is almost all reflected; only about 1/30th of the sound energy is transferred to the liquid. This is why you cannot hear your friends at poolside when you are swimming under water. The energy transfer is poor because liquids cannot be compressed, so they have a low volume of movement in response to sound pressure. These considerations mean that for significant transfer of energy from the eardrum (vibrating in air) to the liquid medium of the inner ear, the pressure developed at the inner ear must be augmented. The middle-ear ossicles achieve this increase in pressure by applying forces from a relatively large area (55 mm² for the human eardrum) onto a much smaller area (3 mm² for the foot plate of the stapes, which covers the oval window). The concentration of force on a small area provides the necessary increase in pressure, allowing efficient transfer of sound energy.

The cochlea is a coiled tube containing chambers filled with fluid. A multicellular, membranous structure termed the **basilar membrane** separates the cochlea into an upper chamber (scala vestibuli) and a lower chamber (scala tympani). As the oval window moves, it creates fluid movement in the cochlea. This movement vibrates the basilar membrane and stimulates the auditory hair cells that sit on it. The basilar membrane varies in width and thickness along its length: It is narrow, thick, and rigid at the base of the cochlea near the oval window, and wider, thinner, and more flexible at the apex, farthest from the oval window (Figure 14.9a).

(a) The basilar membrane (top view)

(b) A diagram with the cochlea unwound (side view)

FIGURE 14.9 Anatomy of the cochlea (a) The surface of the basilar membrane, seen from above. The basilar membrane is narrower and stiffer at its basal end (near the oval window) than at its apical end. (b) A diagrammatic representation of how the inner ear would appear if the cochlea were unwound. The basilar membrane (seen in side view) separates the upper scala vestibuli from the lower scala tympani.

The structure of the cochlea is more easily understood if we schematically uncoil it, as shown in Figure 14.9b. Sound waves pushing in at the oval window set up traveling pressure waves in the fluid-filled cochlea, and these produce minute movements of the basilar membrane. The differences in width and rigidity along its length give the basilar membrane a variable mechanical compliance, so that sound waves of different frequencies vibrate the basilar membrane maximally at different points along its length (see Figure 14.10). High-frequency pressure waves vibrate the stiffer, narrower part of the basilar membrane at the basal end near the oval window. Low-frequency sounds maximally vibrate the basilar membrane at its broader apical end.

The selective movement of the basilar membrane was first described by Georg von Békésy (1899–1972). Using cochleas of human cadavers, he demonstrated the traveling wave of basilar membrane movement and showed that for every frequency there is a different place of maximum amplitude of the traveling wave along the length of the basilar membrane (Figure 14.10a). Modern experiments on living cochleas have used emission of gamma rays to measure basilar-membrane movements. These experiments have confirmed von Békésy's observations in general, but they show that

the basilar-membrane movements are more sharply localized than his measurements indicated (Figure 14.10b). The greater resolution of the living cochlea can be blocked by inhibiting the hair cells with a chemical called furosemide, which is known to block hair cell transduction (Figure 14.10c). This result shows that there must be some active component in the living cochlea that contributes to sound localization along the basilar membrane. This active component of the basilar membrane response to sound is called the **cochlear amplifier**, which we will discuss later.

When the basilar membrane moves, it stimulates the hair cells in a region of the cochlea called the **organ of Corti**. Figure 14.11a shows a cross section of the cochlea, divided by the horizontal basilar membrane. The hair cells and various accessory structures of the organ of Corti sit on the basilar membrane and vibrate up and down with it. Stereocilia of the hair cells project into a separate fluid compartment of the cochlea, called the *scala media*.

The hair cells of the organ of Corti are of two kinds: Typically there are three rows of **outer hair cells** and a single row of **inner hair cells** (Figure 14.11b). Auditory hair cells are similar to the bullfrog hair cells described earlier, but they lose their kinocilium during development and thus have only stereocilia. The hair cells are covered by a flap of tissue termed the *tectorial membrane*. The stereocilia of the hair cells are very close to or in contact with the tectorial membrane (Figure 14.12a). As the basilar membrane moves up and down, it causes the stereocilia to push up against the tectorial membrane, so that the hair bundle is displaced.

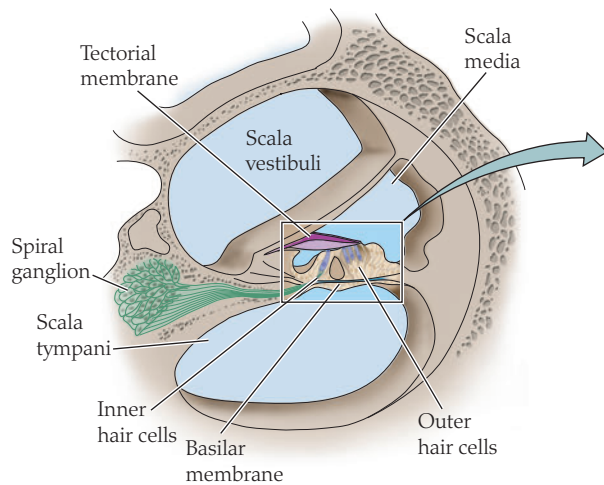

FIGURE 14.10 Amplitude of the basilar membrane differs at different sound frequencies (a) Von Békésy's results with cadavers and loud sounds showed that the position of maximal movement is a function of sound frequency. (b) In living cochleas, amplification of basilar-membrane movement by the cochlear amplifier produces a sharper peak of membrane displacement. Furosemide blocks hair cell transduction, decreasing the amplitude of basilar-membrane displacement by disrupting the cochlear amplifier. In (b) the amplitudes of movement (shown in the y axis) are magnified relative to the position along the length of the basilar membrane (shown in the x axis).

ment in one direction depolarizes the hair cell membrane potential, and displacement in the opposite direction hyperpolarizes it. Intracellular responses of auditory hair cells have been recorded—a feat made difficult by the small size and inaccessibility of the cells. Both inner and outer hair cells depolarize in response to tones, the amount of depolarization depending on sound intensity and frequency. Auditory hair cells make synaptic contact with afferent neurons of the auditory (cochlear) nerve and also receive efferent synapses. Most (80–95%) of the afferent neurons synapse with the *inner* hair cells, which in humans represent only about 20% to 25% of the approximately 24,000 hair cells. Thus the inner hair cells are the major source of auditory input to the brain.

The outer hair cells also respond to sounds and appear to be largely responsible for the cochlear amplifier in mammals (see Figure 14.10b). Outer hair cells change length by as much as 4% in response to changes in their membrane potential (Figure 14.12b). These movements are extremely fast and can track frequencies of several kilohertz. Changes in length of outer hair cells in response to sound-induced receptor potentials probably amplify the local movement of the basilar membrane and thus amplify the forces acting on nearby inner hair cells. A motor protein in the outer hair cell membrane called *prestin* seems to be responsible for the cell's shortening and lengthening, since outer hair cells of knockout mice lacking prestin no longer move in response to changes in membrane potential. Mice lacking prestin show a dramatic loss in auditory sensitivity, indicating that this protein and the outer hair cells play an important role in the function of the cochlea. However, some vertebrate species lack outer hair cells or prestin but still appear to have some cochlear amplification. Thus, there may be additional mechanisms for a cochlear amplifier in some groups.

The organization of hair cells on the basilar membrane allows for specific populations of the hair cells to respond to specific sound frequencies, and for their respective afferent neurons to send action potentials to the CNS. In this way, coding for high- and low-frequency sounds (high and low pitch) is *spatially mapped* on the basilar membrane. This spatial coding of *frequency information* is maintained in the auditory pathways leading to the auditory cortex. As in other sensory systems, information about the intensity (loudness) of the sound stimulus is conveyed by the frequency of action potentials

(b) The organ of Corti

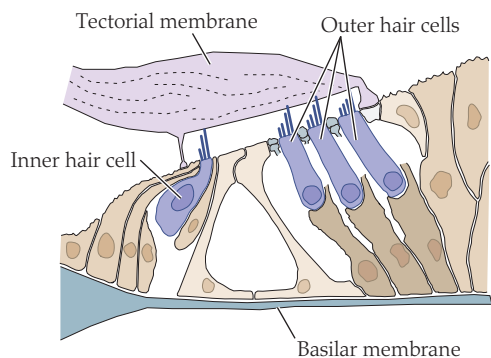

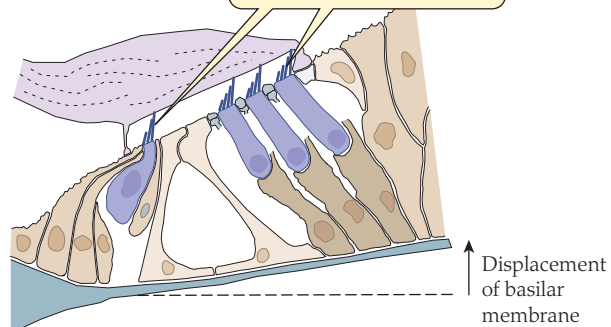

FIGURE 14.11 Internal structure of the mammalian cochlea (a) A cross section through one turn of the cochlea. (b) Detail showing inner and outer hair cells of the organ of Corti, which sits on the basilar membrane. Both inner and outer hair cells synapse with afferent (sensory) and efferent (motor) axons, but most afferent axons receive synaptic input from inner hair cells, and most efferent axons end on outer hair cells, which are thought to magnify local movements and serve as a cochlear amplifier.

(a) Hair cell displacement

Displacement of the basilar membrane bends the stereocilia of inner and outer hair cells.

(b) Outer hair cell response to membrane potential changes

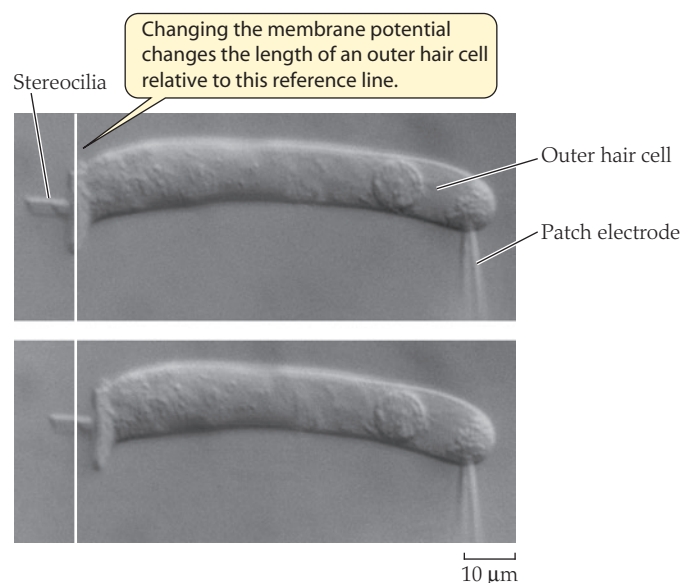

FIGURE 14.12 Movement of the basilar membrane stimulates auditory hair cells (a) Basilar membrane displacement bends the stereocilia of hair cells against the overlying tectorial membrane. This bending transduces sound vibration into electrical signals of the hair cells. (b) Outer hair cells change length in response to changes in their membrane potential. Depolarization of an isolated outer hair cell causes it to shorten (below), whereas hyperpolarization causes lengthening (above). These rapid movements provide positive feedback to amplify the movements of the basilar membrane and enhance hearing sensitivity. (Micrographs courtesy of Jonathan Ashmore; from Holley and Ashmore 1988.)

produced in afferent neurons (which in turn depends on the amount of neurotransmitter released by the hair cells).

The localization of sound is determined by analysis of auditory signals in the CNS

Vertebrates analyze sound in various ways. For example, human brains contain pathways that are most sensitive to tones, clicks, and speech sounds, and different sorts of information are extracted from these different kinds of sound stimuli. We will consider only one aspect of central auditory information processing: How do animals localize the source of a sound stimulus?

Humans are capable of reasonably accurate auditory localization, especially in the horizontal (left–right) plane, but our abilities are greatly overshadowed by those of other vertebrates, such as owls and bats. We will first examine the basic information an animal can use to localize sound, and then consider how this information is processed in the brain. We start with the observation that a single ear can provide no information about where a sound comes from; any auditory localization requires *comparison* of the responses of two ears. We can clarify this statement by examining the two sorts of information used in auditory localization: sound *time* difference and sound *intensity* difference.

First, any sound that is not straight ahead (or behind) will have a **time difference**, arriving at the two ears at slightly different times. A sound from a source that is offset to the left will reach the left ear first, with a difference in time of arrival that increases with increasing offset. Second, an offset sound will have an **intensity difference**: It will be louder in the ear that more directly faces the sound source. The intensity difference results from the fact that sounds do not go around corners well, so the far ear is said to be in a *sound shadow*, shielded from the sound by the head. Sound shadowing is a function of frequency because the head is an effective barrier to high-frequency sounds (with wavelengths smaller than the head) but little barrier to low-frequency sounds (with wavelengths bigger than the head). Because high-frequency sounds have more sound shadowing, the difference in sound intensity between the ears is significant only for high-frequency sounds. For humans, both time differences and intensity differences provide information about horizontal (right–left) location of a sound source, but we have limited ability to localize the vertical (up–down) origin of sounds.

Owls, by contrast, have excellent abilities to localize sounds both horizontally and vertically, and using this ability, they can catch mice hidden under leaf litter. Like other vertebrates, a barn owl uses time differences to determine left–right origin of sounds. Both owls and echolocating bats (Box 14.1) can use time differences as small as 10 microseconds (μs) in auditory localization! The owl's ability to localize the *vertical* component of a sound depends on a structural asymmetry of its two ears: An owl's right ear points more upward; its left ear, more downward. Because of this asymmetry, at higher sound frequencies (with more sound shadowing), a sound from above will stimulate the right ear more than the left, so the intensity difference between ears will code the vertical component of a sound source.

How does the owl's brain put together the information about the horizontal axis of a sound source (coded primarily by time differences) and the vertical axis (coded by intensity differences)? Neurons in a region of the owl midbrain (the nucleus mesencephalicus lateralis dorsalis, or MLD, corresponding to the mammalian inferior colliculus) represent a map—an orderly representation in the brain of the auditory space around the owl's head. Each neuron is said to be *space-specific*, responding to sound only from a particular direction (Figure 14.13). Nearby cells respond to sound from nearby areas, so the outside world of sound sources is mapped in two dimensions onto the MLD. This map is computed from two parallel pathways in the brainstem and midbrain—one processing time-difference

FIGURE 14.13 A map of auditory space in the brain of a barn owl Individual neurons in the midbrain auditory area (MLD, nucleus mesencephalicus lateralis dorsalis, adjacent to the optic tectum) respond to sound stimuli from discrete locations in space around the owl's head, so the locations of sound sources in auditory space are mapped onto the midbrain area. The MLD shown is from the left side of the brain. Rectangles represent the areas of auditory space (mapped onto a globe around the owl) from which sound sources evoke responses in individual space-specific neurons. Sounds to the left (L) or right (R) excite neurons in different positions along the MLD, as shown by the lines connecting the rectangles to the positions in MLD in which neuronal activity was recorded. Only the horizontal component of the MLD map is shown; 10L means 10° to the left of center, 5R is 5° to the right, and so on. (After Knudsen and Konishi 1978.)

BOX 14.1 ECHOLOCAATION

Many kinds of bats have poor vision and yet fly well at night, avoiding obstacles and catching insects at rates as high as two per second. They orient by emitting ultrasonic pulses (i.e., sound at frequencies too high to be audible to humans) and detecting echoes reflected by objects around them. They are able to use the information in the auditory echoes to locate and discriminate prey insects, and catch them in the open and in wooded environments. **Box Extension 14.1** describes how echolocating bats detect and catch insects.

(left–right) information, and one processing intensity-difference (up–down) information. Presumably it is this computed auditory map that allows an owl to localize mice in darkness to within 1° of the sound source.

SUMMARY Vestibular Organs and Hearing

- Hair cells are sensitive and versatile vertebrate mechanoreceptors that transduce displacement of stereocilia into a receptor potential. They are the major receptors of vertebrate hearing and equilibrium sense.
- The structure of the vertebrate ear effectively conveys sound-pressure waves into the inner ear. Sounds of different frequencies stimulate hair cells at different locations along the length of the basilar membrane of the cochlea.
- Central auditory pathways of vertebrates sort coded information about sounds in order to discriminate and map different sound frequencies and locations. The auditory systems of insects, although less complex, can nonetheless provide them with behaviorally important information.

Chemoreception and Taste

Chemoreception is the sensory response to a chemical stimulus. Chemoreception emerged very early in evolution. Even bacteria are able to detect attractive and repellent chemicals in their environment. The cell membrane of a bacterium contains receptor proteins for a variety of chemicals, including sugar, amino acids, and small peptides. The binding of an attractant to one of these receptors produces a change in the phosphorylation of a second messenger, which directly regulates the movement of the flagellum and directs the bacterium toward the food source. Animals detect chemicals with complex and sophisticated systems, which are the subject of this and the next section of this chapter. We divide chemoreceptive systems into two major categories: **taste** (the gustatory sense) and **olfaction** (the sense of smell).

In terrestrial animals, the distinction between taste and olfaction is relatively clear. Taste is mediated by specialized chemoreceptive organs generally located in or near the animal's mouth, and the stimuli are in liquid form. Olfaction also occurs in specialized structures, for example on antennae in insects and other arthropods and in the nose in vertebrates. The stimuli for olfaction are airborne. They must, however, dissolve in the liquid of the insect

bristle or mucus of the vertebrate nasal passage before binding to the receptor molecules.

For animals that live in water, the distinction between taste and smell is less clear, because all chemical stimuli are dissolved in water in the aquatic environment. Nevertheless, the terms *taste* and *olfaction* remain useful because many aquatic animals have separate chemoreceptive organs that serve different functions and respond differently to dilute or distant stimuli and to more concentrated stimuli closer to home. Lobsters, for example, orient and search in response to chemicals at low concentrations (presumably from distant, smell-like sources), which stimulate chemoreceptors on the antennules. High concentrations of chemicals (tastes) can trigger feeding movements by stimulating chemoreceptors on the mouthparts. Fish also have separate organs of taste and smell. They have taste buds structurally similar to mammalian taste buds, not only near the mouth but on the skin, which help them decide what to eat. Fish also have a nasal olfactory epithelium with receptor cells similar to our own, which can sense chemicals in dilute concentration (often from distant sources). It is with its nose that a female salmon finds its breeding ground.

Because the distinction between taste and olfaction is clearest among terrestrial animals, and the greatest progress has been made understanding chemoreception in terrestrial insects and mammals, we focus on these groups in our examination.²

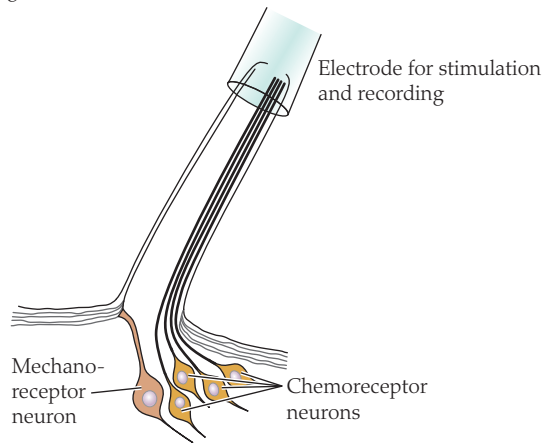

Insect taste is localized at chemoreceptive sensilla

Insect taste receptor cells are located within bristles or sensilla, similar in their anatomy to the bristle mechanosensory sensillum of Figure 14.3a. Within the shaft of a taste sensillum there are dendrites of two to four chemoreceptor cells and often a single mechanoreceptor (Figure 14.14a). The shaft of the sensillum has one or more tiny holes at its tip, through which water and taste molecules can enter. In flies such as the blowfly, these sensilla are located on the *tarsus* (the terminal segment of the leg) and the *labellum* (the tip of the extensible proboscis or mouth used for feeding). A fly detects food in part by stepping on it. Stimulation of even a single tarsal sensory sensillum with a sugar solution elicits extension of the proboscis. Further stimulation of a labellar sensillum on the proboscis with sugar solution then elicits drinking behavior, in which the proboscis works as a suction pump.

Figure 14.14b shows the responses of chemoreceptor cells in a tarsal taste sensillum to different stimuli. The cells were stimulated by placing a pipette containing plain water or water with varying concentrations of sugar, salt, or quinine on top of the sensillum shaft, so that the stimulating fluid could enter the tiny holes at the shaft tip. The chemoreceptor cells produce action potentials, which can be recorded with an electrode. In flies there is generally one cell (termed the *sugar cell*) that responds most strongly to solutions of sugars. The frequency of action potentials in the sugar cell increases with increasing concentration of sugar and thus encodes information about sugar concentration. A second cell (the *salt cell*) responds preferentially to a range of salts, particularly to monovalent cations.

²We should point out, however, that chemoreception includes more than just taste and olfaction. In mammalian nasal chemoreception alone there are multiple receptor fields and their pathways: the main olfactory organ; the accessory olfactory, or vomeronasal, organ (discussed later); and at least three other chemosensory organs. Mammals, other vertebrates, and invertebrates often have multiple types of chemoreception not readily described as taste or olfaction.

(a) Recording from an insect taste sensillum

(b) Responses to taste stimulation

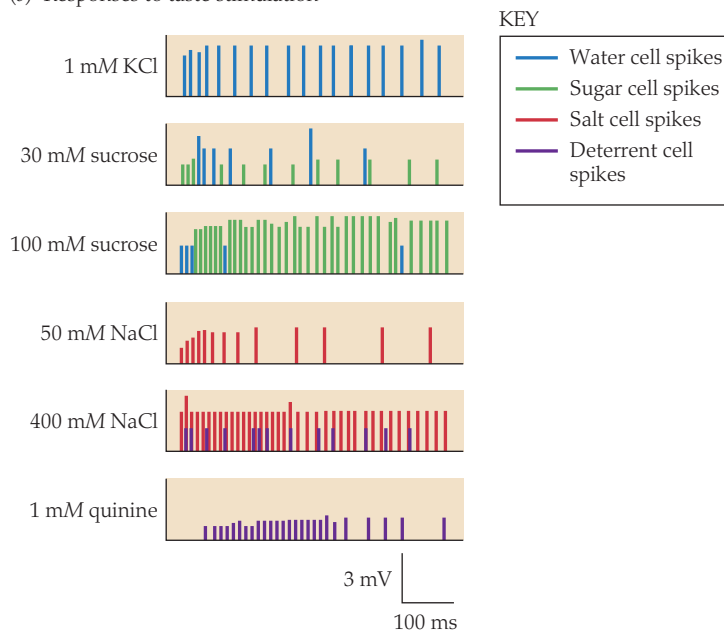

FIGURE 14.14 *Drosophila* taste sensillum and its responses to different stimulatory solutions (a) A typical taste sensillum on the leg tarsus contains four chemoreceptor cells and a mechanoreceptor cell. A pipette electrode both stimulates the sensillum and records action potentials from the sensory cells. (b) Each of the four chemoreceptor cells has spikes (extracellularly recorded action potentials) of a different size. Here the spike responses of different cells are rendered in different colors. The water cell responds best to water (with just enough salt to conduct charges), the sugar cell responds best to sugar solutions, and the salt cell responds best to increasing salt concentrations. The deterrent cell responds to quinine and other bitter alkaloids and also to high concentrations of salt.
