Shown here are the ascending limb of the loop of Henle and adjacent descending limb in the outer zone of the medulla, where the thick segments of the ascending limbs occur. As a thought exercise, the diagrams show how the single effect can be generated from scratch. (a) In the initial condition, all the fluids are identical in their osmotic pressures and ion concentrations. (b) The processes that generate the single effect. (c) The single effect that is produced. The osmotic pressure and the concentrations of ions in the ascending-limb fluid are lowered from their original levels, whereas the osmotic pressure and the concentrations of ions in the interstitial and descending-limb fluids are raised.

Wirz (1914–1993), and several other investigators demonstrated that the concept of **countercurrent multiplication** applies to the loops of Henle. In the classic model of countercurrent multiplication generated by their work, it was assumed that all parts of each ascending limb actively transport NaCl in the manner just described. Here, we develop that classic model. Later, we discuss complexities introduced by more recent research.

The hairpin shape of a loop of Henle sets up two fluid streams that are oppositely directed (countercurrent), intimately juxtaposed, and connected. These properties are all requirements for a countercurrent multiplier system to operate. Such a system also

BOX 29.3 COUNTERCURRENT MULTIPLIERS VERSUS COUNTERCURRENT EXCHANGERS

When oppositely directed fluid streams are closely juxtaposed and commodities are actively or passively exchanged between them, the effect of the countercurrent arrangement is to preserve or magnify differences in the levels of those commodities from *end to end* along the axis of fluid flow. The countercurrent arrangement has this effect because it *impedes end-to-end flux* of commodities that are actively or passively exchanged between the fluid streams.

Two functional types of countercurrent systems are recognized: *active* and *passive*. The active systems are **countercurrent multipliers**, exemplified by the loops of Henle. The passive systems are called **countercur-**

rent exchangers (or *countercurrent diffusion exchangers*) and are exemplified by the heat exchangers in the appendages of mammals (see Figure 10.35*b*).

In an active system, metabolic energy is used *within the countercurrent system itself* to induce flux of commodities into or out of the fluid streams; within the loop of Henle, for example, energy is used to transport NaCl out of the ascending limb. In a passive system, fluxes of commodities into or out of the fluid streams occur without expenditure of metabolic energy *in the countercurrent system itself*. In the heat exchanger in Figure 10.35*b*, for example, heat does not move out of one blood vessel and into another because of any metabolic energy expenditure

within the countercurrent system; instead, heat follows temperature gradients that exist because energy expenditure *elsewhere* in the body has caused the body core to be warmer than the environment.

Active countercurrent systems *create* differences in levels of commodities from end to end along their axis of flow. Note, for instance, that if the loops of Henle were turned off, the gradient of osmotic pressure and NaCl concentration from the outer to the inner end of the loops would disappear. Passive systems, by contrast, do not *create* end-to-end differences; instead they *preserve* or *accentuate* end-to-end differences that already exist for other reasons.

requires an energy investment within the system (Box 29.3). The energy investment in the loop of Henle is provided by the active NaCl transport we have already discussed, which creates a difference in osmotic pressure and ion concentration between adjacent parts of the oppositely directed fluid streams—the single effect (see Figure 29.11*c*).

The countercurrent multiplier system multiplies the single effect. To be more specific, the single effect amounts to a difference of roughly 200 mOsm oriented *from side to side* in the loop of Henle. The countercurrent multiplier system multiplies this difference into a much larger difference in concentration *from end to end* in the loop (Figure 29.12*a*). An end-to-end difference of 600 mOsm would not be unusual. Many mammals can create an end-to-end difference that is much greater.

The mechanism of countercurrent multiplication is diagrammed in Figure 29.12*b*. Although osmotic pressures are shown in the figure and the following discussion is phrased in those terms, it will be important to remember that differences in osmotic pressure in the loop of Henle are paralleled by differences in NaCl concentration. In step ❶ of Figure 29.12*b*, the entire loop of Henle and the interstitial space are filled with fluid of the same osmotic pressure as that exiting the proximal convoluted tubule—approximately isosmotic with the blood plasma (300 mOsm). In step ❷, active transport establishes a single-effect osmotic gradient of 200 mOsm all along the loop. In step ❸, fluid moves through the loop in countercurrent fashion. Fluid that was concentrated in the descending limb during step ❷ is thus brought around into the ascending limb and now lies opposite to the descending limb, so that both limbs and the interstitial space are filled with concentrated fluid at the inner end of the loop. Now when, in step ❹, the single-effect osmotic gradient is again established, the interstitial fluid is elevated to 500 mOsm at the inner end, rather than the 400 mOsm developed in step ❷, and the fluid in the descending limb also reaches this higher osmotic concentration of 500 mOsm. Steps ❺ and ❻, and steps ❼ and ❽, repeat this process and should be studied in order to see how the countercurrent multiplier works. *Fluid concentrated in the*

descending limb moves around into the ascending limb, setting the stage for the single effect to produce an ever-increasing osmotic concentration in the interstitial fluid and descending limb at the inner end of the loop. Meanwhile, the steady influx of 300-mOsm fluid into the beginning of the descending limb, and the dilution of the ascending-limb fluid as it flows from deep in the medulla to the top of the ascending limb, combine to keep the osmotic pressure of the interstitial fluid at the outer (cortical) end of the loop near 300 mOsm. Thus the difference in osmotic pressure between the two ends of the loop becomes greater and greater, so much so that it greatly exceeds the single effect (see Figure 29.12*a*).

As noted previously, during the early years when the countercurrent multiplication concept was initially applied to understanding mammalian kidney function, the single effect was postulated to be created along the entire length of a loop of Henle by active NaCl transport out of the ascending limb. However, by 1970, research had established that the thin segment of the ascending limb deep in the medulla is unlikely to be carrying out such active transport. That discovery started a saga that continues unended today. Active transport of NaCl out of the tubular fluid occurs in the thick segment of the ascending limb, and a consensus exists that the single effect is created according to the classic model (see Figure 29.11) in the outer region of a loop of Henle where the thick ascending segment occurs. However, the single effect is now assumed to be created by some other mechanism in the inner region of a loop of Henle where the ascending limb is thin. The question of the mechanism in the inner region has proved to be very complex and remains unresolved.

That said, it is important to return to the big picture: Countercurrent multiplication of a single effect along much or all of the length of a loop of Henle creates a large gradient of osmotic pressure from one end of the loop to the other. In the medulla, there are thousands of loops of Henle, all aligned in parallel. We would expect that all these loops, by their combined action, would create in the medullary tissue as a whole a dramatic gradient of increasing osmotic pressure from the outer side of the tissue (next to the cortex) to the inner

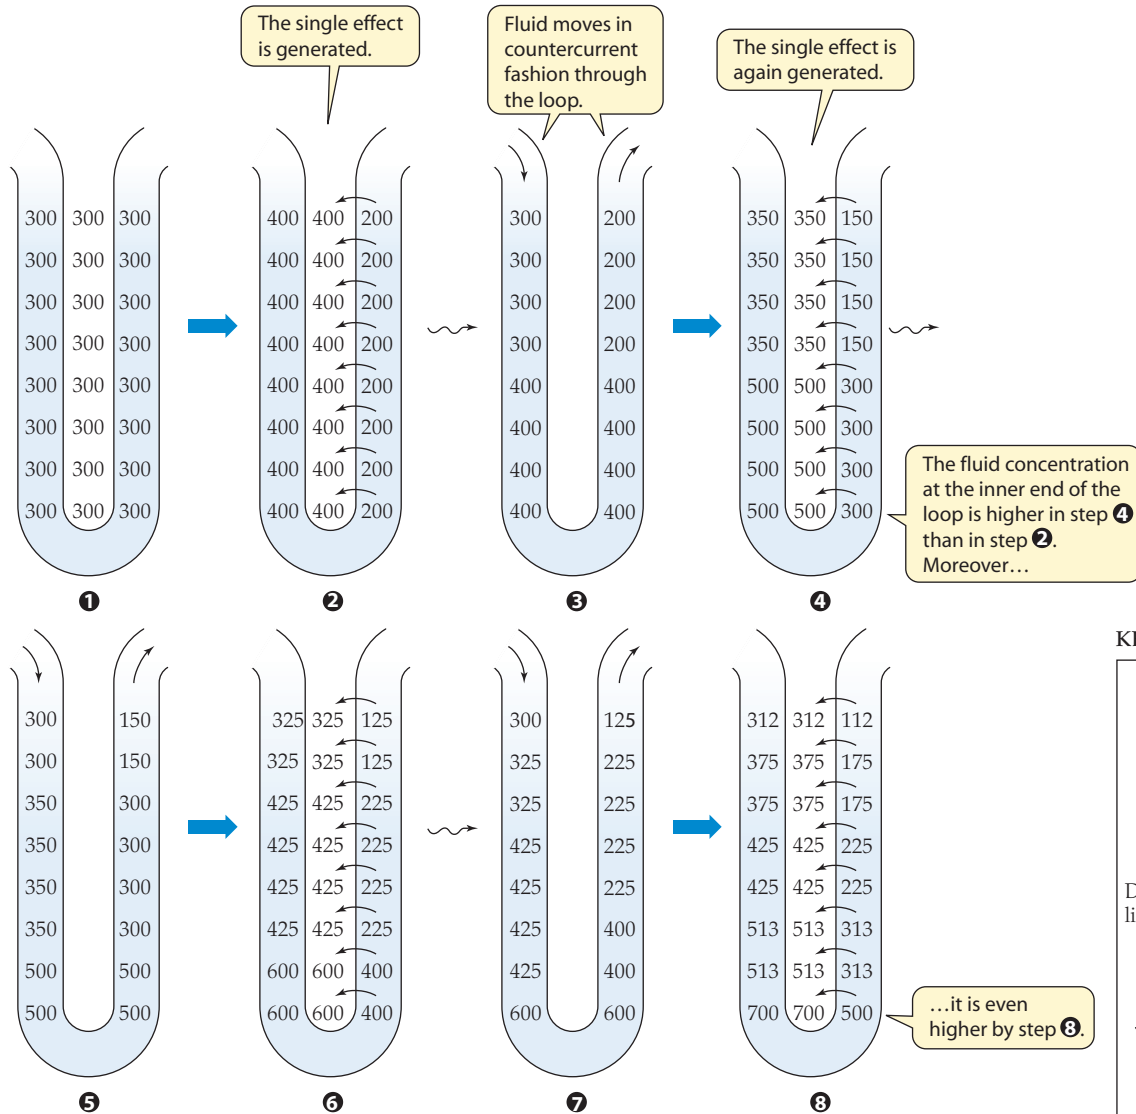

FIGURE 29.12 Countercurrent multiplication in the loop of Henle (a) The distinction between the side-to-side (transverse) difference in osmotic pressure and the end-to-end (axial) difference in the loop of Henle. The side-to-side difference is the single effect. The end-to-end difference is generated from the side-to-side difference by countercurrent multiplication. (b) The process by which countercurrent multiplication occurs. The numbers are osmotic pressures in units of milliosmolarity (mOsm). The operation of the multiplier is presented conceptually as a series of alternating steps. In ❶, the entire system is at 300 mOsm. In ❷, a single-effect osmotic gradient of 200 mOsm is developed all along the loop, and in ❸, fluid flows through the loop. These steps are repeated in ❹ through ❸. The amount of fluid movement through the loop decreases progressively in ❸, ❹, and ❷. Fluid entering the descending limb is always at 300 mOsm, creating a tendency for the osmotic pressure at the cortical end of the descending limb and interstitial space to remain near 300 mOsm. Although both (a) and (b) are presented in terms of osmotic pressures, the differences in osmotic pressure are paralleled by differences in NaCl concentration. The brilliant pedagogical scheme in b was conceived by Robert F. Pitts (1908–1977). (b after Pitts 1974.)

(b) The process of countercurrent multiplication

KEY

FIGURE 29.13 Osmotic pressure increases with depth in the medulla Each vertical red line shows the range of osmotic pressures measured at a particular depth in the cortex or medulla of kidneys taken from five dehydrated laboratory rats. All the rats, in addition to being sampled at various places, were deliberately sampled at the tip of the papilla, accounting for the cluster of data there. On the y axis, 0 represents an osmotic pressure equal to that of the blood plasma in the general circulation, whereas 100 represents the highest osmotic pressure measured (about 1000 mOsm greater). Intermediate osmotic pressures are scaled relative to the two extremes; specifically, any particular measured osmotic pressure (OP) is expressed as $100 \times (\text{measured OP} - \text{plasma OP}) / (\text{maximum OP} - \text{plasma OP})$. Throughout the cortex, the osmotic pressure is equivalent to the osmotic pressure of plasma in the general circulation. The increase in osmotic pressure with depth in the medulla is attributable both to an increase in NaCl concentration and to an increase in urea concentration. (After Wirz et al. 1951.)

side of the tissue (furthest from the cortex). The classic data that originally confirmed this expectation are shown in **Figure 29.13**.

CONCLUDING POINTS ON THE MECHANISM OF CONCENTRATING NONUREA SOLUTES **Figure 29.14** summarizes the changes in the total concentration of nonurea solutes in the tubular fluid of nephrons and collecting ducts when the kidney of a mammal is producing concentrated urine. As fluid in a nephron travels down the descending limb of the loop of Henle, its concentration of nonurea solutes rises, reaching a high level at the hairpin bend of the loop. Thereafter, as the fluid comes back out of the medulla in the ascending limb of the loop of Henle, its concentration of nonurea solutes falls, so that by the time the fluid exits the loop, it is actually *more dilute* than when it started and more dilute than the blood plasma. Then, however, the fluid makes a final, crucial pass through the medulla, traveling down a collecting duct to be discharged into the renal pelvis. On this pass, final concentration of the nonurea solutes occurs.

The *total concentration of nonurea solutes* in the definitive urine depends on the *NaCl concentration* of the interstitial fluids of the innermost medulla, because in a kidney producing concentrated urine, the urine osmotically equilibrates with those interstitial

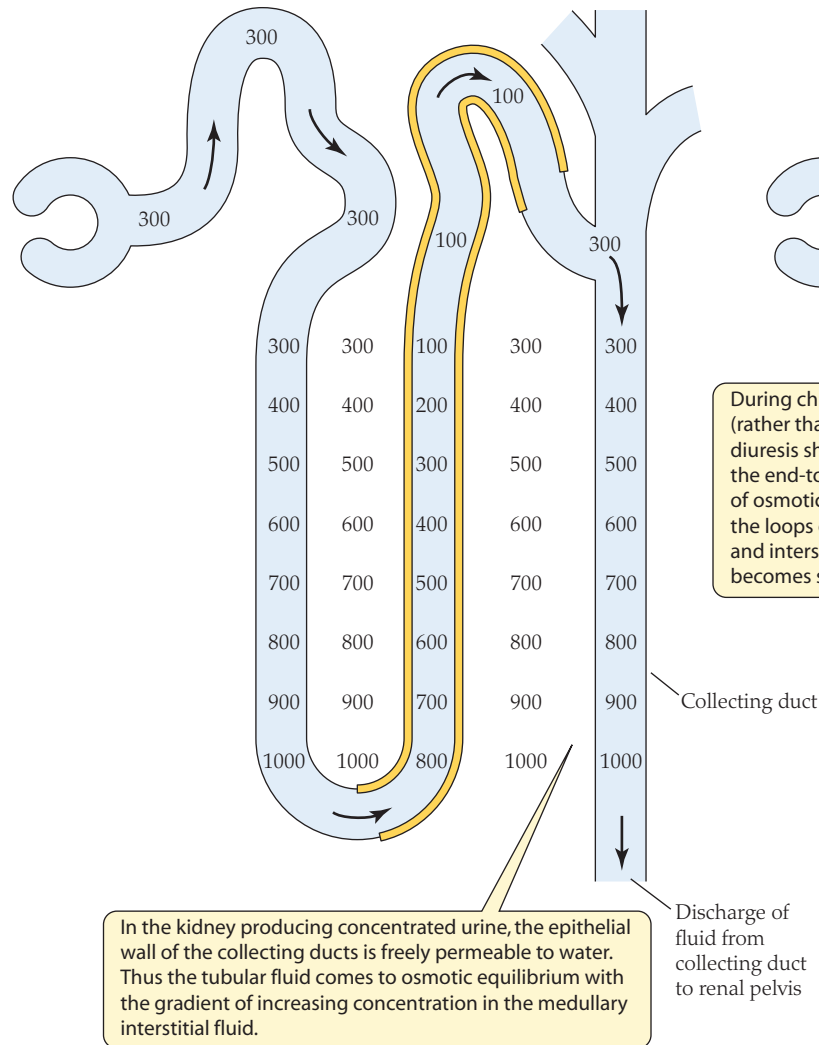

fluids just before leaving the kidney (see **Figure 29.14a**). In turn, the inner-medullary NaCl concentration itself depends on the properties of the countercurrent multiplier system, including the size of the single effect, the rate of fluid flow through the loops of Henle, and the lengths of the loops. Lengthening of the loops tends to increase the end-to-end gradient of NaCl concentration that can be maintained by the loops and thus tends to raise the inner-medullary NaCl concentration. This explains why, among related species of similar body size, the species with relatively thick medullas and prominent renal papillae tend to be capable of producing relatively concentrated urine (see **Figures 29.7** and **29.8**).¹¹

CONCENTRATION OF UREA The mechanisms that concentrate urea differ from those that concentrate the nonurea solutes. Whereas the walls of the collecting ducts block most solutes in the urine and medullary interstitial fluid from diffusing to electrochemical equilibrium, urea is a notable exception. Urea is present at high concentrations in the medullary interstitial fluid, and when mammals are in an antidiuretic state, the walls of the collecting ducts *in the inner medulla* permit free diffusion of urea between the urine inside the ducts and the inner-medullary interstitial fluid (this diffusion is mediated by a facilitated-diffusion *urea transporter [UT] protein* that is dramatically upregulated by ADH). Basically, therefore, high urea concentrations in the urine reflect the diffusion of urea to concentration equilibrium across the walls of the inner-medullary collecting ducts.

How does urea come to be present at high concentrations in the medulla? Put simply, much more urea is filtered than is excreted, and some of the urea reabsorbed along the nephrons accumulates in the medulla. The thick ascending segment of the loop of Henle, the distal convoluted tubule, and the cortical and outer-medullary parts of the collecting duct are poorly permeable to urea. NaCl is actively transported out of the tubular fluid in these tubular regions, and at least in the cortical and outer-medullary collecting duct, water leaves the tubular fluid by osmosis during antidiuresis. Because the permeability to urea in these tubular regions is low, urea—trapped inside the tubules—becomes concentrated in the tubular fluid as water is lost. The important net result is that the tubular fluid has a high urea concentration by the time it enters the inner-medullary collecting duct, which is highly permeable to urea during antidiuresis, permitting free diffusion of urea between the tubular fluid and the medullary interstitial fluid. Urea, therefore, diffuses from the tubular fluid into the inner-medullary interstitial fluid, a process that charges the medullary interstitial fluid with urea. According to present thinking, this entire sequence of events is self-reinforcing because urea *also enters the tubular fluid in the loops of Henle* from the medullary interstitial fluid. By such recycling, the urea concentration in the tubular fluid arriving in the inner-medullary collecting ducts (after passage through the loops of Henle) tends automatically to rise in parallel with the urea concentration of the interstitial fluid. Thus, with a steady influx of new urea from filtration, a gradient favorable for diffusion of urea *into* the interstitial fluid from the collecting ducts is maintained,

¹¹When comparing species that cover a wide range of body sizes, *relative* loop length—estimated as relative medullary thickness—is a far better predictor of concentrating ability than *absolute* loop length (see **Figure 29.8**). Factors other than absolute length thus clearly play major roles in kidney concentrating function, but these additional factors are not yet understood.

(a) Antidiuresis: kidney producing concentrated urine

(b) Diuresis: kidney producing dilute urine

FIGURE 29.14 Osmotic pressures attributable to nonurea solutes in the nephrons and collecting ducts during antidiuresis and diuresis Thick yellow borders symbolize tubules that are poorly permeable to water. Tubules without yellow borders are permeable to water. The change in the water permeability of the collecting ducts between antidiuresis (a) and diuresis (b) is mediated by insertion and removal of aquaporins in apical cell membranes of the collecting-duct epithelium, as discussed later. The interstitial fluids (white areas) exhibit similar gradients of osmotic pressure throughout the medulla. The numbers, expressed in units of milliosmolarity, are approximate and intended only to illustrate general trends.

even though the interstitial-fluid concentration rises to a high level. High concentrations of urea in the interstitial fluid promote high urinary concentrations because diffusive outflux of urea from the collecting-duct fluid continues only to the point of concentration equilibrium with the medullary interstitial fluid.

How does the process of urea concentration relate to the process by which nonurea solutes are concentrated? This is actually an intricate question because of the interacting dynamism of the two processes. However, two important global points should be made. First, because urea and nonurea solutes are concentrated by rather separate mechanisms, a high urea concentration in the urine does not in any simple mathematical fashion displace nonurea solutes or reduce the concentration of nonurea solutes that is possible. The urine

of a mammal can simultaneously contain high concentrations of both urea and nonurea solutes. The second point to be made is that the osmotic reabsorption of *water* from the urine in the inner medulla is controlled by the processing of the *nonurea* solutes. Because urea diffuses to concentration equilibrium across the walls of the inner-medullary collecting ducts, it does not (except transiently) make a direct contribution to the *difference* in osmotic pressure between the collecting-duct fluid and the interstitial fluid. The *difference* in osmotic pressure—which governs the osmotic reabsorption of water—is a consequence of different concentrations of the nonurea solutes.

THE BLOOD SUPPLY OF THE MEDULLA: THE VASA RECTA The blood capillaries of the medulla form hairpin loops—known as **vasa recta**—that parallel the loops of Henle. This arrangement, diagrammed in Figure 29.6b, is vividly evident in Figure 29.10a–c, in which the structures visualized are the blood vessels.

The looped shape of the vasa recta prevents the circulation of blood to the medulla from destroying the concentration gradients of NaCl and urea in the medullary interstitium. To see this, consider what would happen if blood, after flowing into the medulla from the cortex, simply exited the medulla on the pelvic side. The walls of blood capillaries are freely permeable to water and small solutes.

Thus, as blood flowed from the cortex, deeper and deeper into the medulla—encountering ever-more-concentrated interstitial fluids—it would lose water to the interstitium osmotically and take up NaCl and urea by diffusion. Exiting on the side of the renal pelvis, the blood would leave all that water behind and take the solutes away, diluting the medulla in both ways. Instead, after flowing from the cortex to the inner medulla, the blood reverses direction and flows back to the cortex. On its way out, as it encounters ever-more-dilute interstitial fluids, it reabsorbs water and yields NaCl and urea, reversing the processes that occurred on the way in. The familiar tendency of countercurrent flow to preserve gradients oriented parallel to the axis of flow is once again evident. The vasa recta act as *countercurrent diffusion exchangers* (see Box 29.3).

An important function of blood flow through the vasa recta is to remove water from the medullary interstitial fluids. The final process of concentrating the urine, as we have seen, entails osmotic movement of water from the collecting ducts into the inner-medullary interstitial fluid. This water, if allowed to accumulate, would itself dilute the inner-medullary fluid and thereby diminish the medullary concentration gradient. The flow of blood through the vasa recta carries the water away. Evidently, as the blood dynamically loses water during its passage into the medulla and regains water during its passage out, the colloid osmotic pressure resulting from the blood proteins introduces a bias for the gains of water by the blood to exceed losses.

CELL-VOLUME REGULATION, COMPATIBLE SOLUTES, AND COUNTERACTING SOLUTES IN THE MEDULLA The cells in the medulla of the kidney—such as those in the walls of the loops of Henle and vasa recta—are unique among the cells in a mammal's body in that they must tolerate exposure to very high solute concentrations and osmotic pressures in the interstitial fluids that bathe them. The medullary cells must have high levels of intracellular solutes to maintain normal cell volumes rather than being shriveled by osmotic water loss, as explained in Figures 27.8 and 27.9. In comparison with all other cells in a mammal's body, the renal medullary cells are noted for having exceptionally high intracellular concentrations of organic osmolytes of metabolic origin, notably polyhydric alcohols and methylamines (Figure 29.15). These organic compounds serve as *compatible solutes* (see page 714): They balance the high extracellular NaCl concentration while having relatively small effects on cell macromolecules.

The high concentrations of urea in the renal medulla are themselves a challenge to the function of medullary cells because urea can perturb enzymes and other proteins. There is some evidence that the methylamines accumulated in medullary cells (see Figure 29.15) help to offset the perturbing effects of urea. That is, the methylamines act as counteracting solutes (see page 714).

The regulatory roles of the kidney tubules in overview: the concentrating and diluting kidney and the control of transitions

Thus far we have focused on how the mammalian kidney can produce urine more concentrated than the blood plasma. The mammalian kidney resembles other kidneys, however, in that it carries out many processes simultaneously as it performs its overall function of regulating the composition and volume of the blood plasma and other body fluids. In this section we take more of an

FIGURE 29.15 Cell-volume regulation by organic osmolytes in the medulla of the kidney The cells in the renal medulla produce high intracellular concentrations of organic osmolytes as a means of regulating cell volume in the face of the high osmotic pressures in the interstitial fluids bathing them. The data shown are for normally hydrated laboratory rats. Each bar represents, at the designated anatomical location, the sum of the four principal organic osmolytes. The four osmolytes are two polyhydric alcohols (sorbitol and *myo*-inositol) and two trimethylamines (glycine betaine and glycerophosphorylcholine). Concentration is expressed as total micromoles of osmolytes per gram of tissue protein. (After Beck et al. 1998.)

overview of nephron and collecting-duct function in mammals. A useful way to approach this task is, first, to discuss how multiple solutes and water are processed when the kidney is producing a concentrated urine, and then discuss—in a synthetic way—how the kidney functions when producing dilute urine and how the switch between concentration and dilution is regulated.

AN OVERVIEW OF EVENTS IN THE CONCENTRATING KIDNEY Glomerular filtration is, of course, the first step in forming urine. In comparison with other vertebrates, mammals—with some known exceptions (e.g., dromedary camels)—tend to maintain relatively stable GFRs and adjust their rate of urine production principally by adjusting the fraction of filtered fluid that they ultimately reabsorb and return to the blood prior to excretion. The fluid introduced into the Bowman's capsule of a nephron by filtration is approximately isosmotic to the blood plasma and contains similar concentrations of inorganic ions, glucose, and amino acids. A major function of the proximal convoluted tubule is net reabsorption of NaCl and water—net return of NaCl and water to the body fluids. In fact, 60–80% of the filtered amounts of NaCl and water are reabsorbed by the time the tubular fluid reaches the beginning of the loop of Henle. The cells of the epithelial walls of the proximal tubule are freely permeable to water because of aquaporins (discussed shortly), so water exits osmotically as NaCl and other solutes are reabsorbed, and the

tubular fluid stays isosmotic to the blood plasma. Glucose, many amino acids, and HCO_3^- (bicarbonate ion) are almost completely reabsorbed and returned to the blood plasma in the proximal tubule.

A major contemporary area for research is establishing the molecular basis for the function of the proximal convoluted tubule and all other segments of the kidney tubules. The ultimate goal of this research is to understand every aspect of reabsorption and secretion along all parts of the renal tubules in terms of the specific transporter proteins, channel proteins, and other molecules that mediate the processes. **Figure 29.16a** summarizes the major molecular ion-transport mechanisms in the epithelial cells of the wall of the early proximal convoluted tubule. Na^+ reabsorption from the urine is driven by primary active transport carried out by $\text{Na}^+-\text{K}^+-\text{ATPase}$ (see page 110) in the basolateral membrane, which creates a Na^+ electrochemical gradient across the apical membrane favoring Na^+ uptake from the tubular fluid. The reabsorption of glucose and amino acids occurs by secondary active transport (see page 112).

Regarding the water permeability of the proximal tubule, aquaporins, as earlier mentioned, provide the molecular basis for the high permeability of the proximal tubule epithelium. The aquaporins in cell membranes of the epithelial cells of the proximal tubule are classified as *constitutive* because they are always present in the cell membranes; their levels are not much affected by external agents.

After fluid leaves the proximal convoluted tubule, its next step is to travel through the loop of Henle. Although the tubular fluid enters the loop isosmotic to plasma ($\sim 300 \text{ mOsm}$), it exits the loop hyposmotic to plasma (perhaps $100\text{--}150 \text{ mOsm}$), as we have seen (see **Figure 29.14a**). In the ascending thick segment of the loop of Henle, active NaCl transport out of the tubular fluid is a key process that both creates the single effect for countercurrent multiplication, and accounts for the hyposmotic state of the tubular fluid as it leaves the loop of Henle. **Figure 29.16b** presents a current model of the molecular biology of the active NaCl transport out of the tubular fluid in the ascending thick segment. **Loop diuretics**—medications employed to treat hypertension (high blood pressure)—are targeted at the Na-K-2Cl cotransporter. These medications inhibit NaCl transport out of the tubular fluid by inhibiting the cotransporter, resulting in increased Na^+ excretion and water excretion, which tend to decrease the volume of the blood plasma (see page 751).

After exiting the loop of Henle, the tubular fluid passes through the distal convoluted tubule. The epithelial walls of much or all of the distal convoluted tubule are poorly permeable to water and actively transport NaCl out. Thus the tubular fluid remains strongly hyposmotic to the blood plasma (see **Figure 29.14a**). Potassium (K^+) is added to the tubular fluid (partly passively, partly actively) in the distal convoluted tubule and cortical collecting duct. This addition of K^+ controls the amount of K^+ that is removed from the body fluids and eliminated in the urine because most K^+ from filtration was reabsorbed from the tubular fluid in earlier parts of the nephron.

Perhaps 5% or less of the originally filtered volume reaches the collecting duct. In the concentrating kidney, the collecting duct is permeable to water because of an aquaporin-based mechanism discussed in the next section.¹² Thus dilute tubular fluid arriving in the collecting duct promptly comes to isosmoticity with the cortical interstitial fluid ($\sim 300 \text{ mOsm}$) by osmotic outflux of water (see **Figure 29.14a**). The tubular fluid then descends deeper and deeper into the

medulla, from the cortical to the pelvic end of the collecting duct. As it does so, it encounters an ever-higher interstitial NaCl concentration and attains higher concentrations of urea and nonurea solutes by the mechanisms we have discussed. Water is reabsorbed osmotically and returned to the blood plasma in the vasa recta. Especially in the cortical part of the collecting duct, but also in the inner-medullary part, NaCl is actively reabsorbed (**Figure 29.16c**). This reabsorption of NaCl in the collecting duct determines the final amount of NaCl that is removed from the body fluids and excreted. It also plays a key role in controlling urine volume—the amount of water removed from the body fluids—because by reducing the amount of nonurea solute in the urine, it enhances osmotic return of water from the urine to the blood. In the end, mammals in antidiuresis typically excrete only 1% or less of the filtered NaCl and water.

THE DILUTING KIDNEY AND THE REGULATION OF SWITCHES BETWEEN CONCENTRATION AND DILUTION

Individual mammals are typically capable of adjusting the concentration and volume of their urine over broad ranges, thereby modulating the effects of urine production on the concentration and volume of the blood plasma and other body fluids. A person in antidiuresis might produce urine that is as concentrated as about 1200 mOsm ($U/P = 4$) and limited in volume to less than 1% of the filtered amount. In diuresis, by contrast, that person might produce urine as dilute as about 50 mOsm ($U/P = 0.2$) and increase the volume to about 15% of the filtered amount. The effects on the body fluids vary commensurately. *In antidiuresis the high osmotic concentration of the urine tends to dilute the body fluids (see **Figure 27.7**), and the low urine volume has the synergistic effect of conserving water. Conversely, in diuresis, the low urine osmotic concentration tends to concentrate the body fluids, and the high urine volume voids water.*

The principal agent of control of switches between antidiuresis and diuresis is antidiuretic hormone (ADH). The ADH of most mammals is *arginine vasopressin*; therefore, ADH is often called **vasopressin** in books on mammalian physiology and medicine. As knowledge advances, the known effects of ADH become more extensive and complex. The action of ADH that is of most central importance in mammals is that it modulates the permeability of the collecting ducts to water.

The effect of ADH on the permeability of the collecting duct epithelium is mediated by a specific molecular form of aquaporin, AQP-2, that is inserted into and retrieved from the apical cell membranes of the collecting-duct epithelial cells; **Figure 16.16** shows this process in detail. The presence of ADH causes insertion of aquaporin molecules into the apical cell membranes and an increase in epithelial permeability to water (**Figure 29.17**). When ADH levels fall, the aquaporin molecules are retrieved from the apical cell membranes and epithelial permeability to water decreases.

In the concentrating kidney, although we have not said so heretofore, the high permeability of the collecting ducts to water is elicited by high blood levels of ADH. This high water permeability permits water to leave the collecting ducts by following the osmotic gradient between the collecting-duct fluid and medullary interstitial fluid. The osmotic exit of water, as previously stressed, accounts for both the *low volume* and *high concentration* of the urine produced during antidiuresis.

When blood levels of ADH are low and aquaporins are retrieved from the apical cell membranes of the collecting-duct epithelium, the

¹²The terminal distal tubule may also be permeable to water.

In all three parts of the kidney tubule, Na^+ diffuses into the epithelial cells from the tubular fluid because there is an electrochemical gradient favoring such diffusion.

In the early proximal tubule, the tubular fluid is rich in glucose and amino acids, and much of the Na^+ entry into a cell occurs by means of cotransporters that bring about the secondary active transport of glucose and amino acids into the cell. Only the Na-glucose cotransporter is shown here.

(a) Early proximal convoluted tubule

KEY

(b) Thick ascending limb of loop of Henle

In the thick ascending limb, much of the Na^+ entry into a cell occurs by means of a Na-K-2Cl cotransporter that carries K^+ and Cl^- inward by secondary active transport. **Loop diuretics** inhibit this cotransporter.

In all three parts of the kidney tubule, energy for Na^+ reabsorption comes from ATP used for primary active transport by Na^+-K^+ -ATPase. The ATPase removes Na^+ from each type of epithelial cell across the basolateral cell membrane. Na^+ enters each cell across the apical cell membrane by diffusion down the electrochemical gradient generated by Na^+-K^+ -ATPase. The membrane proteins involved in Na^+ entry are different in all three types of epithelial cells, however.

(c) Collecting duct Na^+ -reabsorbing cell (principal cell)

In the collecting duct, Na^+ enters the principal cells by a channel. The collecting-duct principal cells are the *main targets* of *aldosterone*, which promotes Na^+ reabsorption by increasing synthesis of the Na^+ channel protein and the Na^+-K^+ -ATPase protein, as well as other actions. **Diuretic drugs such as amiloride** block or inhibit the Na^+ channel.

FIGURE 29.16 Major molecular mechanisms of NaCl reabsorption and associated processes in three parts of the mammalian kidney tubule Each drawing shows a representative epithelial cell in the epithelial wall of the tubule. (a) The early proximal convoluted tubule. Cl^- is removed from the tubular fluid at this site by simple diffusion, largely via paracellular pathways, following an electrochemical gradient created by Na^+-K^+ -ATPase. The Na-H countertransporter in the apical membrane moves H^+ into the tubular fluid, where the H^+ combines with tubular bicarbonate (HCO_3^-), forming CO_2 , which enters the cell, supplying CO_2 to the intracellular reaction shown. (b) The thick segment of the ascending limb of the loop of Henle. Here, Cl^- is reabsorbed through the cells, rather than by the paracellular route, in a process mediated by a Na-K-2Cl cotransporter in the apical membrane. (c) In the collecting ducts, different cells carry out Na^+ and Cl^- reabsorption. The drawing shows a Na^+ -reabsorbing cell, known as a *principal cell*. In all three segments, most K^+ brought into cells by Na^+-K^+ -ATPase diffuses out via channels.

(a) Number of aquaporin molecules in apical cell membranes as a ratio of number in intracellular membranes

(b) Permeability to water

FIGURE 29.17 The collecting-duct epithelium: Cellular position of aquaporin-2 (AQP-2) and permeability to water when ADH is present or absent Studies were carried out on collecting ducts from the inner medulla. The distribution of AQP-2 molecules was determined by visualizing and directly counting the molecules by means of immunological labels and electron microscopy. According to the shuttle hypothesis, the AQP-2 molecules in each epithelial cell are shuttled back and forth between the apical cell membrane and intracellular vesicular membranes. (a) The number of AQP-2 molecules in apical cell membranes as a ratio of the number in intracellular vesicular membranes. (b) Permeability of the collecting-duct epithelium to water. (After Knepfer et al. 1996.)

collecting ducts are poorly permeable to water. The distal convoluted tubules are also poorly permeable. Thus, during diuresis, from the time the tubular fluid exits the loops of Henle to the time it is discharged into the renal pelvis, it is blocked from coming freely to osmotic equilibrium with the surrounding cortical and medullary interstitial fluids. Recall that the tubular fluid is hyposmotic to plasma when it exits the loops; therefore, it would lose water osmotically if it could. However, the low water permeability of the walls of the distal tubules and collecting ducts in diuresis—when ADH levels are low—impedes such water loss. Figure 29.14b shows that in fact, because of the low water permeability, as NaCl is actively reabsorbed in the distal tubules and collecting ducts during diuresis, the tubular fluid becomes ever-more hyposmotic to the plasma. The urine produced is both *abundant* (because of little water reabsorption) and *dilute* (because of the diluting process just described).

Notice how fundamentally similar the action of ADH is in mammals and in amphibians. In both groups—and indeed, in all groups of tetrapod vertebrates—the primary effect of ADH on the renal tubules is to increase the permeability to water of tubular epithelia that otherwise are poorly permeable.¹³ This increase in permeability to water has the important consequence that it allows the tubular fluids to come to osmotic equilibrium with the fluids surrounding the tubules. In amphibians, the fluids surrounding the distal tubules and collecting ducts are osmotically similar to the blood; thus the presence of ADH causes production of urine that approaches isosmoticity with the blood. In mammals, the collecting ducts are surrounded by fluids that are hyperosmotic to the blood. Consequently, ADH causes production of hyperosmotic urine. In both mammals and amphibians, ADH principally controls the excretion of *water* and thus controls the removal of *water* from the body fluids.¹⁴ Although the amount of each nonurea *solute* excreted is adjusted by solute-specific tubular mechanisms (e.g., active reabsorption or secretion), the concentration of ADH determines the amount of water that is extracted from the body fluids and excreted with the solutes.

When an individual mammal switches between chronic antidiuresis and chronic diuresis, an additional change besides the permeability adjustments occurs: The magnitude of the osmotic gradient in the medullary interstitial fluids—the gradient between the cortex and inner medulla—diminishes. For example, in a dog shifted from chronic antidiuresis to chronic diuresis, the osmotic pressure of the inner-medullary interstitial fluid might change from 2400 mOsm (about 2100 mOsm higher than the cortical osmotic pressure) to 500 mOsm (about 200 mOsm higher). Periods of hours or days are required for such changes to be fully realized.

ADH is not the only hormone that controls kidney function. As discussed in Chapter 28 (see page 751), aldosterone and natriuretic hormones help control the reabsorption and secretion of Na⁺ and K⁺. In addition, calcitonin affects renal function, and the kidneys themselves employ paracrines, such as eicosanoids and kinins, as *local* chemical messengers.

Modern molecular methods create new frontiers in the study of kidney function

As is true throughout the study of animal physiology, modern molecular methods are enabling kidney researchers to study subjects that seemed utterly beyond reach two decades ago. A stunning example is provided by recent studies of the fine structure of the mammalian renal medulla. Different elements of the medulla often differ categorically in one or more cell-membrane proteins. When this is the case, elements can be distinguished by immunological labels. For the immunocytochemical study in [Figure 29.18a](#), fluorescent antibodies were prepared against three distinguishing proteins. A blue-fluorescing antibody was prepared against aquaporin-2, which is found only in collecting ducts. Red- and green-fluorescing antibodies were prepared against aquaporin-1 and a urea transporter found, respectively, in the descending thin segments of the loops of Henle and the descending vasa recta. [Figure 29.18a](#) shows just a single section through the kidney. By synthesizing information from many sections, the three-dimensional fine structure can be

¹³This is postulated to occur in all cases by aquaporin insertion.

¹⁴See Chapter 28 (page 750) for a full explanation of this point and [Figure 29.5](#) for a diagram of how changes in tubular permeability to water can alter the amount of water excreted in the urine.

reconstructed. **Figure 29.18b** shows the collecting ducts and the ascending and descending thin segments of loops of Henle in just the very tip—0.5 mm long—of the medullary papilla. Function is intimately related to structure in the kidney, as we have often seen. This new knowledge of the exact structure of the papilla is helping investigators better understand how urine is concentrated in the inner medulla. For instance, the structural studies reveal geometric regularities that previously were unknown and also reveal that there is far more contact among the loops of Henle and the collecting ducts in the medullary tip than would be predicted from a random arrangement of the two types of elements relative to each other.

SUMMARY Urine Formation in Mammals

- The loops of Henle, collecting ducts, and vasa recta form parallel arrays in the medulla of the mammalian kidney, creating the structural basis for the ability to form urine hyperosmotic to the blood plasma. Among species of mammals of a particular body size, the species with long loops of Henle tend to be able to produce more-concentrated urine than those with shorter loops.
- The proximal convoluted tubule reabsorbs—and returns to the body fluids—much of the NaCl and water from the filtrate by processes that do not alter the osmotic pressure of the tubular fluid. It also fully reabsorbs glucose and amino acids, returning them to the body fluids
- After the tubular fluid passes through the loop of Henle, it is less concentrated than when it entered. Nonetheless, processes in the loop of Henle create the gradients of osmotic pressure and NaCl concentration in the medullary interstitial fluid that are responsible

for the ultimate concentration of the urine. In the part of the loop where the ascending limb is thick, active NaCl transport creates a single-effect difference in osmotic pressure and NaCl concentration between adjacent parts of the ascending and descending limbs. By acting as a countercurrent multiplication system, the loop generates a difference in osmotic pressure and NaCl concentration from end to end that is much larger than the single effect.

- During antidiuresis, as tubular fluid makes its last pass through the medulla in the collecting ducts, nonurea solutes are concentrated because the collecting-duct walls are freely permeable to water, permitting osmotic equilibration between the tubular fluid and the medullary interstitial fluid. The high permeability of the collecting-duct epithelial walls to water results from insertion of aquaporin-2 molecules into cell membranes in response to ADH (vasopressin).
- During diuresis, the collecting-duct walls are poorly permeable to water, so tubular fluid is osmotically isolated from the medullary interstitial fluid and can be diluted by solute reabsorption.

Urine Formation in Other Vertebrates

Freshwater and marine teleost fish differ in nephron structure and function

The sort of nephrons we described in amphibians apparently evolved in their freshwater progenitors, because the nephrons of nearly all freshwater teleost (bony) fish are structurally similar to those of amphibians. In freshwater fish, as in amphibians, the distal convoluted tubule plays a key role in diluting the urine. The

walls of the tubule are nearly impermeable to water. Thus, as NaCl is reabsorbed and returned to the body fluids, water remains behind in the tubule, and a dilute urine is produced. The effect is to help keep the blood osmotic pressure high (see Figure 27.7) despite the water overload that occurs in freshwater fish because of inward osmosis from the environment.

Marine teleost fish commonly lack the distal convoluted tubule. If they are descended from freshwater ancestors, as is usually thought (see Box 28.2), the absence of the distal tubule probably represents a secondary loss rather than a primitive condition. The reason for the loss seems straightforward: Marine teleosts are hyposmotic to their seawater environment and thereby face continuous osmotic desiccation. They have no need of a nephron segment specialized for the production of a voluminous, dilute urine rich in osmotically free water.

In addition to differing in the presence or absence of the distal convoluted tubule, freshwater and marine teleosts differ in other ways. Freshwater teleosts typically have relatively large numbers of nephrons and well-developed glomeruli. Their GFRs are relatively high, as suits animals that have excesses of water that must be voided in urine. In contrast, marine teleosts tend to have relatively few nephrons and small glomeruli. They have low GFRs, a condition that seems adaptive for animals that face desiccation and produce relatively little urine.

Many marine teleosts—according to present evidence—do not form their primary urine entirely by ultrafiltration. Instead, they form their primary urine partly by *secretion* into the proximal tubules. The mechanism of secretion is that ions—including Na^+ , Cl^- , Mg^{2+} , and SO_4^{2-} —are actively transported into the proximal tubules, and water and other solutes follow (see Figure 29.2).

In about 30 known species of marine teleosts—described as **agglomerular**—the trend toward small glomeruli in the marine environment is carried to its logical extreme, and the nephrons lack glomeruli. These agglomerular species form their primary urine entirely by secretion. Agglomerularism has evolved on three independent occasions, suggesting it is adaptive under some circumstances. Some seahorses and pipefish, some Antarctic fish, and the oyster toadfish (*Opsanus tau*) are agglomerular.

Some of the most interesting fish from the viewpoint of kidney function are the euryhaline teleost species that can live in either freshwater or seawater, such as salmon and migratory eels. The control of kidney function in teleosts has in fact been most thoroughly studied in some of these species. When a euryhaline fish is transferred from seawater to freshwater, it typically undergoes a large increase in GFR, mediated for the most part by an increase in the number of filtering nephrons. Active secretion of Mg^{2+} and SO_4^{2-} into the urine, which is vigorous in seawater, is curtailed in freshwater (where ambient Mg^{2+} and SO_4^{2-} concentrations are vastly lower). Moreover, when fish are transferred from seawater to freshwater, the nephrons—and sometimes other excretory structures (e.g., the bladder)—undergo decreases in their overall permeability to water, a change that favors water excretion. Prolactin, arginine vasotocin (the “ADH” of fish; see Table 16.2), and angiotensin II are implicated in controlling these changes, but the controls are not well understood.

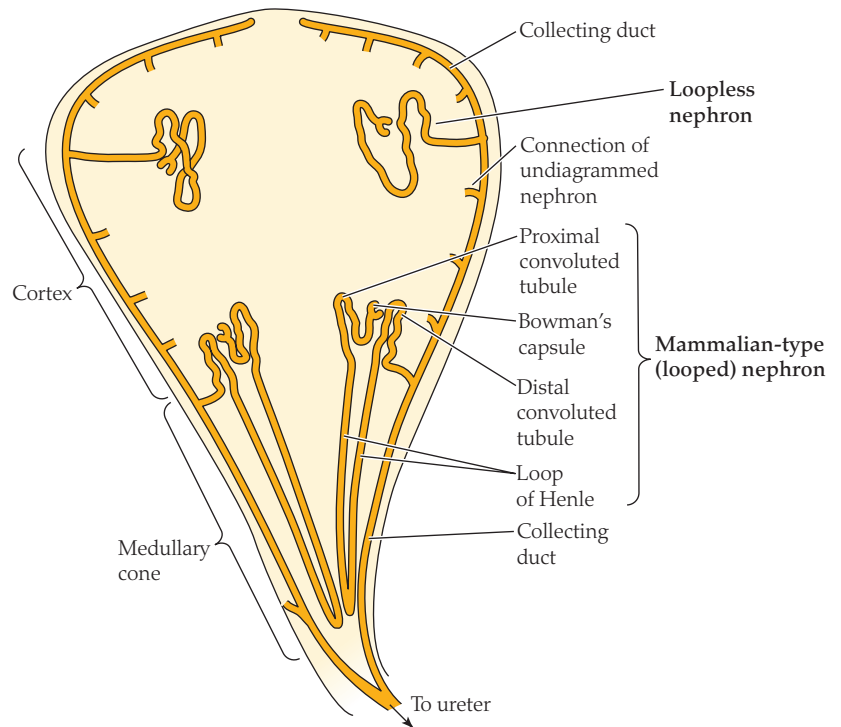

FIGURE 29.19 A lobe of a bird's kidney in cross section (After Willoughby and Peaker 1979.)

The reptiles other than birds have nephrons like those of amphibians, but birds have some mammalian-type nephrons

The nephrons of lizards, snakes, turtles, and crocodilians are broadly similar to those of amphibians. Birds, by contrast, have a range of nephron forms, which are usually categorized into two major types (Figure 29.19). Some of the nephrons of birds have short, uncomplicated proximal and distal tubules, and they lack loops of Henle. These nephrons superficially resemble the nephrons of nonavian reptiles in structure, and they are called **loopless nephrons**. Other avian nephrons have a loop of Henle interposed between the proximal and distal convoluted tubules and are called **looped nephrons** or **mammalian-type nephrons**. These nephrons have relatively large glomeruli and elaborate proximal tubules. Approximately 10–30% of the nephrons in a bird's kidney are typically of the mammalian type; the remainder are of the loopless type. The mammalian-type nephrons are organized into sets. Among the nephrons of a set, the Bowman's capsules and proximal and distal convoluted tubules are all positioned near the same part of the kidney that houses the loopless nephrons, but the loops of Henle all project in a compact parallel array toward the direction of the ureter. Each parallel array of loops of Henle is called a medullary cone (see Figure 29.19). Each kidney includes many cones. Collecting ducts carrying the outflow from both the loopless and the mammalian-type nephrons run through the medullary cones on their way to the ureter.

Neither the nephrons in the kidneys of nonavian reptiles nor the loopless nephrons in a bird's kidneys can produce urine that is hyperosmotic to blood. However, the loops of Henle of the mammalian-type nephrons in a bird's kidney carry out countercurrent multiplication and can raise the urine osmotic pressure above the blood osmotic pressure. Details of the countercurrent mechanism in birds are probably different from those in mammals. For most

species of birds, the maximum urine osmotic pressure is no more than about 2.5 times blood osmotic pressure.

Uric acid, the principal nitrogenous end product of birds and most other reptiles, is introduced into the nephrons by filtration and secretion. It is actively secreted into the urine as the urine flows through the nephrons, and this secretion accounts for the greater part of the excreted amount.

In both birds and nonavian reptiles, the ureters do not discharge directly to the outside of the body but instead discharge into the cloaca. From the cloaca, the urine is often moved by reverse peristalsis into the lower intestine. Because of these attributes, both the cloaca and the intestine may reclaim constituents from the urine and modify the composition and volume of the urine before the urine is excreted. At least four categories of cloaca-intestine processing are recognized, correlated to some extent with the life histories of the birds and other reptiles. When the urine enters the cloaca from the ureters, the uric acid and urates in it are often present largely in the form of supersaturated colloidal suspensions stabilized by specific proteins. The uric acid and urates are then precipitated into solid, particulate form in the cloaca-intestine. Precipitation *after* the urine has left the ureters helps prevent clogging of the renal tubules with the precipitate.

SUMMARY Urine Formation in Other Vertebrates

- Freshwater teleost fish have nephrons structurally similar to amphibian nephrons. Marine teleost fish, however, usually lack the distal convoluted tubule and have a relatively poorly developed glomerular filtration apparatus that seems often to be supplemented by active solute secretion. A few marine fish are aglomerular and depend entirely on secretion.
- Birds and other reptiles have nephrons structurally similar to amphibian nephrons. Birds, in addition, have mammalian-type nephrons (with loops of Henle) organized into parallel arrays—the medullary cones—in which urine hyperosmotic to blood plasma can be made.

Urine Formation in Decapod Crustaceans

An adult crayfish, crab, lobster, or other decapod crustacean has two renal organs, known as **antennal glands** or **green glands**, which are located in its head and open to the outside independently near the bases of its second antennae (Figure 29.20a). Each antennal gland is basically a single tube, sometimes loosely described as resembling “a single giant nephron.” In a freshwater crayfish (Figure 29.20b), each antennal gland begins with a closed **end sac** or **coelomosac** lying to the side of the esophagus. Following the end sac is the **labyrinth** (or green body), a sheet of spongy tissue consisting of a channel that branches and anastomoses extensively along its length. The **nephridial canal**, which also has a spongy internal morphology, leads from the labyrinth to the expanded **bladder**, and the bladder empties to the outside. The nephridial canal is found only in certain freshwater decapod crustaceans.

The walls of the end sac are thin, and arteries from the heart supply a network of small vessels or lacunae on the outer surface of the end sac (see Figure 25.23). This morphological evidence has

(a) Position of the antennal gland (green gland)

(b) Antennal gland unfolded, with urine properties plotted below corresponding anatomical locations

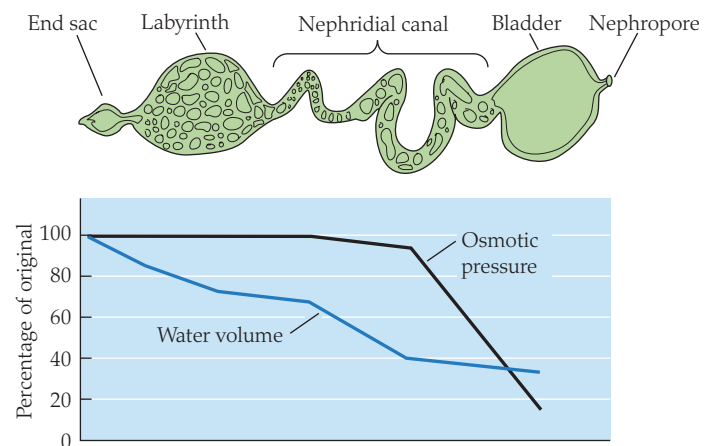

FIGURE 29.20 The antennal gland and urine formation in a freshwater crayfish (a) The position of the antennal gland on the right side of a crayfish's body. (b) Although the nephridial canal is in fact tightly convoluted and partly enveloped by the sheetlike labyrinth, the antennal gland can be stretched out to reveal its parts. The graph shows measured changes in the osmotic pressure and water content of the urine as it passes through the parts of the antennal gland in crayfish (*Australopotamobius pallipes* and *Orconectes virilis*) living in freshwater. Values are plotted immediately below the anatomical locations where they were measured and are expressed as percentages of the values in the end sac. (After Riegel 1977.)

long suggested that fluid enters the end sac by filtration under the force of blood pressure. Additional morphological evidence for this concept is provided by the presence of cells resembling podocytes (see Figure 29.1) in the end-sac epithelium. The physiological evidence that is available supports the hypothesis that primary urine is formed in the end sac by filtration from the blood. Most researchers (although not all) conclude that blood pressure provides the force for filtration.

The composition of the urine is modified in all the structures through which it flows as it passes through the antennal gland. The labyrinth of American lobsters, for example, is known to reclaim glucose, and probably reclaims amino acids, from the filtrate. In marine crabs, the bladder is an important site of glucose reabsorption from the urine and Mg^{2+} secretion into the urine. Unfortunately, a truly synthetic understanding of the handling of solutes by all parts of an antennal gland is not yet available for any species.

Modifications of the osmotic pressure of the urine have been a major focus of study in freshwater decapods. The labyrinth is by all

accounts incapable of rendering the urine hyposmotic to the blood. There is a much-emphasized correlation between the presence of a nephridial canal and the ability to produce urine hyposmotic to the blood. Freshwater crayfish, which can make dilute urine, have a nephridial canal; marine decapods and freshwater crabs such as *Eriocheir sinensis* (see page 723), which are recent immigrants to freshwater and unable to make dilute urine, lack the nephridial canal. Thus the nephridial canal has often been described as being analogous to the vertebrate distal convoluted tubule. Some studies on crayfish indicate that the bladder helps produce dilute urine (see Figure 29.20*b*). Excretion of dilute urine helps keep the osmotic pressure of the body fluids high (see Figure 27.7). Active reabsorption of NaCl—which retains NaCl in the body fluids—is clearly one of the major processes that occurs when a dilute urine is produced.

Urine Formation in Molluscs

The renal organs of molluscs are tubular or saccular structures, called **nephridia**, or **kidneys**, that empty into the mantle cavity or directly to the outside. Bivalves, most cephalopods (octopuses and squids), and some gastropods have two kidneys, but most gastropods have only one. In an arrangement that initially strikes most people as truly bizarre, each kidney typically opens into the pericardial cavity that surrounds the heart, and the fluid in the pericardial cavity—the pericardial fluid—is believed to be the primary urine. A canal called the **renopericardial canal** leads from the pericardial cavity to the main body of each kidney.

The most thoroughly understood molluscan kidney is that of the giant octopus *Enteroctopus dofleini*, a marine mollusc—isosmotic with seawater—found along the Pacific coast of North America. The kidneys of octopuses and squids are associated with the branchial hearts rather than the systemic heart (Figure 29.21*a*). Each branchial heart bears a thin-walled protuberance, the *branchial heart appendage*, which communicates with the lumen of the heart. In *Enteroctopus*, the pericardial cavity of each branchial heart encloses only the side of the heart bearing the heart appendage as seen in Figure 29.21*a*. A kidney connects to each pericardial cavity. Compelling evidence exists in *Enteroctopus* and certain other cephalopods that the pericardial fluid is an ultrafiltrate of the blood, forced into the pericardial cavity across the branchial heart appendage under the force of pressure developed in the heart. In each kidney, this filtrate flows through a long renopericardial canal and then an enlarged **renal sac** before being discharged into the mantle cavity. Studies have shown that the renopericardial canal alters the composition of the urine. Glucose and amino acids are promptly reabsorbed and returned to the body fluids, for example—a process reminiscent of their prompt reclamation in vertebrate nephrons.

The kidneys of bivalve and gastropod molluscs, such as clams and snails, open into the pericardial cavity surrounding the systemic heart (Figure 29.21*b*).¹⁵ Tubular structures called **pericardial glands** are found in the walls of the atria of the heart or in association with the membranes surrounding the pericardial cavity of these animals. Podocytes (suggestive of filtration) are characteristic cells in the pericardial glands. The incomplete physiological evidence that exists indicates that although the pressures developed by the hearts of bivalves and gastropods are usually low, the pericardial

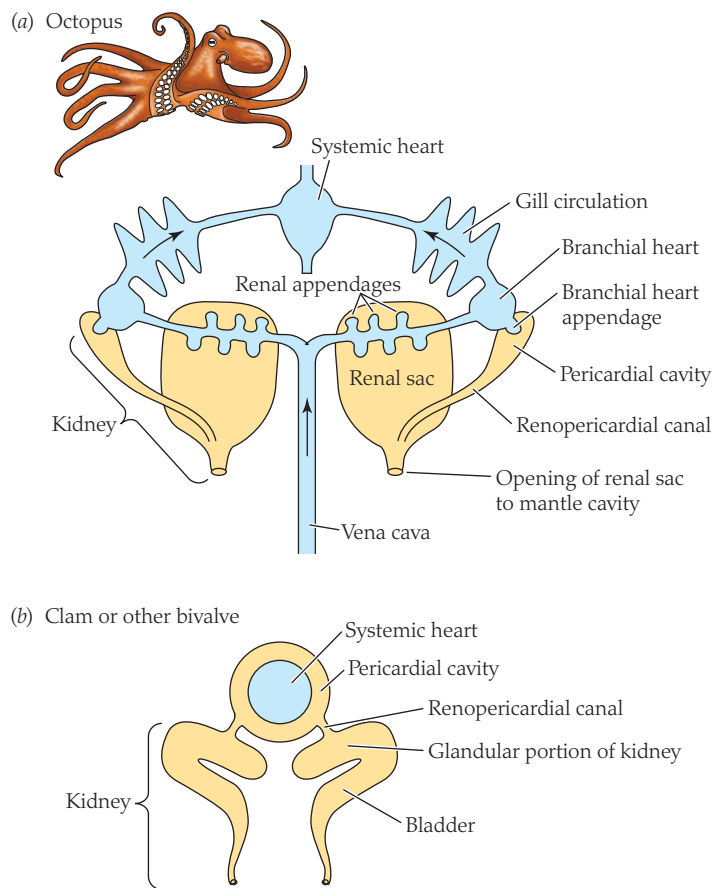

FIGURE 29.21 The kidneys of molluscs and their relations to the circulatory system (a) The kidneys and associated parts of the circulatory system in the giant octopus *Enteroctopus*. After the principal vein returning blood from the systemic tissues, the vena cava, branches, each branch passes by one of the renal sacs, and there it bears many glandular diverticula, called *renal appendages*, which are closely juxtaposed to the walls of the sac. In *Enteroctopus*, ammonia is believed to be secreted into the renal sacs across the renal appendages before blood reaches the branchial hearts, where ultrafiltration occurs. (b) A stylized cross section through the systemic heart in a clam, mussel, or other bivalve, showing the relation of the heart and pericardial cavity to the kidneys. (After Martin and Harrison 1966.)

fluid (which is the primary urine) is formed by filtration, and this filtration occurs in the pericardial glands. The primary urine is altered as it flows through the kidneys, but little is known about the process. In freshwater mussels, the osmotic pressure of the urine is reduced to about half that of the blood by the time the urine arrives in the bladder. Thus, a dilute urine that helps keep the osmotic pressure of the body fluids high (see Figure 27.7) is excreted.

Urine Formation in Insects

The formation of urine has been much more thoroughly studied in insects than in any other group of invertebrates. Most insects possess Malpighian tubules,¹⁶ and these tubules are often called the “excretory tubules.” A point to be stressed from the outset, however, is that the hindgut is as important as the Malpighian tubules in the formation of urine.

¹⁵Bivalves and gastropods lack branchial hearts.

¹⁶The tubules are named after Marcello Malpighi (1628–1694), one of the great early microscopists, who was the first to describe the blood capillaries and renal corpuscles of vertebrates as well as the Malpighian tubules and tracheae of insects.

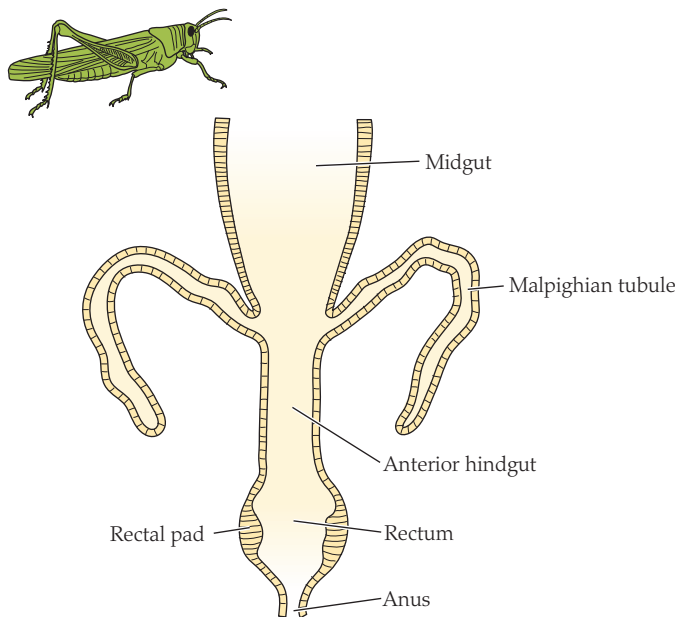

FIGURE 29.22 The posterior gut and Malpighian tubules of an insect The Malpighian tubules empty into the gut at the junction of the midgut and hindgut.

The **Malpighian tubules** are long, slender, blind-ended structures that typically arise from the junction of the midgut and hindgut (Figure 29.22). They number from 2 to more than 200, depending on the species. Projecting into the hemocoel, they are bathed by the blood (hemolymph). The walls of the tubules consist of a single layer of epithelial cells, surrounded on the outside by a thin basement membrane. Although the tubules exhibit little histological differentiation along their length in some species, they are differentiated into two to six (or possibly more) distinct regions in numerous others. In many species, the various tubules within an individual are morphologically similar, but in others, two or more types of tubules are present.

The hindgut, which is lined with cuticle (see Figure 6.19), typically consists of a relatively small-diameter **anterior hindgut** (*ileum* or *intestine*) and an expanded posterior part, the **rectum** (see Figure 29.22). The walls of the anterior hindgut usually consist of a single layer of cuboidal or squamous epithelial cells. The walls of the rectum are similar to those of the anterior hindgut in some insects, but in many other species, parts of the rectal wall consist of thick columnar epithelial cells, sometimes associated with secondary cell layers. These thickened parts of the rectal wall are termed **rectal pads** or **rectal papillae** (see Figure 29.22), depending on their gross morphology.

The Malpighian tubules form and sometimes modify the primary urine

The function shared by the Malpighian tubules of all insects studied is the formation of the primary urine. The tubules are not supplied with blood vessels, and filtration does not occur. Instead, the primary urine is formed by a secretory mechanism in insects (see Figure 29.2). In the most common scenario, potassium chloride (KCl) is secreted vigorously by the epithelium of a Malpighian tubule from the blood bathing the tubule into the lumen of the tubule—so vigorously that the K^+ concentration in the tubular fluid is 6–30 times higher than the blood K^+ concentration. According to theories that have rapidly matured in the last 25 years, the K^+ secretion occurs

by secondary active transport; a H^+ -ATPase uses ATP bond energy to create electrochemical gradients that drive the secondary active transport of K^+ . The secretion of K^+ into a Malpighian tubule is electrogenic, and Cl^- accompanies the K^+ passively by following the electrical gradient (inside positive) set up by K^+ secretion. The result is that KCl is secreted at a cost of ATP. The flux of KCl into the lumen of a Malpighian tubule drives osmotic entry of water, which typically occurs briskly enough that the tubular fluid remains approximately isosmotic to the blood (a case of near-isosmotic water transfer). Many additional solutes then enter the tubular fluid passively, as by following solute concentration gradients set up by the osmotic influx of water; these solutes include amino acids, sugars, diverse organic wastes and toxins, and several inorganic ions. Proteins are largely excluded from the tubular fluid because of their molecular size. Certain organic compounds—notably some detoxification products plus secondary compounds synthesized by plants to deter herbivory (e.g., alkaloids)—are actively secreted into the primary urine by some insects.

Although KCl is most commonly the principal salt secreted to initiate primary-urine formation, NaCl plays this role in some species. There are also species in which KCl predominates under some conditions, whereas NaCl does under other conditions.

As primary urine flows through the Malpighian tubules toward the gut, the tubular epithelium may reabsorb salts, water, or other molecules such as glucose—returning them to the blood. In the end, the fluid that enters the hindgut from the Malpighian tubules is approximately isosmotic with the blood and contains numerous solutes. Its solute composition is quite unlike that of the blood, however. In particular, the fluid that enters the hindgut is typically far richer in KCl than the blood is—a consequence of the secretory mechanism of primary-urine formation.

The rate at which primary urine is formed and flows toward the hindgut in an insect's Malpighian tubules can be strikingly high relative to the total volume of the insect's body fluids. Current estimates, for example, indicate that in a female yellow-fever mosquito (*Aedes aegypti*), during an ordinary 24-h day when she has *not* taken a blood meal, the Malpighian tubules produce primary urine equivalent to 12 times her total body volume of extracellular fluid! If this sounds strange, it is really not; recall the very high rate at which human kidneys produce primary urine—also equivalent to about 12 times the entire extracellular fluid volume every day. In insects, as in vertebrates, most primary urine is reabsorbed (mostly by the hindgut) rather than being excreted. The overall process—a high rate of primary-urine formation followed by a high rate of reabsorption—gives the excretory system intimate access to the blood to carry out its regulatory functions, as already stressed.

A noteworthy aspect of the reabsorption process in insects is the reclamation of KCl. KCl must be secreted into the Malpighian tubules at a high rate to drive the production of primary urine, but it could not be lost from the body fluids at that rate. Instead, most KCl is reabsorbed back into the blood by the hindgut and recycled to produce more primary urine.

The hindgut modulates urine volume and composition in regulatory ways

Although the reabsorption of KCl and water from the primary urine sometimes starts in the lower parts of the Malpighian tubules, it occurs predominantly in the hindgut, especially in the rectum.

After urine is discharged from the Malpighian tubules, it flows with the feces through the hindgut, where its composition, concentration, and volume are modified, resulting in the definitive urine, which is excreted. The rectum (which is far better understood than the anterior hindgut) not only reabsorbs—and returns to the blood—most of the water, K^+ , Na^+ , and Cl^- introduced into the hindgut by the Malpighian tubules, but also often reabsorbs amino acids, acetate, and phosphate. The rectum also has some secretory functions. For example, H^+ is secreted from the blood into the urine in the rectum, and the resulting acidification contributes to the precipitation of uric acid and urates there.

Research has increasingly clarified that the insect rectum has impressive *regulatory* abilities. It can modify the volume, composition, and osmotic pressure of the urine in ways that help regulate the volume, composition, and osmotic pressure of the blood. The rectum adjusts the osmotic pressure of the urine by varying the relative rates of reabsorption of water and total solutes. It also adjusts the ionic composition of the urine. In one set of experiments, for example, fasting locusts were permitted to drink either tap water or a saline solution containing K^+ , Na^+ , Cl^- , and other ions. The rectum in the water-fed locusts reclaimed ions, returning them to the blood: It *lowered* ion concentrations in the urine, compared with those in the anterior-hindgut fluid. However, the rectum in the saline-fed locusts *raised* ion concentrations (Table 29.1). The saline-fed locusts also accumulated greater volumes of urine in the rectum, so that overall, the quantities of ions excreted in their urine were hundreds of times greater than those excreted by the water-fed animals. In this way the rectum played a major role in helping to regulate blood ion concentrations.

The study of the hormonal control of urine production in insects is a burgeoning field at present, in part because of the expectation that the next generation of controls for insect pests might include procedures that defeat vital control mechanisms. Numerous diuretic and antidiuretic neurohormones—which affect both Malpighian-tubule and rectal function—have been identified in various species.

PRODUCTION OF URINE HYPEROSMOTIC TO THE BLOOD Insects are one of the three major groups of animals that can produce urine that is hyperosmotic to their blood plasma (mammals and birds are the other two groups). When insects produce hyperosmotic urine (see page 742), the process of concentration usually occurs in the rectum. At least three different mechanisms of concentrating the urine have evolved.

In insects that have rectal pads or rectal papillae—such as cockroaches (*Periplaneta*), desert locusts (*Schistocerca*), and blowflies (*Calliphora*)—the urine in the rectal lumen is concentrated by *water reabsorption in excess of solute reabsorption*. This water reabsorption is highly intriguing because it can continue even when the osmotic pressure of the rectal contents has risen to be two or more times higher than the osmotic pressure of the blood bathing the rectum! The existence of this seemingly paradoxical process has been demonstrated in several ways. Perhaps the most compelling evidence comes from experiments in which the rectum has been filled with a *pure* solution of a solute (e.g., trehalose) that is neither reabsorbed nor secreted across the rectal wall. The *amount* of such a solute in the rectum is fixed during the course of an experiment.

TABLE 29.1 Average composition of the rectal fluid and other body fluids in locusts provided with tap water or a saline solution to drink

The animals (*Schistocerca gregaria*) were deprived of food.

Experimental treatment	Fluid	Osmotic pressure (mOsm)	Ion concentration (mM)		
			Cl^-	Na^+	K^+
Water-fed	Rectal fluid	820 ^a	5	1	22
	Anterior-hindgut fluid	420	93	20	139
	Blood	400	115	108	11
Saline-fed	Rectal fluid	1870	569	405	241
	Anterior-hindgut fluid	—	192	67	186
	Blood	520	163	158	19

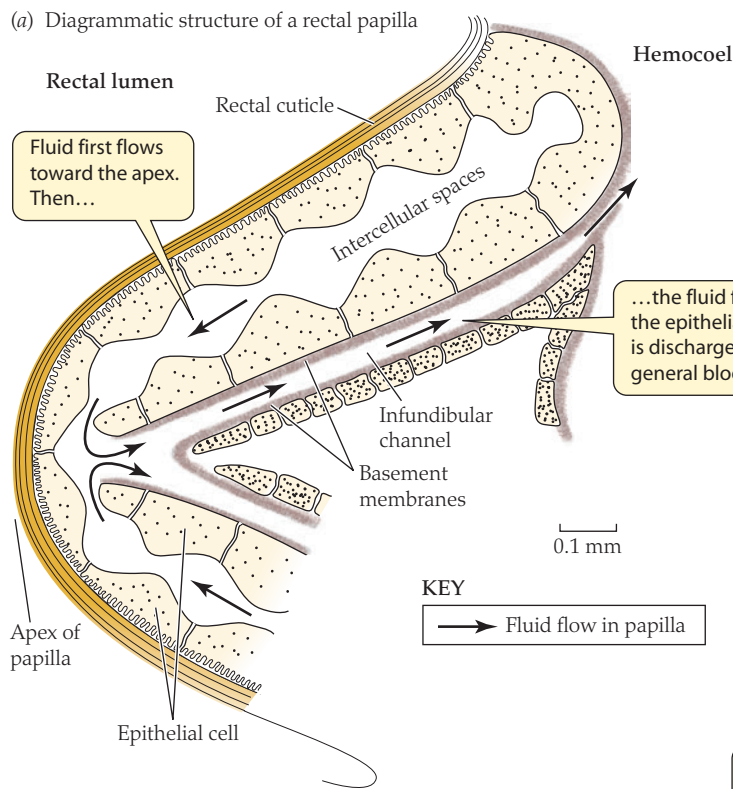

Source: After Phillips 1964.

^aThe high osmotic pressure in the scanty rectal fluid of water-fed animals is presumed to be caused by organic solutes.

When locusts (*Schistocerca*) were treated in this way, they reabsorbed water from their rectal contents and the rectal-fluid osmotic pressure rose. After the rectal fluid osmotic pressure had become twice as high as blood osmotic pressure, it continued to rise and reached nearly three times the blood osmotic pressure. Results of this sort show that the rectal wall can move water against large, opposing osmotic gradients between the rectal fluid on the inside and blood on the outside. The results show, moreover, that in the short term, this water reabsorption can occur even in the absence of simultaneous solute reabsorption.

The mechanism of such water reabsorption was mystifying for many years. Now, however, a consensus exists that it is a case of osmosis on a microscopic scale: *local osmosis*. The mechanism depends in part on a complex microarchitecture in the rectal pads or papillae. The details of structure and possibly of function vary from species to species. Here, we focus on the blowfly (*Calliphora*) as an example.

In the rectal papilla of a blowfly (Figure 29.23a), adjacent cells of the columnar epithelium are tightly joined on the side facing the rectal lumen and on the opposite (basal) side, but in between, the cells are separated by an elaborate network of minute channels and spaces, here termed the **intercellular spaces** (*intercellular*, “between cells”). The network of intercellular spaces communicates at the apex of the papilla with subepithelial spaces—here called **infundibular channels**—that are positioned under the basal side of the epithelial cell layer and connect with general blood spaces. Researchers hypothesize that the epithelial cells actively secrete solutes into the intercellular spaces, thereby rendering the fluid in the intercellular spaces strongly hyperosmotic to both the blood and the fluid in the rectal lumen (Figure 29.23b). Osmosis then carries water out of the rectal lumen into the intercellular spaces; that is, because of the *locally* high osmotic pressure in the intercellular spaces, water is osmotically withdrawn from the rectal fluid, even though the latter is thereby made increasingly hyperosmotic to the blood. Entry of water into the intercellular spaces adds volume to the fluid in the spaces and thereby causes fluid to flow in streams through

(b) Proposed processes of water absorption from the rectal lumen

the intercellular spaces toward the apex of the papilla and then through the infundibular channels toward the main blood cavity of the body (hemocoel). The fluid exiting the intercellular spaces is highly concentrated, but as it flows under the epithelial cells in the infundibular channels, solutes are believed to be actively or passively reabsorbed from the fluid into the cells across membranes poorly permeable to water, with two highly significant consequences. First, the fluid flowing through the infundibular channels is diluted, so that *in the end a fluid rich in water, rather than in solutes, is returned to the blood*—helping, for instance, to keep the osmotic pressure of the blood of a dehydrated insect from rising too high. Second, solutes are returned to the epithelial cells and thus can again be

FIGURE 29.23 The structure and function of the blowfly rectal papilla Each blowfly (*Calliphora erythrocephala*) has four rectal papillae. (a) The structure of a papilla, shown highly diagrammatically. The intercellular spaces, depicted for simplicity as a single broad cavity running through the epithelial cells, actually consist of a complex, interconnecting network of small channels and spaces *between* the epithelial cells. The papilla, being in the rectum, is covered with a thin cuticle; although this material is part of the exoskeleton, it is highly permeable to water and to solutes of small size. (b) The proposed mechanism of water absorption from the rectal lumen. In the short term, water absorption can occur without solute absorption from the rectum. (a after Gupta and Berridge 1966.)

secreted into the intercellular spaces, permitting continued osmotic water absorption from the rectal fluid without great need for new solutes from any source. The nature of the solutes involved is not fully resolved, although Na^+ , K^+ , and Cl^- are strongly implicated; some organic solutes also play roles.

A second type of concentrating mechanism has been described in insects that have a *cryptonephridial complex*. These insects include mealworms (larval *Tenebrio molitor*), certain larval and adult coleopterans (beetles), and certain larval lepidopterans (butterflies and moths). Mealworms can produce pellets of excrement (feces and urine combined) that are particularly concentrated relative to the excrement of other insects, and ostensibly dry. The structural basis for concentrating and drying the excrement is a specialized association between the Malpighian tubules and rectum: the

cryptonephridial complex. In this complex, the distal parts of the Malpighian tubules (the parts nearest the blind ends)—which float freely in the hemocoel of most insects—

are closely associated with the outer rectal wall, and these parts of the tubules and the rectum are together enclosed by a **perinephric membrane**, which separates them from the hemocoel. KCl and NaCl are actively transported from the blood into the lumen of each of these cryptonephric Malpighian tubules. In a marked departure from the usual condition in insects, however, water is prevented from entering the tubular fluid from the blood (probably by water-impermeability of the perinephric membrane). Because the fluid in the cryptonephric Malpighian tubules is formed by the inward secretion of ions without water, it has a dramatically high osmotic pressure (far higher than blood osmotic pressure), creating a gradient that favors osmotic reabsorption of water from the closely juxtaposed rectal lumen. One advantage for the insects probably lies in permitting uptake of water vapor from the air: an extremely unusual capability for animals. Mealworms and some of the other insects with a cryptonephridial complex are known to absorb water vapor from the atmosphere across their rectal linings. The high concentrations of salts in the tubular fluids of the cryptonephric Malpighian tubules—which give the fluids a low water vapor pressure—appear to be responsible (see page 708).

A third mechanism by which insects produce concentrated urine is known in the small subset of insects that live in saline waters. Some, at least, produce concentrated urine by secreting ions into

their rectal fluid. Living in salty water, they face the challenge of keeping their body fluids from becoming too concentrated in ions. They respond by secreting ions out of their blood in abundance.

SUMMARY Urine Formation in Insects

- Primary urine is introduced into the Malpighian tubules by a secretory process usually based on active transport of KCl into the tubular fluid. As the primary urine flows down the Malpighian tubules, it may be modified by reabsorption or secretion, but typically remains isosmotic to the blood.
- The Malpighian tubules empty into the hindgut at the junction of the midgut and hindgut.
- The rectum modifies the volume, composition, and osmotic pressure of the urine in ways that help regulate the volume, composition, and osmotic pressure of the blood. The production of hyposmotic urine occurs by reabsorption of solutes in excess of water. Two of the known mechanisms of producing hyperosmotic urine, on the other hand, enable insects to reabsorb water in excess of solutes. Some of the insects that produce hyperosmotic urine in this way do so by local osmosis and solute recycling in rectal pads or papillae; others do so with a cryptonephridial complex. Saline-water insects may form hyperosmotic urine by secretion of solutes into the rectum.

Nitrogen Disposition and Excretion

When animals catabolize organic molecules to release chemical energy, the atoms of the molecules appear in a variety of catabolic end products. During aerobic catabolism, the three most abundant atoms—carbon, hydrogen, and oxygen—appear in CO_2 and H_2O . The CO_2 is typically voided promptly into the environment across lungs, gills, or skin. The H_2O (metabolic water) simply becomes part of an animal's body water resources. The fourth most abundant atom is nitrogen, which is a characteristic constituent of proteins and nucleic acids. The disposition of nitrogen atoms from catabolism is not as simple as that of carbon, hydrogen, and oxygen. When getting rid of waste nitrogen is a problem, it is a *particular* problem for carnivorous species, which produce waste nitrogen at especially high rates because of their diets.

Some of the compounds into which animals incorporate nitrogen during catabolism are shown in **Figure 29.24**. Each of these nitrogenous end products has advantages and disadvantages for the animals that synthesize it. Some of the compounds are relatively cheap to make, for example, whereas others are low in toxicity. There is no single end product that is ideal in all ways. Thus animals have evolved a variety of strategies for dealing with the nitrogen atoms released from organic molecules by catabolism.

The relation between nitrogen excretion and kidney function varies from one group of animals to another. Mammals, birds, and nonavian reptiles exemplify one end of the spectrum: They excrete nitrogenous end products entirely in their urine. At the other end of the spectrum, there are many aquatic animals in which nitrogenous end products are excreted mainly across the gills or skin, and the kidneys play little or no role.

Animals often produce two or more nitrogenous end products. There are several reasons for this. One is that nitrogen is a major constituent of nucleic acids as well as proteins, and often the catabolic

FIGURE 29.24 Some nitrogenous compounds excreted by animals. Uric acid and guanine are purines. Allantoin and allantoic acid are poorly soluble breakdown products of uric acid. Trimethylamine oxide and its precursor, trimethylamine, are found in a variety of marine animals but do not occur in freshwater animals; both are highly soluble. Creatine and its internal anhydride, creatinine, occur as relatively minor excretory compounds in many vertebrates and some invertebrates. Some animals, mostly invertebrates, also lose significant amounts of amino acids to the environment.

pathways involved in breaking down nucleic acids produce a different nitrogenous end product than those responsible for breaking down proteins or amino acids. Humans and other primates, for example, synthesize uric acid from the nitrogen of nucleic-acid purines, but they synthesize principally urea from protein nitrogen.¹⁷ Protein catabolism dominates as a source of nitrogen. About 95% of waste nitrogen is from protein catabolism, and the products of protein catabolism therefore dominate.

When ammonia (NH_3) or the ammonium ion (NH_4^+) is the principal nitrogenous end product of an animal, the animal is described as **ammonotelic**. If urea is the principal nitrogenous end product, an animal is termed **ureotelic**. If uric acid is the principal end product, an animal is **uricotelic**.

Ammonotelism is the primitive state

Ammonia (NH_3) reacts with hydrogen ions to form the ammonium ion (NH_4^+). At the ordinary pH values of animal body fluids and tissues, this reaction is shifted strongly toward the formation of NH_4^+ . For simplicity, we use the word *ammonia* here to refer to either chemical form.

Ammonia is clearly the primitive nitrogenous end product of animals. Strong evidence for this view comes from the fact that the majority of today's marine invertebrates are ammonotelic.

¹⁷The affliction known as gout results from abnormal uric acid metabolism.

Ammonia is highly toxic. Among other effects, it can disrupt neuron function, the integrity of the blood–brain barrier, and gill permeability at low concentrations. Blood concentrations are ordinarily kept low: usually under 0.3 mM in vertebrates, for example.

Because of its toxicity, ammonia cannot ordinarily be allowed to accumulate in an animal's body. Thus, for an animal to be ammonotelic, it must have a means of unflinchingly voiding ammonia as rapidly as it is formed by catabolism. Aquatic animals can meet this challenge because of the abundance of water in which they live; often, much of the ammonia they produce is voided directly into the ambient water across their gills or other external body surfaces. Not only most marine invertebrates, but also most other water-breathing aquatic animals, are ammonotelic. Both freshwater and marine teleost fish are typically ammonotelic, and both aquatic tadpoles of amphibians and adult aquatic amphibians (e.g., mudpuppies) are ammonotelic. Ammonotelism, however, is unusual on land. A terrestrial animal is likely to depend on excretion in urine to rid itself of nitrogenous wastes. Urinary excretion of ammonia requires the excretion of a great deal of water.¹⁸ Because of this and because it is urgent for an animal to prevent accumulation of ammonia in its body, excretion of ammonia in the urine might sometimes require a terrestrial animal to void large amounts of water when water itself is in short supply.

Although ammonotelism is unusual on land, some *humidic* terrestrial animals are either ammonotelic or at least produce substantial quantities of ammonia. Some of the earliest studies on this phenomenon were carried out on terrestrial isopod crustaceans (e.g., pillbugs), which are ammonotelic. They void much of their ammonia into the atmosphere as NH₃ gas! In this way, they avoid use of water to get rid of ammonia. Many terrestrial snails, although not ammonotelic, void substantial NH₃ gas as well. In both isopods and snails, the fundamental reason for ammonia production may be that ammonia plays a role in the process of deposition of calcium carbonate in their exoskeleton or shell. Production of NH₃ gas is also known to occur in some land crabs and a few species of amphibious fish.

Ammonia is the cheapest nitrogenous end product to produce. This probably explains why ammonotelism is so common among aquatic animals, which can easily avoid problems caused by ammonia's toxicity. Ammonia is generally formed during the catabolism of proteins by way of reactions that have no ATP cost; some of these, termed *transamination* reactions, move amino groups to particular amino acids for which deamination enzymes exist. Then the latter amino acids are *deaminated* (see Figure 6.3b).

Urea is more costly to synthesize but less toxic than ammonia

Urea is highly soluble and generally diffuses readily across membranes. Although hardly benign in its effects on macromolecules, it is far less toxic than ammonia. In humans, blood concentrations are normally in the range of 3–7 mM, and much higher concentrations, although abnormal, can be tolerated. As discussed in Chapter 28, very high urea concentrations occur in marine elasmobranch fish (≥ 300 mM) and some other animals.

If urea is less toxic than ammonia, why are so many animals ammonotelic? There are probably several reasons. One, certainly,

is that urea is more costly to make than ammonia. The synthesis of each urea molecule requires the energy from four or five high-energy phosphate bonds (equivalent to that released by converting four or five ATP molecules to ADP).¹⁹ As is so often the case in biology, animals face trade-offs. Ammonia is toxic but cheap; urea is less toxic but more costly.

Most of the animals that routinely employ urea as their principal nitrogenous end product are terrestrial vertebrates. Adult terrestrial amphibians are predominantly ureotelic. All mammals are ureotelic, as are some turtles. Terrestrial invertebrates have more often evolved uricotelism; only some flatworms and earthworms are at times ureotelic. For reasons that remain baffling, some marine aquatic animals are ureotelic, including some small, planktonic crustaceans and some larval fish.

There is persuasive evidence that vertebrates adopted ureotelism when they emerged onto land. One line of supportive evidence is the fact that modern terrestrial amphibians are ureotelic, in contrast to freshwater fish, which are nearly always ammonotelic. Another line of evidence is that the tadpoles of amphibians are usually ammonotelic, but they express the enzymes for urea synthesis increasingly as they go through metamorphosis, eventually becoming ureotelic adults (Figure 29.25). For terrestrial animals that excrete nitrogenous wastes in their urine, the advantage of ureotelism is that urea excretion requires less water than ammonia excretion. This is a direct consequence of the lower toxicity of urea. Because urea is less toxic than ammonia, steady-state blood concentrations of urea in ureotelic vertebrates—expressed in molar terms—are typically *at least* 20 times higher than steady-state blood concentrations of ammonia in ammonotelic vertebrates. Thus, if a urea-producing and an ammonia-producing species were both to excrete identical quantities of nitrogen in their urine at identical urine-to-plasma ratios, the water cost for the urea-producing species would be no more than 1/40th of that for the ammonia-producing species.²⁰ These considerations have no significance for aquatic animals that void nitrogen across general body surfaces. The considerations have great significance, however, for animals on land that excrete nitrogen in urine.

Some animals employ ureotelism for functions other than the simple, routine excretion of nitrogen, meaning that the evolution of ureotelism cannot always be interpreted strictly in terms of waste processing. Three cases are worthy of note:

1. Some marine fish routinely accumulate urea as an osmolyte to aid osmoregulation in the ocean—notably marine elasmobranchs, holocephalans, and the coelacanth *Latimeria*. This use of urea is discussed at length in Chapter 28 (see page 731).
2. Some aquatic, ammonotelic vertebrates switch to producing urea during water crises. For example, lungfish of the genus *Protopterus* (see page 738) and some freshwater teleost species from stillwater environments switch from being ammonotelic to being ureotelic when confronted with drying of their habitat or other stresses. They then can

¹⁹Authorities differ in whether they estimate the cost to be four or five per molecule.

²⁰This is true because the urinary molar concentration of urea would be at least 20 times higher than that of ammonia, and each molecule of urea contains two atoms of nitrogen, rather than just one.

¹⁸This topic is discussed at greater length in the next section.

FIGURE 29.25 Bullfrogs shift from ammonotelism to ureotelism as they undergo metamorphosis Bullfrogs (*Lithobates catesbeianus*; until recently named *Rana catesbeiana*), which start life as aquatic tadpoles, metamorphose into semiterrestrial adults. Developmental biologists identify the successive stages of development using the stage numbers on the x axis. The activities (in the liver) of four enzymes of the metabolic pathway that synthesizes urea (the ornithine–urea cycle) are shown as functions of stage. The excretion of urea is also shown. (“Arginine synthetase” is now recognized to represent the activity of two enzymes that together produce arginine.) (After Brown and Cohen 1958.)

stop voiding urine and allow their nitrogenous waste to accumulate in their body fluids, a strategy that would be impossible if they were synthesizing highly toxic ammonia.

3. Recently it was discovered that when toadfish living in the ocean excrete urea, the urea interferes with the ability of predators to find the toadfish by chemosensory processes.

The most thoroughly known biochemical mechanism for the synthesis of urea from protein nitrogen—the mechanism used by all vertebrates and some invertebrates—is the **ornithine–urea cycle**, a set of biochemical reactions requiring five enzymes.²¹ In the ornithine–urea cycle, one of the nitrogen atoms incorporated

into urea originates from free ammonia derived from deamination reactions, especially deamination of glutamic acid. The second nitrogen incorporated into urea comes from the amino group of aspartic acid. Amino groups from most amino acids can make their way to glutamic acid or aspartic acid by transamination reactions. In vertebrates that synthesize urea, the liver is the one tissue that expresses the full suite of enzymes of the ornithine–urea cycle.

The earliest vertebrates probably had all the genes required for the ornithine–urea cycle (see Box 28.4). A current working hypothesis, therefore, is that all living vertebrates have the genes, and that the existence of a functioning ornithine–urea cycle in a species depends on whether the genes are expressed in the species. If the ability to synthesize urea is such a “readily available” option, it would help explain why ureotelism occurs in a notably scattered and wide variety of vertebrates (see the cladogram in Box Extension 28.4).

Uric acid and related compounds remove nitrogen from solution

An animal is classified as uricotelic if its primary nitrogenous end product is uric acid, the dihydrate of uric acid, urate salts, or a mix of these compounds, all of which are purines. These compounds all have low toxicities and solubilities. Uric acid itself is poorly soluble in water (0.4 mmole—65 mg—dissolves in a liter at 37°C). The urate salts, although more soluble than uric acid, also have very low solubilities in comparison with urea or ammonia. Because of their low solubilities, uric acid and urates remove nitrogen from solution, reducing the water costs of excretion; they can be excreted as semisolid pastes or even as dry pellets or powders.

Experiments have shown that a variety of cations—including Na^+ , K^+ , NH_4^+ , Ca^{2+} , and Mg^{2+} —can be incorporated into uric acid excrement in a poorly soluble state. Uncertainty exists over the chemical form assumed by these ions; they can be present as urate salts, but apparently they also can be bound in some manner to undissolved uric acid. Regardless, the cations are removed from solution, and this state can appreciably reduce the water demands of cation excretion. Calculations indicate, for example, that desert iguanas (*Dipsosaurus*) can void as much as 5000 milliequivalents of undissolved K^+ per liter of water in combination with uric acid—an effective concentration that is well above the highest K^+ concentration achieved by reptilian salt glands!

Focusing again on nitrogen, uric acid and urates not only permit nitrogen to be excreted with little water, but also have great advantages in times of water crisis when urine production is curtailed or stopped. If a ureotelic animal in water crisis stops producing urine, the urea concentration in its body fluids steadily rises because urea is so soluble that its solubility limits are never reached. This buildup cannot continue indefinitely because at high concentrations, urea becomes toxic. By contrast, if a uricotelic animal stops producing urine, uric acid and urates are deposited as precipitates within its body. Because the solubilities of these compounds are low, their concentrations in the body fluids cannot increase above low levels regardless of the amounts stored. Uric acid and urates, therefore, are suited to indefinite storage.

In addition to uric acid and urates, other purines or compounds derived from purines are sometimes employed as nitrogenous end products. The purine *guanine*—which is even less soluble than uric acid—is a primary nitrogenous end product in some

²¹The reactions are presented in any biochemistry text.

BOX 29.4 WHY ARE MAMMALS NOT URICOTELIC?

If birds, lizards, and snakes are uricotelic, why aren't mammals? An informed biologist knowing the patterns of nitrogen excretion in other animal groups, but knowing nothing about nitrogen excretion in mammals, would surely predict uricotelism in mammals, at least in desert species. Yet, without known exception, all mammals are ureotelic. We do not know the answer to this riddle. However, a point worth stressing is that mammals are able to do things with urea that are quite unique.

The mammalian kidney is in a class by itself in its ability to concentrate urea. The maximum U/P ratio for urea in mammalian urine is typically higher than that for any other solute and can greatly exceed the maximum osmotic U/P ratio—signifying that urea can

be concentrated to a much greater extent than solutes as a whole. In humans, for example, the maximum osmotic U/P ratio is about 4.2, and the maximum Cl^- U/P ratio is about 3.5, but the maximum urea U/P ratio is about 170. Many desert rodents can achieve urinary urea concentrations of 2.5–5.0 M, corresponding to 70–140 g of nitrogen per liter! Because the urinary urea concentrations achieved by mammals are much greater than those attained by other animals, the water losses obligated by nitrogen excretion in mammals are exceptionally low in comparison with other ureotelic groups. In fact, urinary nitrogen-to-water ratios attainable by desert rodents can equal or exceed those observed in some of the uricotelic vertebrates that void their uric acid in a relatively fluid mix

(e.g., certain birds). However, some birds and other reptiles that void uric acid in the form of relatively dry pellets achieve nitrogen-to-water ratios that are several times higher than the highest mammalian values.

Some researchers have argued that mammals have remained ureotelic because the elaborately developed countercurrent multiplication system of the mammalian kidney provides such great potential for concentrating urea that the selective advantage of uricotelism has been blunted. The reverse argument is that mammals for some reason were unable to evolve the biochemical and physiological attributes required for uricotelism. Being tied to ureotelism, so this argument goes, the mammals experienced great selective pressures to evolve exceptional urea-concentrating abilities.

animals. *Allantoin* and *allantoic acid*—compounds formed by the partial breakdown of uric acid—may also be primary nitrogenous end products; although more soluble than uric acid, they have low solubilities.

Uricotelism—or the production of other purines as principal nitrogenous end products—is the most common state in terrestrial animals. This is true even though uric acid probably requires considerably more energy per nitrogen atom for its synthesis than urea.²² Birds, lizards, and snakes are uricotelic (Box 29.4). (The white matter in bird droppings is uric acid.) Turtles that inhabit dry terrestrial habitats tend toward uricotelism. Most terrestrial invertebrates that live in the open air employ purines or purine derivatives as their primary nitrogenous end products. In most terrestrial insects, for example, the principal nitrogenous excretion is uric acid, allantoin, or allantoic acid. Spiders, scorpions, and certain ticks excrete mostly guanine. Temporary or permanent storage of purines has been observed in many insects and snails and in certain land crabs.

The biochemical pathways employed for the synthesis of uric acid or related compounds from protein nitrogen are complicated.²³ However, they in fact are only relatively small modifications of very ancient and universal pathways for the synthesis of the purine constituents of DNA and other purine-containing cellular macromolecules—helping to explain how uricotelism (or “purinotelism”) could have evolved independently in several phyla on land. The convergence of several terrestrial phyla on uricotelism testifies to the advantages of poorly soluble nitrogenous end products for terrestrial existence.

²²Although some biochemists calculate that the synthesis of uric acid from protein nitrogen costs about the same amount of ATP-bond energy per nitrogen atom as urea synthesis (2–2.5 high-energy phosphate bonds per atom), others calculate that each nitrogen atom costs as much as 6 high-energy phosphate bonds to be incorporated into uric acid. Regardless of that consideration, uric acid probably has a higher overall cost than urea in at least some animals because of extra processes that must be carried out to prevent it from precipitating prematurely.

²³These pathways are reviewed in biochemistry texts.

SUMMARY Nitrogen Disposition and Excretion

- Animals that synthesize ammonia or urea as their primary nitrogenous end product are termed, respectively, ammonotelic or ureotelic. Animals that synthesize mainly uric acid or urates are uricotelic.
- Ammonotelism is the primitive condition and is seen in most water-breathing aquatic animals. Ammonia has the advantage of costing no extra ATP to produce. It is toxic, however. Thus, for an animal to be ammonotelic, the animal must have a means to void ammonia reliably as fast as it is produced so that blood levels are kept low. Aquatic animals void ammonia into the ambient water across their gills or general body surfaces.
- Ureotelism is more costly than ammonotelism because producing urea has an ATP cost. Urea is far less toxic than ammonia, however. Ureotelism has evolved principally in certain groups of vertebrates, in which it usually serves one or more of three possible functions: reducing the water requirement of routine nitrogen excretion (e.g., terrestrial amphibians and mammals), adjusting the blood osmotic pressure in advantageous ways (e.g., elasmobranch fish), and detoxification of waste nitrogen during periods when water-stressed animals cease urine production.
- Although uricotelism is even more costly per nitrogen atom than ureotelism, uric acid and related compounds have the advantage that they are so poorly soluble that they are low in toxicity, can be excreted in little water, and can be accumulated in the body indefinitely. Most groups of terrestrial animals, including invertebrates (e.g., insects) and vertebrates (e.g., birds, lizards, and snakes), are uricotelic or produce predominantly other purines (e.g., guanine) or purine derivatives.

Study Questions

1. Considering the distal convoluted tubule of the amphibian nephron, explain how changes in the permeability of the tubule wall to water affect the amount of pure, osmotically free water excreted in the urine. Define what is meant by pure, osmotically free water.

2. Outline how the orientation of nephrons relative to each other imparts gross structure to the kidneys of mammals and birds.
3. If you were attempting to tell whether an animal produces its primary urine by ultrafiltration or secretion, what measurements would you make *on the primary urine*? If your measurements indicated that ultrafiltration might be occurring, what other types of measurements would you make to determine whether physical and physicochemical conditions favorable to ultrafiltration exist? Explain.
4. When researchers first proposed the countercurrent multiplication hypothesis for concentration of urine in the mammalian kidney, there was great resistance to its acceptance in certain quarters. The anatomist Ivar Sperber, whose comparative morphological studies originally helped draw attention to the loops of Henle, pointed out that there were certain rodents in which the anatomy of the kidney should make it relatively simple to sample blood from the hairpin bends of the vasa recta deep in the medulla. Samples of such blood were obtained, and the osmotic pressure of this blood proved to be far higher than the osmotic pressure of blood in the general circulation. This research convinced doubters of the validity of the countercurrent multiplication process. Why does blood at the hairpin bends of the vasa recta have a high osmotic pressure, and why would knowing its osmotic pressure in the cases described provide strong support for the countercurrent multiplication hypothesis?
5. Production of any sort of nitrogenous waste other than ammonia costs energy. Name at least three distinctly different advantages an animal might gain by investing in production of urea or uric acid.
6. Explain how primary urine is introduced into the Malpighian tubules of an insect.
7. The immediate effect of ADH on the renal tubules of frogs and mice is the same, yet when ADH is secreted, frogs produce urine that is approximately isosmotic to their blood plasma, whereas mice produce urine far more concentrated than their blood plasma. Explain this difference in terms of the factors affecting osmosis in the kidneys of frogs and mice.
8. Drugs that increase urine flow (diuretic drugs) are often employed in the treatment of hypertension (high blood pressure) or other disease states. Three physiological categories of such drugs are ones that (1) function as loop diuretics, (2) inhibit the action of aldosterone, and (3) block Na^+ channels in the collecting ducts. Explain why each of these categories would be expected to increase Na^+ excretion and urine flow. (Hint: Rereading the section on hormones at the end of Chapter 28 might prove helpful.)
9. In lab rats studied in a state of antidiuresis, the urea concentration and osmotic pressure in the inner-medullary collecting-duct fluid were about the same as the urea concentration and osmotic pressure in the inner-medullary interstitial fluid. However, the concentration of Na^+ in the collecting-duct fluid was only about one-eighth of the Na^+ concentration in the interstitial fluid, and the collecting-duct fluid was rich in K^+ even though the interstitial fluid contained hardly any K^+ . How are these results to be explained by the difference in concentrating mechanisms for urea and for inorganic ions?
10. In mammals, the kidneys are the only organs that regulate routine excretion of water, salts, and nitrogenous wastes from the blood. As logical as this may sound to us, it is unique among vertebrates. For each of the other groups of vertebrates, describe the functions of as many organs as you can—in addition to the kidneys—that participate in these processes. Consider the discussions of these groups of animals in Chapter 28 as well as in this chapter.
11. Whenever the concentrating ability of mammalian kidneys has been studied in relation to the lengths of the loops of Henle in various species, a clear correlation between the two has been found—indicating that loop length matters—but in addition, there has been a great deal of scatter in the data (e.g., see Figure 29.8).

Fifty years from now, physiologists will probably understand the mechanistic reasons *why* loop length is not a perfect predictor of concentrating ability. Suppose a government agency has decided to give you all the resources you need to study whatever you desire. As a brainstorming exercise, what specific aspects of mammalian kidney function other than loop length would you investigate to try to account better for differences among species in concentrating ability?

Water, Salts, and Excretion

at Work: Mammals of Deserts and Dry Savannas

In deserts, large herbivores such as the oryxes in this photograph are usually the equivalent of nomads, moving about to find moisture to survive. Similarly, in the dry savannas—the grassland plains—large herbivores often function as nomads or migrants. Conditions vary so much from time to time and from place to place in these arid zones that living in an invariant locale is often not a viable strategy. The same can be said for humans in a state of nature; most of the traditional cultures of the deserts and dry savannas were nomadic.

Our goal in this chapter is to explore how the oryxes and other species of sizable mammals—5 kg or larger in body weight—can live in hot deserts or dry-savanna ecosystems. One way to understand these mammals is to compare them with small species, so we will sometimes mention the kangaroo rats, gerbils, and other small mammals that coexist in arid habitats with the large species. However, the small mammals were discussed in Chapter 28, and we will not return to them here in any detail. The mammals of Africa will receive greatest emphasis because they form the most diverse and abundant set of large, arid-land mammals in the world today, and their diversity has drawn the interest of physiologists for decades.

Desert and Dry-Savanna Environments

Deserts and semideserts by most accountings cover about a third of the land on Earth. There is no uncomplicated way to define a desert. One of the simplest definitions is that a desert receives less than about 25 cm (10 inches) of precipitation per year, but this is an imperfect standard because there are regions that receive much more than that but are undoubtedly deserts. Following the lead of Imanuel Noy-Meir, most biologists prefer a definition that emphasizes two attributes of deserts that are of extreme importance for plants and animals. First, a **desert** is a place where precipitation is so low that *availability of water exerts a dominant controlling effect on biological processes*. Second, *when precipitation occurs in deserts, it comes in infrequent, largely unpredictable events*. Rains in deserts are highly irregular and unreliable in both time and space. One year may bring 5 times (or even 20 times) the rain of another. One 30-km² area may be drenched during a storm while a nearby area of similar size receives nothing, because rains in deserts are usually produced by isolated storms rather than broad fronts. Large herbivores must often conduct their lives in ways that—more than anything—are opportunistic, taking advantage of rain or moisture whenever and wherever it occurs.

The classic look of the **dry savannas** is of endless plains of grass with trees dotted here and there. Taking a big-picture view of Earth,

Oryxes are extreme examples of large mammals that can survive indefinitely in hot deserts without drinking water Physiologists are still learning how these animals orchestrate their water losses and gains to stay in water balance in such water-poor and thermally stressful places. The animals shown are gemsbok oryxes (*Oryx gazella*), often called simply gemsbok.

dry savannas are in many cases neighboring environments to deserts. Gradients of moisture often occur on continental scales of space, with moist forests in some regions, deserts in others, and dry savannas between the two—in intermediate regions where there is more moisture than in the deserts, but far less than in the forests. In dry savannas—as in deserts—water is a dominant controlling factor for biological processes. This is true in a somewhat different way than in deserts, however. Savannas usually have discrete rainy seasons interrupted by discrete rainless seasons. Because of the rainless season each year, although on an annual basis savannas receive more rain than deserts do and receive it more predictably, the plants and animals living in savannas must often endure profound drought for long lengths of time. The Serengeti plains of East Africa are examples of this second sort of water-controlled ecosystem. Routinely during the long dry season each year, no rain falls for 4–6 months; thus streams dry up, and soils become so parched that the grasses turn crisp and brown.

Deserts and dry savannas exist for several reasons. The single most important cause of desert and semidesert conditions on a planetary scale is the global pattern of air movements, whereby air warmed at the equator rises to high altitudes and displaces air at those altitudes in such a way that high-altitude air descends to Earth's surface somewhere else. Air at high altitudes, partly because it is cold (see Table 27.2), contains little moisture, even when saturated with water vapor. Thus, in regions where high-altitude air tends consistently to fall to low altitude, the land can become parched. The present global pattern is for high-altitude air to descend in two bands encircling the globe at latitudes roughly 30° north and 30° south of the equator. Most of the world's great deserts (see Figure 27.6)—including the largest, the Sahara—are products of this process. Another common but more localized cause of desert or savanna conditions is rain-shadowing caused by highlands. If a region's only reliable source of moisture is winds blowing in from the ocean, and if intervening highlands force the winds to rise—so that the air cools and its moisture condenses to form rain or snow—the winds may have little moisture left by the time they blow into the region of interest. Near Los Angeles, for example, the coastal mountains force the prevailing winds blowing east from the Pacific Ocean to rise, causing mountain rain. Seen from above, the land still farther east, the Mojave Desert, looks much like a dry, sandy-colored shadow cast by the mountains.

The existence and extent of deserts and dry savannas, we see, often depend on nothing more permanent than the gossamer movements of air. Accordingly, over the long reaches of geological time, deserts and savannas have come and gone as patterns of air movement have changed. The modern Sahara Desert, for example, has existed for less than 6000 years. Nonetheless, desert conditions have come and gone in North Africa for at least 7 million years. Currently the Sahara Desert is tending to expand north and south. Thus, for example, a recent consensus report by climate scientists concluded that the southern reaches of Europe (e.g., Italy and southern Spain) are likely to become far drier over the upcoming decades.

Despite the variability just discussed, deserts and savannas have probably always existed somewhere. Thus they have long presented plants and animals with special challenges, and they have long presented opportunities for species that are able to make do with little water and tap the meager water resources available.

The Relations of Animals to Water

Large mammals have both disadvantages and advantages compared with small mammals in hot deserts and dry savannas. Many of the most apparent disadvantages of large size are behavioral. Large mammals cannot take shelter underground by digging burrows, as small rodents do, and they are less likely than small species to find adequate shade or other protective microhabitats on the surface of the ground. In hot environments, large mammals therefore confront the heat more directly than small mammals do, and the heat stress they experience can place demands on their water resources. In contrast to the *behavioral* limitations they face, however, large mammals are often in a distinctly more favorable *physiological* position than small mammals are.

Large body size is a physiological advantage in terms of water costs

To explore the physiological implications of body size, let's compare mammals of large and small size while making two simplifying assumptions.¹ Let's assume that the animals *thermoregulate physiologically* by use of evaporative cooling and that they are actually confronted with stressfully hot conditions. For an animal to thermoregulate under such circumstances, it must evaporate water to void from its body not only the *exogenous* heat that enters its body from the hot environment but also the *endogenous* heat produced by its own metabolism. Large body size is an advantage from both of these perspectives.

Speaking of exogenous heat inputs, large mammals enjoy an advantage because they have less body-surface area per unit of weight than small mammals do (their surface-to-volume ratios are lower; see Equation 7.6). When the air temperature is higher than body temperature and the sun is beating down, environmental heat enters an animal's body across its body surfaces. Because large mammals have relatively little body-surface area per unit of weight, they tend to experience less heat entry per unit of weight over a period of time than small mammals do. Thus their water costs to void the incoming heat are lower per unit of weight.

Speaking of endogenous heat inputs, large mammals are in a more favorable position than small ones because of the allometric relation between metabolic rate and body size. Large mammals tend to have far lower weight-specific metabolic rates than small mammals (see Figure 7.9). Thus their rates of endogenous heat production per unit of body weight are relatively low, and their weight-specific water costs to void endogenously produced heat are also low.

Quantitatively, the physiological advantages of large size are dramatic. In the 1930s, D. B. Dill (1891–1986)—a pioneer in the study of exercise and heat—undertook famous “walks in the desert” that provided the very first quantitative information on the water costs of mammalian exercise under hot conditions. He himself was one of the human subjects, and he took along with him both dogs and burros. Together, man and beast trekked under the searing sun in the Nevada desert, sweating or panting to thermoregulate; and as they walked, Dill measured their rates of dehydration. Knut Schmidt-Nielsen (1915–2007), another pioneer in desert research, used fundamental principles and Dill's data to construct the classic line shown in red in [Figure 30.1](#). Later, Dill and collaborators gathered more data of a similar sort on burros and high-school students in

¹These assumptions are not realistic in all cases but bring out important principles.

FIGURE 30.1 The rate of evaporative water loss experienced by mammals exposed to heat stress depends strongly on their body size

The graph shows weight-specific rates of evaporative water loss for exercising animals (red) and resting animals (blue) directly exposed to hot conditions. The resting humans and burros were studied while resting in the desert; the resting mice and rats were studied in a laboratory chamber maintained at an air temperature of 40°C (104°F). The equation for the red line is $E = 6.03W^{-0.33}$, where E is rate of evaporative water loss in percentage of body weight per hour and W is body weight in kilograms. The equation for the blue line is $E = 1.38W^{-0.21}$. The two species of kangaroo rats included in the resting studies are Merriam's kangaroo rats (*Dipodomys merriami*) and desert kangaroo rats (abbreviated "desert k-rats"; *D. deserti*), weighing 34 g and 114 g, respectively. (After Schmidt-Nielsen 1954; Sohlt et al. 1977.)

the Colorado desert, accounting (along with Dill's original data) for the five data points plotted in red on the figure.

The red line shows that there is a very strong relation between body size and the water cost of thermoregulation when mammals are active in the daytime desert. The line applies specifically to mammals that thermoregulate at a body temperature of about 37°C as they exercise.² To interpret the line, it is important to recognize that the rate of evaporation is plotted in *weight-specific* terms on the y axis. Specifically, the rate of evaporation is expressed as grams of water lost from the body per 100 grams of body weight during an hour; that is, *percentage of body weight lost per hour*. As you can see, the water cost of being active in the daytime desert is predicted to *soar* at small body sizes.

According to the red line, if a 100-g rat were to walk along under the desert sun and thermoregulate by evaporation of water, its water cost would be almost 13% of its body weight *per hour*. If a 25-g mouse were to do so, its water cost would be about 20% per hour. Dehydration ordinarily becomes lethal under hot conditions when 10–15% of body weight has been lost. Thus the rat walking along under the sun would die of dehydration after about an hour, and the mouse would die after a half hour! In other words, from what we know, it would be *impossible* for rat- and mouse-size mammals to lead fully exposed, active lives in the daytime desert. Of course, rats and mice have never been actually tested to see if these predictions hold true for animals walking under the desert sun. However, the blue line in Figure 30.1 shows actual data for four species of rats and mice—as well as burros and humans—that were studied while resting under milder heat-stress conditions. These data verify that water costs rise steeply at body sizes as small as those of rats and mice. From this perspective, it is indeed fortunate that small mammals can readily escape the full intensity of the daytime desert heat by burrowing and other *behavioral* means.

Physiologically, small mammals are ill-equipped to face the full brunt of desert conditions.

Facing the full brunt of desert conditions, however, is exactly what large desert mammals must often do. And fortunately, as Figure 30.1 shows, large mammals are in a far better physiological position to do so than small mammals. Based on the red line, a 100-kg mammal, such as a small adult burro, can thermoregulate while exercising in the heat of the desert day at a water cost of just 1.3% of its body weight per hour, and a 400-kg mammal, such as an adult dromedary camel, can do so at a water cost of only 0.8% per hour. The water costs of large mammals in the desert are still lower when the animals are not exercising, as shown by the blue line. Large size, in brief, is a great advantage physiologically when animals directly confront hot conditions. This is not to say that all large mammals can solve the problems they face in deserts by the simple evaporation of water; for animals that live where water is almost impossible to find, even a loss as low as 0.8% per hour during midday hours would become life-threatening within a few days. We will see later in this chapter that animals such as oryxes and camels have evolved specific adaptations that enable them to reduce water costs to levels far below the ordinary costs associated with their body sizes.

Coexisting species are diverse in their relations to drinking water

One might imagine that all large species of mammals that have long histories in arid environments would have evolved minimal water requirements. That is not the case, however. Among the species that are common in dry, hot places, some are classified as **drinking-water-independent** because they are able to remain healthy for many days or weeks without access to drinking water. Although most of these animals must drink on occasion, some species may be literally independent of drinking water and *never* need to drink. However, other coexisting species are classified as **drinking-water-dependent** because they must drink each day, or at least every other day.

²The humans, dogs, and burros used to construct the line in fact thermoregulate in approximately this way, although not all species do.

FIGURE 30.2 Common wildebeests are drinking-water-dependent antelopes that seek shade. Also called blue wildebeests, common wildebeests (*Connochaetes taurinus*) weigh about 200 kg as adults. They seek shade when it is available, as under the acacia tree in the photograph on the right.

Whether a particular species falls into the drinking-water-independent or the drinking-water-dependent category depends in part on the severity of conditions. A species that is independent of drinking water in the cool seasons of the year might, for example, become dependent in the hot seasons. Despite such ambiguities, the distinction between drinking-water-independent and drinking-water-dependent species is a useful organizing principle for discussing large desert and dry-savanna herbivores.

An outstanding example of coexisting drinking-water-independent and drinking-water-dependent species is provided by the fabled herds of herbivores in the Serengeti ecosystem and other similar ecosystems in East Africa and South Africa. Two of the most prominent drinking-water-dependent species in the Serengeti are wildebeests and zebras.³ During the hot seasons of the year, they must drink every day or every other day. This means, in effect, that

³The species discussed in this paragraph are the common or blue wildebeest (*Connochaetes taurinus*), the plains or Burchell's zebra (*Equus burchelli*), the common eland (*Tragelaphus oryx*; also called *Taurotragus oryx*), Grant's gazelle (*Gazella granti*), and Kirk's dik-dik (*Madoqua kirkii*).

they cannot wander more than about 25 km (15 miles) from standing water. Species that often coexist with wildebeests and zebras, but are drinking-water-independent, include Grant's gazelle, the common eland, and the dik-dik (dwarf antelope). These animals are able to travel far from standing water (because they need not return to it every day), and in that way they gain access to food resources that are unavailable to the drinking-water-dependent species. On even just modestly hot days in areas where trees are found, wildebeests seek shade in the heat of the day (Figure 30.2), whereas Grant's gazelles on such days are indifferent to sun or shade (Figure 30.3). This contrast in shade-seeking behavior correlates with the water physiology of the two species: The species that dehydrates more readily in the absence of drinking water also exploits shade more readily when shade is available.

The most dramatic manifestation of the difference between drinking-water-independent and drinking-water-dependent species in the Serengeti ecosystem is the differential participation of the two categories of animals in the annual migration. The annual migration in the Serengeti is itself perhaps the most dramatic

FIGURE 30.3 Grant's gazelles are drinking-water-independent antelopes noted for their indifference to sun or shade. These gazelles (*Gazella granti*) weigh about 50 kg as adults. Grant's gazelles are one of the species often reputed by naturalists to be able to live indefinitely without drinking water in the dry savannas and deserts.

KEY

- Wildebeests and zebras
- Nonmigratory drinking-water-independent species of herbivores

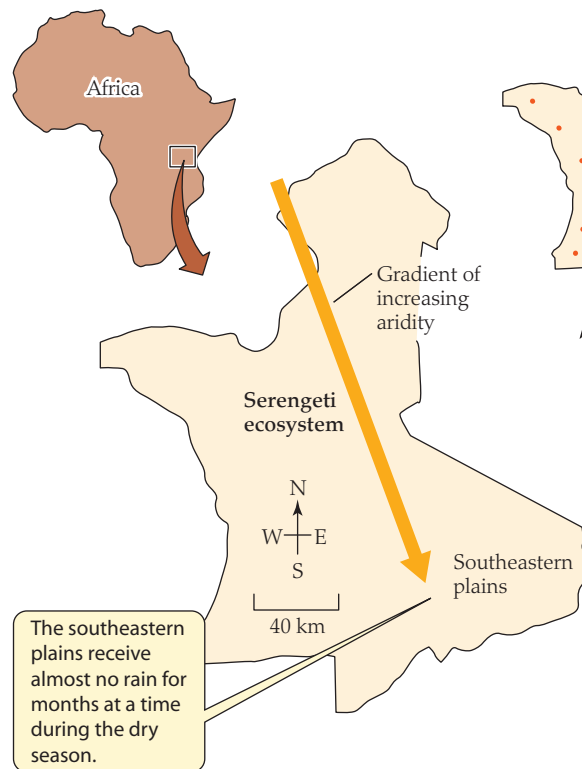

FIGURE 30.4 The annual migration in the Serengeti ecosystem. Driven by seasonal changes of water availability, the drinking-water-dependent wildebeests and zebras migrate from the northwest in the dry season (a) to the southeast in the rainy season (b,c) and back again (d,e), whereas most drinking-water-independent species adjust only in much more subtle ways to the seasonal rhythm of dry and rainy seasons. The Serengeti ecosystem as mapped here includes not just Serengeti National Park but also other surrounding conservation areas. The general trend is for the land to receive less and less rain per year as one moves from the northwest to the southeast.

illustration in today's world of the way water can exert a dominant controlling effect on biological processes in an ecosystem.⁴

In the Serengeti, there is a gradient of decreasing moisture availability (increasing aridity) from the northwest to the southeast because of the positions of mountains and highlands, the directions of winds, and the courses followed by rivers; total annual rainfall in the northwest (~110 cm/year) is about twice that in the southeast (~50 cm/year). In the rainy season, enough rain falls everywhere for lush growth of grasses. However, during the long dry season between June and November, the southeastern plains typically receive almost no rain. As the dry season progresses, streams and rivers in the southeast first stop flowing, and they become nothing but a series of puddles and ponds. Then even the puddles and ponds dry up. The soil becomes parched, and the grasses turn brown and brittle. These seasonal patterns set the stage for the annual migration.

Not all species of large herbivores participate in the migration. In fact, most of the drinking-water-independent species do not. Grant's gazelles, elands, dik-diks, and most other drinking-water-independent species simply "stay put," even as the thronging herds of migrating animals move through. The most abundant migratory species is the wildebeest, which in recent times has numbered about 1 million. Another highly visible migratory species is the zebra. Both the wildebeest and zebra are drinking-water-dependent. They spend the dry season in the far northwest (Figure 30.4a). Then, as the rainy season starts in November or December, they move on a broad front from the northwest toward the southeastern plains

(Figure 30.4b). While the rains fall in the southeast (Figure 30.4c), they find water and lush grass there. However, after the rains stop in the southeast during the following May or June, they must get out of the area. First they move west (Figure 30.4d), and then—as the landscape becomes ever drier—they move in thundering herds back to the far northwest (Figure 30.4e), where they have the best chance of finding the water they require during the season of little rain. As we discussed in Chapter 6 (see page 135), scientists have only hypotheses—not certain knowledge—about why wildebeests and zebras move from the northwest to the southeast when the rainy season arrives. However, there can be no doubt why these animals leave the southeast when the rains stop: They need to drink each day, and doing so in the southeast becomes impossible. Meanwhile, drinking-water-independent species are free to stay put or make just relatively subtle adjustments to the strong seasonality of water availability.

Although the Serengeti migration seems almost unique today, it was not unique primordially. Migratory herds evolved in other settings as well. For example, wildebeests in the large Kalahari ecosystem at the border of Botswana and South Africa used to migrate in much the same pattern as those in the Serengeti. Most of these other migrations have been ended by human intervention. The Kalahari migration, for instance, was disrupted by fences and

⁴Recall Imanuel Noy-Meir's famous definition of a desert, mentioned at the start of this chapter.

the installation of wells, which the wildebeests congregate around rather than migrating to seek water.

Carnivorous mammals such as lions and cheetahs are generally assumed (on the basis of little evidence) to achieve water balance without having to drink much (if at all) because of the high water content of their foods. Some predators in the Serengeti are indifferent to the migration, whereas others follow the prey animals.

Water conflicts threaten animals and people

Water conflicts seem to be almost inevitable, as well as intrinsically ominous, in ecosystems where water exerts dominant controlling effects on biological processes. The conflicts that presently exist are worth noting because they threaten the future existence of the species and systems of life we are discussing.

One sort of water conflict is that between the water needs of desert and dry-savanna ecosystems and the water claims of human enterprises outside the ecosystems. In the United States, burgeoning cities in arid parts of the West and equally burgeoning demands for agricultural irrigation water have led to the draining and diversion of many of the rivers that once flowed through the western deserts and savanna-like prairies. A dramatic example is provided by the Colorado River, which is tapped for so many human uses as it flows from the Rocky Mountains to the Sea of Cortez (Gulf of California) that in many years it now runs out of water before reaching its ancient destination and dries up in the desert. Near the northern boundary of the Serengeti ecosystem, several actual or proposed human ventures pose threats of water conflict with the wildlife. The drinking-water-dependent species in the ecosystem, as we have seen, rely on a dependable supply of drinking water in the northwest to survive the dry season. The sufficiency of this supply is already less than fully adequate; during drought years, 20–30% of the wildebeest have been known to die. The principal reliable water source in the northwest is the Mara River, which brings water into the Serengeti ecosystem from forested highlands farther north. Deforestation of the highlands, diversion of river flow for irrigation uses, and diversion for hydroelectric power production have been proposed. All could create water conflicts with the wild animals in their dry-season refuge, potentially disrupting the migration and the entire Serengeti ecosystem.

Another major sort of water conflict arises from the traditional lifestyles of indigenous peoples living within desert and dry-savanna ecosystems. Throughout the world, the traditional way of life for hundreds of cultural groups in such places was nomadism. The indigenous people survived on very small amounts of water compared with modern urban water usage (Table 30.1), and they obtained the water they needed by moving with the rains. As notions of private land ownership spread around the world in the last few centuries, such ways of life became threatened or were eliminated because private land ownership is not readily compatible with nomadism; a nomad today would be encroaching on one piece of private property after another. Thus, as we look at a modern-day Maasai (Figure 30.5) or modern-day representative of any other nomadic group, we see two things. First we are reminded of the peoples—not just the wild animals—that lived for millennia in the deserts and dry savannas, integrated with these places in their natural state. Second, we see the troubled ending of a way of life as modern governments impose changed relationships to the land and, importantly, to water. Many nomadic peoples have been

FIGURE 30.5 A Maasai youth of college age He is a member of the current generation of a people who until recent times were nomadic in the dry savannas of East Africa.

settled on their own private parcels of land, but in the deserts and dry savannas, a single parcel is unlikely to provide adequate water through all years and all seasons; the people used to be nomads precisely because movement was necessary.

A debate that today has reached its time of ultimate resolution is whether some nomadic cultures should be given a chance to continue by protecting large tracts of land for nomadic use or even by assimilating the people into parks now reserved exclusively for wild animals. The challenges are particularly acute for the herding cultures, whose herds of cattle or goats traditionally provided them with a way to glean the essentials of life from the arid land, but today greatly magnify water conflicts. Protected parks for wild animals in deserts and dry savannas have nearly always had their borders set to include the most reliable water sources. When the herds kept by nomadic peoples are banned from the parks, the herds are kept

TABLE 30.1 Water use by people in four sorts of communities in Arabia

People in indigenous desert settlements use one-tenth the water of people in modern towns. The figures are for all domestic water use, including drinking, washing, bathing, and other water demands.

Type of community	Domestic water use per person (L/day)
Modern Arabian town without major industry ^a	240
Traditional agricultural village	120
Small desert settlement with supply by government water truck	80
Small desert settlement with traditional water supply	28

^aNew York City has a similar usage rate.

from the most dependable places to drink, but when the herds are let into the parks, they compete with the wild animals for water.

All species of large herbivores require considerable amounts of preformed water

Let's now take a more quantitative approach to understanding the water physiology of oryxes, gazelles, wildebeests, and the other large wild herbivores of deserts and dry savannas. Recall that under many conditions, kangaroo rats and other small desert rodents get well over half their water as metabolic water; at 25°C, for example, up to 90% of a kangaroo rat's water needs are met by metabolic water (see Figure 28.24). In sharp contrast, *all the species of large herbivores of deserts and dry savannas acquire most of their water as preformed water*.

To see this more clearly, let's consider the water budgets of two very different mammals of similar body size: the highly drinking-water-dependent common wildebeest and the highly drinking-water-independent beisa oryx. These animals were studied under two sets of conditions. The first set of conditions was designed to be about as mild as the animals would ever experience in nature; the environmental temperature was kept constantly at about 22°C. The second set of conditions was intended to simulate more closely the high water stresses the animals sometimes encounter; during each 24-h day, the temperature was raised to 40°C (104°F) (simulating daytime heat) for 12 h and lowered to 22°C (simulating night) for the other 12 h. Under both sets of conditions, the animals were gradually given less and less preformed water per day until they reached the minimum they required to maintain health. They were then maintained on that minimum for 2 weeks so that their water budgets could be studied.

The results (Figure 30.6) reveal that the drinking-water-dependent wildebeest has a far greater total water need, and a far greater need for preformed water, than the drinking-water-independent oryx when both species are studied side by side under identical conditions. Physiologically, the two species are dramatically different.

A second major insight revealed by the results, however, is that even the oryx—which is famous for being one of the most drinking-water-independent of all large mammals—requires considerable quantities of preformed water to stay in water balance. Metabolic water met only about 20% of the oryx's total water need under both sets of conditions (see Figure 30.6b). Preformed water, therefore, had to meet about 80% of its need. How is it possible for a species to be drinking-water-independent yet require preformed water to meet much of its daily water requirement? The answer is that the oryx must meet much of its daily water need using preformed water *in its foods*.

In their water budgets, the wildebeest and oryx are quite typical of the large herbivores that live in deserts and dry savannas. Keeping the data on the wildebeest and oryx in mind (see Figure 30.6), we can make the following key points about the large herbivores as a group:

- All the species of large herbivores depend more on preformed water than on metabolic water to meet their water needs.
- Drinking-water-dependent species cannot get all the preformed water they need from their foods, either because they need more preformed water than available foods could ever provide or because they are ineffective in selecting and processing foods to maximize their acquisition of preformed

(a) Water losses

(b) Water gains

FIGURE 30.6 Water budgets of wildebeests and oryxes The wildebeests (*Connochaetes taurinus*) that were studied averaged 160 kg in body weight; the oryxes (*Oryx beisa*) were about the same weight, averaging 100 kg. The two species were studied in identical chambers that permitted their water losses (a) and gains (b) to be quantified. During some experiments (left) the air temperature was a constant 22°C. During others (right) the air temperature was 22°C for half of each 24-h day and 40°C for the other half. The animals had been acclimated to water restriction before the start of these measurements and were maintained on water restriction throughout the study. (After Taylor 1968, 1970.)

water. Therefore, they have to drink each day for their total intake of preformed water to be adequate to keep them healthy.

- Drinking-water-independent species, in contrast, can get all the preformed water they need to stay healthy—for many days in a row—from their foods. This is why they are classed as drinking-water-independent; it is why they do not require drinking water very often. This said, it is important to note that obtaining adequate preformed water from foods is far from simple, as we will soon see, because the foods available in deserts and dry savannas are often parched.

- Most drinking-water-independent species in fact need to drink occasionally during the hot-dry seasons of the year. Although the preformed water they get from their foods is *almost* enough to meet their total need for preformed water, it is not *fully* adequate. Thus, when they do not drink on a given day, they become a bit dehydrated. They become a bit more dehydrated the next day, and so forth, until ultimately—after a week or two (or longer)—they need to find drinking water.
- A few drinking-water-independent species are believed to be able to meet their entire need for preformed water from the preformed water in their foods even in the hot-dry seasons of the year, meaning that they need never drink. The oryx and eland are often cited as examples. Field biologists report that these species are never observed to drink in water-poor regions. Moreover, physiological data (which we will soon discuss) make it plausible to believe that these animals acquire enough preformed water from their foods that they never require drinking water.

Water and food resources in the deserts and dry savannas are often complex

Now that we have addressed the needs of large herbivores for preformed water in drink or food, a next logical step is to consider the nature of the drinking-water and food resources available to them. These resources are often far more complex in their properties than meets the eye.

One complexity in both deserts and dry savannas is that *when standing water is found, it is often salty water*. Recent measurements have revealed, for example, that in the central and southeastern Serengeti ecosystem, salinities of 5–15 g/kg are common in the headwaters of major rivers, and salinities of 20–30 g/kg (approaching equality with seawater) are common in stagnant pools or landlocked lakes. Not all Serengeti waters are this salty; some have salinities lower than 1 g/kg. Nonetheless, one cannot help but be impressed with how salty the waters can be in this benign-looking grassland ecosystem. Some investigators postulate, in fact, that the immediate stimulus for the migrating herds to leave the southeast Serengeti at the end of the rainy season is the increasing salinity of the drinking water as the landscape dries.

Why are waters in deserts and dry savannas so often salty? Briefly speaking, soils in arid regions are commonly salty, and the waters become salty by dissolving salts out of the soils. A key reason the soils are salty is that they get so little rain that they are rarely thoroughly flushed with water. Typically, each rain brings a trace of salt with it.⁵ When the rain hits the ground in arid regions, it soaks in to only a shallow depth and evaporates. Rain after rain causes salts to build up incrementally in the upper layers of the soil. These salts then dissolve into any pools of water that form on top of the soil, making the water salty until it itself evaporates, leaving the salts behind once more. This process is accentuated in low places where rain tends to settle in pools or flow in temporary streams. In such places, particularly large amounts of water accumulate after each rain and leave particularly large quantities of salts behind after evaporating.

⁵Aerosolized seawater can be detected in tiny amounts in the atmosphere hundreds of miles inland from the oceans, for example. The salts dissolve in cloud droplets and are carried to Earth in rain.

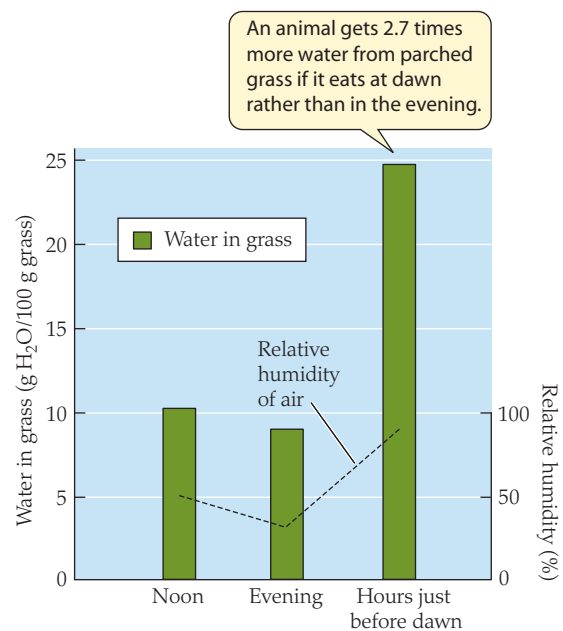

FIGURE 30.7 The moisture content of “dry” grass varies with time of day or night. Data were gathered on dead, brown blades of the perennial desert grass *Stipagrostis uniplumus* in the Namib Desert. The water content of the grass is highest near dawn, when the relative humidity is highest. (After Louw 1972.)

When animals find salty water to drink, their kidneys must be able to excrete each ion in the water at a higher concentration than in the water itself if the animals are to gain H₂O by drinking the water (see page 709). Thus the evolution of kidneys with exceptional concentrating abilities has been important for desert and savanna mammals *both* because a high concentrating ability allows ordinary soluble wastes to be excreted with relatively little water *and* because it permits animals to gain H₂O from saltier water sources than would otherwise be acceptable. Despite kidney specializations, when drinking waters approach half the concentration of seawater, they cease being useful H₂O sources for some of the species of mammals that are native to the deserts and dry savannas.

A second important complexity of water and food resources in deserts and dry savannas is that *in dry seasons, the leaves of plants often undergo large and rapid swings in their content of preformed water because of equilibration with the humidity of the air*. When this phenomenon was first reported about 40 years ago, it seemed that it might be merely a footnote in the biology of a few species. By now, however, desert biologists recognize the phenomenon as being often of extreme significance in the water biology of large herbivores. **Figure 30.7** shows how a perennial grass that is a favored food of herbivores varies in its moisture content because of equilibration with changing atmospheric humidity between midday, evening, and the dark hours before dawn in the Namib Desert. The measurements were made in the dry season, when the blades of the grass were dead and brown. Although ostensibly “dry” all the time, dead grass blades quickly equilibrate with changes in atmospheric humidity and have a far higher water content at the end of the night than at midday or evening. Accordingly, animals can increase their input of preformed water by eating preferentially in the hours around dawn, and research has shown that many species do.

A third aspect of the complexity of water and food resources has both obvious and less obvious aspects. In deserts and dry savannas, *both the growth and the nutritional composition of plants tend to be highly*

FIGURE 30.8 The nutritional content of some plants varies with rainy and dry seasons The percentage of protein in two species of perennial grasses (*Eragrostis lehmanniana* and *Stipagrostis obtusa*) eaten by wildebeests and oryxes was measured throughout the year in the southern Kalahari Desert ecosystem. (After Lovegrove 1993.)

correlated with changes in water availability. The effects of rainfall on plant growth are obvious: In deserts, where rainfall occurs irregularly and unpredictably, plant growth is likewise irregular and unpredictable. In savannas, plant growth waxes in the wet season and wanes in the dry season. What is not obvious is that some plants vary markedly in their content of nutritionally important materials as rains come and go. Certain of the important perennial grasses in the Kalahari Desert ecosystem, for example, vary dramatically in their protein content between the wet and dry seasons (Figure 30.8).⁶ A recent study of grasses in a hyperarid Arabian desert showed that protein content (computed relative to plant dry weight) falls exponentially during long periods of drought, from about 9% in the early weeks of drought (just after the cessation of rain) to 5% a year later. After long periods of drought, the concentrations of phosphorus, copper, and other minerals are sometimes too low in desert plants to meet the nutritional needs of herbivores.

A final aspect of the complexity of water and food resources is the formation of fog and the deposition of fog water on plants and other objects. Fog and fog water are potentially significant sources of water in deserts or savannas located within about 80 km of sea-coasts, particularly coasts where—because of upwelling or other oceanographic processes—there is a narrow band of cold seawater along the shore. Fogs often recur so frequently in such places that they can make a major contribution to the ecosystem water budget. Although several mechanisms of fog formation are likely, the most common is that warm moist air blowing landward from the open ocean is cooled just before making landfall by passing across the cold coastal band of water, and this cooling of the air causes its saturation vapor pressure to decline (see Table 27.2), forcing water out of the vapor state to form fog droplets. In hyperarid coastal regions that have frequent fogs—such as parts of the deserts in Namibia, Chile, and Oman—there is so little rainfall and so much fog that plants may receive several times more water by deposition of fog water on their surfaces than they receive from rain! Some desert arthropods, such as certain beetles and scorpions, are specialists in gathering

FIGURE 30.9 The desert beetle *Onymacris unguicularis* collects water from fog in the Namib Desert When fog rolls in from the sea, as it does often because of local conditions, the beetle goes to the crests of sand dunes and positions itself, as shown, in a “fog-basking” stance, in which its broad dorsal surface faces into the fog-laden sea-breeze. As the fog water accumulates on the beetle’s body, the water runs down to the beetle’s mouth.

the fog water (Figure 30.9). For the large desert herbivores that are our focus in this chapter, the effects of fog are more indirect: Fogs provide water to the plants that these herbivores eat. This input of water not only increases the water content of the plants but helps maintain plant health, so that—for example—plant protein stays higher than it otherwise would, making the plants more nutritious.

The Dramatic Adaptations of Particular Species

For the most part, the physiologists who have made the effort to study the large mammals of deserts and dry savannas have been water-balance specialists. It’s a commentary on human nature, rather than animal nature, that scientists—like all people—have personal proclivities that lead them to attach greater importance to some things they observe than to others. Water-balance physiologists tend to attach greatest importance to adaptations that permit animals to live with as little water as possible. With water-balance physiologists organizing most physiological research in the deserts and dry savannas, wildebeests—noted for their slavish dependence on sources of drinking water—have often been dismissed as uninteresting.

Before we turn to the “water-balance champions”—species famed for extreme degrees of independence from drinking water—we would do well to pause a moment to recognize how remarkably successful wildebeests are. Here is a stunning fact: In the Serengeti, wildebeests outnumber all the other species of large mammals combined! This is true even though they are noted more for needing water than for conserving it. Faced with life in an environment that dries out for months at a time, instead of evolving exceptional modes of surviving without drinking water, wildebeests have evolved ways of getting themselves reliably to places where they can find the drinking water they need. If wildebeests have extraordinary adaptations, their special abilities probably reside in their brains

⁶The leaves and seed pods of Kalahari trees, however, do not show such strong seasonal changes.

and sense organs, which physiologists other than water-balance physiologists will ultimately study. Clearly wildebeests are able to *navigate* during their long migratory treks each year. They probably have other exceptional nervous system abilities as well. Naturalists report, for example, that wildebeests in the northwestern Serengeti often start moving southeast at the start of the rainy season before rain is actually falling in the northwest. Do they hear distant thunder or smell distant rain and respond by moving out across a mental map? The answers cannot help but be fascinating.

Let's now discuss four case studies of the sort that intrigue water-balance physiologists: the cases of the oryxes, the Thomson's and Grant's gazelles, the sand gazelle, and the dromedary (one-humped) camel. These are all large animals that, because of their size, have limited opportunities to find protective microenvironments. Consequently, when they live in hot, dry environments, they often actually experience heat stress during all the hours it prevails, and they therefore confront directly the fundamental conflict between heat balance and water balance: Although use of water for evaporative cooling provides a *physically straightforward* way to rid the body of excess heat, it is not *ecologically straightforward* when environmental water is in short supply. We saw earlier that large body size is a physiological advantage in hot, dry environments (see Figure 30.1). Large size in itself, however, does not permit an animal to be completely independent of drinking water in deserts and dry savannas. All of these animals have evolved exceptional species-specific adaptations for maintaining water balance in places where water exerts a dominant controlling effect on life.

Oryxes represent the pinnacle of desert survival

Among the truly wild large mammals, oryxes (Figure 30.10) represent the pinnacle of evolution in their ability to survive in deserts. Dromedaries might be their equal physiologically, but wild dromedaries went extinct before historical times, and today's dromedaries are either domesticated or escaped from domestication. Four types of oryxes are recognized, although taxonomists debate whether some are species or subspecies. The three types that have featured in physiological research are the gemsbok oryx (*Oryx gazella*) and beisa oryx (*O. beisa*)—which closely resemble each other—and the Arabian oryx (*O. leucoryx*). The Arabian oryx, a species that weighs 70–100 kg, was driven to extinction in the wild for a time but has been reestablished. Oryxes can live in some of the most inhospitable places on Earth—including hyperarid deserts where summer air temperatures sometimes exceed 45°C (113°F), the sun shines inexorably, there is no drinking water except immediately after rains, and the rains themselves are so infrequent that average precipitation is less than 5 cm (2 inches) per year.

A decade ago, researchers measured the total water turnover rates of *free-living* Arabian oryxes by use of isotopically labeled water (see page 743). They found the water turnover rates of the oryxes to be only one-quarter to one-half as high as would be expected for free-living mammals of their body size. The same team also measured evaporative water loss in *caged* Arabian oryxes. They found that as oryxes are acclimated to water restriction, they conserve water better: They reduce their metabolic rate (lowering respiratory evaporation), lower their total rate of evaporative water loss so it is only about half as high as in nonacclimated oryxes, and achieve a total rate of evaporative water loss that is only 40%

FIGURE 30.10 Oryxes in deserts often exist on dead, dry grasses and the leaves of water-stressed bushes and trees Oryxes are able to stay in water balance with their only preformed water coming from such sources because they conserve water exceptionally well by mechanisms that are only partly understood. The animal shown is a gemsbok (*Oryx gazella*).

as high as expected for ungulates of their body size studied under caged conditions. These recent results confirm the conclusion reached by the earlier laboratory studies we discussed (see Figure 30.6) that oryxes have evolved unusually low water needs. Oryxes are far more effective than average mammals of their body size in limiting their rates of water loss and, therefore, the rates at which they must resupply themselves with water.

The *mechanisms* by which oryxes achieve exceptional water conservation and low water-turnover rates are only starting to be understood. The kidneys of beisa and Arabian oryxes can concentrate urine to an osmotic urine-to-plasma (U/P) ratio of about 8 (Table 30.2)—a high value for animals of their size (see Figure 28.20). Free-living Arabian oryxes lower their metabolic rates in summer to be only half as high as in winter, based on doubly labeled water studies (see page 208). Although oryxes are famous for being indifferent to shade under many circumstances, they methodically remain inactive in shade—if they can find it—during the heat of the day when under water stress. At least two species sometimes dig shallow depressions in which they settle down; this behavior is thought, without evidence, to shield them from the sun or allow them to lose heat to the cool subsoil they expose. Pregnancy and lactation place substantial water demands on females, and a recent study indicates that in Arabian oryxes, reproduction is curtailed during drought; both mating behaviors and conceptions were only about 20% as high during a dry year as during a moist year.

The water-conserving mechanism that is now best understood in oryxes—and thought generally to be widely used by other desert and dry-savanna species—is modulation of body temperature in ways that minimize the use of water for thermoregulation (see pages 260–261). A person placed in a hot desert maintains a stable body-core temperature of about 37°C, but at the price of profuse sweating, which entails rapid water loss (up to 2L/h). Oryxes and other species of large mammals with long evolutionary histories in

TABLE 30.2 Maximum urine concentrations and minimum fecal water concentrations in selected African mammals

^aU/P ratios depend in part on plasma values, explaining why they do not always correlate exactly with urine osmotic pressures.

hot-dry environments are hypothesized in general to exploit the advantages of a *variable* body-core temperature when necessary to save water. The firmest supporting evidence for this hypothesis available today in any species is in fact provided by two recent studies of Arabian oryxes living wild in the deserts of Saudi Arabia. The body temperatures of the animals were monitored remotely for hundreds or thousands of hours by use of radiotelemetry in one study and by data loggers⁷ in the other. The results of one study are presented in **Figure 30.11**. The average body-core temperature rose and fell to a small extent over the 24-h day during winter (see **Figure 30.11b**), when the ambient air temperature varied from an average low of 13°C at night to an average high of 27°C during the day. In summer, however, when the ambient air temperature varied from a nighttime low of 29°C to a daytime high of 44°C (111°F), the amplitude of the oryxes' cycle of body-core temperature became much larger (see **Figure 30.11a**). On average, the oryxes in summer let their body temperatures fall to 36.5°C overnight, but then rise to 40.5°C during the day: an average amplitude of about 4°C. The second, completely independent study on Arabian oryxes obtained similar results; the average amplitude in summer was 5°C. In the two studies taken together, three individuals were observed at times to allow their body-core temperature to cycle by 7.5–7.7°C between night and day—the highest amplitude daily cycle ever observed in any mammal.

The oryxes' high-amplitude cycles of body temperature are believed to save water in two ways (see pages 260–261). First, when

⁷Data loggers are devices that, as they collect data, log the data into digital memory. They are later recovered and the data downloaded.

FIGURE 30.11 Average body-core temperatures of free-living Arabian oryxes over the 24-h day The six oryxes (*Oryx leucoryx*) studied were living in their natural environment in Saudi Arabia and monitored using implanted radiotelemeters during (a) summer and (b) winter. (After Ostrowski et al. 2003.)

the animals let their body temperatures rise during the heat of the day, they are in effect *storing* heat instead of panting or sweating to get rid of it. They then exploit the coolness of the nighttime environment to lose the heat by nonevaporative means (convection and thermal radiation). The water savings per day from allowing the body temperature to cycle—rather than holding it constant by panting or sweating—is about 0.3–0.4 L for an oryx of average size. The elevation of body temperature during the day also has a second advantage: It *reduces the difference in temperature between an oryx's tissues and the hot environment during the heat of the day*, thereby slowing the rate at which heat enters its body.

Remote-monitoring techniques—such as radiotelemetry and automated data collection by data loggers—have only recently started to be used to study the physiology of desert and dry-savanna mammals, and only three studies have been completed on the body temperatures of free-living oryxes (none has been completed on free-living camels or gazelles). Two of the studies are those we have just discussed. The third study did not find large cycles of body temperature in the oryxes monitored (*O. gazella*). This may mean only that the animals were not experiencing a tendency to dehydrate. Many laboratory investigations have demonstrated that desert and dry-savanna mammals are in general far more likely to allow large swings in body temperature when they are tending to dehydrate than otherwise. Moreover, one of the studies on free-living Arabian oryxes found a correlation between the amplitude of body temperature cycles and environmental moisture: The cycles became greater as the environment became drier. A goal for physiologists as they make greater use of remote-monitoring techniques will be to understand better how free-living animals modulate their use of the water-conserving mechanisms they possess.

Up to now we have discussed just one side of the water-balance equation in oryxes: their ability to limit water losses. What about water gains? Studies on free-living oryxes in the wild confirm that, as laboratory data suggest (see Figure 30.6), they must meet most of their water needs with preformed water. Metabolic water can account for only one-quarter or less of their water inputs in the wild.

Although oryxes drink when they find water and are even known at times to dig for water in riverbeds, there can be no doubt that they often live for months or even years without drinking. They then get the preformed water they need from their foods—an astounding proposition, because the foods available to them often seem to the eye to be distinctly unpromising. Oryxes eat the leaves of desert trees, such as acacia trees. These leaves, although they are firm and not ostensibly juicy, turn out, when analyzed, to be at least 50–60% water, even in the midst of severe droughts. Oryxes also eat dried grasses and other dead, dry plants (see Figure 30.10), and when they do so, they time their feeding to occur principally in the predawn hours, when the plants are richest in water (see Figure 30.7). In dry times, oryxes become nomads in the deserts, seeking out places where fog, dew, or rain has allowed plants to build up more water than average. According to some orthodox scientific evidence plus reports of the San people, who have lived in African deserts and dry savannas for millennia, oryxes have uncanny abilities to find and excavate the underground dormancy organs of desert plants, structures that can be 1 m deep but contain 50–70% water. All these strategies used by oryxes to obtain preformed water from food seem so marginal that they might not work to sustain life, and in fact there is no quantitative proof that they do work.

However, they apparently must work, because the oryxes survive. One reason life is possible on such meager water resources is water conservation. Surviving on the water in the leaves of water-stressed or dead plants would be impossible without mechanisms that can profoundly limit the amount of water an animal needs.

Oryxes have been recorded to survive rainless droughts in the desert for at least 34 months. Sometimes their body condition declines under such extreme duress, and some die. Even after 2–3 years without drinking, however, the problem that undermines oryxes seems most likely *not* to be dehydration, based on studies of recently dead animals. Instead, they seem most likely to die of severe protein deficiency (or other nutritional deficiency) caused by the deteriorating nutritional quality of the plants in their environment.

Grant's and Thomson's gazelles differ in their relations to water

Grant's gazelle (*Gazella granti*) and Thomson's gazelle (*G. thomsoni*) are two look-alike antelopes, weighing 10–50 kg, that often coexist in abundance in the savannas of East Africa (see Figure 30.3). Both are drinking-water-independent⁸ and often stand in the open all day long, indifferent to shade. For five decades the contrasts between these two species have highlighted that straightforward studies of water input and water output do not always tell the entire story about the water relations of savanna animals.

When Grant's and Thomson's gazelles are subjected to standard water-balance analyses in laboratory settings, they prove to be similar. If anything, Thomson's gazelle seems more adept at conserving water during such tests. However, in their natural environment, the species clearly have different relations to water, and of the two, Thomson's gazelle paradoxically seems to be the inferior one in coping with water stress. In the Serengeti, Thomson's gazelles participate in the annual migration; despite being drinking-water-independent, they trek along in great numbers with the drinking-water-dependent wildebeests and zebras. Where savannas give way to deserts, although Grant's gazelles occupy the deserts as well as the savannas, Thomson's gazelles stay largely in the moister savannas.

The study of physiology has yet to explain the divergence of the water relations of these two gazelle species in the wild. Some insight is probably provided by their different responses to extreme ambient temperatures in laboratory tests. Exposed to an air temperature of 45°C, Grant's gazelle allows its body temperature to rise to 45°C or higher; some individuals reach a rectal temperature of 46.5°C (116°F), among the highest ever recorded in a vertebrate. Thomson's gazelle, however, keeps its body temperature below 43°C, a process that means more panting and more use of water for thermoregulation. The two species may also differ in food selection (the plants they select to eat and the times when they eat them), behavioral thermoregulation, or other traits that only careful field studies will bring fully to light.

The sand gazelle is drinking-water-independent in hyperarid deserts

The sand gazelle (*Gazella subgutturosa*), which weighs about 20 kg and therefore is similar in size to Grant's and Thomson's gazelles,

⁸Recall that “drinking-water-independent” is a category of drinking behavior. Drinking-water-independent species do not need to drink each day but can skip drinking for many days or weeks in a row. They may not, however, be entirely independent of drinking water.

FIGURE 30.12 Dromedary camels—the “ships of the desert”—do not carry extra water in their bodies, as legend has often held. Instead, they depend on water conservation, an ability to eat diverse desert foods, and extreme tolerance of dehydration to be able to go for days or weeks without drinking. They have a long history of use as beasts of burden in much of northern Africa and southern Asia and have been imported into Australia. They are the largest of the mammals adapted to desert life, sometimes reaching adult weights of 500–600 kg.

dramatically illustrates the physiological diversification that can occur within sets of closely related animals (in this case three species in the single genus *Gazella*). The sand gazelle lives in full-fledged deserts, including hyperarid deserts, and therefore—averaged over the course of an entire year—tends to face greater problems of water availability than savanna-dwelling Grant’s and Thomson’s gazelles. Recent research has revealed that the sand gazelle has evolved a strikingly low rate of evaporative water loss (EWL). Its total EWL is only about 20% as high as the EWL of Grant’s or Thomson’s gazelles—and also only about 20% as high as expected for an average ungulate of its body size. The mechanisms by which EWL is so profoundly reduced remain to be fully understood. Two mechanisms documented thus far are cycling of body temperature (summer amplitude: 2.6°C) and a reduction of metabolic rate by as much as 45% when acclimated to food and water restriction.

The dromedary camel does not store water, but conserves it and tolerates profound dehydration

The modern era of physiological research on large desert mammals began with studies on dromedary camels (Figure 30.12) by Knut and Bodil Schmidt-Nielsen in the mid-twentieth century. More has steadily been learned since then. Dromedaries drink, in part because they are domesticated and their human handlers

water them. Nonetheless, they are capable of extreme performance in some of the most inhospitable places. During the cool seasons of the year, for example, dromedaries are able to travel for several weeks and cover hundreds of desert miles—serving as beasts of burden—without drinking along the way.

From the time of ancient Rome until the Schmidt-Nielsens’ pioneering studies, the reigning theory about the camels’ low requirement for drinking water was that they had a canteen onboard. That is, people assumed that camels have a greater amount of body water than ordinary mammals when they start a trek. For centuries, debate therefore focused on the location of the canteen, with most commentators supposing that the rumen or parts of the rumen played this role. After early biochemists established that water is made by metabolism, even the hump became a proposed site of canteen function. Not that the hump contains water: Scientists have long recognized that the hump is filled with fat. However, fat yields more than its own weight in H_2O when it is oxidized (see Table 27.3), and thus it seemed only logical that the fat in the hump was a lightweight way to carry H_2O . The Schmidt-Nielsens and later investigators systematically demolished all these myths, some of which had “provided the answer to the camel question” for 2000 years. A camel’s rumen contains no more water than any other ruminant’s rumen. When the total amount of water in a camel’s body is measured, it is no more than the average for all mammals. The hump fat actually *costs* H_2O to oxidize because the H_2O lost in breathing to obtain O_2 for the oxidation of the fat exceeds the metabolic water produced (see page 710). In the end, researchers established beyond doubt that camels drink only to make up for prior water losses, never to store water in their bodies in anticipation of future water needs.

There are two principal keys to the extraordinary ability of camels to survive in deserts for long periods without drinking. One of these

is by now a familiar theme: Camels conserve water extraordinarily well. Based on studies of penned animals, we know that dromedaries dramatically exploit the water-conservation benefits of large daily changes in body temperature. When dehydrated, they sometimes allow their body temperature to rise as much as 6°C during the day and fall to the same extent in the cool of night. One reason they can permit their body temperature to rise as high as it does is that they keep their brain cooler than the rest of their body (see page 261)—a trait also reported in oryxes and gazelles. Dromedaries also employ several other water conservation strategies: (1) they can produce dry feces and concentrated urine (see Table 30.2); (2) they curtail their urine production relatively rapidly and profoundly when faced with dehydration; (3) they have thick, sometimes glossy, fur that acts as a heat shield, helping to slow influx of heat from the fur surface and reflect or reradiate incoming solar radiation (see page 260); and (4) they minimize heat influx behaviorally, as by steadily facing the sun when allowed to rest during the day, a practice by which they consistently present a narrow body profile to the sun's direct rays.

The second known key to the ability of camels to survive for weeks without drinking water is their unusual tolerance of dehydration. Species of mammals without long evolutionary histories in deserts, such as dogs or horses, are in danger of death if they dehydrate by 10–15% of their body weight while under heat stress. Dromedaries, in contrast, can tolerate at least twice this extent of dehydration. There are known cases of dromedaries being alert and functional in the desert heat while dehydrated by 30–40% of their body weight.

Thus, when a dromedary sets off on a desert trek, it has the same amount of body water, in relation to its body size, as you or I. However, it dehydrates by a smaller percentage of its body weight per day because it conserves water exceptionally well, and it can tolerate a level of total dehydration at least twice what we can tolerate. Along the way it munches desert plants, ranging from green leaves to dried-out thorn bushes and saltbushes, replacing some of its water losses using preformed water from its food. Thus it can forestall its need to drink for many days in the summer and many weeks in the cool seasons.

Study Questions

1. What are the pros and cons of studying water physiology in the laboratory and in the field? Could an animal's water physiology be fully understood by field studies alone? By laboratory studies alone? Explain.
2. In Chapter 1 we noted that an animal's body size is one of its most important properties. Considering all the mammals that live in deserts, explain why their body sizes matter. Include discussion of physiological mechanisms where appropriate.
3. The effects of water loss in milk on the water budgets of lactating female mammals in arid environments are not well understood. Specify three hypotheses regarding mechanisms by which females might prevent water losses in their milk from forcing them into negative water balance (which could lead to fatal dehydration). For each hypothesis, design a study to test or evaluate the hypothesis.
4. Contrast the body-temperature responses of humans and Arabian oryxes during exposure to a hot-arid desert. In each case, state implications for water balance. Include both day and night in your analysis.

APPENDIX

A

The Système International and Other Units of Measure

Physiology is in transition to full use of a system of units of measure called the **Système International (SI)**. Some subdisciplines of physiology today use almost entirely SI units, whereas other subdisciplines continue to use older systems of measure along with SI units. The SI recognizes seven base units of measure, listed in the first section of the accompanying table: the meter, kilogram, degree Celsius, second, ampere, mole, and candela. All other units in the SI are to be derived from these seven; thus, for example, the SI unit for velocity (distance per time) is the meter/second. Many derived SI units are listed in the second section of the table. Some derived units are given special names; for example, the unit of force (mass \times acceleration) is technically a (kilogram \times meter)/second², which is more commonly known as a newton. The unit for energy (force \times distance) is a newton \times meter, called a joule. Note that when names of people are used for units of measure, the names are written entirely in lowercase (although *abbreviations* are uppercase; e.g., 1 newton is abbreviated 1 N).

Prefixes indicating orders of magnitude greater or smaller are acceptable in the SI. For instance, the prefix kilo- can be used to indicate “three orders of magnitude greater” (a kilojoule [kJ] is 1000 J). See Appendix B for definitions of prefixes. Note that in scientific writing, abbreviations for symbols are not followed by a period (unless by coincidence, as at the end of a sentence). For example, “kg”—not “kg.”—is the correct abbreviation for “kilogram.”

Two sorts of notation are used for derived units: *numerator/denominator* notation and *exponential* notation. In numerator/denominator notation the unit of velocity, for example, is the meter/second or m/s; in exponential notation the unit is written $\text{m}\cdot\text{s}^{-1}$. In this text we use numerator/denominator notation because we consider it more intuitive and easier to understand, but many students are also familiar with exponential notation and find it easier for complex calculations. In this appendix we list units in both numerator/denominator notation and exponential notation.

Relations between SI units and selected traditional units are shown in the table, in the column labeled “Relations among units.” Some relations between different sets of traditional units are also listed. To obtain the relations converse to those shown, divide both sides of the relevant equation by the number to the right of the equals sign. For instance, the table states, “1 m = 3.28 ft.” Dividing both sides by 3.28 yields, “1 ft = 0.305 m.”

More information on the SI and traditional units of measure can be obtained in *Handbook of Chemistry and Physics* (CRC Press, Boca Raton, FL) or *Lange’s Handbook of Chemistry* (McGraw-Hill, New York).

Quantity	SI Unit	Relations among units	
Base SI Units			
Length	meter (m)	1 m = 3.28 feet (ft) 1 inch (in) = 25.4 millimeter (mm) 1 statute mile (mi) = 1609.3 m	
Mass	kilogram (kg)	1 kg = 2.20 pound, avoirdupois (lb) 1 ounce, avoirdupois (oz) = 28.3 gram (g)	
Temperature	1 degree Celsius (°C) = 1 kelvin (K)	A difference of 1°C = a difference of 1.8 degree Fahrenheit (°F)	
Time	second (s)	—

Prefixes Indicating Orders of Magnitude

You undoubtedly know that kilo- means “three orders of magnitude greater.” This and a series of less-

familiar prefixes are summarized for convenience in the following table.

Prefix	Abbreviation (placed before unit abbreviation)	Meaning in words	Meaning in powers of 10
tera-	T	12 orders of magnitude greater	$\times 10^{12}$
giga-	G	9 orders of magnitude greater	$\times 10^9$
mega-	M	6 orders of magnitude greater	$\times 10^6$
kilo-	k	3 orders of magnitude greater	$\times 10^3$
deci-	d	1 order of magnitude smaller	$\times 10^{-1}$
centi-	c	2 orders of magnitude smaller	$\times 10^{-2}$
milli-	m	3 orders of magnitude smaller	$\times 10^{-3}$
micro-	μ	6 orders of magnitude smaller	$\times 10^{-6}$
nano-	n	9 orders of magnitude smaller	$\times 10^{-9}$
pico-	p	12 orders of magnitude smaller	$\times 10^{-12}$
femto-	f	15 orders of magnitude smaller	$\times 10^{-15}$

Gases at Standard Temperature and Pressure

Temperature and pressure exert such great effects on gas volume that they must be specified for a volume to have meaning. Physiologists usually convert all measured gas volumes to volumes at **standard temperature and pressure (STP)**—0°C and 1 atmosphere—so that the volumes can be compared. Reported values are assumed to be at STP unless otherwise stated. The equation for making the conversion is

$$\begin{aligned} \text{volume at STP} \\ = \text{volume measured} \times \frac{P_{\text{meas}}}{1 \text{ atm}} \times \frac{273 \text{ K}}{T_{\text{meas}}} \end{aligned} \quad (\text{C.1})$$

where P_{meas} is the pressure prevailing during measurement, in atmospheres, and T_{meas} is the temperature prevailing during measurement, in absolute (Kelvin) degrees.

Suppose, to illustrate, that you study a bird in a chamber where the pressure is 0.92 atm and the temperature is 20°C. On the Kelvin

scale, the temperature is 293 K (273 plus its value on the Celsius scale). Suppose the animal uses 50 mL of O_2 , measured under the prevailing conditions, in an hour. Expressed at STP, the volume used is

$$\begin{aligned} \text{volume at STP} \\ = 50 \text{ mL} \times \frac{0.92 \text{ atm}}{1 \text{ atm}} \times \frac{273 \text{ K}}{293 \text{ K}} = 42.9 \text{ mL} \end{aligned} \quad (\text{C.2})$$

Thus the animal's rate of O_2 consumption *at STP*, a measure of its metabolic rate, is 42.9 mL O_2 /hour.

A significant property of gases is that identical molar amounts of different gases occupy almost identical volumes when at the same pressure and temperature. A mole of gas occupies about 22.4 L at STP, whether the gas is O_2 , N_2 , or some other gas.

Fitting Lines to Data

Suppose you are interested in how two traits of an animal are related to each other. The traits might, for example, be resting heart rate and age, but here we will call them Y and X for generality. If you make measurements on ten individuals, you will have ten pairs of values that you can plot as in [Figure A1](#) to display visually the relation between the traits. Each point is for one of the studied individuals and represents that particular individual's measures for traits Y and X .

The points plotted seem to fall along a straight line. You could simply sketch a line through them, but that would be subjective. A better approach is to use a statistical procedure to determine which line best fits the data according to objective criteria. The procedure most commonly used to do this is called **linear least squares regression**. This procedure starts by assuming that a linear equation applies. That is, it assumes that the equation for the line of best fit will take the form $Y = a + bX$, where a and b are constants. An investigator must decide first whether that assumption is reasonable. If one doubts the suitability of the linear model, there are advanced statistical procedures that will help one to decide. Once the decision is made to use the equation $Y = a + bX$, the procedure of linear least squares regression provides an objective way to find the values for a (intercept) and b (slope) that position the line most appropriately relative to the data.

A proposed line relating Y to X is drawn in blue in [Figure A2](#). The red lines in the figure show the vertical distance between each data point and the proposed line. The central proposition (axiom) of least squares regression, approximately stated, is that the best line relating Y to X is the one that minimizes the sum of the lengths of the red lines. Exactly stated, the procedure squares the length of each red line, adds the squares of all the red lines, and determines the best blue line as the one that minimizes this sum of squares

(thus, "least squares"). You might guess from appearances that the blue line in [Figure A2](#) is not the best line relating Y to X , by this standard. It isn't, but you need not try one blue line after another to find the best. Instead, the calculus of minimization (i.e., minimization of the sum of squares) provides algorithms for carrying out the procedure, and these algorithms are simple enough to be programmed into even cheap calculators today. [Figure A3](#) shows the line that best fits the data by the least squares standard; the line is plotted, and its equation is given in the lower right.

An important reason for understanding the procedure as described is that you will see that the best line is strictly a function of the data (Y, X values) used for the computation. Different data invariably lead to different values for a and b . If one investigator measures Y and X on ten individuals and another measures them on ten different individuals, the investigators will obtain different values for a and b , and different "best" lines. Even the addition of one individual to a data set will change a and b ; in [Figure A4](#), data for an eleventh individual are added to the ten data points in [Figure A3](#), resulting in a new line of best fit by the least squares procedure. These facts do not mean that the statistically fitted lines are "just guesses." The facts merely reflect the reality that a fitted line can be no more certain than the data on which the line is based. Ten data points typically leave much room for uncertainty. If you had a hundred data points, the uncertainty would be diminished, and a and b would probably be altered only slightly by adding one more data point. Statistical procedures permit one to calculate a numerical measure of the level of uncertainty of a fitted line. Mastery of statistics is in fact crucial for the choice of line-fitting procedures, because there are several nuances involved in applying the procedures correctly.

(1) Data for 10 individuals

(3) Least squares fit to the data in (1)

(2) A rough line through the points with deviations marked

(4) Least squares fit to the data in (1) plus one more point

The red lines show the vertical deviations between the data points and line. (3) The line of best statistical fit to the ten points, based on the linear least squares model. (4) An additional data point has been added, and the line of best statistical fit has been recalculated to take account of the information provided by all 11 data points.

APPENDIX

E

Logarithms

The ruler in **Figure A1** is calibrated in a linear scale of numbers of the sort we use in everyday life; each major marking is 1 unit greater than the preceding one. The ruler in **Figure A2** is calibrated in a nonlinear, *logarithmic* scale; each marking on the scale is an *order of magnitude* greater than the preceding one. Note that the logarithmic ruler covers a far wider range. That ruler runs between 0.01 and 100,000; for the linear ruler to do the same, it would need to be extremely long, or the markings would need to be extremely close. One reason logarithmic scales are sometimes used by biologists is their wide range. For instance, a physiologist comparing metabolic rates in all mammals would find a logarithmic scale useful because the range of mammalian adult body sizes—from 2 grams to over 4,000,000 grams—is far too wide to fit on any single linear scale. One type of ruler is as good as another in the abstract. One can calibrate a ruler in any way one pleases, provided account is taken of the particular calibration when measurements are interpreted and analyzed. Thus, if a logarithmic ruler suits one's purposes, one is free to use it.

The **common logarithm** of a number N is defined to be the value of L for which $10^L = N$. That is, common logarithms are exponents of 10. The ruler in **Figure A3** is the same as that in **Figure A2** except that the numbers printed on the ruler are logarithmic values. Where the ruler in **Figure A2** says "1000," that in **Figure A3** says "3" because 3 is the common logarithm of 1000 ($10^3 = 1000$). Similarly, where the ruler in **Figure A2** says "0.1," that in **Figure A3** says "−1" because $10^{-1} = 0.1$. The scales (markings) on the rulers in **Figure A2** and **Figure A3** are logarithmic, but whereas the numbers on the ruler in **Figure A2** are ordinary numbers, those on the ruler in **Figure A3** are logarithms. Biologists usually use the sort of "hybrid" format in **Figure A2**—a logarithmic scale labeled with nonlogarithmic, ordinary numbers—rather than an "all-logarithmic" presentation like **Figure A3**.

The ruler in **Figure A4** shows a range of two orders of magnitude in greater detail than in **Figure A2**. The presentation is hybrid;

that is, whereas the markings are logarithmic, the numbers are ordinary. Note that numbers that would be evenly spaced on a linear ruler—such as the numbers 2, 3, 4, and 5—are not evenly spaced on the ruler in **Figure A4** because of the logarithmic scaling. Very commonly, logarithmic scales are printed as on the ruler in **Figure A5**, with the major markings labeled but the intermediate markings unlabeled. When you see this format, you can determine the meaning of the intermediate markings in the following way: As you move toward higher values between two major markings, the first intermediate mark is 2 times the next lower major mark, the second is 3 times the next lower major mark, and so forth.

Common logarithms are the principal ones used in physiology. However, powers of any number can in principle be used as logarithms. **Natural logarithms**, which are powers of the irrational number e (2.71828...), are second in importance in physiology. The number that is raised to a power to derive logarithms is called the **base** of the logarithms; thus common logarithms are base 10, whereas natural logarithms are base e .

The value x in the expression \log_x is the base of a logarithm; by convention, the expression "log" (written without a subscript) means " \log_{10} " and "ln" means " \log_e ." Logarithms in two different base systems are simply proportional to each other (if m and p are any two bases and c is a constant equal to $\log_p m$, $\log_p N = c \times \log_m N$). Thus *the mathematical nature of a relationship in logarithmic coordinates is not altered by the choice of base*; for example, if a relation is linear when expressed in common logarithms, it remains linear in natural logarithms.

Before the invention of the cheap electronic calculator around 1970, logarithms were essential as computational tools. Today, logarithms are rarely used that way and have two principal applications: graphical and mathematical/statistical, both mentioned in Appendix F.

(1) An ordinary ruler (linear scale)

(2) A ruler scaled logarithmically

(3) The same ruler as in (2) with values expressed in logarithmic units

Exponential and Allometric Equations

The two most common types of nonlinear equations in the study of physiology are exponential and allometric equations. A variable Y is an **exponential function** of a variable X if Y changes by a fixed *multiplicative factor* every time X changes by a fixed *additive increment*. An example of exponential increase would be a rate that doubles every time the temperature increases 10°C . In this instance, the multiplicative factor would be 2, and the additive increment would be 10°C . If the actual rate at 0°C is 6 (in arbitrary units), the rate would be 12 at 10°C , 24 at 20°C , 48 at 30°C , and 96 at 40°C , as shown by the blue line in **Figure A**. The multiplicative factor need not be an integer; the green line in **Figure A**, for instance, is constructed from the same assumptions as the blue, except that the multiplicative factor is 1.73. Exponential decrease occurs when the multiplicative factor is less than 1; for instance, the red line in **Figure A** results when the factor is 0.5.

The general mathematical form of an exponential function is

$$Y = m \times 10^n \times X \quad (\text{F.1})$$

where m and n are constants. The number 10 is the *base* in this writing of the equation; any base, such as e , could be freely substituted for 10 in the general formulation, although in an actual numerical example, the value of n changes if the base is changed. The exponential equation is commonly applied to cases in which Y is time-dependent and X represents time. In such cases, since $Y = m$ when $X = 0$, m is simply the value of Y at the start (time zero). If n is positive, exponential increase occurs, whereas if n is negative, exponential decrease occurs. Whether increase or decrease is occurring, the rate of change becomes greater as the absolute value of n becomes greater; thus n represents the rate of change.

The **allometric function**—also often called a **power function**—is defined as follows:

$$Y = a \times X^b \quad (\text{F.2})$$

where a and b are constants and $b \neq 1$. Note that despite their superficial similarities, this equation is very different from the exponential function. Whereas the independent variable X is in the exponent in the exponential equation, it is raised to a power (thus, *power function*) in the allometric equation. The allometric equation first became prominent in biology as a mathematical means of describing nonproportional relative growth of body structures. One of countless examples is the relative growth of the head and the rest of the body in people. The head of a newborn baby is far larger relative to the rest of the newborn's body than the head of an

FIGURE A Three exponential equations Each point plotted along the blue line, at 10°C steps from left to right, is 2 times higher than the point preceding. Each point along the green line is 1.73 times higher. These examples of exponential increase illustrate the self-reinforcing nature of exponential change. Each point along the red line is 0.5 times the height of the preceding point, illustrating exponential decrease.

adult person is to the rest of the adult body. Thus, as people grow from birth to adulthood, an allometric, rather than proportional, equation describes the relation between head size and body size. Today, the allometric equation is extremely important in physiology, developmental biology, paleontology, and other fields that focus on the *relative scaling of animal traits*. If b is negative in Equation F.2, trait Y decreases as trait X increases (e.g., green line in **Figure B**). If b is positive but less than 1, trait Y increases as X increases, but not as fast (e.g., blue line in **Figure B**). A value of b greater than 1 signifies that Y increases disproportionately rapidly as X increases (e.g., red line in **Figure B**).

Logarithmic scales are very useful in the study of both exponential and allometric relations. If one takes the common logarithm of both sides of Equation F.1, one gets the *logarithmic form of the exponential equation*:

$$\log Y = \log m + n \cdot X \quad (\text{F.3})$$

This equation tells you that for an exponential relation, if you plot the logarithm of Y on one axis of a graph and X itself on the other axis—a plot called *semilogarithmic* because one axis is logarithmic and the other is not—you will get a straight line with slope n and intercept $\log m$.

The *logarithmic form of the allometric equation* is obtained by taking the logarithm of both sides of Equation F.2:

$$\log Y = \log a + b \cdot \log X \quad (\text{F.4})$$

This equation reveals that for an allometric relation, plotting the logarithm of Y on one axis and the logarithm of X on the other—a graph termed *log-log* because both axes are logarithmic—yields a straight line with b as slope and $\log a$ as intercept.

The constants in the exponential and allometric equations (n , m and a , b) are predicted from theory in some applications. More

usually, however, they are determined empirically: Actual data are gathered on the relation between Y and X , and the data are used to estimate the values of the constants. For this approach, the usual practice is to plot the raw data (X, Y values) on the sort of graph that produces a straight line (semilogarithmic if exponential, log-log if allometric). Linear least squares regression (see Appendix D) is then used to fit a line through the data. Finally, the slope and intercept of the line are used to estimate the equation parameters. R. H. Peters (*The Ecological Implications of Body Size*, Cambridge University Press, Cambridge, 1983) thoughtfully discusses the theoretical details and limitations of this approach.

FIGURE B Three allometric equations The parameter a in the allometric equation (Equation F.2) is set equal to 1 in all three lines shown. The three lines differ in the value of b , the exponent in the allometric equation.

Phylogenetically Independent Contrasts

The goal of the study of **phylogenetically independent contrasts**, stated simply, is to take phylogenetic information properly into account in the statistical analysis of comparative data. Suppose data have been gathered on 1000 species. The traditional approach to analyzing such data is to treat them as 1000 independent data points. However, when a family tree is available for the set of species, we know that the 1000 data points are not in fact equally independent. Some of the species will be more closely related than others; this means that some of the relations among data will be more likely to be affected by common ancestry than others. An extreme but quick-to-grasp example would be to think of eight friends who happen, actually, to be four pairs of identical twins. You could analyze information on them, such as eye color or muscle mass, as if they are eight independent people, or you could analyze the information with full recognition that some are much more closely related than others. Obviously, you might reach different conclusions by use of the two methods. The expression *phylogenetically independent contrasts* is used to refer both to (1) the general study of how phylogenetic information should be taken into account in the analysis of comparative data and (2) a specific method for such studies developed by Joseph Felsenstein. Here we use the term in its general sense.

Why, specifically, might the use of phylogenetically independent contrasts be important? For many purposes (but not all), the simplest way to understand the importance of this approach is to appreciate that the approach helps to minimize *pseudoreplication artifacts* in the statistical analysis of data.

To see this point, let's start by discussing the problem of *pseudoreplicates*: literally, *false replicates*. Suppose you have two types of animals, M and P, and you measure a physiological property on a single individual of each type. Suppose, moreover, that the individual of type M displays a greater value of the property than the individual of type P. It's obvious that—with only two data points—you could not conclude that *type M* has a greater value than *type P* with a statistically high level of certainty; perhaps the result for the single individual of M is merely a fluke—a statistical oddity. Suppose, however, that you write down the value you measured on the M individual 12 times, and you write down the value for the P individual 12 times, so that now you have 24 values. All 12 of the values for type M will be higher than all 12 of the values for type P, and if you simply enter the 24 values into a statistical test, the test will almost inevitably tell you that there is a statistically significant difference between types M and P. In the terminology of statistics, you have increased your total *sample*

size from 2 to 24, and because large sample sizes tend to permit enhanced statistical certainty, this increase in sample size raises the likelihood of reaching a statistically significant conclusion. Of course, we realize in this blatant case that the analysis based on 24 values is totally bogus. You have measures on only two animals. You have not really increased your sample size: The number of useful values cannot be increased merely by writing the numbers down over and over! Most of your replicate values for each type are, in fact, *false replicates*, pseudoreplicates. A **pseudoreplicate** is a “measurement” that masquerades as an independent measure but, in fact, is a duplicate (or partial duplicate) of other measures—it is not fully independent of the other measures.

Pseudoreplication can be *far* more difficult to spot than it is in this blatant example. Sometimes biologists—despite trying to be straightforward and meticulous—are misled by complexities and subtleties into believing they have more independent measures than they actually do. Thus deceived, they use inflated sample sizes in statistical analyses, and they may reach conclusions that, in fact, their data do not support. For good reason, therefore, statistics books and courses warn biologists to be on the alert for pseudoreplication. (Sometimes these warnings are phrased in terms of undesirable “correlation” because pseudoreplicates are correlated with each other in a way—nonindependence—that can confound correct analysis.)

To see how knowledge of family trees is relevant, let's once again imagine that we have 24 pieces of data, but in this case they are actual data gathered by direct measurements on 24 different modern species. For each species, we have measures of a physiological trait *T* and body weight *W*. Thus the data plot as 24 points on a graph of *T* versus *W* (Figure A).

If we are interested in the relation between *T* and *W*, Figure A gives the impression that we have 24 independent data points relevant to our interest. Suppose, however, that an analysis of the family tree reveals that the 24 species are not in fact independent, but instead—much like the four pairs of twins mentioned before—they fall into four distinct groups based on their evolutionary relationships. Suppose, specifically, that all four species placed in group I in Figure B are *closely related* descendants of a single common ancestor. Suppose the same can be said of the seven species in group II, the six in group III, and the seven in group IV. Moreover, suppose that the four ancestral species—the common ancestors of groups I to IV—were themselves *distantly related*.

Recognition of this phylogenetic information alters the way in which we might view the raw data in Figure A. Initially we

FIGURE A Measured data for 24 modern-day species of a single major type (e.g., 24 birds or 24 beetles). T is a physiological trait. W is body weight.

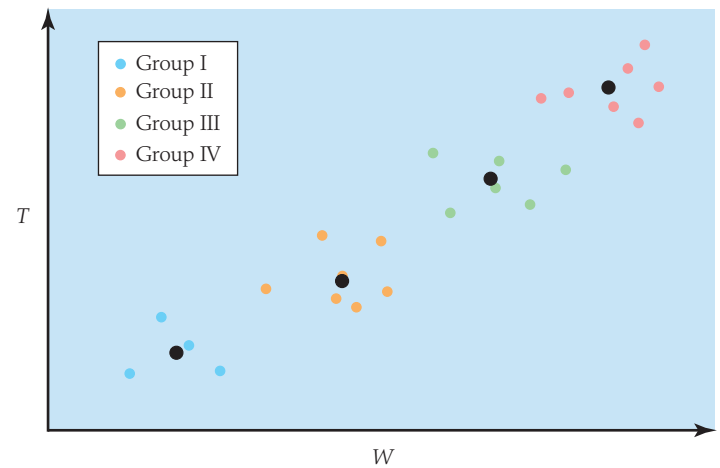

FIGURE C Estimated values (black symbols) for T and W in the four ancestors of groups I, II, III, and IV. The values are reconstructed from analysis of the modern species in each group (colored symbols).

perceived the data as consisting of 24 independent data points. A more valid view might be that the four ancestral species diverged dramatically in traits T and W , and later—when the modern species evolved from the ancestral species—groups I, II, III, and IV simply retained the properties of their four distinct ancestors, with a relatively small amount of added variation. In this case, if we are trying to understand the fundamental relation between T and W , the most accurate view might be that the number of *independent* data points relevant to our interest is 4 (not 24), as seen in **Figure C**. From a statistical viewpoint, the four blue data points in **Figure B** might best be viewed as pseudoreplicates (with a bit of added variation) of the one ancestral value for group I. Similarly, the seven orange data points might best be considered pseudoreplicates of the ancestral value for group II, and so forth.

Why would this matter? **Figure D** shows lines put through the two sets of data, the 24 data points in **Figure A** and the 4 data points (black symbols) in **Figure C**. Although one of these two lines does

FIGURE B Related groups of species within the set of 24, identified by study of the family tree. Each color identifies a distinct group. Each group of modern species is descended from a common ancestor that is only distantly related to the common ancestors of the other three groups.

not recognize the family tree and the other does, they are almost identical. This is actually a common (although not universal) finding: Regressions and correlations are often similar whether or not phylogenetic information is taken into account. However, the purported *statistical certainty* of the two lines in **Figure D** is radically different because the sample size for one line is purported to be 24, whereas the sample size for the other is 4.

One goal in the study of phylogenetically independent contrasts is to articulate procedures for statistical analysis that identify and use a *valid sample size*. Sample size is important because confidence in the outcome of an analysis depends on it. In the simple example we have used here, the true sample size—the number of *independent* pieces of information—is clearly far less than 24, and it might be as low as 4! This shift in the recognized sample size could cause us to downgrade considerably our confidence in the exact relation we have identified between T and W .

Methods based on phylogenetically independent contrasts are not without problems. One problem is that each such method makes

FIGURE D Lines of best statistical fit to the 24 data points in **Figure A** and the 4 data points (black symbols) in **Figure C**.

its own assumptions about the way in which evolution proceeds. A common assumption, for example, is that evolution proceeds along paths (random walks) analogous to those exhibited by molecules undergoing Brownian motion—an assumption that probably applies to certain types of evolutionary change but certainly does not apply to others. A second problem is that the family tree of a group of animals is almost never known with anything approaching 100% certainty. An analysis based on a family tree is thus vulnerable to being rendered second-rate, or even worthless, because at a later date the family tree may well be revised.

Problems such as these help explain why *ordinary least squares regression applied to all available data points* is still commonly used (rather than having been displaced by methods based on phylogenetically independent contrasts). Some thoughtful investigators have decided that—at the present time in the maturation of evolutionary biology—the most prudent course of action is to analyze data by both ordinary least squares regression applied to all data and by methods based on phylogenetically independent contrasts. The two types of methods often agree relatively closely in the trends they identify. If they do not agree, then at least physiologists are put on notice that ambiguity exists.

Mitosis and Meiosis

All cells use the information encoded in the genes of their DNA to orchestrate their functions. When cells divide, it is critical that the DNA be duplicated and distributed properly to the daughter cells so that they receive a complete set of operational instructions. To accomplish this function, DNA forms chromosomes that are inherited when the cell replicates itself in cell division. One chromosome includes one complete molecule of DNA, which incorporates many genes. The majority of cells in the body, the **somatic cells**, contain two copies of each DNA molecule, one inherited from each parent. Such cells are referred to as *diploid*, which means having two identical sets of chromosomes. A set of two copies of the same chromosome is called a *homologous pair*. By contrast, **germ cells**—sperm or ova—have only one copy of each DNA molecule, so they are *haploid*, which means having a single set of chromosomes. When a sperm cell and an ovum unite in fertilization, each contributes one member of each homologous pair, and the resulting zygote is diploid.

Animals use two types of cell division. A diploid somatic cell uses **mitosis** to produce two diploid daughter cells. A specialized diploid cell in the testis or ovary uses **meiosis** to produce haploid daughter cells that develop into germ cells. The life cycle of a cell is separated into two main segments: the time during which it is not dividing, which is called **interphase**, and the time during which it is actively dividing. Some cells, once differentiated, don't divide at all. A motor neuron in the vertebrate spinal cord is a good example of such a cell. It remains in interphase continuously. Other cells, such as the epithelial cells lining the gut, divide frequently by mitosis. The figures in this appendix outline the events that occur during mitosis (**Figure A**) and meiosis (**Figure B**; see next page for figures). In both types of cell division, the DNA is present as *chromatin* during interphase. It is incorporated into visible chromosomes only when the cell is dividing. In both types of division, the DNA

is replicated (doubled) while the cell is still in interphase (near the end of interphase), and duplicated chromosomes form in the first phase of cell division. The duplicates of each chromosome, called *sister chromatids*, are joined by a *centromere*.

The main difference between mitosis and meiosis is that a cell undergoing mitosis divides once after doubling its DNA, whereas a cell undergoing meiosis divides twice after doubling its DNA. In mitosis, at the conclusion of telophase (see Figure A), each daughter cell receives the same number of chromosomes as the original cell had prior to division; that is, each cell receives two copies of each chromosome—homologous pairs. At the conclusion of meiosis, each daughter cell receives only one copy of each chromosome (Figure B), and thus has half the number of chromosomes the original cell had prior to the initiation of meiosis.

A further difference between meiosis and mitosis is that meiosis permits exchange of genetic material between chromosomes. When the duplicated homologous chromosomes align themselves in *tetrads* during late prophase I of meiosis (see Figure B), their close apposition allows parts of the nonsister chromatids to swap with each other. This physical exchange of genetic material, called *crossing-over*, produces chromosomes that have a completely new, unique mix of genes different from both of the original chromosomes. If these chromosomes contribute to the formation of a zygote in fertilization, the new individual will be unique, not only because it contains chromosomes from two different parents, but also because the genetic material of the contributing parents' chromosomes was reshuffled in the process of crossing-over. Biologists have observed that genetic diversity among the members of a species appears to contribute to the endurance of that species over long evolutionary periods. The reasons underlying this adaptive advantage of genetic diversity are being actively investigated.

FIGURE A Mitosis

MITOSIS

Interphase:
The "unwound" DNA is present as chromatin, not as condensed chromosomes. When the cell prepares to divide, it replicates its DNA.

Prophase:
The nuclear envelope breaks down, the chromatin condenses into chromosomes, and a spindle of microtubules forms at the centromeres at each pole of the cell. For simplicity, we show just four chromosomes—each consisting of two sister chromatids (formed by DNA replication during the lead-up to prophase).

Prometaphase:
The chromosomes attach to spindle fibers at their centromeres.

Metaphase:
The chromosomes align at the equator of the cell.

Anaphase:
The sister chromatids are pulled apart into daughter chromosomes.

Telophase:
The chromosomes approach the poles of the cell, and a contractile ring of actin causes the cell membrane to pinch in. Each daughter cell receives a daughter chromosome from each original chromosome, maintaining a full, diploid set of chromosomes in each cell.

Interphase:
The DNA reverts to the form of chromatin rather than discrete chromosomes.

FIGURE B Meiosis**MEIOSIS I****Interphase:**

The DNA is present as chromatin rather than condensed chromosomes. Red and blue represent homologous DNA. DNA replicates.

Early prophase I**Mid prophase I:**

For simplicity, we show only two pairs of homologous chromosomes. To distinguish the pairs, one is short, whereas the other is long. The two (homologous) chromosomes in a pair are distinguished by coloring one red and the other blue. Because of prior DNA replication, each chromosome consists of two sister chromatids, connected by a centromere (see Key in Figure A). The two members of a homologous pair come together and align with each other.

Late prophase I:

The nuclear envelope breaks down. The four chromatids of each homologous pair represent a tetrad in which physical exchange of chromosomal material can take place between nonsister chromatids. The exchange is called crossing-over.

Metaphase I:

The chromosomes, arrayed in homologous pairs, line up midway between the poles.

MEIOSIS II**Anaphase I:**

One chromosome of each pair is pulled toward each of the poles.

Telophase I:

Each daughter cell receives one already-replicated chromosome from each homologous pair. No further replication occurs.

Metaphase II:

This step is similar to Metaphase I. However, each cell has only one of each type of chromosome.

Anaphase II:

The sister chromatids of each chromosome are pulled toward opposite poles.

Telophase II:

Each of the four final daughter cells is haploid: Each has only one chromosome of each type.

APPENDIX

The Standard Amino Acids

The standard amino acids are those employed in the synthesis of most proteins and polypeptides. The 20 most common standard amino acids are listed here, along with their usual abbreviations. There are two systems of abbreviation. In the three-letter system, each amino acid is represented by a three-letter code (the first letter of which is uppercase). In the one-letter system, each is represented by a single uppercase letter. Figure 6.3 shows the chemical structures of five of the standard amino acids.

In addition to the standard amino acids used in protein synthesis, many other amino acids are known and play various roles in organisms.

Names and abbreviations of the 20 most common standard amino acids		
Amino acid	Three-letter code	One-letter code
Alanine	Ala	A
Arginine	Arg	R
Asparagine	Asn	N
Aspartic acid	Asp	D
Cysteine	Cys	C
Glutamic acid	Glu	E
Glutamine	Gln	Q
Glycine	Gly	G
Histidine	His	H
Isoleucine	Ile	I
Leucine	Leu	L
Lysine	Lys	K
Methionine	Met	M
Phenylalanine	Phe	F
Proline	Pro	P
Serine	Ser	S
Threonine	Thr	T
Tryptophan	Trp	W
Tyrosine	Tyr	Y
Valine	Val	V

Basic Physics Terms

This appendix defines and interrelates basic terms in mechanics and the physics of electricity, and refers back to some places in the text where these are discussed in a physiological context. It is deliberately selective rather than comprehensive in both these respects. Symbols for *units* are roman (upright) and symbols for *variables* are italic (slanted); for example, *m* is meters and *m* is mass. Note that Appendix A treats units of measure and Appendix C discusses gases at standard temperature and pressure. Physical principles not treated here are discussed elsewhere in the text; for example, the physics of gas transfer is discussed in Chapter 22 and supplemented with treatment of water vapor in Chapter 27.

Mass (*m*) The amount of material in an object. The basic unit is the *kilogram* (kg), which is a unit of mass, not of weight.

Velocity (*v*) Rate of movement; $v = dx/dt$, where *x* is distance and *t* is time. Velocity is similar to speed, except that velocity is a vector quantity that considers direction as well as speed; speed is scalar and is independent of direction.

Acceleration (*a*) Rate of change of velocity; $a = dv/dt$.

Force (*F*) A push or pull on a body; what it takes to make mass accelerate. $F = ma$ and is measured in *newtons*; $1\text{N} = \text{kg}\cdot\text{m}/\text{s}^2$.

Weight (*w*) The force exerted on a mass by Earth's gravitational acceleration; $w = mg$, where *g* is the acceleration due to gravity.

Pressure Force per unit of area. The standard unit of pressure is the *pascal* (Pa; $1\text{Pa} = 1\text{N}/\text{m}^2$). Pressure differences determine direction when materials flow and affect the rate of flow, whether the flow is in blood circulation (Chapter 25), breathing (Chapter 23), or filtration of water (Chapters 25, 29).

Work (*W*) The mechanical definition of work is the product of force and distance; $W = Fd$, measured in *joules*. The mechanical definition of work does not apply in all contexts of work in physiology. Physiological work is discussed in Chapter 7, pages 163–166. Work in the study of muscle action is discussed in Chapter 20, page 535, particularly Figure 20.12, and in Chapter 21, page 551.

Energy The capacity to do work. In mechanics, this is divided into kinetic energy and potential energy. Energy is measured in joules (the same units as work).

Kinetic energy (*K*) Energy inherent in the motion of mass; it increases with increasing mass and velocity; $K = 1/2mv^2$.

Potential energy Stored energy that can be released to do work. An object that gravity can move downhill, a coiled spring, a battery, and the chemical bond energy in molecules all represent examples of potential energy.

Power Work per unit of time. The standard unit of power is the *watt* ($1\text{W} = 1\text{J}/\text{s}$). Power in the study of muscle action is discussed in Chapter 21, page 551, particularly Figure 21.1 and Equation 21.1.

Light Electromagnetic radiation with a wavelength of about 400–700 nm; wavelengths shorter than about 400 nm are ultraviolet radiation, and wavelengths longer than about 700 nm are infrared radiation.

Sound Waves of compression of air or water, which propagate away from a vibrating source. See Chapter 14, page 366.

Temperature The atoms and molecules within any substance undergo constant random motions on an atomic–molecular scale. The temperature of a substance is a measure of the speed—or intensity—of these random motions, and is independent of the macroscopic mass of the substance (although it is dependent on molecular mass). Chapter 10 discusses the physics of heat transfer, and of temperature and heat in general.

Heat Heat (unlike temperature) is a form of energy: the energy that a substance possesses by virtue of the random motions of its atomic–molecular constituents. The amount of heat in a substance depends on both the number and kinds of atoms and molecules in the substance and on the speed of each. A large copper block with many copper atoms moving at a given average speed contains proportionally more heat energy than a small copper block with fewer atoms moving at the same speed, although they are at the same temperature.

Electricity The flow of electricity through electrical circuits is analogous to the hydraulic flow of water or any other liquid through pipes. Similar relationships and equations describe both systems, and the hydraulic analogy helps to develop an intuitive understanding of electrical concepts. The section in Chapter 12 titled “The Ionic Basis of Membrane Potentials” (starting on page 301) discusses electrical concepts in a physiological perspective.

Electrical charge (*Q*) All matter is made up of charged particles (protons and electrons). Atoms or molecules that have unequal numbers of positive and negative charges are called *ions*. Ions of unlike charge attract each other, and ions of like charge repel each other. Charge can be defined as the source of this electrical force of attraction/repulsion. The standard unit of charge is the *coulomb* (C), which is the charge carried by 6.24×10^{18} protons or by a like number of electrons. Charge relates to mass through Faraday's constant (96,500 C/mol).

Current (*I*) Electric current is the flow of charge, measured in *amperes* ($1\text{A} = 1\text{C}/\text{s}$). In biological systems, currents are carried by ions moving in solution.

Voltage (V or E) Potential difference; the electromotive force or electrical potential. (In common usage these terms mean the same thing.) The potential difference in an electrical circuit is analogous to the pressure difference in a hydraulic circuit. No current will flow between two points at the same pressure, or the same voltage. In a hydraulic circuit, a pump or a difference in height supplies the pressure difference (the latter because water flows downhill due to the force of gravity). In an electrical circuit, a battery separates positive and negative charges to provide the potential difference (acting as a voltage source). Potential difference is measured in *volts* (V); 1 V is the energy required to move 1 C of charge a distance of 1 m against a force of 1 N. Chapter 12, pages 305–309 describes how membrane permeability to ions generates a membrane potential difference.

Resistance (R) The property that hinders the flow of current. In an analogous hydraulic system, for a given pressure difference, more water will flow through a pipe that presents relatively low resistance to current flow than through a pipe that presents relatively high resistance to current flow. Similarly, in an electrical circuit, the lower the resistance of an element of a circuit, the more current will flow

through the element for a given difference of electrical potential or voltage. The unit of resistance is the *ohm* (Ω).

Conductance The inverse of resistance; the ease of current flow for a given difference of electrical potential or voltage, measured in *siemens* (S).

Ohm's law $E = IR$. The voltage (difference of electrical potential) is the product of the current and the resistance in a circuit, or by rearrangement, the current equals the voltage over the resistance ($I = E/R$).

Capacitance (C) A measure of the ability of a nonconductor to store charge. Capacitance is the amount of charge stored per unit of voltage ($C = Q/E$) and is measured in *farads* (F). A capacitor has two conducting plates separated by an insulator; capacitance increases with increased size of the plates and with decreased distance between them. When a capacitor is first connected to a battery, positive charges flow onto one plate of the capacitor and negative charges onto the other. Although no charges cross from one plate to the other, a transient capacitive current flows because the charges on one plate will repel like charges and attract unlike charges on the other plate. See Figures 12.8 and 12.24.

APPENDIX

K

Summary of Major Bloodborne Hormones in Mammals

We list here the major hormones and neurohormones secreted by endocrine and neuroendocrine tissues in mammals, along with the vast repertoire of their major functions. Given ongoing advances in technologies to measure blood-borne chemical signals and define their functions, it is likely that researchers will continue to identify hormonal roles for molecules not previously known to be hormones or neurohormones, and discover new functions of known hormones and neurohormones.

Secreting tissue	Hormone	Class of molecule	Main functions
Adrenal cortex	Aldosterone (mineralocorticoid)	All steroids	Stimulates Na ⁺ reabsorption and K ⁺ secretion in kidney.
	Androgens		Act on bone to cause growth spurt at puberty; increase sex drive in females by action on brain.
	Glucocorticoids (cortisol, cortisone, corticosterone)		Part of stress response; affect metabolism of many tissues to increase blood glucose and cause protein and fat catabolism.
Adrenal medulla	Epinephrine and norepinephrine	Catecholamines	Part of stress response; reinforce sympathetic nervous system; influence cardiovascular function and organic metabolism of many tissues.
Anterior pituitary gland (adenohypophysis)	Prolactin (PRL)	All peptides	Promotes development of mammary gland during pregnancy; stimulates milk synthesis and secretion during lactation; promotes caring for young by both males and females in many species of fish, birds, and mammals.
	Growth hormone (GH, somatotropin)		Stimulates growth and metabolism of bone and soft tissues; promotes protein synthesis, glucose conservation, and fat mobilization.
	Melanocyte-stimulating hormone (MSH)		Stimulates secretion of insulin-like growth factors (IGFs, also called somatomedins) by liver.
	Adrenocorticotrophic hormone (ACTH, corticotropin)		In mammals, also produced in hypothalamus; reduces appetite, suppresses immune system. In amphibians, nonavian reptiles, and fish, causes skin darkening by stimulating dispersal of granules containing the pigment melanin.
	Thyroid-stimulating hormone (TSH, thyrotropin)		Stimulates glucocorticoid secretion by adrenal cortex and supports adrenal cortical tissue (tropic action).
	Follicle-stimulating hormone (FSH)		Stimulates hormone synthesis and secretion by thyroid gland; is tropic.
	Luteinizing hormone (LH)		Stimulates sperm production in the testis, follicular growth in the ovary, and sex hormone production in male and female gonads; is tropic.
	γ -Lipotropin and β -endorphin		Stimulates sex hormone production in male and female gonads, ovulation, and development of corpus luteum; is tropic.
			Possibly decrease perception of pain.

(continued on next page)

Secreting tissue	Hormone	Class of molecule	Main functions
Bone osteoblasts	Osteocalcin	Peptide	Regulates metabolism by increasing secretion of insulin, reducing fat storage by adipose cells, and increasing sensitivity of body's cells to insulin (demonstrated in mice). In combination with luteinizing hormone (LH), stimulates testosterone synthesis by Leydig cells in the testis (demonstrated in mice).
Fat (white adipose) tissue	Leptin Adipokines (e.g., adiponectin, apelin, vaspin)	Peptide	Influences food intake (promotes weight loss), metabolic rate, and reproductive functions; regulates bone remodeling. Influence metabolism, inflammation, cardiovascular functions.
Gastrointestinal (GI) tract	Stomach: gastrin; ghrelin ("hunger hormone") Small intestine: secretin, cholecystokinin, glucagon-like peptide-1 (GLP-1), glucagon-like peptide-2 (GLP-2), glucose-dependent insulinotropic peptide; motilin, somatostatin	Peptides	Listed gastrointestinal peptides aid in digestion and absorption of nutrients by various actions on GI tract, liver, pancreas, and gallbladder. In addition, some serve to stimulate secretion of other hormones (e.g., GLP-1 stimulates insulin secretion).
Gonad: ovary and testis	Estrogens Progesterone Inhibin Activins Relaxin Müllerian-inhibiting hormone Androgens	Steroids Steroid Peptide Peptide Peptide Peptide Steroid	Promote maturation of follicle, ovulation, and secondary sex characteristics; prepare uterus for pregnancy by actions during estrous and menstrual cycles; promote closure of epiphyseal growth plate of bone. Prepares uterus for pregnancy. Inhibits secretion of FSH from anterior pituitary in males and females. Stimulate secretion of FSH; promote spermatogenesis and follicle development. May make cervix and pelvic ligaments more pliable; increases sperm motility in semen. Functions in male fetal development. Promote sperm production and secondary sexual characteristics; promote sex drive in males; enhance growth at puberty; promote closure of epiphyseal plate of bone.
Heart: cells in atria	Atrial natriuretic peptide (ANP)	Peptide	Promotes Na ⁺ and water excretion in kidney.
Hypothalamus	Releasing and inhibiting hormones Corticotropin-releasing hormone (CRH) Thyrotropin-releasing hormone (TRH) Growth hormone–releasing hormone (GHRH) Somatostatin (SS, GHIH) Gonadotropin-releasing hormone (GnRH) Gonadotropin-inhibiting hormone (GnIH) Dopamine (DA, prolactin-inhibiting hormone, catecholamine) Melanocyte-stimulating hormone–inhibiting hormone (MSH-IH)	All peptides (except DA)	Stimulate or inhibit secretion of anterior pituitary hormones; releasing hormones are tropic. Stimulates secretion of ACTH. Stimulates secretion of TSH and prolactin. Stimulates secretion of GH. Inhibits secretion of GH. Stimulates secretion of FSH and LH. Inhibits secretion of FSH and LH. Inhibits secretion of prolactin. Inhibits secretion of MSH.

Secreting tissue	Hormone	Class of molecule	Main functions
	Ghrelin		Stimulates GH secretion.
	Kisspeptins		Stimulate GnRH neurons and serve as the main relay signal for sex steroid feedback to the GnRH cells.
	Orexins		Promote wakefulness; modulate reward pathways; stimulate food intake.
Kidney	Renin	Peptide	Cleaves angiotensinogen to form angiotensin I.
	Erythropoietin (EPO)	Peptide	Stimulates red blood cell production in bone marrow.
	Calcitriol (active form of vitamin D, 1,25 [OH] ₂ D)	Steroid	Increases body calcium and phosphate.
Liver	Angiotensinogen	Peptide	Converted in blood to angiotensin II, which stimulates aldosterone secretion, promotes thirst, and causes vasoconstriction and secretion of vasopressin.
	Insulin-like growth factors (IGFs, also called somatomedins)	Peptides	Promote cell division and growth of many tissues (IGFs are also secreted by other tissues, such as muscle).
Pancreas (endocrine cells)	Insulin (β cells)	Peptide	Promotes uptake and storage of nutrients by most cells.
	Glucagon (α cells)		Maintains blood levels of nutrients after a meal and during stress.
	Somatostatin (δ cells)		Inhibits digestion and absorption of nutrients by the gastrointestinal tract.
Parathyroid gland	Parathyroid hormone	Peptide	Increases Ca ²⁺ and decreases phosphate levels in the blood by action on kidney and bone; stimulates vitamin D activation by action at kidney nephron.
Pineal gland	Melatonin	Amine	Controls circadian rhythms; seasonal breeding, migration, hibernation; possibly sexual maturity; causes skin lightening in amphibians and lampreys.
Placenta of pregnant female mammal	Estrogens and progesterone	Steroids	Support pregnancy and fetal and maternal development.
	Chorionic gonadotropin	Peptide	Extends functional life of corpus luteum in ovary (horses, primates).
	Relaxin	Peptide	May make cervix and pelvic ligaments more pliable.
	Placental lactogen	Peptide	May support mammary gland development during pregnancy; changes maternal metabolism to support fetus.
Posterior pituitary gland (neurohypophysis)	Vasopressins (ADH)	Peptides (produced in hypothalamus and transported to posterior pituitary)	Regulate water reabsorption at kidney; vasoconstriction.
	Oxytocin		Stimulates uterine contraction during parturition and milk ejection from mammary glands during suckling.
Skin	Vitamin D	Steroid	Increases body calcium when activated.
Thymus gland	Thymosin, thymopoietin	Peptides	Stimulate T-lymphocyte development and proliferation.
Thyroid gland	Thyroid hormones (iodothyronines): Tetraiodothyronine (T ₄ , thyroxine) and triiodothyronine (T ₃)	Iodinated amines	Increase metabolism of many tissues; necessary for normal growth and development of the nervous system.
	Calcitonin	Peptide	Decreases blood Ca ²⁺ levels in some animals by inhibiting bone resorption (secreted by C cells).

Glossary

A

A band In striated muscle, the region of a sarcomere that spans the length of the thick filaments. It includes the H zone and regions on both ends where thick and thin filaments overlap. It appears dark in muscle sections prepared for microscopy. It takes its name from the fact that it is described as *anisotropic* because its refractive index in polarized light changes with the plane of polarization.

Absolute refractory period In, e.g., a neuron, the time during and immediately after an action potential in which the voltage threshold is infinite. Thus, no depolarization can exceed threshold and no new action potentials can be initiated.

Absorbed energy In the study of nutritional physiology, the chemical-bond energy of the compounds that an animal absorbs (assimilates) from its digestive tract. Also called *assimilated energy*.

Absorption In the study of nutritional physiology, the entry of organic molecules into the living tissues of an animal from outside those tissues. Absorption includes the entry of materials from the lumen of the gut inasmuch as the lumen is continuous with the outside environment and therefore outside the animal. Also called *assimilation*.

Absorption coefficient The dissolved concentration of a gas when the partial pressure of that gas in solution is 1 atm. See also *Henry's law*.

Absorption efficiency In the study of nutritional physiology, the fraction of molecules or the fraction of chemical-bond energy absorbed from the digestive tract expressed in relation to the amount ingested. Also called *assimilation efficiency*.

Absorption spectrum The absorption of electromagnetic energy by a molecule or other object as a function of the wavelength of the energy.

Accessory heart In an animal with two or more hearts, a heart other than the primary heart. Also called *auxiliary heart*.

Acclimation A chronic response of an individual to a changed environment in cases in which the old and new environments differ in just one or two highly defined

ways. A form of *phenotypic plasticity*. Acclimation is a laboratory phenomenon.

Acclimatization A chronic response of an individual to a changed environment in cases in which the new and old environments are natural environments that can differ in numerous ways, such as winter and summer environments, or low and high altitudes. A form of *phenotypic plasticity*.

Acidosis A state in which the pH of the body fluids is excessively acid.

Acoustico-lateralis system A vertebrate sensory system in which the sensory receptors are hair cells and their derivatives. Includes auditory receptors, organs of balance and gravity detection, and the lateral line system of fish and amphibians.

Acrosomal reaction The release of enzymes from the acrosome in the head of a sperm; occurs when the cell membrane of the sperm head binds to species-specific receptor sites on the zona pellucida surrounding the oocyte.

Actin One of the contractile proteins of muscle cells. Globular G-actin monomers polymerize to form the filamentous F-actin of the thin myofilaments. Actin also contributes to motility in many other kinds of cells.

Action potential A brief electrical signal of about 100 mV across the cell membrane of a neuron or other excitable cell. It is initiated by a depolarization above threshold and is propagated to the end of the axon or cell. Also called a *nerve impulse*.

Activation energy The minimal amount of energy a molecule must gain to enter its transition state during a chemical reaction. Without entering its transition state, a molecule cannot react. Enzymes speed reactions by lowering the activation energy, making achievement of the transition state more likely.

Active change in lung volume In the study of ventilation, a change in lung volume driven by muscle action. Contrast with *passive change in lung volume*.

Active evaporative cooling Evaporative cooling that occurs because evaporation is accelerated by some physiological process other than the simple production of heat,

such as panting or sweating. See also *evaporative cooling*.

Active site A specific region of an enzyme molecule, at or near the surface of the molecule, where the enzyme binds with its substrate and where the conversion of substrate to product is catalyzed. Also called a *substrate-binding site*.

Active transport The transport of a solute across a membrane by a mechanism that is capable of using metabolic energy to cause solute molecules to move across the membrane. An active-transport mechanism is capable of making a solute move away from equilibrium (against its electrochemical gradient). Also called *uphill transport*.

Acute response A response exhibited by an animal during the first minutes or hours after an environmental change.

Adaptation (1) In evolution, a genetically controlled trait that, through the process of natural selection, has come to be present at high frequency in a population because it confers a greater probability of survival and successful reproduction in the prevailing environment than available alternative states. (2) In a sensory receptor, a decrease in the frequency of action potentials in response to a stimulus, during prolonged exposure to the stimulus, even though the stimulus is maintained at a constant level. *Tonic receptors* adapt slowly, and *phasic receptors* adapt rapidly.

Adenohypophysis The nonneural endocrine portion of the vertebrate pituitary gland. It is commonly called the anterior pituitary and includes three parts with variable representation in different species: the pars tuberalis, pars intermedia, and pars distalis.

Adequate stimulus The kind of stimulus energy to which a receptor is most sensitive, or the kind of stimulus to which it normally responds.

Adipocyte An animal cell specialized for the storage of fats or oils.

Adrenergic neuron A neuron that synthesizes and releases norepinephrine (noradrenaline) or epinephrine (adrenaline) as a neurotransmitter.

Aerobic Requiring O₂.

Aerobic capacity A synonym for $\dot{V}_{O_2\max}$.

G-2 Glossary

Aerobic dive limit (ADL) In diving mammals and birds, the length of the longest dive that can be undertaken without net accumulation of lactic acid above the resting level.

Aerobic expansibility An animal's peak rate of O₂ consumption during locomotion expressed as a ratio of its resting rate of O₂ consumption. Sometimes used to refer to the same calculation as *aerobic scope*.

Aerobic scope for activity The difference between an animal's peak rate of O₂ consumption during locomotion and its resting rate of O₂ consumption. Sometimes used to refer to the same calculation as *aerobic expansibility*.

Afferent Going toward. Thus, for example, an afferent blood vessel carries blood toward an organ of interest. Contrast with *efferent*.

Afferent neuron A neuron, normally sensory, that conducts signals from the periphery into the central nervous system.

Affinity See *enzyme–substrate affinity*, *oxygen affinity*.

Aglomerular Lacking a glomerulus.

Air capillaries Minute, gas-filled, blind-ended channels that branch off from the principal respiratory tubules, the parabronchi, within the lungs of a bird and that act as the primary sites of respiratory gas exchange between the air and blood.

Alkalosis A state in which the pH of the body fluids is excessively alkaline.

Akt1 A signal transduction molecule that stimulates cells to survive and grow; activated by phosphatidylinositol 3-kinase (PI-3 K) when PI-3 K is activated by an extracellular signal. Also called *protein kinase B*.

All-or-none Occurring fully or not at all; not graded.

Allometric equation Two variables, X and Y, are related in an allometric manner when $Y = aX^b$ ($b \neq 1$). See Appendix F. Also called the *power equation*.

Allosteric modulation (1) In relation to enzymes, modulation of the catalytic properties of an enzyme by the binding of nonsubstrate ligands to specific nonsubstrate-binding sites, called regulatory sites or allosteric sites; a type of *cooperativity*, commonly important in the regulation of enzyme-catalyzed reactions and pathways. (2) In relation to respiratory pigments, modulation of O₂ binding by the binding of ligands other than O₂. See also *cooperativity*.

Allosteric modulator (1) In relation to enzymes, a nonsubstrate ligand of an enzyme that modulates the catalytic activity of the enzyme by binding to a

specific regulatory site on the enzyme molecule. (2) In relation to respiratory pigments, a ligand other than O₂ that modulates binding with O₂.

Alpha (α) motor neuron A relatively large motor neuron in a vertebrate spinal cord that innervates extrafusal muscle fibers.

Alphastat hypothesis The hypothesis that in poikilotherms the pH of body fluids is typically regulated at a relatively fixed difference from neutral pH—even as the body temperature changes and the neutral pH therefore also changes—as a way of maintaining a relatively constant state of electrical charge on proteins (particularly on protein imidazole groups).

Alveoli (singular alveolus) (1) In the lungs of vertebrates, the blind-ended terminations of the branchings of the respiratory tract that form the surface for exchange of gases between the air and the blood. (2) In the mammary glands of mammals, the hollow glandular structures that secrete milk.

Amacrine cell A retinal neuron that mediates lateral antagonistic effects and is sensitive to visual movements.

Ambient Relating to the surroundings of an organism. Synonymous with *environmental*; for instance, the ambient temperature is the environmental temperature.

Ammonotelic Incorporating most nitrogen from the catabolism of nitrogenous compounds into ammonia. “Most” is defined differently by different authorities; a common approach is to categorize an animal as ammonotelic if 50% or more of the nitrogen released by catabolism is incorporated into ammonia.

Amniotic egg A vertebrate egg in which the developing embryo is enclosed in the amnion, a sac (extra-embryonic membrane) that contains a bathing amniotic fluid. The amnion evolved and develops in conjunction with other extra-embryonic membranes that support the embryo, notably the chorion, allantois, and yolk sac. The internally developing eggs of mammals are amniotic eggs, as are the cleidoic eggs of birds and other reptiles. See also *cleidoic egg*.

Amphipathic molecule A molecule that consists of a polar subpart and a nonpolar subpart.

Amplification In a sequence of enzyme-catalyzed biochemical reactions, an increase in the number of reacting molecules resulting from the fact that one enzyme molecule can catalyze the formation of more than one product molecule.

Anabolism Constructive metabolism; the set of metabolic processes that build

relatively large molecules from smaller molecular building blocks using energy.

Anadromous Relating to an aquatic animal that undergoes most of its growth in seawater but enters freshwater to breed.

Anaerobic Capable of functioning without O₂.

Anaerobic glycolysis The reactions that convert glucose to lactic acid.

Anastomose To form an interconnected network of tubules, vessels, or similar structures by patterns of branching, reconnection, and rebranching.

Anatomical dead space In the lungs of an animal, the sum total of the conducting airways; that is, that portion of the lungs that does not participate in the exchange of respiratory gases between air and blood.

Androgen A masculinizing hormone such as testosterone.

Angiogenesis The formation of new blood vessels (e.g., new capillaries) by sprouting of branches from existing vessels.

Angiotensin converting enzyme (ACE) A membrane-bound enzyme produced by vascular endothelial cells that converts inactive angiotensin I to angiotensin II.

Anhydrobiosis Survival while dried as fully as possible by desiccation in air.

Animal physiology The study of the functional properties of animals; the study of “how animals work.”

Anion A negatively charged ion.

Annotation In the study of genomics, the process of adding interpretive information to gene identities. For example, if a genomic analysis indicates the likely presence of a particular gene that is known in some organisms to code for a detoxification enzyme, stating that the gene is “involved in detoxification” would be an act of annotation.

Anoxia In relation to the tissues of an animal, the state of being devoid of O₂.

Antagonism A type of influence of one substance (such as a hormone) in relation to another in which one opposes the action of the other on a target tissue.

Antagonist An opponent. In biochemical reactions, a substance that opposes the action of another substance. See also *antagonistic muscle pair*.

Antagonistic muscle pair Two muscles, or groups of muscles, that perform coordinated, opposing actions. When one muscle contracts to close the angle of a joint, its antagonist relaxes. To open the joint, the formerly relaxed muscle contracts and the formerly contracted muscle relaxes.

Antennal gland The urine-producing structure of a decapod crustacean. Also called a *green gland*.

Anterior pituitary The nonneural endocrine portion of the vertebrate pituitary gland. It includes three parts with variable representation in different species: the pars tuberalis, pars intermedia, and pars distalis. Also called the *adenohypophysis*.

Antidiuresis The production of urine at a low rate. Such urine is usually concentrated as well as scanty.

Antidiuretic Opposing diuresis; promoting antidiuresis.

Antidiuretic hormone (ADH) A hormone that promotes antidiuresis. In mammals, also called *vasopressin*.

Antifreeze compound A metabolically synthesized compound, added to a body fluid, that has the principal function of lowering the freezing point of that body fluid.

Anti-Müllerian hormone See *Müllerian inhibitory substance*.

Antioxidants A collective term referring to molecules that prevent or delay damaging oxidation of macromolecules (or other molecules) involved in normal function by reactive oxygen species. See also *reactive oxygen species*.

Antiporter See *countertransporter*.

Apical membrane In an epithelial cell, the part of the membrane that faces toward the lumen or open space lined by the epithelium of which the cell is a part.

Apical surface In an epithelium, the surface that faces toward the lumen or open space lined by the epithelium. Also called the *mucosal surface*.

Apnea The absence of breathing.

Aquaporin A chemically defined type of water channel, often highly specific for water as opposed to solutes. See also *water channel*.

Arachnid A spider, tick, scorpion, or mite.

Archimedes' principle The principle that states that a body immersed in a fluid is buoyed up by a force equal to the weight of the fluid displaced.

Aromatase The enzyme that converts androgens such as testosterone to estrogens such as estradiol.

Arousal (1) In the study of hibernation, the emergence of an animal from hibernation, involving the rewarming of tissues to ordinary homeothermic temperatures. (2) In the study of sleep, the transition from sleep to wakefulness.

Arousal threshold In the study of sleep, a measure of the difficulty of waking a

sleeping individual at a particular time; a low threshold signifies that sleep terminates relatively easily.

Arteriole A microscopically fine blood vessel with muscular walls that carries blood from arteries to capillaries in a microcirculatory bed of a vertebrate. Contraction and relaxation of the muscular walls controls the rate of blood flow to the capillaries supplied by the arteriole.

Artery A macroscopic blood vessel that carries blood away from the heart.

Asexual reproduction The formation of new individuals without the union of gametes from two different parents. The offspring are genetically identical to their parent.

Assimilation In the study of nutritional physiology, synonymous with *absorption*.

Astrocyte A type of glial cell (non-neuronal cell) of the vertebrate central nervous system that regulates extracellular ion concentrations and metabolically supports neurons. Important in the *blood-brain barrier*.

Atmosphere A unit of measure for pressure. An *atmosphere* or, more technically speaking, a *normal atmosphere* is the average pressure exerted by Earth's atmosphere at sea level. It is quantitatively specified by international agreement to be 1.01325×10^5 pascal at 15°C. It is also specified to be equal to the pressure exerted by a column of mercury 760 mm high under standard gravitational acceleration.

ATPase An enzyme capable of hydrolyzing adenosine triphosphate (ATP) and thereby releasing energy from ATP.

Atrial natriuretic peptide A member of a family of peptide hormones secreted by specialized cells in the atria of the heart that stimulate the excretion of water and sodium.

Atrophy A decrease in the mass of a tissue or organ by the loss of cells or of intracellular components of cells. Also called *wasting*.

Audition Hearing; sound detection and perception.

Autocrine A locally acting chemical signal that binds to receptors and exerts a regulatory effect on the same cell that secreted it.

Autonomic effector An effector other than skeletal muscle; includes smooth and cardiac muscles and tissues of the viscera and exocrine glands.

Autonomic nervous system (ANS) The division of the nervous system that innervates and controls autonomic effectors

and conveys sensory information from internal organs.

Autoreceptor In synaptic processes, a receptor protein on a presynaptic terminal that is stimulated by neurotransmitter released by the same neuron.

Autotroph An organism that can obtain the energy it needs to stay alive from sources other than the chemical bonds of organic compounds. Some autotrophs (*photoautotrophs*) use photon energy; others (*chemoautotrophs*) use energy from inorganic chemical reactions. Contrast with *heterotroph*. See also *primary production*.

Auxiliary heart See *accessory heart*.

Average daily metabolic rate (ADMR) An animal's rate of metabolism averaged over all hours of the 24-hour day.

Avogadro's number The number of molecules in a mole; also, the number of independent dissolved entities in an osmole. Equal to 6.022×10^{23} .

Axis In the study of endocrinology, two or more hormone-secreting tissues that together form an hierarchical control system.

Axon A process of a neuron specialized for conveying action potentials (usually) away from the cell body. An axon may be myelinated (ensheathed in *myelin*) or unmyelinated.

Axonal transport The transport of materials within the cytoplasm of an axon; may be either anterograde (away from the cell body) or retrograde (toward the cell body).

B

Baculum A rodlike structure of cartilage or bone that gives stiffness to the shaft of the penis of some species of mammals.

Basal ganglia In the vertebrate brain, a collection of cell groups in the ventral forebrain that organize motor behavior. The *caudate nucleus*, *putamen*, and *globus pallidus* are major components of the basal ganglia; the *subthalamic nucleus* and *substantia nigra* (midbrain) are usually included.

Basal lamina See *basement membrane*.

Basal membrane In an epithelial cell, the part of the cell membrane that faces toward the underlying tissue on which the epithelium rests or to which the epithelium is attached.

Basal surface In an epithelium, the surface that faces toward the underlying tissue on which the epithelium rests or to which the epithelium is attached. Also called the *serosal surface*.

Basal metabolic rate (BMR) The metabolic rate of a homeothermic animal

G-4 Glossary

when it is in its thermoneutral zone, resting and fasting.

Basement membrane A thin, permeable, noncellular, and nonliving sheet of matrix material on which an epithelium rests, or that surrounds a cell such as a muscle or fat cell. It is composed of glycoproteins and particular types of collagen and is secreted by cells; for example, the cells of an epithelium help secrete the basement membrane on which the epithelium rests. Also called a *basal lamina*.

Basilar membrane A membranous tissue within the cochlea of the vertebrate ear that contains the auditory sensory hair cells and is vibrated by sound waves.

Basolateral membrane In an epithelial cell, the basal cell membrane plus the lateral cell membranes between the basal membrane and the ring of tight junctions, in contradistinction to the *apical membrane*. See *basal membrane*.

Behavioral thermoregulation (1) In poikilotherms, the maintenance of a relatively constant body temperature by behavioral means. (2) In homeotherms, the use of behaviors to assist in the maintenance of a relatively constant body temperature.

Bends See *decompression sickness*.

Bile salt A type of emulsifying compound, produced by the biliary system in the liver of a vertebrate, that plays a key role in lipid digestion and absorption because of its ability to emulsify lipids within the gut lumen.

Bimodal breather See *dual breather*.

Biological clock A physiological mechanism that gives an organism an endogenous capability to keep track of the passage of time.

Bioluminescence Biochemical production of light by cells.

Bipolar cell A type of neuron in the vertebrate retina that mediates the direct (straight-through) pathway connecting rods and cones to ganglion cells.

Bivalve mollusc A clam, mussel, scallop, oyster, or related animal.

Black-body temperature See *radiant temperature*.

Blastocyst A hollow sphere of cells formed in early mammalian development that implants in the uterus. Its inner cell mass will form the embryo and extra-embryonic structures, and its outer trophoblast cells will contribute to formation of the placenta.

Blood The fluid (including suspended cells) that is circulated within the circulatory system.

Blood-brain barrier Phenomenologically, a tendency for many substances to exchange much less readily between the blood plasma and the extracellular tissue fluids in the brain than such exchanges in most other tissues. Structurally, a specialized morphology of blood capillaries and glial cells in the brain that interferes with passive transport between blood and extracellular tissue fluid.

Blood plasma The part of the blood that remains after blood cells are removed; the part of the blood other than cells.

Blood pressure The extent to which the pressure of the blood exceeds the ambient pressure.

Bohr effect A decrease in the O₂ affinity of a respiratory pigment (a shift of the oxygen equilibrium curve to the right) caused by a decrease in pH or an increase in CO₂ partial pressure.

Bomb calorimeter A device used to measure the energy content of organic materials.

Book gills Unusual gill structures consisting of many sheets of tissue arrayed like pages of a book; found in horseshoe crabs.

Book lungs Lungs within which sheets of gas-exchange tissue alternate with sheetlike air spaces, like pages of a book slightly separated by air. Found in spiders, scorpions, and some other arachnids.

Brackish water Water that is intermediate in salinity between seawater and freshwater. One criterion sometimes used is that water is considered brackish if its salinity is between 0.5 and 30 g/kg.

Bradycardia A heart rate that is unusually low.

Brain The anterior enlargement of the central nervous system in an animal with a cephalized nervous system.

Branchial Relating to gills.

Brown adipose tissue (BAT) A metabolically active form of adipose tissue, known only in mammals, that serves as the primary site of mammalian nonshivering thermogenesis and expresses a distinctive mitochondrial protein, *uncoupling protein 1* (UCP1). Also called *brown fat*. Contrast with *white adipose tissue*.

Brush border An apical epithelial surface bearing microvilli.

Buccal pressure pump The development of positive pressure within the buccal cavity of a vertebrate, used to force air into lungs or water across gills.

Buffer reaction A chemical reaction in a solution that tends to stabilize the pH of the solution by removing H⁺ from the solution when H⁺ is added by some exter-

nal process and by adding H⁺ to the solution when H⁺ is removed by an external process.

Bulk solution Solution that is not immediately next to a membrane or other surface.

Burst exercise Sudden, intense exercise.

C

Caching behavior The storage of food or other material for later use.

Caisson disease See *decompression sickness*.

Calorie (cal) A unit of energy equal to the amount of heat required to raise the temperature of 1 g of water by 1°C, from 14.5°C to 15.5°C. Some people outside science distinguish the calorie from the kilocalorie (kcal; 1000 calories) by writing "calorie" (small "c") to represent the calorie and "Calorie" (large "C") to represent the kilocalorie. Sometimes, in fact, in writing outside science, "calorie" (small "c") is used to refer to the kilocalorie; thus one must be cautious in interpreting uses of "calorie" outside science.

Camera eye An eye that optically resembles a camera, with a lens that focuses an image on a retina of light-sensitive cells.

cAMP See *cyclic adenosine monophosphate*.

Capacitance An electrical term meaning the ability of a capacitor or a capacitor-like structure, such as a cell membrane, to store electrical charges. A cell membrane acts like a capacitor because of its electrically insulating properties. Capacitance (C, in farads) is a measure of the amount of charge stored per unit of voltage. See *capacitor*.

Capacitance coefficient (β) In the study of respiratory gas exchange, the change in total gas *concentration* per unit of change in gas *partial pressure* in air, water, or a body fluid like blood. The capacitance coefficient sometimes differs from simple gas-solubility coefficients such as the absorption coefficient because in the case of the capacitance coefficient, the gas concentration includes bound gases, such as O₂ bound to hemoglobin.

Capacitation The final maturation of sperm that takes place in the female reproductive tract to make the sperm capable of rapid forward swimming and fertilization.

Capacitor Two conducting plates separated by an insulating layer. If the plates are close enough to each other, charges on one plate can electrostatically attract or repel charges on the other plate, even if charges cannot cross the insulation. A capacitor can store electrical charge.

- Capillary** A microscopically fine blood vessel, the wall of which consists of only a single layer of epithelial cells. Capillaries are the principal sites of exchange between blood and other tissues in a closed circulatory system.
- Carbon dioxide dissociation curve** See *carbon dioxide equilibrium curve*.
- Carbon dioxide equilibrium curve** In relation to the CO₂-carrying properties of blood, a graph of the *total carbon dioxide concentration* as a function of the CO₂ partial pressure of the blood. Also called the *carbon dioxide dissociation curve*.
- Carbonic anhydrase (CA)** An enzyme that accelerates the conversion of CO₂ and H₂O into HCO₃⁻ and H⁺, or the reverse reaction.
- Cardiac muscle** Muscle that forms the wall of the heart. In vertebrates, cardiac muscle consists of branched, generally uninucleate, striated muscle cells that are connected by intercalated discs. The contractions of the cells are initiated by endogenously generated myogenic action potentials and may be modified by neural and hormonal factors. The cardiac muscle of invertebrates may consist of striated or nonstriated cells that may be endogenously active (myogenic) or controlled by neural input (neurogenic).
- Cardiac output** The volume of blood pumped by a heart per unit of time, calculated as the stroke volume multiplied by the number of beats per unit of time (heart rate). In the case of the mammalian or avian heart, the cardiac output is specifically the output of the left ventricle into the systemic aorta unless stated otherwise.
- Carrier** See *transporter*.
- Carrier-mediated transport** Solute transport across a membrane that requires the reversible, noncovalent binding of solute molecules with a protein (called a *transporter* or *carrier*) in the membrane. There are two kinds of carrier-mediated transport: *active transport* (which employs metabolic energy) and *facilitated diffusion* (which does not).
- Catabolism** Destructive metabolism; the set of metabolic processes by which complex chemical compounds are broken down to release energy, create smaller chemical building blocks, or prepare chemical constituents for elimination.
- Catadromous** Relating to an aquatic animal that undergoes most of its growth in freshwater but enters seawater to breed.
- Catalyst** A compound that facilitates a chemical reaction—in which covalent bonds are made or broken—without, in the end, being modified by the reaction. *Enzymes* are catalysts.
- Catalytic rate constant (k_{cat})** The number of substrate molecules a unit of enzyme is capable of converting to product per unit of time when the enzyme is saturated.
- Catalytic vacuole** The part of an enzyme molecule that provides a suitable setting for catalysis during the conversion of substrate to product; includes, but is not limited to, the *active site*.
- Cation** A positively charged ion.
- Cell body** The portion of a neuron that contains the cell nucleus; also called the *soma* or *perikaryon*.
- Cell membrane** The membrane that encloses an animal cell and forms the outer boundary of the cell. Also called the *plasma membrane*.
- Cell signal transduction** The processes by which cells alter their intracellular activities in response to extracellular signals.
- Cell theory** The theory, developed in the nineteenth century, that organisms are composed of cells, which act as structural, functional, and developmental units of organization.
- Cellular oscillator** A neuron that can generate a rhythmic change in membrane potential or activity without needing synaptic input to do so; one possible basis of a central pattern generator.
- Central circulation** The heart and the veins and arteries that connect immediately to the heart.
- Central nervous system (CNS)** The consolidated integrative part of an animal's nervous system; in vertebrates, consists of the brain and spinal cord.
- Central pattern generator (CPG)** A neural circuit (or a single neuron) that generates a behaviorally significant pattern of motor output in space and time without requiring temporally patterned sensory input.
- Centralization** Over the course of evolution, the tendency of animal groups to concentrate integrative neural functions into a central nervous system.
- Cephalization** The concentration of structures of the nervous system toward the anterior end of an animal, a trend underlying the evolution of anterior brains in many animal groups.
- Cephalopod mollusc** An octopus, squid, cuttlefish, or related animal.
- Cerebellar cortex** The outer layer of the cerebellum of the vertebrate hindbrain; involved in motor coordination and learning.
- Cerebellum** A prominent structure of the vertebrate hindbrain, concerned with motor coordination, posture, and balance. Consists of the *cerebellar cortex* and *deep cerebellar nuclei*.
- Cerebral cortex** The outer part of the cerebral hemispheres of the vertebrate forebrain; greatly enlarged in birds and mammals.
- cGMP** See *cyclic guanosine monophosphate*.
- Channel** A membrane protein that aids the passive transport of a solute across a membrane without undergoing any sort of chemical binding with that solute. Channels participate particularly in passive transport of inorganic ions across membranes. See also *water channel*.
- Chaperones** See *molecular chaperones* or *chemical chaperones*.
- Chemical chaperones** Synonym for *counteracting solutes*.
- Chemical energy (chemical-bond energy)** Energy that is liberated or required when atoms are rearranged into new configurations. Animals obtain the energy they need to stay alive by reconfiguring atoms in food molecules, thereby liberating chemical energy.
- Chemical potential** Qualitatively speaking, the strength of the tendency of a chemical substance to undergo a physical or chemical change. Measures of chemical potential are useful for predicting the direction of change because chemical substances tend to go from high chemical potential to low chemical potential.
- Chemical synapse** A synapse that for signal transmission employs a chemical neurotransmitter that is released presynaptically and acts on postsynaptic neurotransmitter receptors.
- Chemiosmotic hypothesis** A hypothesis concerning the biochemical relationship between electron transport and oxidative phosphorylation in mitochondria. According to the hypothesis, electron transport pumps protons into the mitochondrial intermembrane space, and the back-diffusion of the protons through ATP synthase results in ATP formation.
- Chemoautotroph** An organism that can obtain the energy it needs to stay alive from energy-yielding inorganic chemical reactions.
- Chemoreception** A sensory response to a chemical stimulus. Chemoreception includes *taste* (also termed the *gustatory sense*) and *olfaction* (the sense of smell), as well as other chemical sensitivities.
- Chloride cell** See *mitochondria-rich cell*.

G-6 Glossary

Chloride shift In vertebrate blood, diffusion of Cl^- from the blood plasma into the red blood cells in exchange for diffusion of HCO_3^- out of the cells, or the reverse process. Mediated by a membrane countertransporter often called the *band 3 protein*.

Chlorocruorin A type of respiratory pigment found in certain marine annelid worms, formed by the combination of hemelike structures with protein. Undergoes reversible combination with O_2 at the hemelike loci.

Cholinergic neuron A neuron that synthesizes and releases acetylcholine as a neurotransmitter.

Chorionic gonadotropin (CG) A hormone secreted by the embryonic placenta in horses and primates that maintains the function of the corpus luteum beyond the time when it would degenerate if pregnancy did not occur.

Chromatophore (1) In most animals, a type of cell containing pigment granules that can undergo changes in dispersion, thereby altering their influence on the color of the skin or other structure; a color-change cell. (2) In cephalopod molluscs (e.g., squids), the same term is used to refer to a very different color-change structure, namely an organ composed of a pigment cell and many muscle cells that can change the size of the pigment cell.

Chronic response A response expressed by an animal following days, weeks, or other prolonged exposure to new environmental conditions.

Ciliary photoreceptor A photoreceptor cell in which the light-sensitive part is a modified cilium; characteristic of vertebrates.

Circadian oscillator The biological clock that times a circadian rhythm.

Circadian rhythm An endogenous rhythm with a period of about a day (ca. 24 hours).

Circannual rhythm An endogenous rhythm with a period of about a year.

Circatidal rhythm An endogenous rhythm with a period approximating a tidal cycle (ca. 12.4 hours).

Circulation The pressure-driven mass flow of blood through a system of tubular vessels or other passages that brings the blood to all parts of the body.

Circulatory system The blood and the system of vessels or other passages through which it circulates.

Classical conditioning A form of associative learning in which an animal learns the association between two stimuli.

Clearance See *plasma clearance*.

Cleidoic egg Metaphorically, a cleidoic egg is a “locked box” (*cleido*, “key”) (in contrast to an egg that exchanges nutrients with its surroundings throughout development). In a cleidoic egg—exemplified by the eggs of birds and other reptiles—everything needed by an embryo to develop from a single cell to a hatchling is present within the shell of the egg. The egg includes all nutrients required by the embryo, a method of gas exchange, and mechanisms to store or eliminate metabolic wastes. See also *amniotic egg*.

Clone A new individual, produced by asexual reproduction, that is genetically identical to its parent, or a group of such individuals. Used as a verb, to *clone* means to make an exact genetic copy.

Closed circulatory system A circulatory system in which the blood is enclosed within blood vessels throughout and is therefore distinct from the interstitial fluids. Contrast with *open circulatory system*.

Cochlea A part of the inner ear of many vertebrates, coiled in mammals, that contains the auditory sensory hair cells.

Cocurrent Referring to two fluids flowing in the same direction. Also called *concurrent*.

Colligative properties The properties of an aqueous solution that depend simply on the number of dissolved entities per unit of volume, rather than on the chemical nature of the dissolved entities. The three principal colligative properties in animal physiology are osmotic pressure, freezing point, and water vapor pressure.

Colloid osmotic pressure The difference in osmotic pressure that arises between two solutions on either side of a cell membrane or epithelium because the two solutions differ in their concentrations of nonpermeating protein solutes. Because the solutes responsible for colloid osmotic pressure cannot cross the membrane or epithelium, the colloid osmotic pressure represents a “fixed” difference in osmotic pressure between the solutions. Also called *oncotic pressure*.

Commissure A bundle of axons that connects the two sides of a bilaterally symmetrical central ganglion or bilateral regions of a central nervous system.

Comparative method A method of analysis that seeks to identify adaptive traits or adaptive evolutionary trends by comparing how a particular function is carried out by related and unrelated species in similar and dissimilar environments.

Compass direction North, south, east, west, or a combination of these; the direction of a movement or orientation as it could be described using a compass.

Compatible solute A solute that, when concentrated enough to contribute significantly to the osmotic pressure of a fluid, has little or no effect on the structure and function of macromolecules with which the fluid is in contact.

Compensation In the study of acclimation or acclimatization, the return of a physiological property toward its value that existed prior to an environmental change even though the animal remains in the changed environment. Compensation is *partial* if the physiological property returns only partly toward its preceding value. It is *complete* if the physiological property returns to the value that existed prior to the environmental change.

Complete compensation See *compensation*.

Complex cell A neuron found in the mammalian primary visual cortex that has an orientation-selective receptive field but lacks distinct subparts excited or inhibited by reception of light. A complex cell responds to a bar or edge of a certain size and orientation, anywhere in the cell’s receptive field.

Compound eye A multifaceted eye characteristic of arthropods, composed of many individual optical units called *ommatidia*.

Concentration gradient Technically, the difference in the concentration of a solute between two places divided by the distance separating those two places. Often used more loosely to refer simply to a difference in concentration.

Concentric muscle contraction An isotonic muscle contraction in which the muscle shortens while generating force.

Concurrent See *cocurrent*.

Condensation A change in the physical state of a compound from a gas to a liquid.

Conductance A measure of how easily electrical current will flow through a conductive pathway. Contrast with electrical *resistance*. See also *thermal conductance*.

Conducting airways In the lungs of an animal, the airways that do not participate in the exchange of respiratory gases between air and blood, but rather simply conduct air from one place to another.

Conducting system A system of specialized muscle cells by which depolarization spreads throughout the vertebrate heart.

Conduction (1) In the study of heat, the transfer of heat by intermolecular collisions through a material that is macroscopically motionless. (2) In the study of heart physiology, the process by which depolarization spreads through the verte-

- brate heart or any other myogenic heart.
(3) In the study of electrical phenomena, the transmission of electrical currents or signals through a conductive pathway.
- Cone** A type of photoreceptor in the vertebrate retina. Cones are smaller and less light sensitive than rods and are used for diurnal vision and color vision.
- Conformity** A state in which an animal's internal conditions match the external environmental conditions.
- Connective** A bundle of neuronal axons in the central nervous system that connects central ganglia; found in the ganglionic nervous systems of arthropods, annelids, and molluscs.
- Connexin** The protein that makes up connexons.
- Connexon** The protein channel of a gap junction at which cytoplasmic continuity is established between two adjacent cells. Two connexons, positioned respectively in the cell membranes of the two cells, form the channel. Channels of this sort electrically couple cells (permitting current flow between them) and permit small molecules to move between cells.
- Constitutive enzyme** An enzyme (or other protein) that is always expressed in a tissue. Contrast with *inducible enzyme*.
- Consumption, of energy** Conversion of chemical-bond energy to heat or external work.
- Contact chemoreceptor** A chemosensory cell (of a terrestrial animal) that is normally stimulated by chemicals that contact it in a liquid. Contrast *distance chemoreceptor*.
- Contraction** The condition in which a muscle is activated to produce force. In a skeletal muscle, contraction can be shortening (isotonic), isometric (remaining the same length), or lengthening (isotonic).
- Convection** Always refers to mass flow, but has different specific meanings depending on context. (1) In the study of heat transfer, *convection* is the transfer of heat by the mass flow of a material substance (e.g., wind). (2) In the study of material transport, *convection* refers to (i) the flow of a fluid from place to place and (ii) the transport of molecules in the fluid from place to place by the fluid flow. Blood flow, for example, is a type of convection, and when the blood carries a material such as O₂ from place to place, the material is said to undergo convective transport.
- Convergence** Coming together. In neurophysiology, a pattern in which signals from many presynaptic neurons come together to affect a particular postsynaptic neuron. Contrast with *divergence*.
- Cooperativity** A type of chemical behavior that occurs in protein molecules that have multiple ligand-binding sites, in which the binding of any one site to its ligand may facilitate or inhibit the binding of other sites on the same molecule to their ligands. The binding sites do not interact directly; instead, binding at one site induces protein conformational shifts that affect other sites at a distance.
- Coronary artery** An artery that carries blood into the myocardium of a heart.
- Coronary vein** A vein that carries blood out of the myocardium of a heart.
- Corpus allatum (plural corpora allata)** One of a bilateral pair of organs in insects that serve both as neurohemal organs, where prothoracicotrophic hormone (PTTH) is released from axon terminals of neurosecretory cells in the brain, and as nonneural endocrine tissue, which secretes juvenile hormone.
- Corpus luteum (plural corpora lutea)** An endocrine structure in the vertebrate ovary formed by reorganization of the cells of an ovarian follicle that has undergone ovulation. In mammals, it secretes progesterone, estrogen, and inhibin. If fertilization occurs, it remains active during pregnancy; if not, it degenerates.
- Cost of transport** For an animal that is undergoing directional locomotion, the energy cost of covering a unit of distance.
- Costal suction pump** The development of negative pressure within the thorax of an air-breathing vertebrate by action of the costal muscles between the ribs, used to suck air into the lungs.
- Costamere** In muscle fibers, a complex of protein molecules that serves as a region of attachment between the myofibrils, sarcolemma, and extracellular matrix. Costameres are organized into many parallel bands that circumscribe each muscle fiber at regular intervals coincident with the Z discs.
- Cotransmitter** In neurons that synthesize and release more than one kind of neurotransmitter molecule, the second kind of neurotransmitter.
- Cotransporter** A transporter protein that obligatorily carries two different solutes in the same direction simultaneously. Through the participation of a cotransporter, the diffusion of one solute in the direction of its electrochemical gradient can cause a second solute to move away from equilibrium. Also called a *symporter*.
- Counteracting solutes** Osmolytes that act in teams of two or more to modify the osmotic pressures of body fluids without greatly perturbing macromolecules because the individual members of the teams have mutually offsetting effects on the macromolecules.
- Countercurrent** Referring to two fluids flowing in opposite directions.
- Countercurrent exchange** Exchange of heat, O₂, or other substances by passive-transport processes (e.g., diffusion) between two closely juxtaposed fluid streams flowing in opposite directions (e.g., blood flowing in opposite directions in two blood vessels).
- Countercurrent multiplication** A process that occurs in a system consisting of two juxtaposed fluid streams flowing in opposite directions, in which metabolic processes produce a difference (termed the *single effect*) between adjacent parts of the two streams. Because of the dynamics of such a system, the difference produced between adjacent parts of the two streams is multiplied to create a much larger difference between the two ends of the system.
- Countertransporter** A transporter protein that obligatorily carries two different solutes in opposite directions simultaneously. Through the participation of a countertransporter, the diffusion of one solute in the direction of its electrochemical gradient can cause a second solute to move away from equilibrium. Also called an *antiporter*.
- Coupling** In the study of cell energy transduction, the use of energy released in the electron-transport chain to synthesize adenosine triphosphate (ATP). It can be graded; i.e., the two processes—electron transport and ATP synthesis—can be tightly or loosely coupled.
- Covalent bond** A chemical bond in which atoms fully share electrons. Covalent bonds are strong and, for the most part in biological systems, require enzyme catalysis to be made or broken.
- Covalent modulation** Modulation of the catalytic properties of an enzyme, or the functional properties of another type of protein, by chemical reactions that make or break covalent bonds between a modulator and the enzyme or other modulated protein. The most common mode of covalent modulation is phosphorylation and dephosphorylation catalyzed by protein kinases and protein phosphatases. Also called *covalent modification*.
- Cranial nerves** Peripheral nerves that connect to the brain.
- Critical temperature** (1) In the study of poikilotherms, a body temperature (high or low) at which animals have little or no ability to increase their rate of O₂ consumption above their resting rate—making them incapable of much physical

G-8 Glossary

- activity. (2) In the study of homeotherms, an ambient temperature that defines the upper or lower limit of the thermoneutral zone; see also *lower critical temperature* and *upper critical temperature*.
- Cross-bridge** The head of a myosin molecule interacting with actin molecules to produce muscle contraction by repeated oarlike power strokes. Each myosin molecule has two heads, and each head has an actin-binding site and an enzymatic site that binds and hydrolyzes ATP to liberate energy to fuel each power stroke.
- Cross-current exchange** A type of exchange between two fluid streams, most commonly found in breathing organs in which O₂ and CO₂ are exchanged between air and blood. During cross-current exchange of this sort, the total blood flow is broken up into multiple separate streams, each of which “crosses” the flow of air at a particular point, thereby exchanging respiratory gases with the air at just one point along the path of airflow. The streams then coalesce to reestablish a unified total blood flow.
- Cryptobiosis** Latent life. A resting state in which there is little or no metabolism, so that there are few, if any, signs that the organism is still alive.
- Cryptonephridial complex** A specialized, close association between the Malpighian tubules and rectum that occurs in certain types of insects (e.g., mealworms) and plays a role in the production of concentrated urine and the absorption of water vapor from the atmosphere.
- Current, electric** The flow of electrical charge.
- Cutaneous** Relating to the skin.
- Cuticle** The exoskeleton of an arthropod, or the material of which the exoskeleton is composed.
- Cyclic adenosine monophosphate (cyclic AMP, cAMP)** A second messenger produced intracellularly in response to several neurotransmitters and hormones.
- Cyclic guanosine monophosphate (cyclic GMP, cGMP)** An intracellular messenger in rod and cone photoreceptors and a second messenger in some neurotransmitter actions.
- Cytokines** Peptide regulatory molecules that are involved in cell development and differentiation and in immune responses.
- Cytoskeleton** Intracellular structural support elements (e.g., microtubules, intermediate filaments, actin microfilaments) composed primarily of fibrous protein polymers.
- Cytosol** See *intracellular fluids*.
- D**
- D₂¹⁸O method** See *doubly labeled water method*.
- Daily torpor** In mammals and birds, a form of controlled hypothermia in which the body temperature is able to approximate ambient temperature for part (but only part) of each 24-hour day, generally on many consecutive days.
- Dale's principle** The idea that a neuron releases the same kind of neurotransmitter at all its endings. With the discovery of cotransmitters, Dale's principle may be revised to say “the same kind(s) of neurotransmitters.”
- Dalton (Da)** A unit of measure for atomic and molecular mass, equal to 1/12 the mass of an atom of the most abundant carbon isotope, ¹²C. Thus the mass of a ¹²C atom is 12 daltons.
- Dark current** The ionic current, carried mainly by Na⁺ ions, that flows into the outer segments of vertebrate photoreceptors in the dark. Light absorption leads to closing of the Na⁺ channels, turning off the dark current and hyperpolarizing the photoreceptor.
- Data logger** A small microcomputer with a large amount of memory that can be placed in or on an animal to collect and store time-labeled information on physiological or behavioral variables. After the data logger is recovered from the animal, the information it has stored is off-loaded to a computer.
- Deamination** Removal of nitrogen-containing amino groups from amino acids or proteins.
- Decapod crustacean** A lobster, crayfish, crab, shrimp, or related animal.
- Decompression sickness** A pathological state that arises after diving when bubbles are formed within body fluids because the reduction in pressure during surfacing allows gases (especially N₂) present at high dissolved partial pressures to come out of solution. Also called *the bends*, *caisson disease*.
- Decremental spread** Spread of a signal in such a way that signal strength decreases with distance. In electrophysiology, passive voltage changes (synaptic potentials, receptor potentials, etc.) spread decrementally, in contrast to propagated action potentials. Also called *electrotonic conduction*, *passive spread*.
- Definitive urine** The final urine that is excreted by an animal. Contrast with *primary urine*.
- Degradation of energy** Conversion of energy from a high-grade form to heat.
- Delayed implantation** Embryonic diapause in placental mammals. A programmed state of arrested embryonic development that occurs after an embryo has arrived in the uterus but before it implants in the uterine wall.
- Denaturation** A change in the tertiary (three-dimensional) structure of an intact protein that renders the protein nonfunctional. May be reversible or irreversible. The primary structure is not altered during denaturation.
- Dendrite** The receptive element of most neurons, which receives synaptic input from other neurons. Most neurons have many, multiply branching dendrites, in contrast to one sparsely branching axon.
- Dendritic** Branching in a way that resembles the branching of a tree. Also: Of or having to do with a dendrite.
- Dendritic spine** A knoblike protrusion on a dendrite of a neuron that is typically the postsynaptic site of a single synapse. Common in mammalian central neurons.
- Deoxygenation** The release of O₂ from a combined state with a respiratory pigment such as hemoglobin. Not equivalent to *reduction*.
- Depolarization** A decrease in amplitude of the inside-negative electrical potential of a cell membrane toward zero. More generally, any increase in the inside positivity of a cell membrane, even if it exceeds zero.
- Desmosome** A “spot weld” type of junction between two adjacent cells in which protein filaments intermingle across the space between the cells, thereby strengthening and stabilizing the morphological arrangement of the cells.
- Developmental physiology** The study of functional properties in successive stages of the development of an individual animal. It includes studies of function in early developmental stages as well as in adults.
- Developmental polyphenism** See *polyphenic development*.
- Diapause** A programmed state of suspended development or suspended animation in the life history of an animal. See also *embryonic diapause*, *delayed implantation*.
- Diaphragm** A sheet of muscular and connective tissue that completely separates the thoracic and abdominal cavities, found only in mammals.
- Diastole** The period of relaxation during each beating cycle of a heart.
- Diet-induced thermogenesis (DIT)** A chronic increase in metabolic rate induced in certain types of animals by chronic overeating.

Diffusion See *simple diffusion*.

Diffusion lung A lung within which the air is still, so that O₂ and CO₂ must travel the full length of the lung passages by diffusion.

Digestion The process of splitting up ingested food molecules into smaller chemical components that an animal is capable of distributing to the tissues of its body. Most commonly carried out by hydrolytic enzymes.

Dihydropyridine receptor (DHPR) The voltage-sensitive molecule in the transverse tubules of vertebrate striated muscle fibers that links excitation to the release of Ca²⁺ ions from the sarcoplasmic reticulum. It serves as a Ca²⁺ channel in cardiac muscle and as a voltage sensor in skeletal muscle.

Dipnoan A lungfish. A member of the sarcopterygian class of bony fish, believed to be among the closest living relatives of the ancestors of amphibians. There are three genera of dipnoans: *Protopterus* in Africa, *Neoceratodus* in Australia, and *Lepidosiren* in South America.

Direct calorimetry Measurement of metabolic rates by quantifying heat and external work.

Direct measurement A measurement procedure that quantifies a property by measuring exactly what the *definition* of the property specifies. Contrast with *indirect measurement*.

Distance chemoreceptor A chemosensory cell (of a terrestrial animal) that is normally stimulated by chemicals that are airborne over a considerable distance. Distance chemoreceptors are usually more sensitive than contact chemoreceptors. Contrast with *contact chemoreceptor*.

Diuresis The production of urine at a high rate. Such urine is usually dilute as well as abundant.

Diuretic Promoting diuresis.

Diurnal Active in the daytime.

Divergence Spreading apart. In neurophysiology, a pattern in which signals from a particular presynaptic neuron synaptically excite or inhibit many postsynaptic neurons. Contrast with *convergence*.

Diving bradycardia Slowing of the heart rate during diving.

DNA microarray A grid of numerous, diverse DNA spots that, by hybridizing with messenger RNA molecules (mRNAs) in a mix of mRNAs, reveals which mRNAs are present in cells or tissues—thereby revealing which genes are being transcribed. A major tool in transcription profiling. Also called a *DNA microchip* or *gene chip*.

Donnan equilibrium A complex multi-ionic equilibrium state that tends to be reached by the interacting diffusion of multiple permeating ions and water across a cell membrane or epithelium when there is a set of nonpermeating ions (ions that cannot cross the membrane or epithelium) that are more abundant on one side than on the other. Because of their content of nonpermeating anionic proteins and nucleic acids, animal cells would approach Donnan equilibrium if it were not for the fact that living processes hold them away from any sort of equilibrium.

Dorsal root ganglion A type of peripheral ganglion found at the dorsal root of a spinal nerve, containing cell bodies of the sensory neurons in that nerve.

Doubly labeled water method A method used to measure the metabolic rate of a free-living animal in which water labeled with unusual isotopes of hydrogen and oxygen is injected into the animal. It estimates the animal's rate of CO₂ production. Also called the *D₂¹⁸O method*.

Downregulation A downward shift in the catalytic activity of an enzyme, the rate of functioning of a biochemical pathway, or the rate of some other similar process brought about in a controlled manner by a regulatory system.

Dry heat transfer Heat transfer by conduction, convection, or thermal radiation; heat transfer that does not involve evaporation or condensation of water.

Dual breather An animal that simultaneously possesses the ability to breathe from air and from water. Also called *bimodal breather*.

Dynamic viscosity See *viscosity*.

Dystrophin A cytoskeletal protein in muscle fibers that connects actin filaments of the cytoskeleton to a complex of proteins in the sarcolemma.

E

Eccentric muscle contraction An isotonic muscle contraction in which the muscle lengthens as it exerts force while resisting stretch. Also called a *lengthening contraction*.

Ecdysis The process of shedding the outer body covering. In arthropods, the shedding of the old cuticle (exoskeleton) from one instar as the animal makes the transition to the next instar. Also called *molting*.

Ecdysone The steroid prohormone secreted by the thoracic glands of arthropods that stimulates ecdysis, or molting. Also called *molting hormone*.

Ectotherm See *poikilotherm*.

Effector A tissue, organ, or cell that carries out functions under the direction of the nervous system or another physiological control system (e.g., the endocrine system).

Efferent Going away. Thus, for example, an efferent blood vessel carries blood away from an organ of interest. Contrast with *afferent*.

Efferent neuron A neuron that conveys signals from the central nervous system to the periphery, usually exerting motor control.

Efficiency of energy transformation In any process that transforms high-grade energy from one form to another, the output of high-grade energy expressed as a ratio of the input of high-grade energy. See also *absorption efficiency*, *gross growth efficiency*, *net growth efficiency*.

Elasmobranch fish Sharks, skates, and rays.

Electrical energy Energy that a system possesses by virtue of the separation of positive and negative electrical charges.

Electrical gradient Technically, the difference in electrical potential (voltage) between two places divided by the distance separating those two places. Often used more loosely to refer simply to a difference in electrical potential.

Electrical synapse A synapse at which current spreads directly from cell to cell through a low-resistance gap junction.

Electrocardiogram (EKG, ECG) A recording as a function of time of differences in electrical potential set up in extracellular body fluids by the depolarization and repolarization of the myocardium during heart contraction and relaxation. These differences can be detected on the surface of the body and recorded from there.

Electrochemical equilibrium A term that is synonymous with *equilibrium*, but emphasizes that the equilibrium state for an ion or other charged solute depends on both electrical and chemical effects. A charged solute is at electrochemical equilibrium across a membrane when the effect of concentration on its diffusion and the effect of the electrical potential difference on its diffusion sum to zero.

Electroencephalogram (EEG) A record of gross electrical activity in the brain, usually recorded using multiple electrodes placed on the skin of the head or on the brain surface. In sleep studies, it is used to measure the stages of sleep during each sleep period.

Electrogenic pump An active-transport process that pumps net charge across a membrane, acting to generate an electric

G-10 Glossary

- current across the membrane and to produce a voltage difference across the membrane. Contrast with *electroneutral pump*.
- Electrolyte** An inorganic ion in a body fluid.
- Electroneutral pump** An active-transport process that pumps charges across a membrane such that no difference of charge is created across the membrane; it therefore is not a current source. Contrast with *electrogenic pump*.
- Electroreceptor** A sensory receptor cell that responds to environmental electrical stimuli (e.g., in weakly electric fish).
- Electrotonic conduction** See *decremental spread*.
- Embryonic diapause** A programmed state of arrested or profoundly slowed embryonic development. See also *delayed implantation*.
- Empirical** Based on data rather than merely reasoning.
- Endocrine cell** A nonneural epithelial cell or a neuron that secretes a hormone or neurohormone.
- Endocrine gland** A gland or tissue without ducts that secretes a hormone into the blood. Nonneural endocrine cells may form glands that are discrete (with all cells grouped together), diffuse (with cells scattered within other tissues), or intermediate between discrete and diffuse. Contrast with *exocrine gland*.
- Endogenous rhythm** A rhythmic pattern of physiological or behavioral activity, the rhythmicity of which arises as an intrinsic property of an animal's cells (e.g., in the nervous system) without need of external timing information.
- Endometrium** In the mammalian uterus, the inner tissue layer that during pregnancy helps form the placenta.
- Endothelium** The epithelium that lines the heart and the lumen of blood vessels in vertebrates.
- Endotherm** An animal in which the body temperature is elevated by metabolically produced heat.
- Endurance exercise** Exercise that consists of many repetitions of relatively low-intensity muscular actions over long periods of time. Exercise that emphasizes aerobic catabolism as the source of ATP. Also termed *endurance training*. Contrast with *resistance exercise*.
- Energy** The ability to maintain or increase order in a system.
- Energy degradation** See *degradation of energy*.
- Energy metabolism** The set of processes by which energy is acquired, transformed, channeled into useful functions, and dissipated by cells or organisms.
- Enteric division** One of three divisions of the autonomic nervous system; exerts largely autonomous control over the gut.
- Entrainment** The process of synchronizing an endogenous rhythm to an environmental rhythm.
- Environment** An organism's surroundings, including other organisms as well as the abiotic conditions that prevail in the surroundings, such as temperature. Sometimes called the *external environment* to distinguish it from the *internal environment*. See also *internal environment*.
- Environmental** See *ambient*.
- Enzyme** A molecule—usually a protein—that catalyzes a chemical reaction in which covalent bonds are made or broken.
- Enzyme–substrate affinity** The proclivity of an enzyme to form a complex with its substrate when the enzyme and substrate meet.
- Epicuticle** The outermost layer of the exoskeleton of an arthropod, where lipids that protect against desiccation are deposited in insects and arachnids.
- Epigenetic mark** A change in a gene or its immediate biochemical environment *other than a change in the DNA sequence*—such as methylation of cytosine residues—that modifies expression of the gene and that, when the gene replicates, also replicates so that the resulting gene copies also have their expression modified in the same way. The gene is said to be *marked* or *tagged*.
- Epigenetics** The study of modifications of gene expression that are transmitted when genes replicate despite there being *no change in the DNA sequence*. See also *epigenetic mark*.
- Epithelium** A sheet of cells that lines a cavity or covers an organ or body surface, thereby forming a boundary between functionally different regions of the body or between an animal and its external environment.
- Epitoke** In polychaete annelid worms, a specialized reproductive stage that is formed by either transformation of an ordinary individual or budding from an ordinary individual.
- Equilibrium** The state toward which an *isolated* system changes; that is, the state toward which a system moves—internally—when it has no inputs or outputs of energy or matter. A system is *at equilibrium* when internal changes have brought it to an internally stable state from which further net change is impossible without system inputs or outputs. The state of equilibrium is a state of minimal capacity to do work under locally prevailing conditions. See also *electrochemical equilibrium*.
- Equilibrium potential** The membrane potential at which an ion species is at electrochemical equilibrium, with concentration-diffusion forces offset by electrical forces so that there is no net flux of that ion species across the membrane.
- Erythrocyte** See *red blood cell*.
- Erythropoiesis** Production of red blood cells.
- Essential** In the study of nutrition, a required material—such as an amino acid, fatty acid, vitamin, or mineral element—that an animal must obtain from outside sources, i.e., sources other than biosynthesis by the animal.
- Essential amino acid** A standard amino acid that an animal cannot synthesize and that thus must be obtained from food, microbial symbionts, or other sources besides biosynthesis by the animal.
- Essential fatty acid** A type of fatty acid that an animal cannot synthesize from scratch and that necessitates acquisition of precursors from food, microbial symbionts, or other sources besides biosynthesis by the animal. The omega-3 and omega-6 fatty acids are the major types.
- Estivation** (1) In mammals and birds, a form of controlled hypothermia in which the body temperature is able to approximate ambient temperature continuously for two or more consecutive days during summer. (2) In other animals, a non-specific term referring to a resting or dormant condition during the summer or during drought.
- Estrogen** A feminizing hormone such as estradiol. Estrogens, which may be secreted by the ovary, placenta, testis, and possibly the adrenal cortex, are essential for female secondary sexual characteristics and reproduction.
- Estrous cycle** A cycle of behavioral readiness to copulate (correlated with ovulation) in most female mammals.
- Estrus** A stage of the estrous cycle around the time of ovulation during which a female uses behaviors to indicate that she is ready to conceive offspring. Also called *heat*.
- Estuary** A body of water along a seacoast that is partially enclosed by land and that receives inputs of both freshwater and seawater; it is intermediate in salinity between freshwater and seawater.
- Euryhaline** Referring to aquatic animals able to live over a wide range of environmental salinities. Contrast with *stenohaline*.

Eurythermal Referring to poikilotherms, able to live over a broad range of body temperatures. Contrast with *stenothermal*.

Euthermia The state of having a usual or normal body temperature. Specifically, in the study of mammals or birds that undergo controlled hypothermia, the state of having a fully homeothermic body temperature (e.g., about 37°C in a placental mammal).

Evaporation A change in the physical state of a compound from a liquid to a gas; most commonly used to refer to water. Evaporation can in principle occur at any temperature.

Evaporative cooling Removal of heat by the evaporation of water. The evaporative cooling caused by the evaporation of a gram of water equals the *latent heat of vaporization* of water per gram.

Evolution A change in gene frequencies over time in a population. Evolution can result in *adaptation*, or it can be *nonadaptive*.

Excess postexercise oxygen consumption (EPOC) An elevation of the actual O₂ uptake by breathing above the theoretical O₂ requirement of rest when an animal is resting immediately after exercise; “breathing hard” after exercise. Also called *oxygen debt*.

Excitable cells Cells that can generate action potentials because their cell membranes contain voltage-gated channels, notably neurons and muscle cells.

Excitation–contraction coupling In a muscle cell, linkage of the electrical excitation of the cell membrane with contractile activity by facilitation of the availability of Ca²⁺ in the cytoplasm. Key events occur at the transverse tubules and sarcoplasmic reticulum. Also called *E-C coupling*.

Excitatory Resulting in an increase in activity or probability of activity. In a neuron, depolarization is excitatory because it increases the likelihood of generation of action potentials. Contrast with *inhibitory*.

Excitatory postsynaptic potential (EPSP) A voltage change in a postsynaptic cell—normally a depolarization—that tends to excite the cell.

Exocrine gland A gland with ducts in which secretions exit the gland by way of the ducts, rather than being secreted into the blood. Examples include salivary glands and sweat glands. Contrast with *endocrine gland*.

Exponential Referring to a type of relationship between two variables in which the dependent variable goes up in multiplicative steps as the independent variable goes up in additive steps. See Appendix F.

Expression Synthesis of the protein (or other functional product) encoded by a gene.

Expression profiling Sometimes used (but not in this book) as a synonym for *transcription profiling*. See *transcription profiling*.

External environment See *environment*.

External respiration Breathing.

External work Mechanical work by an animal that involves applying forces to objects outside the animal’s body. Locomotion is the principal example; other examples would be a squirrel chewing into a nut, or a mole pushing soil aside.

Exteroceptor A sensory receptor cell that is activated by stimuli from outside the body.

Extracellular fluids The aqueous solutions (body fluids) outside cells. In animals with closed circulatory systems, subdivided into *blood plasma* and *interstitial fluids*.

Extrafusal muscle fiber In vertebrate skeletal muscle, an “ordinary” muscle fiber that is not associated with a muscle-spindle stretch receptor.

Extrarenal salt excretion Excretion of inorganic ions by structures other than the kidneys, such as the gills in marine teleost fish and salt glands in marine birds.

F

Facilitated diffusion Passive transport of a solute across a membrane mediated by the noncovalent and reversible binding of solute molecules to a solute-specific transporter (carrier) protein in the membrane. Facilitated diffusion is the principal mode of passive transport of polar organic solutes, such as glucose and amino acids, across membranes.

Fast glycolytic (FG) muscle fibers Muscle fibers that are poised to make ATP principally by anaerobic catabolism, develop contractile tension rapidly, have relatively high peak power outputs, and fatigue relatively rapidly.

Fast oxidative glycolytic (FOG) muscle fibers Muscle fibers that produce ATP principally by aerobic catabolism, develop contractile tension at a rate intermediate between the rates of slow oxidative (SO) and fast glycolytic (FG) fibers, have intermediate peak power outputs, and exhibit intermediate resistance to fatigue.

Fasting (1) In life histories, failure to eat, often for prolonged periods of time, because of features intrinsic to an animal’s life history. Often distinguished from *starvation*, which refers to extrinsically imposed food deprivation. (2)

In metabolism studies, not eating for a sufficient period of time so as to end the specific dynamic action of the last meal. See *specific dynamic action*.

Feed-forward A concept in control theory that is in certain respects the opposite of *feedback*. During feedback, deviations of a controlled property from a set-point level are detected, and the control system responds by either diminishing the deviations (negative feedback) or enhancing them (positive feedback). During feed-forward control, however, a system is driven to change by an input external to itself, not by responses to deviations of its own performance from a set point. Contrast with *negative feedback*, *positive feedback*.

Fenestrations Minute, physical openings—pores—in the walls of blood capillaries. Some fenestrations are formed by tiny gaps (about 4 nm in diameter) *between* cells in the capillary endothelium; others are formed in some tissues by holes *through* the capillary endothelial cells. Water and ions can freely cross the capillary endothelium through fenestrations by osmosis and diffusion.

Fermentation Enzyme-catalyzed reactions that occur without O₂, such as reactions that accomplish the anaerobic breakdown of compounds to liberate energy for metabolic use.

Fiber See *muscle fiber*.

Fick equation An equation used to predict the rate of diffusion. See Equation 5.1.

Field metabolic rate (FMR) The *average daily metabolic rate* of an animal when living free in its natural environment.

Filter feeding Feeding on objects suspended in water that are very small by comparison to the feeding animal, when the mechanism of food collection is some sort of sieving. If the mechanism is of another sort or is unknown, the feeding should be termed *suspension feeding*.

Filtrate See *ultrafiltrate*.

Fixed act A simple all-or-none behavioral response to a stimulus. Contrast with *reflex*.

Flexion reflex A reflex response that flexes or withdraws a limb from a painful or noxious stimulus.

Fluid compartment A defined subpart of the body fluids, often distributed throughout the body rather than occupying a discrete physical location. The simplest subdivision of the body fluids recognizes three fluid compartments: blood plasma, interstitial fluids, and intracellular fluids.

Fluid mosaic model A theory of the nature of cell membranes. According to

G-12 Glossary

this theory, a cell membrane consists of a mosaic of protein and lipid molecules, all of which move about in directions parallel to the membrane faces because of the fluid state of the lipid matrix.

Fluidity In reference to the phospholipids in a cell membrane, the ability of individual phospholipid molecules to diffuse through the population of all such molecules in a membrane leaflet because the molecules are not covalently bonded to one another. Fluidity is quantitatively variable. Diffusion is relatively rapid in some membranes, which are said to exhibit high fluidity.

Fluorescence A phenomenon associated with bioluminescence in which preexisting light (e.g., from a bioluminescent mechanism) is absorbed and re-emitted at longer wavelengths. Fluorescence does not produce light *de novo*.

Follicle (1) In secretory tissues such as the thyroid gland, a globe-shaped, hollow structure enclosed by an epithelium. (2) In the ovary, an oocyte and the layers of somatic cells surrounding it.

Follicular phase In a female mammal, the phase of the menstrual or estrous cycle prior to ovulation, during which primary oocytes and associated somatic follicle cells, develop, mature, and secrete hormones.

Foodstuff A material in the body, such as carbohydrate or lipid, that an animal uses as a source of energy or chemical building blocks. Foodstuffs are often derived directly from foods but differ from foods in being already in the body.

Foregut fermenter An animal that has a specialized foregut chamber housing communities of fermenting microbes that assist with the breakdown of food materials and that often provide biosynthetic capabilities the animal lacks. The microbial communities commonly include bacteria, protists, yeasts, and fungi.

Fossorial Living underground. Used usually to distinguish species that live underground but belong to phylogenetic groups that generally live aboveground.

Frank-Starling mechanism An important intrinsic control mechanism of the vertebrate heart in which stretching of the cardiac muscle tends to increase the force of its contraction by an effect exerted at the level of individual muscle cells.

Free-running rhythm An endogenous rhythm that is not entrained by an environmental rhythm.

Freezing point The highest temperature at which a liquid can turn to a solid and freeze. A colligative property.

Freezing-point depression (ΔT_F) The *difference* (sign ignored) between the freezing point of a solution and the freezing point of pure water. For example, if the freezing point of a solution is -1.6°C , its freezing-point depression is 1.6°C . A colligative property.

G

G protein A protein involved in signal transduction that is activated by binding with guanosine triphosphate (GTP). Some G proteins occur in cell membranes and are typically trimers; others occur intracellularly and are typically monomers.

G protein-coupled receptor A membrane receptor protein that, when it binds to its specific extracellular signal ligand, relays a signal into the cell by activating G proteins in the cell membrane.

Gamete A reproductive cell, also called a germ cell; an egg (ovum) produced by an ovary or a sperm produced by a testis.

Gametogenesis The formation of haploid eggs or sperm (gametes) through the process of meiosis. It is called specifically *oogenesis* when referring to processes in the ovary and *spermatogenesis* in the testis.

Gamma (γ) motor neuron A small motor neuron in a vertebrate spinal cord that innervates an intrafusal muscle fiber.

Ganglion (plural ganglia) A discrete collection of neuronal cell bodies. In arthropod nervous systems, most ganglia are segmental components of the central nervous system; in vertebrates, ganglia are components of the peripheral nervous system.

Ganglion cell An output cell of the vertebrate retina, with an axon extending in the optic nerve to visual processing areas of the brain.

Gap junction A region where the cell membranes of adjacent cells are unusually close to each other and share channels (formed by adjoining connexons in vertebrates) that establish cytoplasmic continuity between the cells.

Gas tension See *partial pressure*.

Gated channel A channel that “opens” and “closes” to facilitate or inhibit solute passage. Some gated channels “open” and “close” in response to changes in ligand binding; others do so in response to voltage changes or other changes.

Gene deletion Synonym for *gene knockout*. See *knockout animal*.

Gene expression profiling See *transcription profiling*.

Gene family A group of genes that are evolutionarily related; genes related by common descent from ancestral genes.

Gene knockout See *knockout animal*.

Gene lineage In the study of evolution, a set of genes that are related by descent from a common ancestral gene; also a representation of the family tree of such a set of genes.

Genetic drift Changes in gene frequencies within a population over time resulting primarily from chance.

Genome The full set of genetic material of an organism.

Genome-wide association study (GWAS) A study that compares the complete DNA of individuals with a particular condition to the DNA of individuals without the condition, with the objective of identifying the genes that play roles in causing the condition.

Genomic imprinting An epigenetic phenomenon in which, in a given individual, an allele inherited from the individual's father is expressed exclusively (or predominantly) relative to the allele of the same gene inherited from the individual's mother, or vice versa—because of *epigenetic marks*. At present, genomic imprinting is known to occur only in mammals, insects, and flowering plants.

Genomics The study of the genomes (the full sets of genetic material) of organisms.

Germ cell See *gamete*.

Gills In the most general sense used by physiologists, structures specialized for external respiration that project from the body into the ambient medium and are thereby surrounded by the environmental medium. Contrast with *lungs*.

Glial cells Cells in an animal's neural tissue (e.g., brain) other than neurons. Glial cells are considered support cells, ensheathing neuronal processes or regulating the metabolism of neurons. They may play secondary roles in signaling and integration. Also called *neuroglia*.

Globins A family of structurally similar proteins believed to be evolutionarily related by common descent from ancestral protein forms. Proteins of this family occur, for example, in hemoglobin O_2 -transport pigments.

Glomerular filtration rate (GFR) The rate at which all the nephrons in the kidneys of a vertebrate collectively produce primary urine by ultrafiltration.

Glomerulus A minute anastomosing cluster of blood capillaries associated with a nephron in the kidney of a vertebrate, serving as the site of formation of primary urine by ultrafiltration. The term is also sometimes used to refer not only to such a cluster of capillaries, but also to the Bowman's capsule with which it is associated.

Glucocorticoids Steroid hormones, such as cortisol and corticosterone, that are released from the cortex of the adrenal gland and regulate carbohydrate, lipid, and protein metabolism.

Glycolysis The reactions that convert glucose to pyruvic acid.

Goldman equation An equation that describes membrane potential in terms of the concentrations of and membrane permeabilities to more than one ion species.

Gonadotropin A hormone that stimulates the gonads (ovaries or testes) to produce gametes and secrete hormones, and also supports and maintains the gonadal tissue.

Graded potential A voltage change that is variable in amplitude—that is, not all-or-none like an action potential. Examples include synaptic potentials and receptor potentials.

Granular cells See *juxtglomerular cells*.

Granulosa cells Somatic cells surrounding the primary oocyte in an ovarian follicle.

Gray matter A histological region of a vertebrate central nervous system that contains neuronal cell bodies, dendrites, and synapses as well as axons. See also *white matter*.

Green gland See *antennal gland*.

Grid cell A neuron, commonly in the entorhinal cortex of the brain, that generates action potentials when an animal is at one of several gridlike locations in its environment. The loci at which grid cells are active form an invisible regular hexagonal grid that can provide a distance calibration for a map representation, in the brain, of the animal's environment.

Gross growth efficiency In a growing animal, the chemical-bond energy of new biomass added by growth expressed as a ratio of the animal's ingested energy over the same time period.

Gular fluttering Rapid up-and-down oscillation of the floor of the mouth cavity of a bird or other reptile to enhance the rate of evaporative cooling by increasing air flow over moist membranes in the mouth.

Gustatory Having to do with *taste*.

Gut microbiome Populations of microbes, consisting of many species of bacteria and other heterotrophic microbes, living in the gut lumen of an animal.

H

H zone In striated muscle, a region at the center of a sarcomere that contains only thick filaments; shortens during contraction. Also called *H band*.

Habituation A simple, nonassociative form of learning characterized by a learned decrease in a behavioral response with repeated presentations of a non-threatening stimulus.

Hagen-Poiseuille equation See *Poiseuille equation*.

Hair cell A sensory epithelial cell in a vertebrate acoustico-lateral system that transduces displacement of its apical stereocilia into an electrical signal.

Haldane effect A shift of the carbon dioxide equilibrium curve of the blood caused by the oxygenation and deoxygenation of the blood respiratory pigment. In blood that exhibits a Haldane effect, the total carbon dioxide concentration is higher when the blood is deoxygenated than when it is oxygenated.

Half-life The time required to reduce something by one-half; applies, for example, to the concentrations of substances such as hormones, stored voltages, and radioactivity.

Halophyte A plant that roots in saline soils, often characterized by high salt concentrations in its tissue fluids.

Head direction cell A neuron in the brain that generates action potentials when the animal's head is pointing in a particular direction. Head direction cells provide spatial information about the animal's bearings in its environment. They are presumably used with place cells and grid cells in spatial navigation. See *grid cell* and *place cell*.

Heart A discrete, localized structure specialized for pumping blood. It may be neurogenic or myogenic and associated with an open or a closed circulatory system.

Heat The energy that matter possesses by virtue of the ceaseless, random motions that all of the atoms and molecules of which it is composed undergo on an atomic-molecular scale of distance. Also called *molecular kinetic energy*.

Heat-shock proteins An evolutionarily related group of proteins that are principally inducible—being expressed in the aftermath of heat stress or other stress—and that function as molecular chaperones. Heat-shock proteins use ATP to assist in the repair of stress-damaged proteins by preventing the damaged proteins from aggregating with one another and by promoting molecular folding patterns that restore them to correct three-dimensional conformations.

Heme A particular metalloporphyrin containing iron in the ferrous state: ferrous protoporphyrin IX. It is the O₂-binding site in all hemoglobins.

Hemerythrin A type of respiratory pigment found in scattered groups of animals in three or four phyla, consisting of an iron-based metalloprotein. Undergoes reversible combination with O₂ at iron-containing loci.

Hemocyanin A type of respiratory pigment found in arthropods and molluscs, consisting of a copper-based metalloprotein. Undergoes reversible combination with O₂ at copper-containing loci.

Hemoglobin A type of respiratory pigment formed by the combination of heme (ferrous protoporphyrin IX) with a globin protein. Undergoes reversible combination with O₂ at the heme loci.

Hemolymph A synonym for *blood* in an animal that has an open circulatory system. The term emphasizes that the blood in such animals includes all extracellular fluids, and thus that there is no distinction between the fluid that is in the blood vessels at any one time and the interstitial fluid between tissue cells.

Henry's law A law that relates partial pressure and concentration for gases dissolved in an aqueous solution (or in another liquid solution). One way to express this law is that $C = AP$, where C is dissolved concentration, P is partial pressure in atmospheres, and A is the *absorption coefficient* (dissolved concentration when partial pressure is 1 atm).

Hepatopancreas An organ in crustaceans that connects with the stomach and functions in secretion of digestive enzymes; absorption of nutrient molecules; storage of lipids, glycogen, and Ca²⁺; and sequestration of foreign compounds.

Hermaphrodite An individual that possesses both ovaries and testes. An animal may be a *simultaneous* hermaphrodite, in which both types of gonads produce gametes at the same time, or a *sequential* hermaphrodite, in which only one type of gonad produces gametes at a time.

Heterothermy The property of exhibiting different thermal relations from time to time or place to place. There are two types of heterothermy: (1) In *regional heterothermy*, some regions of an individual animal's body exhibit different thermal relations than other regions at the same time. (2) In *temporal heterothermy*, an individual exhibits one type of thermal relation at certain times and another type of thermal relation at other times (e.g., hibernation at some times and homeothermy at others).

Heterotroph An organism that obtains the energy it needs to stay alive by breaking up organic compounds that it obtains from other organisms, thereby

G-14 Glossary

- releasing the chemical-bond energy of those organic compounds. Contrast with *autotroph*.
- Hibernaculum** The place where an animal resides while in hibernation.
- Hibernation** (1) In mammals and birds, usually refers to a form of controlled hypothermia in which the body temperature is able to approximate ambient temperature continuously for two or more consecutive days during winter. (2) In other animals, a nonspecific term referring to a resting or dormant condition during winter.
- High-grade energy** Energy in a form that can do physiological work. Chemical, electrical, and mechanical energy are forms of high-grade energy.
- High-throughput method** An analytical method that is carried out by computer programs and robots without much direct human attention, and thus can process samples at a relatively high rate.
- Hill coefficient** A measure of the degree of cooperativity among O₂-binding sites in a molecule of a respiratory pigment.
- Hindgut fermenter** An animal that has a specialized hindgut chamber housing communities of fermenting microbes that assist with the breakdown of food materials and that often provide biosynthetic capabilities the animal lacks.
- Histones** Basic proteins with which DNA (acidic) is complexed in the cell nucleus.
- Hodgkin cycle** The cycle that explains the rising phase of an action potential: Depolarization opens voltage-gated Na⁺ channels, increasing membrane permeability to Na⁺. The resulting inflow of Na⁺ further depolarizes the membrane, opening more Na⁺ channels.
- Homeosmotic animal** Synonym for *osmoregulator*.
- Homeostasis** Internal constancy and the physiological regulatory systems that automatically make adjustments to maintain it. In the words of Walter Cannon, who coined the term, "the coordinated physiological processes which maintain most of the [constant] states in the organism."
- Homeotherm** An animal that thermoregulates by physiological means (rather than simply by behavior).
- Homeoviscous adaptation** The maintenance of a relatively constant lipid fluidity regardless of tissue temperature.
- Homing** The ability of an animal to return to its home site after being displaced.
- Homologous** Relating to features of organisms that are similar because of common evolutionary descent.
- Horizontal cell** A neuron in the vertebrate retina that is part of the lateral pathway, mediating center-surround antagonistic effects in retinal neuron receptive fields.
- Hormone** A chemical substance, released by nonneural endocrine cells or by neurons, that is carried in the blood to distant target cells, where it exerts regulatory influences on their function. There are three main chemical classes of hormones: steroids, peptides or proteins, and amines.
- Hormonal axis** A hormonal sequence in which one hormone stimulates the secretion of a second hormone that may in turn stimulate secretion of a third hormone. Known hormonal axes consist of two or three hormones in sequence.
- Hourglass timer** See *interval timer*.
- Humidic** Restricted to humid, water-rich terrestrial microenvironments; unable to live steadily in the open air.
- Humidity** A general term referring loosely to the concentration of gaseous water in a gas. See also *water vapor pressure*, *relative humidity*, and *saturation deficit*—all of which represent ways to express humidity.
- Hydrophilic** Dissolving readily in water ("water loving").
- Hydrophobic** Not dissolving readily in water ("water hating"); typically lipid-soluble.
- Hydrostatic pressure** The sort of pressure that is developed in a fluid (gas or liquid) when forces are applied that tend to increase the amount of matter per unit of volume. Hydrostatic pressure is what is meant by everyday scientific uses of the word *pressure*. A tire pump, for instance, produces a hydrostatic pressure in a tire.
- Hyperbolic kinetics** A type of saturation kinetics in which the velocity of a chemical reaction increases in a smooth, strictly asymptotic way toward its maximum.
- Hyper-hyposmotic regulator** An aquatic animal that maintains a blood osmotic pressure that is (1) higher than the osmotic pressure of the water in which it lives when the ambient osmotic pressure is low, but (2) lower than the osmotic pressure of the water in which it lives when the ambient osmotic pressure is high. Such an animal may have a stable blood osmotic pressure over a wide range of ambient osmotic pressures.
- Hyper-isosmotic regulator** An aquatic animal that maintains a blood osmotic pressure that is (1) higher than the osmotic pressure of the water in which it lives when the ambient osmotic pressure is low, but (2) the same as the osmotic pressure of the water in which it lives when the ambient osmotic pressure is high.
- Hyperosmotic** Having a higher osmotic pressure. Said of a solution in comparison to another, specific solution. *Hyperosmotic* is a relative term that is meaningless unless the comparison solution is specified.
- Hyperosmotic regulator** An aquatic animal that maintains a blood osmotic pressure higher than the osmotic pressure of the water in which it lives.
- Hyperpolarization** A voltage change that makes a cell membrane potential more inside-negative (normally moves it further from zero).
- Hyperthermia** The state of having a body temperature that is higher than the temperature considered to be normal or usual.
- Hypertrophy** The addition of structural components to cells in a way that increases the size of a tissue or organ. In muscle, the addition of contractile proteins to skeletal muscle fibers.
- Hyposmotic** Having a lower osmotic pressure. Said of a solution in comparison to another, specific solution. *Hyposmotic* is a relative term that is meaningless unless the comparison solution is specified. The word is a contraction of *hypo-osmotic*.
- Hyposmotic regulator** An aquatic animal that maintains a blood osmotic pressure lower than the osmotic pressure of the water in which it lives.
- Hypothalamo-hypophysial portal system** A system of blood vessels in a vertebrate that connects capillaries in the hypothalamus to capillaries in the anterior pituitary; provides a direct pathway by which hypothalamic hormones can reach specific populations of cells in the adenohypophysis (anterior pituitary).
- Hypothermia** The state of having a body temperature that is lower than the temperature considered to be normal or usual.
- Hypoxia** Referring to the tissues of an animal, the state of having an unusually low level of O₂.
- I band** In striated muscle, a region of two sequentially adjacent sarcomeres that includes only thin filaments and is bisected by the Z disc; shortens during contraction. It appears light in muscle sections prepared for microscopy; takes its name from the fact that it is described as *isotropic* because its refractive index in polarized light changes only minimally with the plane of polarization.
- Ice-nucleating agent** A dissolved or undissolved substance that promotes freezing (i.e., limits supercooling).

Ideal gas law See *universal gas law*.

Imidazole group A type of chemical group, found on the amino acid histidine and some other compounds, that is often extremely important in buffering body fluids because of its particular chemical buffering properties.

Implantation During pregnancy in a female placental mammal, the entry of an early embryo into the cellular matrix of the inner uterine epithelium (*endometrium*).

Imprinting (in molecular genetics)
See *genomic imprinting*.

Inactivation (in ion transport) The closing of an ion channel in response to a stimulus such as membrane depolarization. This occurs in a time-dependent manner.

Indirect calorimetry Measurement of metabolic rates by quantifying respiratory gas exchange or some other property besides heat and external work.

Indirect measurement A measurement procedure that quantifies a property by measuring something other than what the definition of the property specifies. Contrast with *direct measurement*.

Induced ovulation Ovulation (release of an egg from the ovaries of a female) that results from, and is dependent on, stimuli generated by the actual act of copulation. Contrast with *spontaneous ovulation*.

Inducible enzyme An enzyme (or other protein) that is expressed only when “induced” by the presence of a molecule or condition that serves as an inducing agent. An inducible enzyme disappears from a cell or tissue when its inducing agent is absent, but is expressed when the cell or tissue is exposed to its inducing agent. Contrast with *constitutive enzyme*.

Ingested energy The energy present in the chemical bonds of an animal’s food.

Inhibitory Resulting in a decrease in activity or probability of activity. In a neuron, hyperpolarization is inhibitory because it decreases the likelihood of generation of action potentials. Contrast with *excitatory*.

Inhibitory postsynaptic potential (IPSP) A voltage change in a postsynaptic cell—normally a hyperpolarization—that tends to inhibit the cell.

Inka cells Endocrine cells associated with the tracheae of insects that secrete two peptides: pre-ecdysis triggering hormone and ecdysis triggering hormone.

Innate behavior Behavior that has a strong genetic basis or results from genetic preprogramming.

Inner ear In a vertebrate, the cochlea and the semicircular canals of the vestibular organ.

Inner hair cells In the organ of Corti of the cochlea, a single row of hair cells that transduce sound vibrations into voltage changes that excite auditory sensory neurons.

Innervate To provide neural input.

Inorganic ion A non-carbon atom (e.g., Na⁺) or group of atoms (e.g., SO₄²⁻) that bears a net negative or positive charge.

Insensible water loss In humans, water loss across the skin without sweating; a synonym for *transpirational water loss* in people.

Insertion The movement of channel or transporter proteins from inactive intracellular locations into the membrane where they are active.

Instar A period between ecdyses, or molts, in the arthropod life cycle.

Insulation The resistance to dry heat transfer through a material or between an animal and its environment. See also *resistance* (meaning 2).

Integral membrane protein A protein that is part of a cell membrane and cannot be removed without extraction procedures that take the membrane apart.

Integration The coordination of input signals, as by summing, to provide a harmonious control of output. *Cellular integration* refers to the integration of signals within a cell, and *physiological integration* refers to the integration of sensory, central nervous system, and endocrine signals for harmonious control of effectors in the body.

Integument The outer body covering of an animal, such as the skin of a vertebrate or the exoskeleton of an arthropod.

Intercalated disc An intercellular contact between adjacent cardiac muscle fibers of vertebrates that contains desmosomes and gap junctions.

Intercellular fluids See *interstitial fluids*.

Intercostal muscles Sheetlike muscles that run between adjacent ribs, the contraction of which expands or contracts the volume of the rib cage.

Intermittent breathing Breathing in which breaths or sets of breaths are regularly interrupted by extended periods of apnea.

Internal environment The environment of the cells within an animal’s body. The set of conditions—temperature, pH, Na⁺ concentration, and so forth—existing in the body fluids of an animal and therefore experienced by cells within the animal’s body. Also called the *milieu intérieur*.

Internal work Mechanical work performed inside the body, such as the beating of the heart or peristalsis in the gut.

Interneuron A neuron that is confined to the central nervous system and is therefore neither a sensory neuron nor a motor neuron.

Internode The region of a myelinated axon that lies between two nodes of Ranvier and is covered by a myelin sheath.

Interoceptor A sensory receptor cell that is activated by stimuli within the body and thus monitors some aspect of the internal state.

Interspecific enzyme homologs Different molecular forms of a single enzyme occurring in two or more related species; called *homologs* because they are assumed to be related by evolutionary descent.

Interstitial cells See *Leydig cells*.

Interstitial fluids The fluids between cells in tissues. More specifically, in animals with closed circulatory systems, the fluids between cells in tissues other than blood; that is, the interstitial fluids are the extracellular fluids other than the blood plasma. Sometimes called *intercellular fluids* or *tissue fluids*.

Interval timer A biological clock that times an interval shorter than a day but appears to be noncyclic, having to be restarted each time it operates, like a kitchen timer or an hourglass. Also called an “hourglass” timer.

Intracellular fluids The aqueous solutions inside cells. Also called the *cytosol*.

Intracellular membrane A membrane, such as the endoplasmic reticulum, found inside a cell. Typically has a phospholipid-bilayer structure similar to that of the outer cell (plasma) membrane. Also called a *subcellular membrane*.

Intracrine A peptide signaling molecule that regulates intracellular functions and is known to act as a hormone, paracrine, or autocrine in different contexts. It may be retained within the cell that synthesized it or internalized from the extracellular space.

Intrafusal muscle fiber A specialized muscle fiber associated with a vertebrate muscle-spindle stretch receptor. Muscle stretching or activation of the intrafusal muscle fiber by a gamma motor neuron can activate the stretch receptor.

Intraluminal digestive enzyme A digestive enzyme that is secreted into the lumen of the gut or another body cavity, where it mixes with food materials and digests them.

G-16 Glossary

Inulin A polysaccharide widely used in studies of plasma clearance. See *plasma clearance*.

Ion An atom or group of atoms that bears a net negative or positive charge.

Ionic conformity A state in which the concentration of an inorganic ion in the blood plasma matches, and varies with, the concentration of that ion in the external environment.

Ionic regulation The maintenance of a constant or nearly constant concentration of an inorganic ion in the blood plasma regardless of the concentration of that ion in the external environment.

Iontropic receptor (in synaptic function) A neurotransmitter receptor molecule that changes the membrane permeability of the postsynaptic cell to particular ions when it binds neurotransmitter molecules; usually a *ligand-gated channel*.

Iontropic transduction (in sensory function) A kind of sensory transduction in which a sensory receptor molecule is itself an ion channel, changing ion flow into the cell in direct response to a sensory stimulus. It is analogous to ionotropic synaptic action, and stands in contrast to metabotropic (sensory) transduction. See also *metabotropic transduction*.

Islets of Langerhans Clusters of endocrine cells distributed among the exocrine-gland tissue of the pancreas. They contain specific endocrine cells that secrete specific hormones: β (or B) cells secrete insulin, α (or A) cells glucagon, and δ (or D) cells somatostatin.

Isoform In relation to a protein that exists in multiple molecular forms, any one of those molecular forms.

Isolated system A defined part of the material universe that (at least as a thought exercise) cannot exchange either matter or energy with its surroundings.

Isometric contraction A contraction in which a muscle does not shorten significantly as it exerts force (tension) against a load it cannot move.

Isosmotic Having the same osmotic pressure. Said of a solution in comparison to another, specific solution. *Isosmotic* is a relative term that is meaningless unless the comparison solution is specified.

Isotonic contraction A contraction in which a muscle changes its length as it exerts force (tension) against a load. The tension during contraction remains constant and equal to the force exerted by the load.

Isozymes Various molecular forms of a single kind of enzyme synthesized by one species. Also called *isoenzymes*.

Iteroparity A type of reproductive life history in which individuals are physiologically capable of two or more separate bouts of reproduction during their lives. Contrast with *semelparity*.

Iteroparous Characterized by *iteroparity*.

J

Juvenile hormone In insects, a lipid-soluble hormone secreted by the nonneural endocrine cells of the corpora allata that stimulates its target tissues to maintain immature characteristics.

Juxtaglomerular cells Specialized smooth muscle cells in the arterioles associated with the glomerulus of a vertebrate nephron that secrete renin in response to low blood pressure. Also called *granular cells*.

K

Kairomone A chemical signal released by a member of one species in the course of its activities that is detected and exploited by a member of another species. Its detection confers a benefit on the detecting species that is detrimental to the releasing species.

k_{cat} See *catalytic rate constant*.

Kidney An organ that regulates the composition and volume of the blood and other extracellular body fluids by producing and eliminating from the body an aqueous solution (*urine*) derived from the blood or other extracellular fluids.

Knockout animal An animal that has been genetically engineered to lack functional copies of a gene of interest.

L

Labeled lines The principle that sensory neurons encode the modality or quality of a sensory stimulus by having different sensory receptor cells respond to different kinds of stimuli, so that the CNS can decode the stimulus by monitoring which axons ("lines") deliver action potentials.

Lactase persistence In human biology, continued synthesis (expression) in adulthood of the digestive enzyme lactase, permitting milk sugar—lactose—to be digested in adulthood.

Lactation In mammals, the process of producing milk and providing the milk to nursing offspring.

Laminar flow Flow of a fluid without turbulence. When a fluid flows without turbulence over a surface or through a tube, the flow can be envisioned as occurring in a series of thin layers (laminae) of fluid at progressively greater distances from

the surface or tube walls. The layer juxtaposed to the surface or tube wall does not flow at all, and layers at increasing distances from it flow faster and faster.

Laplace's law The tension developed within the walls of a hollow structure exposed to a particular difference in pressure between inside and outside is directly related to the radius of the structure.

Larva A free-living developmental stage that is very different in appearance from the adult stage of the same species.

Latch state A characteristic state of smooth muscle in which dephosphorylated myosin heads remain attached to actin and maintain tension for long periods of time.

Latent heat of vaporization The heat that must be provided to convert a material from a liquid to a gas at constant temperature (called *latent* because although heat is provided, the temperature of the material does not rise). It is expressed per unit of mass of the material under study.

Lateral geniculate nucleus (LGN) A region of the thalamus in the diencephalon of the vertebrate brain that receives axons of retinal ganglion cells and relays visual information to the primary visual cortex.

Leaflet One of the two phospholipid layers within a cell membrane.

Leak channel A channel in a cell membrane that is normally open and mediates the membrane permeability (primarily to K^+ ions) that underlies the resting membrane potential.

Left-to-right shunting In the study of blood flow through the central circulation of an air-breathing fish, amphibian, or nonavian reptile, diversion of pulmonary venous blood directly back to the lungs, bypassing the systemic circuit.

Length constant (λ) The distance along a cell over which a change in passively spreading electrical potential decays in amplitude to 37% of its amplitude at the origin.

Length-tension relationship The relationship between the length of a whole muscle or a sarcomere prior to stimulation and the tension developed during isometric contraction. Maximum tension develops when there is optimal overlap of thick and thin filaments to allow effective cross-bridge action.

Lengthening contraction An isotonic contraction in which a muscle lengthens as it is activated and exerts force. Also called an *eccentric contraction*.

Leydig cells Testosterone-secreting cells located in the connective tissue between

the seminiferous tubules of the vertebrate testis; also called *interstitial cells*.

Ligand Any molecule that selectively binds noncovalently to a structurally and chemically complementary site on a specific protein. The substrate of an enzyme, for example, is a ligand of that enzyme.

Ligand-gated channel A gated channel that opens to allow diffusion of a solute as a result of binding by a neurotransmitter (or other specific signaling molecule) to a receptor site on the channel protein.

Linear heat-transfer equation An equation that relates heat loss from an animal to the difference between body temperature and ambient temperature by means of a proportionality coefficient. See Equation 10.9.

Load The force against which a contracting muscle exerts an opposing force, the latter being referred to as muscle tension.

Load-velocity relationship The principle that the velocity of shortening of a muscle during isotonic contraction decreases as load increases.

Loading Oxygenation of a respiratory pigment.

Long-term potentiation (LTP) A stable, long-lasting increase in the amplitude of the response of a neuron after it has been stimulated repeatedly by presynaptic input at a high frequency.

Loop of Henle A portion of a nephron tubule shaped like a hairpin, found in the nephrons of mammals and some of the nephrons of birds, that is the site of countercurrent multiplication, the process responsible for production of urine hyperosmotic to the blood plasma.

Low-grade energy Energy in a form that cannot do any physiological work (i.e., heat).

Lower-critical temperature In a homeotherm, the ambient temperature that represents the lower limit of the thermoneutral zone. See also *thermoneutral zone*.

Luciferase An enzyme that catalyzes oxidation of a luciferin, resulting in light production, during bioluminescence. Many different chemical forms of luciferase are known.

Luciferin A compound capable of light emission during bioluminescence. Light emission occurs when luciferin is oxidized by an enzyme luciferase. Many different chemical forms of luciferin are known.

Lumen The open central cavity or core of a "hollow" organ or tissue; for example, the open central core of a blood vessel.

Luminal Related to the lumen.

Lungfish See *dipnoan*.

Lungs In the most general sense used by physiologists, structures specialized for external respiration that are invaginated into the body and thereby contain the environmental medium. Contrast with *gills*.

Luteal phase In a female mammal, the ovarian phase of the menstrual or estrous cycle that follows ovulation, during which the corpus luteum forms, is functional, and then degenerates.

Lymph In an animal with a closed circulatory system, the interstitial fluids. *Lymph* is often used in a more restrictive sense to refer specifically to excess volumes of interstitial fluid that are collected from the tissues and returned to the blood by the lymphatic vascular system.

Lymphatic vascular system An elaborate system of vessels that approximately parallels the blood vascular system in vertebrates and serves to remove excess interstitial fluids (lymph) from tissues throughout the body, returning the fluids ultimately to the blood plasma.

M

M line In muscle fibers, a web of accessory proteins at the center of a sarcomere that anchors the thick filaments and titin.

Macula In the vertebrate ear, a sensory area in the vestibular organs containing hair cells that monitor tilt and acceleration of the head.

Magnetic compass A mechanism by which an animal uses Earth's magnetic field to determine compass direction in navigation.

Magnetoreception A mechanism by which specialized animal cells are able to detect Earth's magnetic field by direct or indirect means.

Malpighian tubules Fine tubules that initiate urine formation in insects. They empty their product into the gut at the junction of the midgut and hindgut.

Mantle cavity In molluscs, an external body cavity formed where a sheetlike outfolding of the dorsal body wall, the *mantle*, overhangs or surrounds all or part of the rest of the body. The gills typically are suspended in the mantle cavity.

Map-and-compass navigation Navigation in which an animal has information about where it is in the world (the "map") and about the direction it should take to reach a destination (the "compass").

Mark See *epigenetic mark*.

Mass action The inherent tendency for the reactants and products of a chemical reaction to shift in their concentrations, by way of the reaction, until an equilibrium state—defined by particular concen-

tration ratios—is achieved. Mass action impels reactions toward equilibrium, although other processes may operate against equilibrium and therefore prevent an equilibrium from actually being established.

Maximal aerobic power A synonym for $\dot{V}_{O_2\max}$.

Maximal exercise Exercise that requires an individual's maximal rate of O_2 consumption.

Maximum reaction velocity (V_{\max}) The greatest rate at which an enzyme-catalyzed reaction can convert substrate to product with the number of active enzyme molecules that are present.

Mechanical energy Energy of *organized* motion in which many molecules move simultaneously in the same direction. The energy of motion of a moving arm provides an example. Mechanical energy and heat are the two forms of kinetic energy.

Mechano growth factor A locally acting peptide, produced by muscle fibers when they are stimulated to produce mechanical activity, that stimulates muscle satellite cells to proliferate and become incorporated into the muscle fibers.

Mechanoreceptor A sensory receptor cell specialized to respond to mechanical stimulation.

Membrane-associated digestive enzyme A digestive enzyme that is positioned in the apical membranes of epithelial cells lining the gut or another body cavity. Food materials in the gut lumen must make physical contact with the gut epithelium to be digested by this sort of enzyme.

Membrane fluidity See *fluidity*.

Membrane potential The potential difference (voltage) across a cell membrane or other selectively permeable membrane.

Membrane resistance (R_m) The electrical resistance of a membrane per unit of area. Many cell membranes have an R_m of about $1000 \text{ ohm} \times \text{cm}^2$ ($1000 \Omega \times \text{cm}^2$).

Menarche First menstruation.

Menstrual cycle The cycle in which oocytes mature and are ovulated periodically in females of some primate species; one phase of each cycle is characterized by menstruation, the shedding of the uterine lining in a blood-tinged discharge from the vagina.

Mesic Moderately moist. "Mesic animals" are terrestrial animals that live in moderately moist environments.

Metabolic acidosis or alkalosis Acidosis or alkalosis that is caused by abnormal excretion or retention of bicarbonate

G-18 Glossary

- (HCO_3^-) in the body fluids. Contrast with *respiratory acidosis* or *alkalosis*.
- Metabolic depression** A reduction in the ATP needs of an animal (or a specific tissue) to below the level ordinarily associated with rest in a way that does not present an immediate physiological threat to life.
- Metabolic rate** An animal's rate of energy consumption; the rate at which it converts chemical-bond energy to heat and external work.
- Metabolic scaling** The regular allometric or quasi-allometric relationship that typically exists between metabolic rate and body weight within sets of related species. For example, small-bodied mammals have higher rates of metabolism per unit of body weight than large-bodied species do. This relationship, which is approximately allometric, represents a case of metabolic scaling.
- Metabolic water** Water that is formed by chemical reaction within the body. For example, when glucose is oxidized, one of the products is H_2O that did not previously exist. Also called *oxidation water*. Contrast with *preformed water*. See also *net metabolic water production*.
- Metabolism** The set of processes by which cells and organisms acquire, rearrange, and void commodities (e.g., elements or energy) in ways that sustain life.
- Metabolite** An organic molecule of relatively low molecular weight (e.g., glucose, an amino acid, or lactic acid) that is currently being processed by metabolism.
- Metabolomics** The study of all the organic compounds in cells or tissues other than macromolecules coded by the genome. The molecules encompassed by metabolomics are generally of relatively low molecular weight (roughly <1500 daltons).
- Metabotropic receptor (in synaptic function)** A neurotransmitter receptor that acts via signal transduction to alter a metabolic function of the postsynaptic cell, often by stimulating production of a second messenger.
- Metabotropic transduction (in sensory function)** Sensory transduction by means of a signal transduction cascade, rather than by direct ionotropic action. The sensory receptor molecule is a G protein that activates a second messenger, ultimately producing a receptor potential. See also *ionotropic transduction*.
- Metalloprotein** A protein that includes one or more metal atoms in its structure.
- Metamorphosis** The process of changing from one body form to another, such as changing from a larva to an adult.
- Methylation** Covalent bonding of a methyl group ($-\text{CH}_3$) to another molecule.
- Michaelis constant (K_m)** The half-saturation constant of an enzyme-catalyzed reaction that exhibits hyperbolic kinetics—that is, the concentration of substrate at which the reaction velocity is half of the maximal velocity. This constant is a measure of enzyme–substrate affinity.
- Michaelis–Menten equation** An equation that describes the relation between reaction velocity and substrate concentration in an enzyme-catalyzed reaction that exhibits hyperbolic kinetics. See Equation 2.2.
- Microarray** See *DNA microarray*.
- Microbiome** See *gut microbiome*.
- Microcirculatory bed** In a closed circulatory system, one of the systems of microscopically fine blood vessels that connect arteries and veins, weaving among ordinary tissue cells. In vertebrate systemic tissues, microcirculatory beds consist of arterioles, capillaries, and venules.
- Microclimate** The set of climatic conditions (temperature, humidity, wind speed, and so forth) prevailing in a subpart of a larger environmental system.
- Microenvironment** A place within a larger environment in which the physical and chemical conditions differ significantly from the average conditions characterizing the larger environment.
- Microvilli** Microscopic finger-shaped projections from the apical membranes of certain types of epithelial cells. Microvilli occur most commonly in epithelia that are active in secretion or reabsorption.
- Middle ear** The portion of the vertebrate ear between the tympanic membrane and the cochlea.
- Migration** A seasonal or other periodic movement of animals from one geographic region to another.
- Milieu intérieur** See *internal environment*.
- Miniature EPSP (mEPSP)** A small excitatory postsynaptic potential at a neuromuscular junction or postsynaptic neuron produced by presynaptic release of a single quantal packet of neurotransmitter.
- Minute volume** The amount of air, water, or blood pumped per minute in a breathing system or circulatory system.
- Mitochondria-rich cell** A type of epithelial cell specialized for ion transport, found particularly in the gill epithelia of fish but also in some other epithelia of aquatic animals. Characterized by an abundance of mitochondria and other signs of secretory or absorptive activity. Also called a *chloride cell*.
- Mixed venous blood** The blood in the great veins leading back to the heart, formed by mixing of the venous blood coming from the various regions and organs of the body.
- Modality** The subjective sensation of a particular sense, such as sight, taste, or hearing.
- Molal** A unit of measure of chemical concentration; specifically, the molal concentration is the number of moles mixed with a kilogram of water to make a solution.
- Molar** A unit of measure of chemical concentration; specifically, the molar concentration is the number of moles dissolved in a liter of solution.
- Mole (mol)** A set of 6.022×10^{23} items (i.e., an Avogadro's number of items). For example, a mole of a chemical compound contains 6.022×10^{23} molecules of the compound. The mass in grams of a mole of a chemical compound is identical to the formula mass of the compound. Thus, if you have 18 g of water, a compound that has a formula mass of 18, you have one mole of water, or 6.022×10^{23} water molecules. See also *Avogadro's number*, *osmole*.
- Molecular chaperones** Proteins that use energy from ATP to guide the folding of other proteins into correct three-dimensional configurations. Molecular chaperones ensure that target proteins assume correct tertiary structures during initial synthesis, and they sometimes are able to guide reversibly denatured proteins back to functional conformations, thereby preventing permanent denaturation.
- Molecular kinetic energy** See *heat*.
- Molting** See *ecdysis*.
- Molting hormone** See *ecdysone*.
- Monounsaturated fatty acid** See *unsaturated fatty acid*.
- Motility** Any sort of muscular activity by the gut, such as peristalsis or segmentation.
- Motor cortex** The region of the mammalian cerebral cortex that lies anterior to the central sulcus and is concerned with motor behavior; includes the *primary motor cortex* and associated motor areas in the frontal lobe.
- Motor neuron** A neuron that conveys motor signals from the central nervous system to the periphery to control an effector such as skeletal muscle.
- Motor unit** A motor neuron and all the muscle fibers it innervates.
- Mucosal surface** See *apical surface*.
- Müllerian inhibitory substance** A glycoprotein hormone secreted by Sertoli cells in the developing testes of genetic males that causes degeneration of the Müllerian

ducts, which would otherwise give rise to the uterus and oviducts. Also called *anti-Müllerian hormone*, *Müllerian inhibitory hormone*.

Multiterminal innervation A pattern of innervation in which a single axon branches near its end to make many synaptic contacts along the length of a muscle fiber.

Muscle A group of muscle cells (muscle fibers) and associated tissues. It may be smooth, skeletal, or cardiac.

Muscle fiber A term typically used to refer to skeletal or cardiac muscle cells, but sometimes also applied to smooth muscle cells. This term, now used broadly, was initially introduced to emphasize the long, fibrous appearance of certain muscle cells, such as vertebrate skeletal muscle cells (fibers), that are multinucleate because they are formed during development by the fusion of two or more embryonic myoblasts.

Muscle spindle A stretch receptor that is arranged in parallel with the tension-producing fibers of a muscle and sends action potentials to the central nervous system when the muscle is stretched.

Myelin An insulating sheath around an axon, composed of multiple wrappings of glial cell membranes, that increases the velocity of propagation of action potentials.

Myocardium The muscle tissue of a heart.

Myofibril A longitudinal component of a striated muscle cell that consists of a series of sarcomeres and extends the length of the cell. In cross section, a muscle cell consists of multiple myofibrils, each surrounded by a sleeve of sarcoplasmic reticulum.

Myofilament Either of the two types of longitudinal components of sarcomeres. Thick myofilaments consist of polymerized myosin molecules, and thin myofilaments consist of polymerized actin molecules.

Myogenic heart A heart in which the electrical impulse to contract during each beating cycle originates in muscle cells or modified muscle cells. Contrast with *neurogenic heart*.

Myoglobin Any type of hemoglobin found in the cytoplasm of muscle.

Myometrium In the mammalian uterus, the outer tissue layer, consisting of smooth muscle.

Myosin A molecular motor found in many types of cells that converts chemical energy of ATP into mechanical energy of motion. In muscle cells, it functions as a contractile protein. Myosin monomers polymerize to form thick myofilaments.

Myostatin An inhibitory growth factor that regulates the growth of skeletal muscles by tempering hyperplasia in developing muscles and hypertrophy of adult muscle fibers.

N

Na⁺-K⁺-ATPase A ubiquitous and extremely important transporter protein that directly cleaves ATP molecules to release energy (it is an ATPase) and uses the energy to transport Na⁺ and K⁺ ions in a 3:2 ratio (a case of primary active transport). The ion gradients created are often used as energy sources for secondary active transport.

Natriuretic Promoting loss of sodium in the urine.

Navigation The act of moving on a particular course or toward a specific destination using sensory cues to determine direction and position.

Nebulin In a sarcomere, a large inelastic protein that extends along the thin filament from the Z disc to the margin of the H zone.

Negative feedback A process by which the deviations of a property from a specific set-point level are opposed, thereby tending to keep the property at the set-point level.

Nephridium A term used to refer to a kidney in certain types of animals such as molluscs.

Nephron One of the tubules that forms urine in the kidney of a vertebrate.

Nernst equation An equation used to determine the equilibrium electrical potential for a particular ion, given the ion concentrations on both sides of a membrane.

Nerve A collection of axons running together in the peripheral nervous system.

Nerve impulse See *action potential*.

Nerve net A simple, uncentralized, and unpolarized network of neurons, found in cnidarians and locally in many other groups and considered to be a primitive stage in the evolution of nervous systems.

Nervous system An organized constellation of neurons and glial cells specialized for repeated conduction of electrical signals (action potentials) within and between cells. These signals pass from sensory receptors and neurons to other neurons and effectors. Nervous systems integrate the signals of convergent neurons, generate new signals, and modify the properties of neurons based on their interactions.

Net growth efficiency In a growing animal, the chemical-bond energy of new biomass added by growth expressed as a

ratio of the animal's absorbed energy over the same time period.

Net metabolic water production The production of metabolic water by a process minus the losses of water that are obligatory for that process to take place.

Network oscillator A neural circuit that acts as a central pattern generator as a result of the synaptic interaction of its constituent neurons, rather than as a result of oscillator activity in single cells.

Neurogenic heart A heart in which the electrical impulse to contract during each beating cycle originates in neurons. Contrast with *myogenic heart*.

Neuroglia See *glial cells*.

Neurohemal organ An organ made up of axon terminals of neurosecretory cells in association with a well-developed bed of capillaries or other circulatory specializations, in which the axon terminals store neurohormones and secrete them into the blood.

Neurohormone A hormone secreted by a neuron (also called a neuroendocrine cell or neurosecretory cell) into the blood.

Neurohypophysis The neuroendocrine portion of the vertebrate pituitary gland in which neurohormones are released from axon terminals. It is an extension of the brain, commonly called the posterior pituitary. See *posterior pituitary*.

Neuron A nerve cell; the fundamental signaling unit of the nervous system, composed of a cell body and elongated processes—dendrites and axon—that carry electrical signals.

Neuron doctrine The theory that the nervous system, like other organ systems, is composed of discrete cellular elements (neurons) that are its fundamental signaling elements.

Neuronal integration The process by which a postsynaptic neuron sums the inputs from several presynaptic neurons to control its generation of action potentials.

Neurosecretory cell A neuron that synthesizes and releases hormones.

Neurotransmitter A molecule that is used as a chemical signal in synaptic transmission.

Neutral pH The pH of pure water. The neutral pH varies with temperature; at any given temperature, pH values less than the neutral pH represent an acid solution, whereas pH values above the neutral pH represent an alkaline solution.

Newton's law of cooling A common, although not necessarily historically defensible, synonym for the *linear heat transfer equation*.

G-20 Glossary

Nocturnal Active in the nighttime.

Node of Ranvier In the myelin sheath surrounding an axon, spaces between adjacent glial cells. These interruptions in the sheath allow propagation of action potentials by saltatory conduction.

Nonadaptive evolution Evolution that occurs by processes other than natural selection and that therefore can produce traits that are not adaptations. See also *evolution*, *genetic drift*, *pleiotropy*.

Noncovalent bond A chemical bond that does not involve covalent bonding. Because they are not covalent, noncovalent bonds are flexible rather than rigid, and they can be made and broken with relative ease, without enzyme catalysis. There are four types: hydrogen bonds, ionic bonds, van der Waals interactions, and hydrophobic bonds. Also called *weak bonds*.

Nonpolar molecule A molecule in which electrons are evenly distributed, the various regions of which are all therefore similar in charge.

Nonshivering thermogenesis (NST)

In mammals and some birds, elevation of heat production for thermoregulation by means other than shivering. The same mechanisms potentially function in body weight regulation by serving to get rid of the energy value of excess organic food molecules in the form of heat.

Nonspiking neuron A neuron that transmits information without generating action potentials.

Norm of reaction In phenotypic plasticity, the specific relations between environments and phenotypes. If environment A causes phenotype M to be expressed, and environment B causes phenotype N to be expressed, the relations A-leads-to-M and B-leads-to-N constitute the norm of reaction.

Nucleating agent See *ice-nucleating agent*.

Nucleus (of nervous system) A cluster of functionally related neuronal cell bodies in a vertebrate central nervous system.

Nutrition The study of the chemical components of animal bodies and how animals are able to synthesize those chemical components from the chemical materials they collect from their environments.

O

Olfaction The sense of smell; chemoreception of molecules released at a distance away from the animal. Among chemoreceptors, olfactory receptors are typically more sensitive than taste receptors and respond to distant or dilute chemical

stimuli (odorants) that are usually air-borne in terrestrial animals.

Oligodendrocyte A type of ensheathing glial cell (non-neuron cell) in the vertebrate central nervous system.

Omega 3 and omega 6 fatty acids Fatty acids characterized by double bonds at particular points in their molecular structures. If the first double bond encountered when scanning a fatty acid molecule from its methyl ($-\text{CH}_3$) end is the third bond in the carbon-chain backbone of the molecule, the fatty acid is an omega 3 fatty acid. If the first double bond occurs at the sixth position, the fatty acid is of the omega 6 type.

Oncotic pressure Synonym for *colloid osmotic pressure*.

Ontogeny Individual development.

Oogenesis The formation of haploid eggs through the process of meiosis in the ovary.

Oogonia Diploid cells in the ovary that proliferate by mitosis, then go through meiosis to give rise to female gametes (ova). In elasmobranchs, birds, and most mammals, oogonia are generally thought to proliferate only during embryonic or fetal life and remain suspended in an early stage of meiosis until the female becomes reproductively mature.

Open circulatory system A circulatory system in which the blood leaves discrete vessels and bathes at least some nonvascular tissues directly, meaning that blood and interstitial fluid are the same. Contrast with *closed circulatory system*.

Open system A defined part of the material universe that is not isolated, meaning that it is capable of exchanging matter, energy, or both with its surroundings.

Opsin The protein part of the photopigment rhodopsin, which is a G protein-coupled receptor molecule.

Optogenetics A type of manipulative method for study of neuron function (or function of other excitable cells) in which light-gated (light-modulated) ion channels—obtained from microorganisms—are expressed (through genetic engineering) in neuronal membranes of animals. Light signals can then be used to modulate the membrane potential of the neuronal membranes—for example, by inducing depolarization on very short time scales.

Organ of Corti A region of the cochlea in the vertebrate ear containing the inner and outer *hair cells* that transduce sound vibrations into electrical signals.

Orientation The way an organism positions itself in relation to environmental cues.

Ornithine–urea cycle A cyclic metabolic pathway that produces the nitrogenous end product urea.

Osmoconformer An aquatic animal that allows its blood osmotic pressure to match and vary with the environmental osmotic pressure. Also called a *poikilosmotic animal*.

Osmoconformity See *osmotic conformity*.

Osmolar (Osm) A unit of measure of osmotic pressure. A 1-osmolar solution is defined to be a solution that behaves osmotically as if it has one Avogadro's number of independent dissolved entities per liter.

Osmolarity The osmotic pressure of a solution expressed in osmolar units. See *osmolar*.

Osmole An Avogadro's number of osmotically effective dissolved entities; a set of 6.022×10^{23} osmotically effective dissolved entities.

Osmolyte Any solute that exerts a sufficiently large effect on the osmotic pressure of a body fluid to be of consequence for water–salt physiology.

Osmoregulation See *osmotic regulation*.

Osmoregulator An animal that maintains an approximately constant blood osmotic pressure even as the osmotic pressure of its environment varies.

Osmosis The passive transport of water across a membrane.

Osmotic conformity A state in which the osmotic pressure of the body fluids matches, and varies with, the osmotic pressure in the external environment.

Osmotic effector An osmolyte that an individual animal or individual cell increases or decreases in amount to achieve the regulation of the osmotic pressure of a body fluid or the regulation of cell volume. Also called an *osmoticum*.

Osmotic pressure The property of a solution that allows one to predict whether the solution will gain or lose water by osmosis when it undergoes exchange with another solution; osmosis is always from lower osmotic pressure to higher osmotic pressure. An alternative, measurement-oriented definition is that the osmotic pressure of a solution is the difference in hydrostatic pressure that must be created between the solution and pure water to prevent any net osmotic movement of water when the solution and the pure water are separated by a semipermeable membrane. A colligative property.

Osmotic regulation The maintenance of a constant or nearly constant osmotic pressure in body fluids regardless of the osmotic pressure in the external environment.

Osmotically free water Water that is excreted in the urine above and beyond whatever water is absolutely required for solute excretion.

Osmoticum See *osmotic effector*.

Ossicles The ossicles of the middle ear (malleus, incus, stapes) are three bones, attached to each other in a series, that convey sound pressure waves from the tympanic membrane (eardrum) to the liquid-filled cochlea of the inner ear.

Outer hair cells In the organ of Corti of the cochlea, the three rows of hair cells that amplify the sound-produced local movements that stimulate the inner hair cells to activate cochlear sensory neurons.

Overexpression A genetic manipulation whereby cells or tissues produce unusually large quantities of one or more messenger RNAs of interest.

Ovulation The process of releasing an egg (ovum) from the ovary.

Ovum A haploid gamete (egg) produced in the ovary.

Oxidation Removal of electrons or hydrogen atoms from a molecule.

Oxidation water Synonym for *metabolic water*.

Oxidative phosphorylation The formation of ATP using energy released by the transport of electrons through the electron-transport chain.

Oxidative stress See *oxygen stress*.

Oxygen affinity The readiness with which a respiratory pigment such as hemoglobin combines with O_2 . When oxygen affinity is high, a low O_2 partial pressure is sufficient to cause extensive oxygenation.

Oxygenation (1) Referring to water, the dissolution of O_2 in that water. (2) Referring to respiratory pigments, the combination of those pigments with O_2 ; oxygenation of this sort is reversible and not equivalent to oxidation.

Oxygen-carrying capacity In a body fluid (e.g., blood) that contains a respiratory pigment, the amount of O_2 per unit of fluid volume when the respiratory pigment is saturated with O_2 . More generally, the maximal amount of O_2 per unit of volume in a fluid under ordinary physiological conditions.

Oxygen cascade The sequential drop in the partial pressure of O_2 from one step to the next in the series of steps by which O_2 is transported from the environment of an animal to the animal's mitochondria.

Oxygen conformity A response in which an animal exposed to a decreasing O_2 concentration in its environment allows its rate of O_2 consumption to decrease in parallel.

Oxygen debt An older term for *excess postexercise oxygen consumption*.

Oxygen deficit A difference between actual O_2 uptake by breathing and the theoretical O_2 requirement of exercise during the first minutes at the start of exercise. During the oxygen deficit phase, aerobic catabolism based on O_2 uptake by breathing is unable to meet fully the ATP requirement of exercise, and other ATP-producing mechanisms (such as phosphagens use) must contribute ATP.

Oxygen dissociation curve See *oxygen equilibrium curve*.

Oxygen equilibrium curve Referring to the O_2 -carrying properties of blood, a graph of the amount of O_2 per unit of blood volume as a function of the O_2 partial pressure of the blood. Also called the *oxygen dissociation curve*.

Oxygen regulation A response in which an animal exposed to a decreasing O_2 concentration in its environment maintains a stable rate of O_2 consumption.

Oxygen stress Collectively speaking, the destructive effects of reactive oxygen species on functional or structural properties of cells or tissues. See *reactive oxygen species*.

Oxygen-transport pigment See *respiratory pigment*.

Oxygen utilization coefficient (1) In breathing, the fraction (or percentage) of the total O_2 in respired air or water that is removed by the breathing process. (2) In circulation, the fraction of the total O_2 carried by blood that is removed from the blood as it passes around the body.

Oxytocin A vertebrate neurohormone synthesized by neurosecretory cells that have their cell bodies in the hypothalamus and their axon terminals in the pars nervosa of the posterior pituitary. Its major functions are to stimulate contraction of myoepithelial cells of the mammary glands to cause milk ejection and contraction of the myometrium during parturition.

P

P450 enzymes A set of inducible enzymes that play roles in the detoxification of foreign compounds.

P_{50} The partial pressure of O_2 that causes a blood or respiratory pigment to become 50% saturated with O_2 . A measure of O_2 affinity; a high P_{50} signifies a low O_2 affinity.

P/O ratio During electron transport and oxidative phosphorylation, the number of ATP molecules produced per oxygen atom reduced to H_2O . A measure of the degree of coupling that exists between electron transport and oxidative phosphorylation.

Pacemaker The cell or set of cells that spontaneously initiates a rhythm. In a heart, for example, the pacemaker is the cell or set of cells that spontaneously initiates the rhythmic contractions of the heart muscle.

Panting An increase in the rate of breathing; often serves to increase the rate of evaporative cooling by increasing air flow over moist surfaces of the airways of the breathing system.

Parabronchi The smallest-diameter tubes in the lungs of a bird. They are numerous and collectively constitute most of the lung tissue. Air capillaries—the sites of O_2 and CO_2 exchange—connect to the lumens of the parabronchi.

Paracrine A locally acting chemical signal that binds to receptors and exerts a regulatory effect on cells in the neighborhood of the cell that released it.

Parallel In reference to the arrangement of parts in an electrical circuit, vascular system, or other analogous system in which substances flow from place to place, the parts of the system are in *parallel* if one path of flow branches to give rise to two or more paths in which the parts reside, so that only a fraction of the total flow passes through any one of the parts. Contrast with *series*.

Parasympathetic division A division of the vertebrate autonomic nervous system that is connected to the CNS via cranial and sacral nerves; the parasympathetic and sympathetic divisions tend to exert opposing controls on autonomic effectors.

Parthenogenesis A form of asexual reproduction in which eggs produced by females develop into genetically identical clones of their female parent.

Partial compensation See *compensation*.

Partial pressure (1) The pressure exerted by a particular gas within a mixture of gases. In terms of the pressure it exerts (its partial pressure), each gas in a mixture behaves as if it alone occupies the entire volume occupied by the mixture; thus each gas's partial pressure can be calculated from the universal gas law. (2) The concept of partial pressure is also applied to gases dissolved in aqueous solution: The partial pressure of a gas in aqueous solution is equal to the partial pressure of the same gas in a gas phase with which the solution is at equilibrium. *Gas tension* is synonymous with *partial*

G-22 Glossary

pressure for a gas in solution. See also *universal gas law*.

Passive change in lung volume In the study of ventilation, a change in lung volume that is a consequence of elastic rebound, not driven by muscle action. Contrast with *active change in lung volume*.

Passive electrical properties The electrical properties of a cell that do not involve a change in membrane ion permeability, and thus involve no change in electrical resistance.

Passive spread See *decremental spread*.

Passive transport The transport of a material by a mechanism that is capable of carrying the material only in the direction of equilibrium.

Patch-clamp recording A method of measuring single-channel currents by sealing a glass capillary microelectrode to a patch of cell membrane. Other conformations of patch clamping can measure whole-cell current or voltage.

Path integration An animal's summation of the distances and directions of its past movements, so that the animal knows where it is (relative to home) without using landmarks.

Pay-as-you-go phase A phase during exercise when aerobic catabolism using O_2 taken up by breathing is meeting the full ATP requirement of the exercise.

Perfusion The forced flow of blood through blood vessels.

Pejus temperatures In the study of poikilotherms, a range of body temperatures in which animal performance deteriorates as body temperature is gradually raised (upper pejus range) or lowered (lower pejus range). Pejus means *turning worse*. Contrast with *critical temperature*.

Perikaryon See *cell body*.

Periodic breathing See *intermittent breathing*.

Peripheral activation Conversion of a hormone after secretion to a more physiologically potent form.

Peripheral membrane protein A protein that is associated with a cell membrane, typically on just one side or the other, but that can be removed without destroying the membrane.

Peripheral nervous system (PNS) The portion of a nervous system outside of the central nervous system, consisting of afferent and efferent nerves that connect the central nervous system to various parts of the body.

Peristalsis One of the gut's principal modes of muscular activity, in which constriction of the gut at one point along its length initiates constriction at a neighbor-

ing point farther along the gut, producing a "wave" of constriction that moves progressively along the gut, propelling food material before it.

Permeability In reference to a cell membrane or epithelium, the ease with which a particular solute can move through it by diffusion, or the ease with which water can move through it by osmosis.

Permeating In reference to a solute, able to pass through a cell membrane or epithelium.

Permissiveness A type of relationship between hormones in which one hormone must be present to allow another hormone to exert its effect.

pH The negative of the common logarithm of the concentration of H^+ . The pH is inversely related to the concentration of H^+ (acidity). A low pH signifies acid conditions, whereas a high pH signifies alkaline conditions. See also *neutral pH*.

Phasic receptor See *rapidly adapting receptor*.

Phasing factor An environmental cue that can entrain a biological clock, synchronizing it to environmental changes (such as the daily light-dark cycle). Also called a *zeitgeber*.

Phenotypic plasticity The ability of an individual animal to express two or more genetically controlled phenotypes.

Pheromone A chemical signal that conveys information between two or more individuals that are members of the same species. It typically signals the sexual readiness or social status of the releasing animal and triggers stereotyped behaviors or physiological changes in the detecting animal.

Phosphagens Compounds that can donate high-energy phosphate bonds to ADP to make ATP; thus, compounds that act as stores of high-energy phosphate bonds. The two most common are creatine phosphate and arginine phosphate.

Phospholipid A lipid compound in which a phosphate group or groups occur. A typical membrane phospholipid consists of two hydrocarbon tails linked by a phosphate group to a compound such as choline.

Photoautotroph An organism that can obtain the energy it needs to stay alive from photons; an organism capable of photosynthesis.

Photoperiod Day length; the number of hours of daylight in a 24-hour day.

Photoprotein A type of chemical complex instrumental in bioluminescence in some marine animals. The complex consists of luciferin, O_2 , and an inactive form of

catalyzing protein. Initiation of light production is often dependent on exposure of the photoprotein to Ca^{2+} or Mg^{2+} .

Photoreception Response of a sensory cell to light stimulation. Photoreceptor cells contain a photopigment that absorbs light and triggers a response.

Phyletic See *phylogenetic*.

Phylogenetic Having to do with the evolutionary relationships of organisms; the patterns of relationship that organisms exhibit by virtue of common evolutionary descent. Also called *phyletic*.

Phylogenetic reconstruction A reconstruction of the family tree (the ancestry) of groups of related species, often using molecular genetic data.

Physiological work Any process carried out by an animal that increases order and requires energy. For example, an animal does physiological work when it synthesizes proteins, generates electrical or chemical gradients by actively transporting solutes across cell membranes, or contracts muscles to move materials inside or outside its body.

Physiology The study of function; the study of "how organisms work."

Pilomotor Related to the erection or compression of the hairs in the fur (pelage) of a mammal under the control of muscles attached to the bases of the hairs.

Place cell A neuron in the hippocampus that generates action potentials when an animal is in a particular part of its familiar environment. Place cells are so named because their activity encodes the spatial position of the animal.

Place theory The theory that the pitch or frequency of a sound is encoded by the place of maximal vibration and maximal hair cell stimulation along the length of the basilar membrane of the cochlea of the ear.

Placenta An organ formed jointly by the embryo and the mother in marsupial and eutherian mammals. It allows intimate juxtaposition (but not mixing) of the maternal bloodstream and the embryonic or fetal bloodstream for the exchange of materials.

Plasma See *blood plasma*.

Plasma clearance The volume of blood plasma that would have to be completely cleared of a solute to obtain the amount of that solute excreted in urine over a specified period of time.

Plasma membrane See *cell membrane*.

Pleiotropy The control of two or more distinct and seemingly unrelated traits by an allele of a single gene.

- Podocytes** Distinctive cells with numerous processes that occur in structures where ultrafiltration occurs, such as the vertebrate renal glomerulus. Intricate geometric arrays of the cell processes of multiple podocytes are believed to form a critical part of the filter that determines which solutes can and cannot pass through during ultrafiltration.
- Poikilosmotic animal** See *osmoconformer*.
- Poikilotherm** An animal in which the body temperature is determined by equilibration of the body with the thermal conditions in the environment. Also called an *ectotherm*.
- Poiseuille equation** An equation that describes the quantitative relation between the rate of flow of fluid through a horizontal tube and factors such as pressure, luminal radius, and length. The equation states that flow rate depends directly on the fourth power of the luminal radius. See Equation 25.2. Also called the *Hagen-Poiseuille equation*.
- Polar molecule** A molecule in which electrons are unevenly distributed, so that some regions of the molecule are relatively negative while others are relatively positive.
- Polycythemia** A state of having an unusually high concentration of red blood cells in the blood; seen, for example, in humans and some other lowland mammals when they acclimatize to high altitudes.
- Polyneuronal innervation** A pattern of innervation in which a single muscle fiber receives synaptic contacts from more than one motor neuron.
- Polyphenic development** A developmental phenomenon in which one individual—or a set of *genetically identical* individuals—can assume two or more discrete, highly distinct body forms, induced by differences in the developmental environment. Particularly common in insects.
- Polyphenism** See *polyphenic development* and *seasonal polyphenism*.
- Polysaccharide** A carbohydrate molecule that consists of many simple-sugar (monosaccharide) molecules polymerized together. Starch, cellulose, and chitin are important examples.
- Polyunsaturated fatty acid** See *unsaturated fatty acid*.
- Positive feedback** A process by which deviations of a property from a specific set-point level are reinforced, thereby tending to cause escalating changes in the property.
- Posterior pituitary** The neuroendocrine portion of the vertebrate pituitary gland in which neurohormones are released from axon terminals. The posterior pituitary is an extension of the brain. Also called the *neurohypophysis*.
- Postganglionic neuron** In the autonomic nervous system, a neuron that extends from an autonomic ganglion to an effector.
- Postgenomic** Referring to the study of an animal species or other organism after its full genome is known.
- Postsynaptic cell** A neuron or effector cell that receives a signal (chemical or electrical) from a presynaptic cell at a synapse.
- Postsynaptic potential** See *synaptic potential*.
- Power curve** In a muscle, the relationship between the velocity of shortening and the force exerted against a load.
- Power equation** See *allometric equation*.
- Pre-Bötzinger complex** A bilaterally arrayed pair of neuron clusters within the medulla of the brainstem of a mammal, believed to be the source of the breathing rhythm.
- Preferred body temperature** The body temperature that is maintained in a poikilotherm by behavioral thermoregulation.
- Preflight warm-up** In an insect, warming of the flight muscles prior to flight. Preflight warm-up is often essential for flight because the flight muscles must be warm to generate enough power for flight. It can occur by behavioral means (e.g., sun basking) or by physiological means (shivering).
- Preformed water** Water that enters the body in the form of H₂O. Contrast with *metabolic water*.
- Preganglionic neuron** In the autonomic nervous system, a neuron that extends from the central nervous system to an autonomic ganglion.
- Pressure** The force a fluid (liquid or gas) exerts in a perpendicular direction on solid surfaces with which it is in contact. Expressed per unit of surface area.
- Presynaptic cell** A neuron or other cell that transmits a signal to a postsynaptic cell at a synapse.
- Presynaptic inhibition** Inhibition of a neuron by decreasing the amount of neurotransmitter released by an excitatory presynaptic neuron.
- Primary active transport** Active transport driven by a mechanism that draws energy directly from ATP. Contrast with *secondary active transport*.
- Primary follicle** In the vertebrate ovary, a primary oocyte surrounded by a single layer of somatic cells—called *granulosa cells*—that are of different histological appearance than the somatic cells of a primordial follicle. A primary follicle has started its final maturation and, unless interrupted, will gradually develop more than a single layer of somatic cells and undergo other changes, becoming a secondary follicle and then progressing further.
- Primary oocyte** A cell in the vertebrate ovary that has initiated meiosis during the early development of a female and is destined to produce an ovum but that remains in arrest until the female becomes reproductively mature.
- Primary production** The production of organic matter from inorganic chemical precursors. The most common type of primary production is photosynthesis.
- Primary protein structure** The sequence of amino acids in a protein molecule.
- Primary urine** The fluid initially introduced into the tubules of a kidney. It is processed as it flows through the kidney tubules, ultimately becoming the *definitive urine* that is excreted from the body.
- Primordial follicle** In a vertebrate ovary, a *primary oocyte* surrounded by a single layer of flattened somatic cells. This is the earliest stage of follicle development. See also *primary follicle*.
- Profiling** A research strategy in which investigators look as comprehensively as possible at a class of compounds of interest, such as messenger RNAs (*transcription profiling*) or proteins (*protein profiling*, *proteomics*). Also called *screening*.
- Progesterone** A sex steroid hormone secreted by the corpus luteum of most vertebrates and the placenta of eutherian mammals.
- Prolactin** A hormone secreted by cells in the anterior pituitary that stimulates the production of milk in mammals and performs a variety of other regulatory functions in vertebrates related to reproduction, water and mineral balance, and caring for the young.
- Propagation** Spatial transmission of a signal such as an action potential without any decrease in amplitude with distance.
- Proprioceptor** A sensory receptor that provides an animal with information about the relative position or movement of parts of its body.
- Protein kinase** A regulatory enzyme that covalently bonds a phosphate group to a protein using ATP as the phosphate donor.

G-24 Glossary

Proteomics The simultaneous detection and measurement of large suites of proteins being synthesized by cells or tissues. Protein profiling.

Prothoracic glands The paired glands located in the thorax of insects that synthesize and secrete ecdysone in response to prothoracotropic hormone.

Prothoracotropic hormone A tropic protein neurohormone of insects, secreted by neuroendocrine cells with cell bodies in the brain and axon terminals in the neurohemal region of the corpora allata; stimulates the prothoracic glands to secrete ecdysone.

Ptilomotor Related to the erection or compression of the feathers in the plumage of a bird under the control of muscles attached to the bases of the feathers.

P-type ATPases One of the major families of ATPases (transporter proteins that directly cleave ATP to obtain energy for active transport).

Pulmonary Related to the lungs.

Pulmonary circuit In the circulatory system of an air-breathing animal, the blood vessels that take blood to and from the lungs.

Pump In the study of cellular-molecular biology, a mechanism of *active transport*.

Pupa The stage of development in holometabolous insects in which the larval tissues are destroyed and replaced by adult tissues. The pupa metamorphoses into the adult.

Purinotelic Incorporating most nitrogen from the catabolism of nitrogenous compounds into purines, such as uric acid, guanine, and xanthine.

Q

Q₁₀ See *temperature coefficient*.

Quantal release The release of neurotransmitter molecules in multimolecular packets (quanta) corresponding to exocytosis of synaptic vesicles.

Quantitative trait locus (QTL) analysis A statistical method that links two types of information—phenotypic data (observable traits) and genotypic data (usually chromosomal markers)—in an attempt to explain the genetic basis of variation in complex traits. QTL analysis allows researchers to link complex phenotypes to specific regions of chromosomes.

Quaternary protein structure In a protein molecule that is composed of two or more separate proteins, the three-dimensional arrangement of the protein subunits relative to one another.

R

Radiant heat transfer Transfer of heat by electromagnetic radiation between two surfaces that are not in contact. Also called *thermal radiation heat transfer*.

Radiant temperature The surface temperature of an object as judged by its rate of emission of electromagnetic energy. The radiant temperature is the surface temperature that would have to prevail for the object to emit energy at the rate it actually does if its emissivity were exactly 1 (i.e., if it were a true black body). Radiant temperature is calculated by measuring the intensity of radiation and entering it in the Stefan-Boltzmann equation with the emissivity set equal to 1. Also called the *black-body temperature*.

Radiotelemetry The use of a radio transmitter placed in or on an animal to transmit data on physiological or behavioral variables.

Radular apparatus A feeding apparatus found in snails, slugs, chitons, squids, and some other molluscs. The radula itself is a band of connective tissue, studded with teeth, that is pulled back and forth to create grinding or scraping action.

Ram ventilation A type of gill ventilation observed in certain types of fish (e.g., tunas) in which the fish holds its mouth open as it swims forward, thereby using its swimming motions to drive water over its gills.

Rapidly adapting receptor A sensory receptor cell that exhibits a rapidly decreasing response to a maintained stimulus. Also called a *phasic receptor*.

Reactive oxygen species (ROS) A term that refers collectively to metabolically produced molecules that have a great potential to act as oxidizing agents. Included are free radicals (e.g., superoxide)—which are molecules that have an odd number of electrons—and other oxidizing agents (e.g., hydrogen peroxide and ozone). Although many reactive oxygen species play roles in normal metabolism, they can also be destructive.

Receptive field In sensory systems, the region of a sensory surface within which stimulation changes the activity of a particular neuron.

Receptor A protein that binds noncovalently with specific molecules and, as a consequence of this binding, initiates a change in membrane permeability or cell metabolism. Receptors mediate the response of a cell to chemical messages (signals) arriving from outside the cell. Although most receptors are in the cell membrane, some are intracellular. See also *sensory receptor*.

Receptor adaptation See *adaptation* (meaning 2).

Receptor molecule See *sensory receptor molecule*.

Receptor potential The graded change in membrane potential that occurs in a sensory receptor cell when it is stimulated.

Receptor, sensory See *sensory receptor*.

Reciprocity A principle of motor control in which signals that activate motor neurons and muscles also inhibit activation of antagonist motor neurons and muscles.

Red blood cell A hemoglobin-containing cell in the blood of an animal. Also called an *erythrocyte*.

Red muscle In general, a loose term referring to a vertebrate muscle that is rich in myoglobin and thus reddish in color. In fish, a large mass of muscle that consists almost entirely of myoglobin-rich muscle fibers that make ATP mostly by aerobic catabolism; routine cruising by fish is powered by red muscle.

Redox balance (reduction–oxidation balance) A state in which a cell has the capability to remove electrons from a compound that undergoes reversible reduction and oxidation as fast as electrons are added to the compound.

Reduction Addition of electrons or hydrogen atoms to a molecule.

Reflex A simple, relatively stereotyped, but graded behavioral response to a specific stimulus.

Regional heterothermy See *heterothermy*.

Regulation The maintenance of internal conditions at an approximately constant level while external conditions vary.

Relative humidity In air of a particular temperature, the existing water vapor pressure divided by the saturation water vapor pressure characteristic of that temperature.

Relative refractory period In a neuron or other excitable cell, the brief period following an action potential during which the voltage threshold is elevated and it is therefore difficult, but not impossible, to generate another action potential.

Release-inhibiting hormone A hormone secreted by neuroendocrine cells in the hypothalamus of a vertebrate that travels to the anterior pituitary through the hypothalamo-hypophysial portal system and inhibits the secretion of a hormone by a specific population of anterior pituitary endocrine cells. All release-inhibiting hormones are peptides except the catecholamine dopamine, which is known to inhibit the secretion of prolactin.

Releasing hormone A peptide hormone secreted by neuroendocrine cells in the

hypothalamus of a vertebrate that travels to the anterior pituitary through the hypothalamo–hypophysial portal system and stimulates the secretion of a hormone by a specific population of anterior pituitary endocrine cells; may also exert a tropic action to maintain and support those anterior pituitary cells.

Renal Related to kidneys.

Renal corpuscle In the kidney of a vertebrate, a glomerulus and its associated Bowman's capsule. See also *glomerulus*.

Renin A substance secreted into the blood by juxtaglomerular cells of the vertebrate nephron in response to low blood pressure; converts angiotensinogen to angiotensin I.

Renin–angiotensin–aldosterone system A hormonal complex that ensures adequate arterial blood pressure. Set in motion by renin, it produces angiotensin II, which stimulates secretion of aldosterone (important in renal conservation of sodium) and vasopressin, promotes thirst, and stimulates vasoconstriction.

Residue In biochemistry, the modified form assumed by a small molecule when it is incorporated by covalent bonding into a larger molecule. For example, when an amino acid is incorporated into a protein, it is technically an amino acid *residue* because its structure is no longer the full structure of the free amino acid.

Resistance (1) In electrical circuits, the property that hinders the flow of electric current (charge movement) through a material, measured in ohms (Ω). It is the inverse of electrical conductance, the ease of current flow, measured in siemens. See also *membrane resistance*. (2) In heat transfer, the property that hinders dry heat transfer either through a material or between an animal and its environment. Speaking of the latter case, resistance to heat transfer is defined to be the difference between body temperature and ambient temperature divided by the rate of dry heat transfer between the animal and the environment. Contrast with *thermal conductance*. (3) See *vascular resistance*.

Resistance exercise Exercise that consists of relatively short periods of high-intensity muscular actions against a large load, often repeated with intervening interruptions. The periods of high-intensity activity are usually characterized by significant dependence on anaerobic mechanisms of ATP production. Also called *resistance training*. Contrast with *endurance exercise*.

Resonant frequency In any elastic system, the frequency at which the system oscillates when left alone following activation by a pulse of energy; the natural

frequency. The energy cost of energy-driven oscillation tends to be lowest if the oscillation is at the resonant frequency of the system involved.

Respiratory acidosis or alkalosis Acidosis or alkalosis that is caused by an abnormally rapid or slow rate of removal of CO_2 from the body fluids by breathing. Contrast with *metabolic acidosis* or *alkalosis*.

Respiratory gases Oxygen (O_2) and carbon dioxide (CO_2).

Respiratory pigments Any of the metalloprotein pigments that undergo reversible combination with O_2 and thus are able to pick up O_2 in certain places in an animal's body (e.g., the breathing organs) and release it in other places (e.g., systemic tissues). Respiratory pigments include hemoglobin, hemocyanin, hemerythrin, and chlorocruorin. Also called *O_2 -transport pigments*.

Respiratory quotient (RQ) The moles of CO_2 produced by a cell expressed as a ratio of the moles of O_2 simultaneously consumed. Because the RQ changes with the type of foodstuff being oxidized, it can be used to assess what foodstuffs a cell is using in aerobic catabolism.

Resting membrane potential (V_m) The normal electrical potential across the cell membrane of a cell at rest.

Rete mirabile A Latin expression, meaning literally “wonderful net.” A morphological term referring to any intricately complex vascular system composed of closely juxtaposed, small-diameter arterial and venous blood vessels. The term *rete* is a shorthand synonym.

Retina The layer of photoreceptor cells and other neurons that line the inside of a vertebrate eye.

Retinal The aldehyde of vitamin A, one of two components of the photopigment rhodopsin.

Retrieval The movement of channel or transporter protein molecules out of the membrane where they are active to intracellular locations where they are inactive.

Retrograde messenger In a synapse, a chemical signal thought to be released by a postsynaptic cell that alters the synaptic properties (such as neurotransmitter release) of the presynaptic cell.

Reversal potential The membrane potential at which the amplitude of a voltage response (such as a postsynaptic potential or receptor potential) is zero because there is no net driving force for ion flow. For example, E_{EPSP} is the reversal potential of an EPSP.

Rhodopsin The light-absorbing pigment of photoreceptors that initiates the visual response to light; composed of retinal and the protein opsin.

Rhythmogenesis Generation of a rhythm. Usually refers to rhythm generation by neurons or sets of neurons, such as the sets of neurons that rhythmically originate nerve impulses that stimulate the breathing muscles to contract.

Right-to-left shunting In the study of blood flow through the central circulation of an air-breathing fish, amphibian, or nonavian reptile, diversion of systemic venous blood directly back into the systemic circuit, bypassing the lungs.

RNA interference (RNAi) A cellular process that destroys specific mRNA molecules (produced naturally in cells) when specific double-stranded RNA molecules are introduced into cells. The pathway effectively silences the genes that produced the targeted mRNAs.

Rod A type of photoreceptor in the vertebrate retina. Rods are larger than cones, respond at lower light levels, and are used for nocturnal vision.

Root effect A decrease in the amount of O_2 a respiratory pigment can bind at saturation—and thus a decrease in the oxygen-carrying capacity of blood—caused by a decrease in pH or an increase in CO_2 partial pressure. Unusual; observed only in certain fish and molluscs.

ROS See *reactive oxygen species*.

Ryanodine receptor The calcium channel of the sarcoplasmic reticulum in striated muscles.

S

Salinity The sum total concentration of inorganic dissolved matter in water, usually expressed as grams of dissolved matter per kilogram of water.

Salt A synonym for *inorganic ion*, or a compound formed by inorganic ions.

Salt glands Organs other than kidneys that excrete concentrated solutions of inorganic ions. Examples include the cranial salt glands of marine birds and the rectal salt glands of marine elasmobranch fish.

Saltatory conduction Propagation of action potentials in a spatially discontinuous manner along a myelinated axon by jumping from one node of Ranvier to another.

Sarcolemma The cell membrane of a muscle fiber.

Sarcomere The contractile unit of striated muscle that consists of contractile, regulatory, and cytoskeletal proteins. Many sar-

G-26 Glossary

- comeres in series, delineated by Z discs, constitute a myofibril.
- Sarcopenia** The loss of skeletal muscle mass as a result of aging. It involves both the loss of contractile proteins from individual muscle fibers and the loss of complete fibers by cell death.
- Sarcoplasmic reticulum (SR)** A system of internal compartments in a muscle cell that envelops myofibrils and stores Ca^{2+} ions. The sarcoplasmic reticulum has calcium ATPase pumps that transport Ca^{2+} ions into its lumen and calcium channels that open in response to excitation along the associated transverse tubules.
- Satellite cells** Muscle stem cells that lie immediately outside the sarcolemma.
- Saturated air** Air in which a temperature-specific maximum partial pressure of water vapor prevails. Fully humidified air.
- Saturated enzyme** An enzyme that is catalyzing its reaction at a maximum rate because substrate molecules are abundant enough that they bind with the enzyme at as great a number per unit of time as is possible.
- Saturated fatty acid** A fatty acid in which all the bonds between carbon atoms in the carbon-chain backbone of the molecule are single bonds. Also called a *SFA* or a *saturate*.
- Saturated respiratory pigment** A respiratory pigment that has combined with as much O_2 as it can possibly hold.
- Saturated transporter** A transporter protein that is catalyzing transport at a maximum rate because the molecules being transported are abundant enough that they bind with the transporter at as great a number per unit of time as is possible.
- Saturation deficit** In air of a particular temperature, the difference between the saturation water vapor pressure characteristic of that temperature and the existing water vapor pressure.
- Saturation kinetics** The kinetics characteristic of a chemical reaction or other chemical process that is limited to a maximum velocity by a limited supply of some type of molecule with which other molecules must reversibly combine for the reaction or process to take place.
- Saturation water vapor pressure** The maximum possible water vapor pressure that can stably exist in a gas of a particular temperature. If the water vapor pressure rises above the saturation water vapor pressure, condensation occurs. The saturation water vapor pressure varies strongly with temperature.
- Scaling** The study of the relations between physiological (or morphological) features and body size within sets of phylogenetically related species, e.g., the study of metabolism-weight relations.
- Schwann cell** A type of ensheathing non-neuronal glial cell found in the vertebrate peripheral nervous system. Schwann cells form, for example, the myelin sheath of myelinated axons.
- Screening** See *profiling*.
- Seasonal polyphenism** A phenomenon seen in some insects that go through two or more generations per year, in which *genetically identical* individuals can assume two or more discrete, highly distinct body forms depending on the season during which they develop.
- Second law of thermodynamics** A law, believed to apply without exception in the biosphere, stating that if an isolated system undergoes internal change, the net effect of the change in the system as a whole is always to increase disorder (entropy).
- Second messenger** An intracellular signaling molecule that is produced inside a cell in response to the binding of a chemically different extracellular signaling molecule to specific cell-membrane receptors.
- Secondary active transport** Active transport driven by a mechanism that does not draw energy directly from ATP, but instead obtains it from the potential energy inherent in an electrochemical gradient. During secondary active transport, an electrochemical gradient of a solute (e.g., Na^+) is created using ATP-bond energy, and the active-transport mechanism obtains its energy from that gradient. Contrast with *primary active transport*.
- Secondary lamellae** In fish gills, the microscopically fine folds of tissue on the surfaces of the gill filaments that serve as the primary sites of exchange of respiratory gases between the ambient water and blood.
- Secondary oocyte** The cell formed at the time of ovulation by the primary oocyte when it concludes its first meiotic division and extrudes the first polar body.
- Secondary protein structure** The arrangement of the amino acids within subregions of a protein molecule into highly regular geometric shapes. The two most common types of such highly ordered arrays of amino acids are the α -helix and the β -sheet (pleated sheet).
- Segmentation** One of the gut's principal modes of muscular activity, in which circular muscles contract and relax in patterns that push the gut contents back and forth.
- Selective permeability** The state of having a high permeability to some solutes but a low permeability to others. See also *permeability*.
- Semelparity** A type of reproductive life history in which individuals are physiologically capable of only one bout of reproduction during their lives. In semelparous species, individuals are often programmed to die after reproducing once. Contrast with *iteroparity*.
- Semelparous** Characterized by *semelparity*.
- Semicircular canal** A component of the *vestibular organ* of the vertebrate inner ear containing receptors that respond to head rotation.
- Semipermeable membrane** A membrane that is permeable only to water. All true semipermeable membranes are human-made, as there are no natural biological membranes that are strictly semipermeable.
- Sense organ** A complex multicellular structure specialized to detect a particular type of sensory stimulus.
- Sensillum** A sensory hair of arthropods; not related to vertebrate hair, but rather a hollow chitinous projection of the exoskeleton that is associated with sensory receptor neurons.
- Sensitization** Enhancement of a learned behavioral response to a harmless stimulus after exposure to a strong or harmful stimulus.
- Sensory adaptation** See *adaptation* (meaning 2).
- Sensory modality** The class of stimulus that evokes a sensory response. The classical sensory modalities are vision (light is the stimulus that evokes a response), hearing (sound), touch, smell, and taste.
- Sensory neuron** A sensory receptor that is a neuron, or a peripheral neuron that is excited by a non-neuronal sensory receptor cell.
- Sensory receptor cell** A sensory cell that is specialized to respond to a particular kind of environmental stimulus.
- Sensory receptor molecule** A molecule in a sensory receptor cell that is particularly sensitive to a kind of sensory stimulus, and that participates in transducing a stimulus into a cellular response.
- Sensory system** The sense organs (or other sensory receptors) for a particular sensory modality and all of the central processing areas and pathways associated with those organs (or other receptors).
- Sensory transduction** The process by which the energy of a physical stimulus

is converted into an electrical signal in a sensory receptor cell.

Septate junction A type of junction between epithelial cells that differs in fine structure from a tight junction but otherwise has similar properties. Found in invertebrates.

Series In relation to the arrangement of parts in an electrical circuit, vascular system, or other analogous system in which substances flow from place to place, the parts of the system are in *series* if they occur sequentially along a single path of flow, so that all flow must occur sequentially through all parts. Contrast with *parallel*.

Serosal surface See *basal surface*.

Sertoli cells Somatic cells in the seminiferous tubules of the testes of vertebrates that function to support spermatogenesis.

Sexual reproduction The formation of a new, genetically unique individual from the union of male and female gametes.

Shivering (1) In a mammal or bird, the unsynchronized contraction and relaxation of motor units in skeletal muscles in high-frequency rhythms, producing heat rather than organized motion as the primary product. (2) In an insect, contraction of the flight muscles in a nonflying mode to generate heat rather than flight.

Short-chain fatty acids (SCFA) Fatty acids that consist of relatively few carbon atoms, including acetic acid (2 carbons), propionic acid (3), and butyric acid (4). They are produced, for example, by symbiotic fermenting microbes and are readily absorbed and metabolized by animals. Also called *volatile fatty acids*.

Signal transduction In the study of cell signaling, the translation of a signal from one chemical form (e.g., a hormone) into another chemical form (e.g., a second messenger inside a cell).

Simple cell A neuron found in the mammalian primary visual cortex that has an elongated orientation-selective receptive field, so that it responds most to a bar or edge at a particular angle of orientation. The receptive fields of simple cells have distinct excitatory and inhibitory subregions.

Simple diffusion Transport of solutes, water, gases, or other materials that arises from the molecular agitation that exists in all systems above absolute zero and from the simple statistical tendency for such agitation to carry more molecules out of regions of relatively high concentration than into such regions.

Simple epithelium An epithelium consisting of a single cell layer.

Single effect The difference produced by use of metabolic energy between adjacent parts of the two oppositely flowing fluid streams in a countercurrent multiplier system. See also *countercurrent multiplication*.

Skeletal muscle Muscle that produces locomotory movements or other external movements of the body. In vertebrates, skeletal muscle is attached to the endoskeleton. In most types of invertebrates, it is attached to the exoskeleton, shell, or other external covering. Vertebrate skeletal muscle consists of large, cylindrical, multinucleate striated cells (*muscle fibers*). Invertebrate skeletal muscle may consist of striated or smooth muscle cells, depending on the phylogenetic group under consideration.

Sliding-filament theory The well-documented theory that muscle contraction results from active interaction between thick and thin myofilaments, which causes them to slide past each other.

Slow oxidative (SO) muscle fibers Muscle fibers that are poised to make ATP principally by aerobic catabolism, develop contractile tension slowly, have relatively low peak power outputs, and are relatively resistant to fatigue.

Slowly adapting receptor A sensory receptor cell that responds to a maintained stimulus in a way that decreases slowly and incompletely. Also called a *tonic receptor*.

Smooth muscle Muscle that consists of small, spindle-shaped, uninucleate cells without striations. Thin actin filaments and thick myosin filaments are present, but not organized into sarcomeres. In vertebrates, smooth muscle is found in hollow and tubular internal organs, such as certain blood vessels and the gut.

Sociobiology The study of the social relations and behaviors of animals from an evolutionary perspective.

Solute An entity, notably a molecule or ion, that is in solution.

Soma (plural somata) See *cell body*.

Somatic nervous system The part of the vertebrate peripheral nervous system that controls skeletal muscles and provides afferent information from sensory receptors not associated with internal organs.

Somatotopic map The topographic representation or mapping of the body surface onto a region of the brain—for example, in the vertebrate somatosensory cortex.

Spatial summation The summation of postsynaptic potentials that result from presynaptic action potentials at different synapses onto a single postsynaptic cell.

Specific dynamic action (SDA) A rise in the metabolic rate of an animal caused by the processing of ingested food.

Spermatogenesis The formation of haploid sperm through the process of meiosis in the testis.

Spermatozoa Haploid gametes, produced by spermatogenesis in the testis. Also called *sperm cells* or *sperm*.

Sphincter In a vertebrate, a circular muscle, located between two chambers, that can contract tightly and steadily (tonically) for long periods of time, thus preventing exchange between the chambers.

Spinal nerves In a vertebrate, segmental nerves of the peripheral nervous system that attach to the spinal cord.

Spinal reflex A reflex mediated by neural circuits of the vertebrate spinal cord.

Spiracle In a terrestrial arthropod (e.g., insect), a porelike aperture on the surface of the body that opens into the breathing system (e.g., tracheal system).

Spontaneous ovulation Ovulation (release of an egg from the ovaries of a female) that results from processes endogenous to the female, more or less independent of the actual act of mating. Contrast with *induced ovulation*.

Standard amino acid One of the 20–22 amino acids that are employed by organisms to synthesize proteins.

Standard metabolic rate (SMR) The metabolic rate of a poikilothermic (ectothermic) animal when it is resting and fasting. The SMR is specific to the body temperature prevailing during measurement.

Standard temperature and pressure (STP) A temperature of 0°C and a pressure of 1 atm (101 kPa; 760 mm Hg). Gas volumes are often expressed under these conditions as a way of standardizing the effects of temperature and pressure on volume.

Star compass A mechanism by which an animal can use the positions of stars and constellations (and an internal clock) to determine compass direction in nocturnal navigation.

Statocyst A sense organ that can detect acceleration and the direction of gravitational force.

Statolith A stony mineral concretion in a statocyst that is denser than the medium in which it sits, so that it is pulled downward by gravity and stimulates mechanoreceptors.

Stefan-Boltzmann equation An equation that relates the temperature of a surface and the rate at which the surface emits electromagnetic energy.

G-28 Glossary

Stenohaline Referring to aquatic animals, able to live only within a narrow range of environmental salinities. Contrast with *euryhaline*.

Stenothermal Referring to poikilotherms, able to live only within a narrow range of body temperatures. Contrast with *eurythermal*.

Stimulus A change in the external environment or in internal conditions that can be detected by an animal.

Stoichiometry The existence of fixed ratios in chemical reactions. For instance, the fact that hydrogen and oxygen atoms react in a 2-to-1 ratio to form water is an example of stoichiometry.

Stomatogastric ganglion A small ganglion containing 30 or more neurons that controls rhythmic activity of stomach muscles in crustaceans. The stomatogastric ganglion is a model system for study of central pattern generators.

Stress response The response of an animal to a threatening situation. In vertebrates, it typically involves functions of the autonomic nervous system and the hypothalamus–pituitary–adrenal cortex axis.

Stretch-gated channel A channel protein that opens and closes in response to stretching or pulling forces that alter the physical tension on a membrane.

Stretch reflex A vertebrate spinal reflex in which muscle stretching activates a muscle spindle stretch receptor, generating nerve impulses in 1a afferent axons that excite motor neurons innervating the same muscle to oppose the stretch.

Striated muscle Muscle that consists of cells in which the thick myosin and thin actin filaments are arranged in sarcomeres. The sarcomeres in a cell are aligned in register to form stripes or striations at right angles to the long axis of the cell. In vertebrates, skeletal and cardiac muscles are striated.

Stroke volume In reference to a heart or other organ that pumps fluid by rhythmic cycles of contraction, the volume of fluid pumped per cycle.

Subcellular membrane See *intracellular membrane*.

Submaximal exercise Exercise that requires less than an individual's maximal rate of O₂ consumption.

Substrate One of the initial reactants of an enzyme-catalyzed reaction.

Substrate-binding site See *active site*.

Summation (1) In excitable cells, the addition of graded subthreshold potentials (electrical events). (2) In muscle fibers, the addition of twitches (mechanical events)

produced by high frequencies of action potentials.

Sun compass A mechanism by which an animal can use the sun's position and an internal clock to determine compass direction in navigation.

Supercooling Cooling of a solution to below its freezing point without freezing.

Supercooling point The highest temperature at which freezing is almost certain to occur promptly in a supercooled solution. (Freezing of a supercooled solution is probabilistic. At some temperatures freezing is unlikely. The temperature needs to be lowered to the supercooling point for prompt freezing to be likely.)

Suprachiasmatic nucleus The part of the hypothalamus of the brain that acts as the master circadian clock in mammals.

Supramaximal exercise Exercise that requires ATP at a greater rate than it can be made aerobically even when an individual's rate of O₂ consumption is maximized.

Surface-to-volume ratio The ratio of the total area of the outer surface of a three-dimensional object over the volume of that object.

Suspension feeding Feeding on objects suspended in water that are very small by comparison to the feeding animal. See also *filter feeding*.

Sweating The secretion onto the skin surface of a low-salinity aqueous solution (*sweat*) by specialized *sweat glands* to increase the rate of evaporative cooling. Occurs only in some groups of mammals.

Symmorphosis A hypothesis about the evolution of multiple organ systems in a species, which posits that the performance limits of all systems remain roughly matched because it would make no sense for any one system to have evolved capabilities that could never be used because of more-restrictive limits in other systems.

Sympathetic division A division of the vertebrate autonomic nervous system that is connected to the CNS via thoracic and lumbar spinal nerves; the sympathetic and parasympathetic divisions tend to exert opposing controls over autonomic effectors.

Symporter See *cotransporter*.

Synapse A specialized site of communication between two neurons, between a neuron and an effector, or between a non-neuronal sensory cell and a neuron.

Synaptic antifacilitation A decrease in the amplitude of postsynaptic responses to repeated presynaptic action potentials. Also called *synaptic depression*.

Synaptic cleft The extracellular gap between presynaptic and postsynaptic cells at a synapse, typically 20–40 nm wide.

Synaptic facilitation An increase in the amplitude of postsynaptic responses that occurs after repeated presynaptic action potentials.

Synaptic homeostasis A form of *synaptic plasticity* that provides a means for neurons and neuron circuits to maintain stable function in the face of perturbations (such as developmental or activity-dependent changes in synapse number or strength). Sleep may play roles in synaptic homeostasis.

Synaptic plasticity Change in properties of synapses or strength of synaptic interactions with time or circumstance. Changes of nervous system function during development or learning are thought to reflect synaptic plasticity.

Synaptic potential A graded change in a postsynaptic cell's membrane potential produced by synaptic input. Also called a *postsynaptic potential*.

Synaptic transmission The process whereby one neuron influences the excitability of another neuron or effector. Synaptic transmission can be either chemical or electrical.

Synergism Interactions between two or more agents (e.g., hormones) whereby they have a greater effect acting together than the simple sum of their individual effects.

Systemic circuit In a circulatory system, the blood vessels that take blood to and from the systemic tissues.

Systemic tissues All tissues other than those of the breathing organs.

Systole The period of contraction during each beating cycle of a heart.

T

Tachycardia A heart rate that is unusually high.

Target cell A cell that responds to a chemical signaling molecule such as a paracrine or hormone because it expresses specific receptors for that molecule. It may express receptors for more than one signaling molecule. Its sensitivity depends on the number of receptors present, and can be changed by upregulation or downregulation of the receptors.

Taste Chemoreception of stimuli that are dissolved or suspended in liquids, typically requiring higher stimulus concentrations than olfaction. Taste chemoreceptors are often, but not always, localized around the mouth.

- Taste bud** A collection of epithelial taste receptor cells and support cells on the tongue or, in fish, on the skin surface.
- Telemetry** See *radiotelemetry*.
- Teleost fish** The principal group of fish having bony skeletons.
- Temperature** A measure of the speed or intensity of the ceaseless random motions that all the atoms and molecules of any substance undergo on an atomic-molecular scale. More exactly, the temperature of a substance is proportional to the product of the mean square speed of random molecular motions and the molecular mass.
- Temperature coefficient** The ratio of the rate of a process at one body temperature over the rate of the same process at a body temperature 10°C lower. Symbolized Q_{10} .
- Temperature gradient** Technically, the difference in temperature between two places divided by the distance separating those two places. Often used more loosely to refer simply to a difference in temperature. Also called a *thermal gradient*.
- Temporal heterothermy** See *heterothermy*.
- Temporal summation** The summation of synaptic potentials in response to repeated presynaptic action potentials at the same synapse.
- Tension (muscular)** The force produced by cross-bridge action in a contracting muscle.
- Tension (gas)** See *partial pressure*.
- Tertiary protein structure** The natural arrangement of an entire protein molecule in three dimensions, including its secondary structure and the other patterns of folding that give the molecule its particular conformation. Tertiary structure is flexible because it is stabilized by noncovalent bonds.
- Testosterone** A sex steroid hormone, produced by the Leydig cells of the testes, that is essential for male secondary sexual characteristics and reproduction. An androgen.
- Tetanus** Summed twitches of skeletal muscles produced by trains of motor action potentials. *Fused tetanus* is a smooth rise in tension produced by a high-frequency train of action potentials. *Unfused tetanus* is produced by a lower-frequency train of action potentials and shows some relaxation of each twitch between action potentials.
- Theca cells** Somatic connective tissue cells that form the outer layer of a developing ovarian follicle.
- Thermal conductance** A measure of the ease of dry heat transfer between an animal and its environment. Contrast with *resistance* (meaning 2).
- Thermal gradient** See *temperature gradient*.
- Thermal hysteresis protein (THP)** A protein or glycoprotein that acts as an antifreeze by chemically interfering with the formation or growth of ice crystals. Thermal hysteresis proteins lower the freezing point more than the melting point, thus their name.
- Thermal radiation heat transfer** See *radiant heat transfer*.
- Thermogenesis** In the context of thermal relations, production of heat for the specific function of warming tissues.
- Thermogenic tissue or process** In the context of thermal relations, a tissue or process that specifically increases production of heat when activated.
- Thermogenin** An older term referring to uncoupling protein 1. See *UCP1*.
- Thermoneutral zone (TNZ)** In a homeotherm, the range of ambient temperatures over which the metabolic rate is constant regardless of ambient temperature.
- Thermoregulation** The maintenance of a relatively constant body temperature.
- Tidal flow** Flow that occurs alternately in and out through a single set of passageways.
- Tidal volume** In an animal that exhibits tidal breathing, the amount of air inhaled and exhaled per breath.
- Tight junction** A place where the cell membranes of adjacent cells in an epithelium are tightly joined so that there is no extracellular space between the cells.
- Time constant (τ)** The time required for an exponential process to reach 63% of completion. In neurophysiology, it is a measure of the time needed to change membrane potential and is proportional to the product of resistance and capacitance.
- Time-energy budget** A method used to estimate an animal's average daily metabolic rate (ADMR). In this method, the time per day spent in each type of activity is measured and multiplied by an estimate of the energy cost of the activity per unit of time to get the total daily energy cost of the activity. The total costs of all activities are then added to get the ADMR. See also *average daily metabolic rate*.
- Tissue** A group of similar cells organized into a functional unit.
- Tissue fluids** See *interstitial fluids*.
- Titin** A giant elastic protein molecule that in a striated muscle spans an entire half-sarcomere from Z disc to M line.
- Tonic receptor** See *slowly adapting receptor*.
- Total carbon dioxide concentration** The amount of CO₂ a solution or body fluid takes up per unit of volume to reach a particular CO₂ partial pressure, regardless of the chemical form the CO₂ assumes when in the solution or body fluid.
- Totipotent** Capable of all things. For animals, chemical energy is the only form of *totipotent* energy.
- Trabeculae** Strands of muscle tissue that run through the open central cavity of a heart chamber, crisscrossing from one part of the chamber wall to another.
- Trachea** A principal tube in the breathing system of a terrestrial animal, typically with reinforced walls. (1) In vertebrates, the trachea is the initial, large airway that carries air from the buccal cavity to the lungs. (2) In insects, a trachea is any of multitudinous airways that ramify throughout the body to form the tracheal respiratory system. See also *tracheole*.
- Tracheole** A very fine, thin-walled end-tubule at the innermost reaches of the tracheal breathing system of an insect or other tracheate arthropod. The tracheoles are believed to be the principal sites of O₂ and CO₂ exchange with the tissues.
- Tract** A bundle of axons within a vertebrate central nervous system.
- Trafficking** The movement of protein molecules between active and inactive locations in a cell, thereby controlling the functional activity of the protein molecules. A common scenario for trafficking is for transport-protein molecules to be active in transport when in the cell membrane but inactive when in an intracellular membrane. See *insertion* and *retrieval*.
- Transcription profiling** A research strategy in which investigators detect and measure large sets of messenger RNA molecules simultaneously, as a way of assessing patterns of gene transcription in cells or tissues. Also called *transcriptomics*.
- Transcriptomics** See *transcription profiling*.
- Transducin** A G protein that is activated by rhodopsin in photoreceptors, leading to a receptor potential.
- Transduction** (1) In the study of energy, the transformation of one form of energy into another. (2) In the study of cell signaling, the translation of a signal from one chemical form to another chemical form. (3) In neurophysiology, the conver-

G-30 Glossary

sion of stimulus energy into an electrical signal in sensory receptor cells; the electrical signal is usually a receptor potential.

Transient receptor potential (TRP) channel A kind of ion channel found in membranes of many sensory cells; it opens in response to stimuli and produces a receptor potential.

Transpirational water loss Water loss across the integument of an animal that occurs without sweating or any other active mechanism of transporting water across the integument; passive water loss across the integument.

Transport An entirely general term referring to any and all movements of solutes, water, gases, or other materials from place to place, regardless of the mechanisms of movement.

Transporter A membrane protein that mediates the transport of solute molecules across a membrane and must undergo reversible, noncovalent bonding with the solute molecules in order to do so. Transporters participate in *facilitated diffusion* and *active transport*. Also sometimes called a *carrier*.

Transverse tubules (t-tubules) Finger-like indentations of the cell membrane at regular intervals over the entire surface of a muscle cell. Transverse tubules conduct electrical excitation into the interior of the cell and are intimately associated with the sarcoplasmic reticulum.

Triacylglycerol A fat or oil; a lipid composed of glycerol esterified with three fatty acids. Also called a *triglyceride*.

Triglyceride See *triacylglycerol*.

Trophoblast In a mammal, the outer layer of cells of a blastocyst that will form the fetal portion of the placenta.

Tropic action An action performed by a hormone acting on a target endocrine gland to stimulate secretion of hormone by the target gland and also to maintain the structure and function of the target gland.

Tropomyosin (TM) In muscles, a coiled protein molecule that spans seven actin monomers on a thin filament and is associated with one troponin molecule.

Troponin (TN) In muscles, a protein consisting of three subunits that is associated with actin and tropomyosin on the thin filaments.

Twitch A single contraction and relaxation of a skeletal muscle fiber produced by an action potential that triggers release of Ca^{2+} ions from the sarcoplasmic reticulum. A single twitch is produced by many repeated cross-bridge power strokes that

draw the thin filaments toward the center of each sarcomere.

Tympanal organ An organ of hearing in which sound vibrates a tympanal membrane ("eardrum") to activate auditory receptor cells. The term is usually used for insect hearing organs, although the vertebrate ear is also a tympanal organ.

U

UCP1 An uncoupling protein that is expressed in the mitochondria of *brown adipose tissue* in mammals. UCP1 permits protons from the space between the inner and outer mitochondrial membranes to move to the matrix (core) of a mitochondrion without driving the production of ATP; thus it promotes uncoupling of oxidative phosphorylation and production of heat from the energy released by electron transport.

U/P ratio The concentration of urine expressed as a ratio of the concentration of blood plasma. The *osmotic* U/P ratio is the ratio of urine osmotic pressure over plasma osmotic pressure. The U/P ratio for a particular *ion* is the ratio of the urine concentration of that ion over the plasma concentration of that ion.

Ubiquitination Tagging of proteins for destruction. Target proteins are linked with one or more molecules of ubiquitin, a small tagging protein. Proteins thus tagged are later broken up by proteasomes.

Ultrafiltrate An aqueous solution produced by ultrafiltration. Also called *filtrate*.

Ultrafiltration Pressure-driven bulk flow (oozing, streaming) of fluid out of the blood plasma across the walls of blood capillaries (or sometimes through other barriers), considered a form of filtration because solutes of high molecular weight are left behind while ones of low molecular weight travel with the fluid. In ordinary tissues, fluid that leaves the blood plasma by ultrafiltration enters the tissue interstitial fluids. In kidneys that form primary urine by ultrafiltration, the fluid that leaves the blood plasma enters the kidney tubules (e.g., nephrons).

Umami One of five taste qualities in mammals, stimulated by glutamate. It is the savory taste of proteinaceous foods.

Uncoupling of oxidative phosphorylation The state of making little or no ATP from the energy that is released by the transport of electrons through the electron-transport chain.

Uncoupling protein (UCP) Unless otherwise stated, refers to UCP1. See *UCP1*.

Universal gas law In the study of gases, an equation that relates pressure (P), volume (V), molar quantity (n), and absolute temperature (T): $PV = nRT$, where R is the universal gas constant (8.314 J/mol·K, where K is a Kelvin and equivalent to one degree Celsius). Also called the *ideal gas law*.

Unloading Deoxygenation of a respiratory pigment.

Unsaturated In lipid chemistry, characterized by one or more double bonds between carbon atoms in a carbon chain.

Unsaturated fatty acid A fatty acid in which one or more of the bonds between carbon atoms in the carbon-chain backbone of the molecule are double bonds; also called a *UFA* or an *unsaturate*. *Mono-unsaturated fatty acids (MUFAs)* have a single double bond in their structure. *Polyunsaturated fatty acids (PUFAs)* have two or more double bonds in their structure.

Uphill transport See *active transport*.

Upper-critical temperature In a homeotherm, the ambient temperature that represents the upper limit of the thermoneutral zone. See also *thermoneutral zone*.

Upregulation An upward shift in the catalytic activity of an enzyme, the rate of functioning of a biochemical pathway, or the rate of some other similar process brought about in a controlled manner by a regulatory system.

Ureotelic Incorporating most nitrogen from the catabolism of nitrogenous compounds into urea. "Most" is defined differently by different authorities; a common approach is to categorize an animal as *ureotelic* if 50% or more of the nitrogen released by catabolism is incorporated into urea.

Uricotelic Incorporating most nitrogen from the catabolism of nitrogenous compounds into uric acid or closely similar compounds such as urate salts. "Most" is defined differently by different authorities; a common approach is to categorize an animal as *uricotelic* if 50% or more of the nitrogen released by catabolism is incorporated into uric acid.

Urine The fluid excreted by a kidney.

V

$\dot{V}_{\text{O}_2\text{max}}$ An animal's maximal rate of O_2 consumption. It is usually measured by inducing an animal to exercise at its peak sustained exercise intensity. Also called *aerobic capacity*.

Vaporization A change in the physical state of a material from a liquid to a gas.

Vasa recta Blood vessels of minute diameter that are arranged in long hairpin

shapes and that constitute the principal vasculature of the medulla of the mammalian kidney. They function as countercurrent diffusion exchangers because blood flow is in opposite directions in the two limbs of each hairpin.

Vascular endothelial growth factor

(VEGF) A locally acting cytokine that stimulates angiogenesis.

Vascular resistance The resistance to blood flow through a blood vessel or system of blood vessels, calculated as the pressure drop divided by the flow rate.

Vasomotor Related to changes in the inside (luminal) diameters of blood vessels mediated by contraction and relaxation of smooth muscles in the blood vessel walls.

Vasopressin A neurohormone of mammals, consisting of nine amino acids, that stimulates the reabsorption of water by the collecting ducts in the kidneys. Also called *antidiuretic hormone*. Its molecular structure is similar to that of the neurohormone vasotocin that controls water conservation in many nonmammalian vertebrates. Both are synthesized by neurosecretory cells that have their cell bodies in the hypothalamus and their axon terminals in the pars nervosa of the posterior pituitary.

Vein A macroscopic blood vessel that carries blood toward the heart.

Venous reserve In the study of O₂ transport, the amount of O₂ remaining in venous blood after the blood has passed through the systemic tissues.

Ventilation Forced flow (convection) of air or water into and out of structures used for external respiration or over body surfaces used for external respiration.

Ventilation-perfusion matching In a breathing organ, matching of the rate of blood flow and the rate of ventilation so that efficiency is promoted in the transfer of O₂ from air or water to the blood.

Vesicle A small, membrane-bound, spherical organelle in the cytoplasm of a cell.

Vestibular organ A vertebrate sense organ consisting of statocysts (maculae) and semicircular canals, which together detect gravity and acceleration.

Viscosity Internal friction in a moving fluid; a lack of intrinsic slipperiness between fluid layers that are moving at different linear velocities. Fluids that are particularly high in internal friction—

low in internal slipperiness—have high viscosities and exhibit syruplike properties. Viscosity can also be thought of as resistance to shear forces within a moving fluid.

Vitamin An organic compound that an animal must obtain from food, symbiotic microbes, or another source other than the animal's biosynthesis because the animal cannot synthesize it, yet requires it in small amounts.

Volatile fatty acids See *short-chain fatty acids*.

Voltage A measure of the potential energy present because of charge separation. Separated electrical charges exert electrostatic force on each other. These forces can cause charges to move, and when charges move, work is done. Voltage, also called *electrical potential* or *potential difference*, provides a measure of the rate of charge movement that can be achieved.

Voltage clamp An experimental method to measure ionic current flow by imposing a selected membrane potential on a cell and monitoring the exogenously applied current necessary to maintain that potential.

Voltage-gated channel An ion channel that opens in response to membrane depolarization.

Voltage threshold The critical value of membrane depolarization that is just enough to trigger an action potential.

Volume regulation The maintenance of a constant or nearly constant volume (amount) of body fluid. The term can be applied to cells, in which case it refers to a constant volume of intracellular fluid. It can also be applied to whole animals, in which case it refers to a constant volume of all body fluids.

Volumes percent (vol %) Milliliters (at STP) of gas dissolved or chemically combined within a fluid per 100 milliliters of the fluid.

Vomeronasal organ An accessory olfactory organ of vertebrates that mediates many (but not all) sensory responses to pheromones.

W

Wasting See *atrophy*.

Water channel A membrane protein that aids passive water transport—osmosis—through a cell membrane.

Water vapor Water in the gaseous state.

Water vapor pressure (1) In reference to a gas phase, the prevailing partial pressure of gaseous water. (2) In reference to an aqueous solution, the partial pressure of gaseous water that the solution will create by evaporation in a gas phase with which it is in contact if permitted to come to equilibrium with the gas phase. A colligative property.

Water-vapor-pressure depression The difference between the water vapor pressure of a solution and that of pure water under the same conditions. A colligative property.

Weak bond See *noncovalent bond*.

White adipose tissue The ordinary fat-storage tissue of vertebrates, exemplified by the "fat" we speak of in poultry or beef prepared for food. Also called *white fat*. Contrast with *brown adipose tissue*.

White matter A histological region of the vertebrate central nervous system that consists largely of tracts of neuronal axons. The abundance of myelin imparts a glistening white sheen to the tissue.

White muscle In general, a loose term referring to a vertebrate muscle that is poor in myoglobin and thus whitish (rather than reddish) in color. In fish, a large mass of muscle that consists almost entirely of myoglobin-poor muscle fibers that make ATP mostly by anaerobic catabolism; white muscle powers burst exercise in fish.

Work See *external work*, *internal work*, *physiological work*.

X

Xeric Able to live steadily in the open air and thus face the full drying power of the terrestrial environment.

Z

Z disc In striated muscle, a web of accessory proteins at each end of a sarcomere that anchors the proteins titin and nebulin and the actin thin filaments. Also called *Z line*, *Z band*.

Zeitgeber See *phasing factor*.

Zona pellucida An extracellular layer of glycoproteins secreted by a primary oocyte.

Zygote A genetically unique, diploid cell produced by the union of an egg (ovum) and a sperm in sexual reproduction.

Additional References

In this section, we provide extensive lists of references, in which you will find additional information.

We start with books that each cover a wide variety of physiological systems. These books are categorized into “General Works,” “Works Dealing with Specific Groups of Invertebrates,” and “Works Dealing with Specific Groups of Vertebrates.” Many of these books are excellent sources for both information and added references on specific topics. They are not generally listed with individual chapters, however, because, in many cases, they would need to be listed with virtually every chapter, such is their breadth of coverage. We include some relatively old titles that have not yet been superseded in their coverage by more-recent publications.

Following the three lists of books of relatively broad interest, you will find additional lists of references specific to each chapter. They are listed by chapter number.

General Works

About the Book

Editor: Andrew Sinauer

Project Editor: Laura Green

Copy Editor: Elizabeth Pierson

Production Manager: Christopher Small

Photo Researcher: David McIntyre

Book Design and Layout: Joan Gemme

Cover Design and Layout: Joan Gemme

Illustration Program: Elizabeth Morales

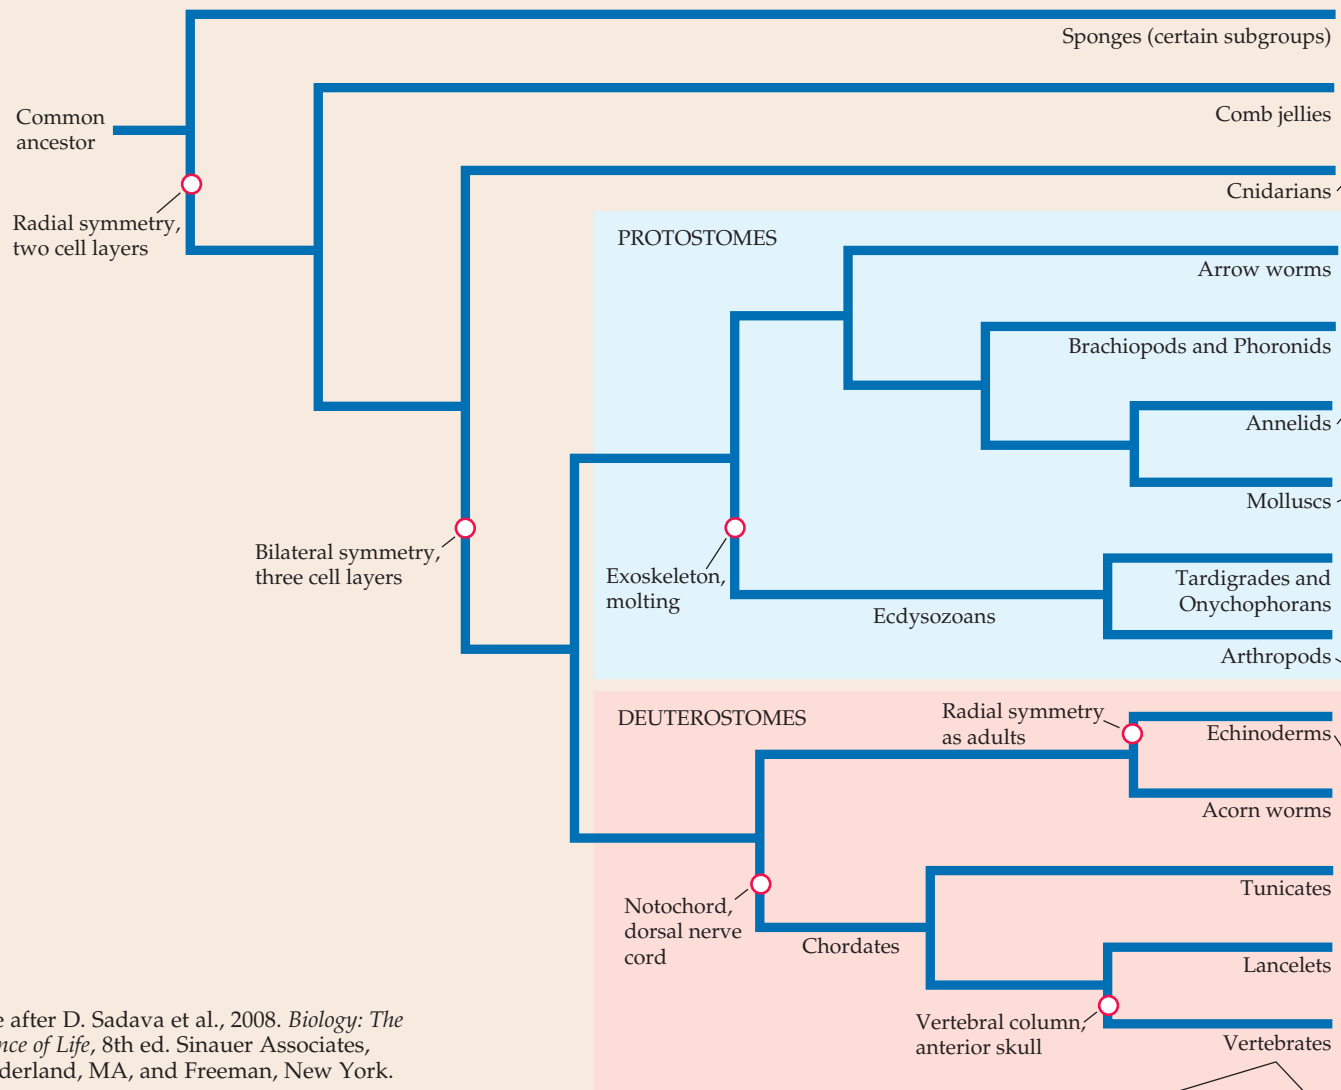

Indexer: Grant Hackett

Cover and Book Manufacturer: Courier Companies, Inc.

A Simplified Phylogenetic Tree of the Animals and Descriptions of Major Phyla

This tree and the accompanying descriptions emphasize the animals that receive greatest attention in this book. The descriptions highlight properties of importance in the study of physiology and are not intended as formal definitions. The numbers of species are estimates of numbers of living species

currently described. The protostomes and deuterostomes differ in features of embryonic development, e.g., whether the mouth develops at or near the embryonic blastopore (protostomes) or far from it (deuterostomes).

Tree after D. Sadava et al., 2008. *Biology: The Science of Life*, 8th ed. Sinauer Associates, Sunderland, MA, and Freeman, New York.

Vertebrates (e.g., fish, mammals), although not a phylum in themselves, are the principal subphylum of chordates. Have an internal skeleton (calcified in all but cartilaginous fish) with dorsal vertebral column. Major longitudinal nerve cord (spinal

cord) dorsal. Head with brain, eyes, and other sense organs well developed. Circulatory system elaborate and closed, blood rich with hemoglobin. 54,000 species.

Fish (which include several distinct subgroups) are by far the most diverse vertebrates in number of species. Some, notably *elasmobranchs* (e.g., sharks, rays), have cartilaginous skeletons. Most, including *teleosts* (the principal bony fish), have calcified skeletons. Breathe with gills, but ~400 species can breathe air. Most ectothermic even if very large; some (notably tunas, lamnid sharks) endothermic. Some with (weak or strong) electric organs evolved from muscle. 25,000 species.

Amphibians are *tetrapods* (four-legged, or derived from four-legged, animals) that typically have water- and gas-permeable skin rich with secretory (e.g., mucus) glands. With exceptions,

adults are physiologically poorly defended against desiccation and must stay near moisture to minimize dehydration and rehydrate. Over half are tied to water for reproduction, start life as freshwater larvae. 6000 species.

Reptiles other than birds—i.e., lizards, snakes, turtles, and crocodilians—are, for the most part, tetrapod ectotherms well defended against desiccation. Skin is less permeable than that of amphibians, sometimes of very low permeability. Usually terrestrial. Unlike amphibians, have amniotic eggs (as do birds and mammals). 7500 species.

Cnidarians (e.g., hydras, jellyfish, corals)—also termed **coelenterates**—are radially symmetrical animals with no head and only two major cell layers (most animals have three). Occur principally in ocean, also freshwater. Nervous system diffusely

structured (*nerve net*). Have distinctive subcellular stinging structures, *nematocysts*, that fire minute threads (often with toxins) into prey. No true circulatory system. Mouth opens into blind *gastrovascular cavity*. 11,000 species.

Annelids (e.g., earthworms, fan worms) are *segmented* worms that occur in marine, moist terrestrial, and freshwater environments. Certain organ systems (e.g., for excretion and circulation) are highly segmental in some annelids—with structures repeated in multiple body segments.

Feed in diverse ways, e.g., teeth, ciliary tracts, mucus nets. Circulatory system well developed and closed in many, with blood containing hemoglobin or alternative O₂-transport pigment. Often have distinct head with brain, eyes, and other sense organs. Major longitudinal nerve cords ventral. 16,500 species.

Molluscs (e.g., clams, snails, squids) have a body plan in which flaps of shell-secreting *mantle* tissue overhang and partially envelop the principal body mass. Calcified shell is secreted by the mantle and encloses rest of body in clams and most snails, not squids and

octopuses. Space between flaps of mantle tissue and principal body mass forms external body cavity (*mantle cavity*) containing gills (in aquatic forms). 93,000 species.

Bivalves (e.g., mussels, clams, scallops) and **gastropods** (snails, slugs) are slow-moving and occur in or on the bottom in aquatic habitats, or crawl on objects on land (terrestrial snails and slugs). Circulatory system open, with little or no blood O₂-transport pigment. No distinct head in bivalves; head with brain, eyes, and other sense organs typical in gastropods. Feeding is with gills (collecting particulate food from water) in bivalves, or with distinctive scraping organ, *radular apparatus*, in gastropods. Breathe with gills, except terrestrial pulmonate snails and slugs which have evolved a lung. 90,000 species.

Cephalopods (e.g., squids, octopuses) have far more active lifestyles and higher metabolic demands than other molluscs. Evolutionarily, squids parallel fish, being fast-moving (often schooling) predators. Can swim powerfully by jet propulsion driven by high water pressures in mantle cavity. Strictly marine. Head, brain, and sense organs (incl. vertebrate-like eyes) particularly well developed. Circulatory system closed, blood with O₂-transport pigment. Feed with beak and radular apparatus. Have distinctive muscle-operated color-change organs permitting very rapid color change. 900 species.

Arthropods (e.g., insects, spiders, crayfish) are by far the most diverse phylum in number of species. All external surfaces covered with external skeleton, *exoskeleton*, composed of chitin and protein (calcified in crustaceans). Exoskeleton must be shed (molted) periodically for individual to grow. Have externally

jointed appendages. Lack external cilia (unlike most types of invertebrates). Have head with brain, often with *compound eyes* and/or other elaborate sensory structures. Major longitudinal nerve cords ventral. Circulatory system open in all groups. >1,200,000 species.

Insects (e.g., butterflies, bees, beetles), which are extremely diverse, have three pairs of thoracic legs and, usually, wings in adulthood. Common on land and in freshwater (often as immature stages of land species); uncommon in ocean. Breathe with gas-filled tubes (*tracheae*) that ramify throughout body. Circulatory system usually not responsible for O₂ transport and relatively simple. Excretion by Malpighian tubules that empty into gut. Usually ectothermic, but endothermy and homeothermy are common (esp. in flight). 1,000,000 species.

principally terrestrial; breathe with *tracheae* (gas-filled tubes ramifying throughout body) or distinctive *book lungs*. Horseshoe crabs marine, breathe with *book gills*. 70,000 species.

Chelicerates (e.g., spiders, scorpions, horseshoe crabs) are physiologically diverse, lack antennae, have four pairs of defined *walking legs*. Spiders and scorpions

Crustaceans, including the *decapod crustaceans* emphasized in this book (e.g., crayfish, lobsters, crabs, shrimps), are mostly aquatic arthropods (marine and freshwater) with five or more pairs of thoracic legs, the most anterior pair often specialized as claws. Typically breathe with gills. Circulatory system responsible for O₂ transport and often elaborate (incl. blood O₂-transport pigment). Excretion often by paired *antennal glands* (*green glands*) in head. Terrestrial and semiterrestrial crabs and crayfish often with specialized gills and lung-like structures. 67,000 species.

Echinoderms (e.g., sea stars, sea urchins) are radially symmetrical as adults, typically lacking a defined head. Strictly marine. Feed in diverse ways, e.g., by teeth, eversion of stomach to digest foods externally, or

collection of particulates from water. No true circulatory system. Have distinctive *water-vascular system* that aids circulation and provides hydraulic forces for *tube feet* used in locomotion. 7000 species.

Vertebrates (continued)

Mammals have hair and nourish their young with milk. Although mammals and birds evolved independently, they share dramatic and important properties: Both have much higher metabolic rates than other animals of similar size, and typically are homeotherms (physiologically maintain high, relatively constant body temperatures). Their high metabolic rates necessitate circulatory and breathing systems with great O₂-transport capabilities. Diving mammals (e.g., seals), in extreme cases, can stay

submerged 2 hours and reach depths of >1 mile (pressure: >160 atmospheres). 5500 species.

Birds are feathered reptiles, and most fly. They evolved homeothermy, high metabolic rates, and high-performance circulatory/breathing systems independently of mammals. Some are probably the most highly adapted animals to high altitudes. Some dive, but not as long or deep as mammals. 9500 species.
