To our teachers and our students

## ABOUT THE AUTHORS

**JEREMY M. BERG** received his B.S. and M.S. degrees in Chemistry from Stanford (where he did research with Keith Hodgson and Lubert Stryer) and his Ph.D. in Chemistry from Harvard with Richard Holm. He then completed a postdoctoral fellowship with Carl Pabo in Biophysics at Johns Hopkins University School of Medicine. He was an Assistant Professor in the Department of Chemistry at Johns Hopkins from 1986 to 1990. He then moved to Johns Hopkins University School of Medicine as Professor and Director of the Department of Biophysics and Biophysical Chemistry, where he remained until 2003. He then became Director of the National Institute of General Medical Sciences at the National Institutes of Health. In 2011, he moved to the University of Pittsburgh where he is now Professor of Computational and Systems Biology and Pittsburgh Foundation Professor and Director of the Institute for Personalized Medicine. He served as President of the American Society for Biochemistry and Molecular Biology from 2011–2013. He is a Fellow of the American Association for the Advancement of Science and a member of the Institute of Medicine of the National Academy of Sciences. He received the American Chemical Society Award in Pure Chemistry (1994) and the Eli Lilly Award for Fundamental Research in Biological Chemistry (1995), was named Maryland Outstanding Young Scientist of the Year (1995), received the Harrison Howe Award (1997), and received public service awards from the Biophysical Society, the American Society for Biochemistry and Molecular Biology, the American Chemical Society, and the American Society for Cell Biology. He also received numerous teaching awards, including the W. Barry Wood Teaching Award (selected by medical students), the Graduate Student Teaching Award, and the Professor's Teaching Award for the Preclinical Sciences. He is coauthor, with Stephen J. Lippard, of the textbook *Principles of Bioinorganic Chemistry*.

**JOHN L. TYMOCZKO** is Towsley Professor of Biology at Carleton College, where he has taught since 1976. He currently teaches Biochemistry, Biochemistry Laboratory, Oncogenes and the

Molecular Biology of Cancer, and Exercise Biochemistry and coteaches an introductory course, Energy Flow in Biological Systems. Professor Tymoczko received his B.A. from the University of Chicago in 1970 and his Ph.D. in Biochemistry from the University of Chicago with Shutsung Liao at the Ben May Institute for Cancer Research. He then had a postdoctoral position with Hewson Swift of the Department of Biology at the University of Chicago. The focus of his research has been on steroid receptors, ribonucleoprotein particles, and proteolytic processing enzymes.

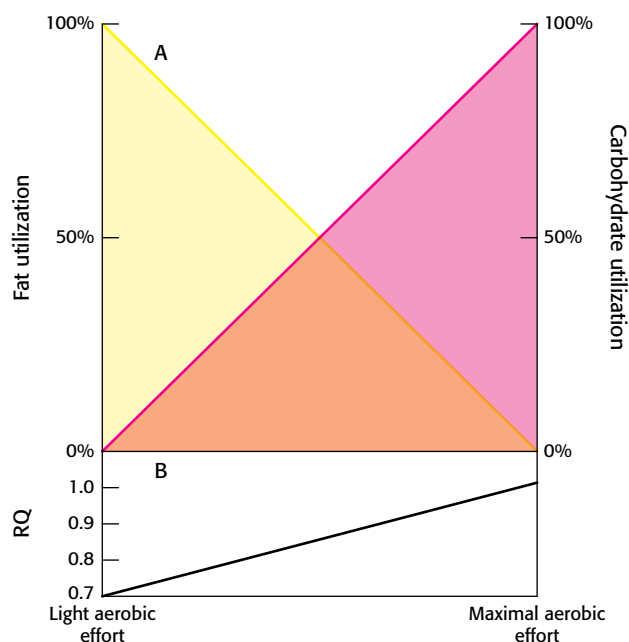

**GREGORY J. GATTO, JR.**, received his A.B. degree in Chemistry from Princeton University, where he worked with Martin F. Semmelhack and was awarded the Everett S. Wallis Prize in Organic Chemistry. In 2003, he received his M.D. and Ph.D. degrees from the Johns Hopkins University School of Medicine, where he studied the structural biology of peroxisomal targeting signal recognition with Jeremy M. Berg and received the Michael A. Shanoff Young Investigator Research Award. He completed a postdoctoral fellowship in 2006 with Christopher T. Walsh at Harvard Medical School, where he studied the biosynthesis of the macrolide immunosuppressants. He is currently a Senior Scientific Investigator in the Heart Failure Discovery Performance Unit at GlaxoSmithKline.

**LUBERT STRYER** is Winzer Professor of Cell Biology, Emeritus, in the School of Medicine and Professor of Neurobiology, Emeritus, at Stanford University, where he has been on the faculty since 1976. He received his M.D. from Harvard Medical School. Professor Stryer has received many awards for his research on the interplay of light and life, including the Eli Lilly Award for Fundamental Research in Biological Chemistry, the Distinguished Inventors Award of the Intellectual Property Owners' Association, and election to the National Academy of Sciences and the American Philosophical Society. He was awarded the National Medal of Science in 2006. The publication of his first edition of *Biochemistry* in 1975 transformed the teaching of biochemistry.

## PREFACE

For several generations of students and teachers, *Biochemistry* has been an invaluable resource, presenting the concepts and details of molecular structure, metabolism, and laboratory techniques in a streamlined and engaging way. *Biochemistry's* success in helping students learn the subject for the first time is built on a number of hallmark features:

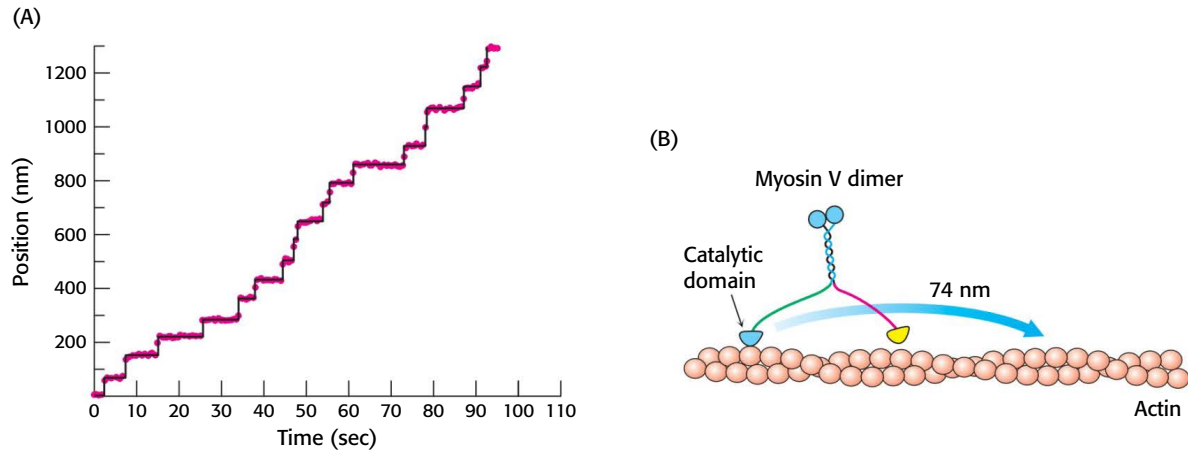

- **Clear writing and simple illustrations.** The language of biochemistry is made as accessible as possible for students learning the subject for the first time. To complement the straightforward language and organization of concepts in the text, figures illustrate a single concept at a time to help students see main points without the distraction of excess detail.
- **Physiological relevance.** It has always been our goal to help students connect biochemistry to their own lives on a variety of scales. Pathways and processes are presented in a physiological context so

**Figure 27.12 An idealized representation of fuels use as a function of aerobic exercise intensity.** (A) With increased exercise intensity, the use of fats as fuels falls as the utilization of glucose increases. (B) The respiratory quotient (RQ) measures the alteration in fuel use.

students can see how biochemistry works in the body and under different conditions, and Clinical Application sections in every chapter show students how the concepts they are studying impact human health. The eighth edition includes a number of new Clinical Application sections based on recent discoveries in biochemistry and health. (For a full list, see p. xi)

- **Evolutionary perspective.** Discussions of evolution are woven into the narrative of the text, just as evolution shapes every pathway and molecular structure described in the text. Molecular Evolution sections highlight important milestones in the evolution of life as a way to provide context for the processes and molecules being discussed. (For a full list, see p. x)
- **Problem-solving practice.** Every chapter of *Biochemistry* provides numerous opportunities for students to practice problem-solving skills and apply the concepts described in the text. End-of-chapter problems are divided into three categories to address different problem-solving skills: Mechanism problems ask students to suggest or describe a chemical mechanism; Data interpretation problems ask students to draw conclusions from data taken from real research papers; and chapter integration problems require students to connect concepts from across chapters. Further problem-solving practice is provided online, on the *Biochemistry* LaunchPad. (For more details on LaunchPad resources, see p. viii)
- **A variety of molecular structures.** All molecular structures in the book, with few exceptions, have been selected and rendered by Jeremy Berg and Gregory Gatto to emphasize the aspect of structure most important to the topic at hand. Students are introduced to realistic renderings of molecules through a molecular model “primer” in the appendices to Chapters 1 and 2 so they are well-equipped to recognize and interpret the structures throughout the book. Figure legends direct students explicitly to the key features of a model, and often include PDB numbers so the reader can access the file used in generating the structure from the Protein Data Bank website ([www.pdb.org](http://www.pdb.org)). Students

**Figure 9.48 Single molecule motion.** (A) A trace of the position of a single dimeric myosin V molecule as it moves across a surface coated with actin filaments. (B) A model of how the dimeric molecule moves in discrete steps with an average size of  $74 \pm 5$  nm. [Data from A. Yildiz et al., *Science* 300(5628)2061–2065, 2003.]

can explore molecular structures further online through the Living Figures, in which they can rotate 3D models of molecules and view alternative renderings.

In this revision of *Biochemistry*, we focused on building on the strengths of the previous editions to present biochemistry in an even more clear and streamlined manner, as well as incorporating exciting new advances from the field. Throughout the book, we have updated explanations of basic concepts and bolstered them with examples from new research. Some new topics that we present in the eighth edition include:

- Environmental factors that influence human biochemistry (Chapter 1)
- Genome editing (Chapter 5)
- Horizontal gene transfer events that may explain unexpected branches of the evolutionary tree (Chapter 6)
- Penicillin irreversibly inactivating a key enzyme in bacterial cell-wall synthesis (Chapter 8)
- Scientists watching single molecules of myosin move (Chapter 9)
- Glycosylation functions in nutrient sensing (Chapter 11)
- The structure of a SNARE complex (Chapter 12)
- The mechanism of ABC transporters (Chapter 13)
- The structure of the gap junction (Chapter 13)
- The structural basis for activation of the  $\beta$ -adrenergic receptor (Chapter 14)
- Excessive fructose consumption can lead to pathological conditions (Chapter 16)
- Alterations in the glycolytic pathway by cancer cells (Chapter 16)
- Regulation of mitochondrial ATP synthase (Chapter 18)
- Control of chloroplast ATP synthase (Chapter 19)
- Activation of rubisco by rubisco activase (Chapter 20)

**Figure 12.39 SNARE complexes initiate membrane fusion.** The SNARE protein synaptobrevin (yellow) from one membrane forms a tight four-helical bundle with the corresponding SNARE proteins syntaxin-1 (blue) and SNAP25 (red) from a second membrane. The complex brings the membranes close together, initiating the fusion event. [Drawn from 1SFC.pdb.]

- The role of the pentose phosphate pathway in rapid cell growth (Chapter 20)
- Biochemical characteristics of muscle fiber types (Chapter 21)
- Alteration of fatty acid metabolism in tumor cells (Chapter 22)
- Biochemical basis of neurological symptoms of phenylketonuria (Chapter 24)
- Ribonucleotide reductase as a chemotherapeutic target (Chapter 25)
- The role of excess choline in the development of heart disease (Chapter 26)
- Cycling of the LDL receptor is regulated (Chapter 26)
- The role of ceramide metabolism in stimulating tumor growth (Chapter 26)
- The extraordinary power of DNA repair systems illustrated by *Deinococcus radiodurans* (Chapter 28)
- The structural details of ligand binding by TLRs (Chapter 34)

All of the new media resources for *Biochemistry* will be available in our new system.

[www.macmillanhighered.com/launchpad/berg8e](http://www.macmillanhighered.com/launchpad/berg8e)

**LaunchPad** is a dynamic, fully integrated learning environment that brings together all of our teaching and learning resources in one place. It also contains the fully interactive **e-Book** and other newly updated resources for students and instructors, including the following:

- **NEW Case Studies** are a series of biochemistry case studies you can integrate into your course. Each case study gives students practice in working with

**Figure 34.3 Recognition of a PAMP by a Toll-like receptor.** The structure of TLR3 bound to its PAMP, a fragment of double-stranded RNA, as seen from the side (top) and from above (bottom). Notice that the PAMP induces receptor dimerization by binding the surfaces on the side of each of the extracellular domains. [Drawn from 3CIY.pdb].

data, developing critical thinking skills, connecting topics, and applying knowledge to real scenarios. We also provide instructional guidance with each case study (with suggestions on how to use the case in the classroom) and aligned assessment questions for quizzes and exams.

- **Newly Updated Clicker Questions** allow instructors to integrate active learning in the classroom and to assess students' understanding of key concepts during lectures. Available in Microsoft Word and PowerPoint (PPT).
- **Newly Updated Lecture PowerPoints** have been developed to minimize preparation time for new users of the book. These files offer suggested lectures including key illustrations and summaries that instructors can adapt to their teaching styles.
- **Updated Layered PPTs** deconstruct key concepts, sequences, and processes from the textbook images, allowing instructors to present complex ideas step-by-step.
- **Updated Textbook Images and Tables** are offered as high-resolution JPEG files. Each image has been fully optimized to increase type sizes and adjust color saturation. These images have been tested in a large lecture hall to ensure maximum clarity and visibility.
- **The Clinical Companion**, by Gregory Raner, The University of North Carolina at Greensboro and Douglas Root, University of North Texas, applies concepts that students have learned in the book to novel medical situations. Students read clinical case studies and use basic biochemistry concepts to solve the medical mysteries, applying and reinforcing what they learn in lecture and from the book.
- **Hundreds of self-graded practice problems** allow students to test their understanding of concepts explained in the text, with immediate feedback.
- **The Metabolic Map** helps students understand the principles and applications of the core metabolic pathways. Students can work through guided tutorials with embedded assessment questions, or explore the Metabolic Map on their own using the dragging and zooming functionality of the map.
- **Jmol tutorials** by Jeffrey Cohlberg, California State University at Long Beach, teach students

how to create models of proteins in Jmol based on data from the Protein Data Bank. By working through the tutorial and answering assessment questions at the end of each exercise, students learn to use this important database and fully realize the relationships between the structure and function of enzymes.

- **Living figures** allow students to explore protein structure in 3-D. Students can zoom and rotate the “live” structures to get a better understanding of their three-dimensional nature and can experiment with different display styles (space-filling, ball-and-stick, ribbon, backbone) by means of a user-friendly interface.
- **Concept-based tutorials** by Neil D. Clarke help students build an intuitive understanding of some of the more difficult concepts covered in the textbook.
- **Animated techniques** help students grasp experimental techniques used for exploring genes and proteins.
- **NEW animations** show students biochemical processes in motion. The eighth edition includes many new animations.
- **Online end-of-chapter questions** are assignable and self-graded multiple-choice versions of the

end-of-chapter questions in the book, giving students a way to practice applying chapter content in an online environment.

- **Flashcards** are an interactive tool that allows students to study key terms from the book.
- **LearningCurve** is a self-assessment tool that helps students evaluate their progress. Students can test their understanding by taking an online multiple-choice quiz provided for each chapter, as well as a general chemistry review.

---

## Updated Student Companion

[1-4641-8803-3]

For each chapter of the textbook, the *Student Companion* includes:

- **Chapter Learning Objectives and Summary**
- **Self-Assessment Problems**, including multiple-choice, short-answer, matching questions, and challenge problems, and their answers
- **Expanded Solutions** to end-of-chapter problems in the textbook

# MOLECULAR EVOLUTION

This icon signals the start of the many discussions that highlight protein commonalities or other molecular evolutionary insights.

- Only L amino acids make up proteins (p. 29)
- Why this set of 20 amino acids? (p. 35)
- Sickle-cell trait and malaria (p. 206)
- Additional human globin genes (p. 208)
- Catalytic triads in hydrolytic enzymes (p. 258)
- Major classes of peptide-cleaving enzymes (p. 260)
- Common catalytic core in type II restriction enzymes (p. 275)
- P-loop NTPase domains (p. 280)
- Conserved catalytic core in protein kinases (p. 298)
- Why do different human blood types exist? (p. 331)
- Archaeal membranes (p. 346)
- Ion pumps (p. 370)
- P-type ATPases (p. 374)
- ATP-binding cassettes (p. 374)
- Sequence comparisons of Na<sup>+</sup> and Ca<sup>2+</sup> channels (p. 382)
- Small G proteins (p. 414)
- Metabolism in the RNA world (p. 444)
- Why is glucose a prominent fuel? (p. 451)
- NAD<sup>+</sup> binding sites in dehydrogenases (p. 465)
- Isozymic forms of lactate dehydrogenase (p. 487)
- Evolution of glycolysis and gluconeogenesis (p. 487)
- The  $\alpha$ -ketoglutarate dehydrogenase complex (p. 505)
- Domains of succinyl CoA synthetase (p. 507)
- Evolution of the citric acid cycle (p. 516)
- Mitochondrial evolution (p. 525)
- Conserved structure of cytochrome *c* (p. 541)
- Common features of ATP synthase and G proteins (p. 548)
- Pigs lack uncoupling protein 1 (UCP-1) and brown fat (p. 556)
- Related uncoupling proteins (p. 556)
- Chloroplast evolution (p. 568)
- Evolutionary origins of photosynthesis (p. 584)
- Evolution of the C4 pathway (p. 601)
- The relationship of the Calvin cycle and the pentose phosphate pathway (p. 610)
- Increasing sophistication of glycogen phosphorylase regulation (p. 629)
- Glycogen synthase is homologous to glycogen phosphorylase (p. 631)
- A recurring motif in the activation of carboxyl groups (p. 649)
- Prokaryotic counterparts of the ubiquitin pathway and the proteasome (p. 686)
- A family of pyridoxal-dependent enzymes (p. 692)
- Evolution of the urea cycle (p. 696)
- The P-loop NTPase domain in nitrogenase (p. 716)
- Conserved amino acids in transaminases determine amino acid chirality (p. 721)
- Feedback inhibition (p. 731)
- Recurring steps in purine ring synthesis (p. 749)
- Ribonucleotide reductases (p. 755)
- Increase in urate levels during primate evolution (p. 761)
- Deinococcus radiodurans* illustrates the power of DNA repair systems (p. 828)
- DNA polymerases (p. 829)
- Thymine and the fidelity of the genetic message (p. 849)
- Sigma factors in bacterial transcription (p. 865)
- Similarities in transcription between archaea and eukaryotes (p. 876)
- Evolution of spliceosome-catalyzed splicing (p. 888)
- Classes of aminoacyl-tRNA synthetases (p. 901)
- Composition of the primordial ribosome (p. 903)
- Homologous G proteins (p. 908)
- A family of proteins with common ligand-binding domains (p. 930)
- The independent evolution of DNA-binding sites of regulatory proteins (p. 931)
- Key principles of gene regulation are similar in bacteria and archaea (p. 937)
- CpG islands (p. 949)
- Iron-response elements (p. 955)
- miRNAs in gene evolution (p. 957)
- The odorant-receptor family (p. 963)
- Photoreceptor evolution (p. 973)
- The immunoglobulin fold (p. 988)
- Relationship of tubulin to prokaryotic proteins (p. 1023)

## CLINICAL APPLICATIONS

This icon signals the start of a clinical application in the text. Additional, briefer clinical correlations appear in the text as appropriate.

- Osteogenesis imperfecta (p. 46)
- Protein-misfolding diseases (p. 56)
- Protein modification and scurvy (p. 57)
- Antigen/antibody detection with ELISA (p. 82)
- Synthetic peptides as drugs (p. 92)
- PCR in diagnostics and forensics (p.142)
- Gene therapy (p. 164)
- Aptamers in biotechnology and medicine (p. 187)
- Functional magnetic resonance imaging (p. 193)
- 2,3-BPG and fetal hemoglobin (p. 201)
- Carbon monoxide poisoning (p. 201)
- Sickle-cell anemia (p. 205)
- Thalassemia (p. 207)
- Aldehyde dehydrogenase deficiency (p. 228)
- Action of penicillin (p. 239)
- Protease inhibitors (p. 263)
- Carbonic anhydrase and osteopetrosis (p. 264)
- Isozymes as a sign of tissue damage (p. 293)
- Trypsin inhibitor helps prevent pancreatic damage (p. 302)
- Emphysema (p. 303)
- Blood clotting involves a cascade of zymogen activations (p. 303)
- Vitamin K (p. 306)
- Antithrombin and hemorrhage (p. 307)
- Hemophilia (p.308)
- Monitoring changes in glycosylated hemoglobin (p. 321)
- Erythropoietin (p. 327)
- Hurler disease (p. 327)
- Mucins (p. 329)
- Blood groups (p. 331)
- I-cell disease (p. 332)
- Influenza virus binding (p. 335)
- Clinical applications of liposomes (p. 349)
- Aspirin and ibuprofen (p. 353)
- Digitalis and congestive heart failure (p. 373)
- Multidrug resistance (p. 374)
- Long QT syndrome (p. 388)
- Signal-transduction pathways and cancer (p. 416)
- Monoclonal antibodies as anticancer drugs (p. 416)
- Protein kinase inhibitors as anticancer drugs (p. 417)
- G-proteins, cholera and whooping cough (p. 417)
- Vitamins (p. 438)
- Triose phosphate isomerase deficiency (p. 454)
- Excessive fructose consumption (p. 466)
- Lactose intolerance (p. 467)
- Galactosemia (p. 468)
- Aerobic glycolysis and cancer (p. 474)
- Phosphatase deficiency (p. 512)
- Defects in the citric acid cycle and the development of cancer (p. 513)
- Beriberi and mercury poisoning (p. 515)
- Frataxin mutations cause Friedreich's ataxia (p. 531)
- Reactive oxygen species (ROS) are implicated in a variety of diseases (p. 539)
- ROS may be important in signal transduction (p. 540)
- IF1 overexpression and cancer (p. 554)
- Brown adipose tissue (p. 555)
- Mild uncouplers sought as drugs (p.557)
- Mitochondrial diseases (p. 557)
- Glucose 6-phosphate dehydrogenase deficiency causes drug-induced hemolytic anemia (p. 610)
- Glucose 6-phosphate dehydrogenase deficiency protects against malaria (p. 612)
- Developing drugs for type 2 diabetes (p. 636)
- Glycogen-storage diseases (p. 637)
- Chanarin-Dorfman syndrome (p. 648)
- Carnitine deficiency (p. 650)
- Zellweger syndrome (p. 657)
- Diabetic ketosis (p. 659)
- Ketogenic diets to treat epilepsy (p. 660)
- Some fatty acids may contribute to pathological conditions (p. 661)
- The use of fatty acid synthase inhibitors as drugs (p. 667)
- Effects of aspirin on signaling pathways (p. 669)
- Diseases resulting from defects in transporters of amino acids (p. 682)
- Diseases resulting from defects in E3 proteins (p. 685)
- Drugs target the ubiquitin-proteasome system (p.687)
- Using proteasome inhibitors to treat tuberculosis (p. 687)
- Blood levels of aminotransferases indicate liver damage (p. 691)
- Inherited defects of the urea cycle (hyperammonemia) (p. 697)
- Alcaptonuria, maple syrup urine disease, and phenylketonuria (p. 705)

High homocysteine levels and vascular disease (p. 726)

Inherited disorders of porphyrin metabolism (p. 737)

Anticancer drugs that block the synthesis of thymidylate (p. 757)

Ribonucleotide reductase is a target for cancer therapy (p. 759)

Adenosine deaminase and severe combined immunodeficiency (p. 760)

Gout (p. 761)

Lesch–Nyhan syndrome (p. 761)

Folic acid and spina bifida (p. 762)

Enzyme activation in some cancers to generate phosphocholine (p. 770)

Excess choline and heart disease (p. 771)

Gangliosides and cholera (p. 773)

Second messengers derived from sphingolipids and diabetes (p. 773)

Respiratory distress syndrome and Tay–Sachs disease (p. 774)

Ceramide metabolism stimulates tumor growth (p. 775)

Phosphatidic acid phosphatase and lipodystrophy (p. 776)

Hypercholesterolemia and atherosclerosis (p. 784)

Mutations in the LDL receptor (p. 785)

LDL receptor cycling is regulated (p. 787)

The role of HDL in protecting against arteriosclerosis (p. 787)

Clinical management of cholesterol levels (p. 788)

Bile salts are derivatives of cholesterol (p. 789)

The cytochrome P450 system is protective (p. 791)

A new protease inhibitor also inhibits a cytochrome P450 enzyme (p. 792)

Aromatase inhibitors in the treatment of breast and ovarian cancer (p. 794)

Rickets and vitamin D (p. 795)

Caloric homeostasis is a means of regulating body weight (p. 802)

The brain plays a key role in caloric homeostasis (p. 804)

Diabetes is a common metabolic disease often resulting from obesity (p. 807)

Exercise beneficially alters the biochemistry of cells (p. 813)

Food intake and starvation induce metabolic changes (p. 816)

Ethanol alters energy metabolism in the liver (p. 819)

Antibiotics that target DNA gyrase (p. 839)

Blocking telomerase to treat cancer (p. 845)

Huntington disease (p. 850)

Defective repair of DNA and cancer (p. 850)

Detection of carcinogens (Ames test) (p. 852)

Translocations can result in diseases (p. 855)

Antibiotic inhibitors of transcription (p. 869)

Burkitt lymphoma and B-cell leukemia (p. 876)

Diseases of defective RNA splicing (p. 884)

Vanishing white matter disease (p. 913)

Antibiotics that inhibit protein synthesis (p. 914)

Diphtheria (p. 914)

Ricin, a lethal protein-synthesis inhibitor (p. 915)

Induced pluripotent stem cells (p. 947)

Anabolic steroids (p. 951)

Color blindness (p. 974)

The use of capsaicin in pain management (p. 978)

Immune-system suppressants (p. 994)

MHC and transplantation rejection (p. 1002)

AIDS (p. 1003)

Autoimmune diseases (p. 1005)

Immune system and cancer (p. 1005)

Vaccines (p. 1006)

Charcot-Marie-Tooth disease (p. 1022)

Taxol (p. 1023)

## ACKNOWLEDGMENTS

Writing a popular textbook is both a challenge and an honor. Our goal is to convey to our students our enthusiasm and understanding of a discipline to which we are devoted. They are our inspiration. Consequently, not a word was written or an illustration constructed without the knowledge that bright, engaged students would immediately detect vagueness and ambiguity. We also thank our colleagues who supported, advised, instructed, and simply bore with us during this arduous task.

We are grateful to our colleagues throughout the world who patiently answered our questions and shared their insights into recent developments.

We also especially thank those who served as reviewers for this new edition. Their thoughtful comments, suggestions, and encouragement have been of immense help to us in maintaining the excellence of the preceding editions. These reviewers are:

Sung-Kun Kim <i>Baylor University</i>	Pamela Osenkowski <i>Loyola University, Chicago</i>	Kerry Smith <i>Clemson University</i>
Roger Koeppe <i>University of Arkansas, Fayetteville</i>	Xiaping Pan <i>East Carolina University</i>	Narashima Sreerama <i>Colorado State University</i>

We have been working with the people at W. H. Freeman/ Macmillan Higher Education for many years now, and our experiences have always been enjoyable and rewarding. Writing and producing the eighth edition of *Biochemistry* confirmed our belief that they are a wonderful publishing team and we are honored to work with

them. Our Macmillan colleagues have a knack for undertaking stressful, but exhilarating, projects and reducing the stress without reducing the exhilaration and a remarkable ability to coax without ever nagging. We have many people to thank for this experience, some of whom are first timers to the *Biochemistry* project.

We are delighted to work with Senior Acquisitions Editor, Lauren Schultz, for the first time. She was unfailing in her enthusiasm and generous with her support. Another new member of the team was our developmental editor, Irene Pech. We have had the pleasure of working with a number of outstanding developmental editors over the years, and Irene continues this tradition. Irene is thoughtful, insightful, and very efficient at identifying aspects of our writing and figures that were less than clear. Lisa Samols, a former developmental editor, served as a consultant, archivist for previous editions, and a general source of publishing knowledge. Senior Project Editor Deni Showers, with Sherrill Redd, managed the flow of the entire project, from copyediting through bound book, with admirable efficiency. Irene Vartanoff and Mercy Heston, our manuscript editors, enhanced the literary consistency and clarity of the text. Vicki Tomaselli, Design Manager, produced a design and layout that makes the book uniquely attractive while still emphasizing its ties to past editions. Photo Editor Christine Buese and Photo Researcher Jacalyn Wong found the photographs that we hope make the text not only more inviting, but also fun to look through. Janice Donnola, Illustration Coordinator, deftly directed the rendering of new illustrations. Paul Rohloff, Production

Coordinator, made sure that the significant difficulties of scheduling, composition, and manufacturing were smoothly overcome. Amanda Dunning and Donna Brodman did a wonderful job in their management of the media program. In addition, Amanda ably coordinated the print supplements plan. Special thanks also to editorial assistants Shannon Moloney and Nandini Ahuja. Sandy Lindelof, Executive Marketing Manager, enthusiastically introduced this newest edition of *Biochemistry* to the academic world. We are deeply appreciative of Craig Bleyer and his sales staff for their support. Without their able and enthusiastic presentation of our text to the academic community, all of our efforts would be in vain. We also wish to thank Kate Ahr Parker, Publisher, for her encouragement and belief in us.

Thanks also to our many colleagues at our own institutions as well as throughout the country who patiently answered our questions and encouraged us on our quest. Finally, we owe a debt of gratitude to our families—our wives, Wendie Berg, Alison Unger, and Megan Williams, and our children, especially Timothy and Mark Gatto. Without their support, comfort, and understanding, this endeavor could never have been undertaken, let alone successfully completed.

# BRIEF CONTENTS

## Part I THE MOLECULAR DESIGN OF LIFE

- 1 Biochemistry: An Evolving Science 1
- 2 Protein Composition and Structure 27
- 3 Exploring Proteins and Proteomes 65
- 4 DNA, RNA, and the Flow of Genetic Information 105
- 5 Exploring Genes and Genomes 135
- 6 Exploring Evolution and Bioinformatics 169
- 7 Hemoglobin: Portrait of a Protein in Action 191
- 8 Enzymes: Basic Concepts and Kinetics 215
- 9 Catalytic Strategies 251
- 10 Regulatory Strategies 285
- 11 Carbohydrates 315
- 12 Lipids and Cell Membranes 341
- 13 Membrane Channels and Pumps 367
- 14 Signal-Transduction Pathways 397

## Part II TRANSDUCING AND STORING ENERGY

- 15 Metabolism: Basic Concepts and Design 423
- 16 Glycolysis and Gluconeogenesis 449
- 17 The Citric Acid Cycle 495
- 18 Oxidative Phosphorylation 523
- 19 The Light Reactions of Photosynthesis 565
- 20 The Calvin Cycle and the Pentose Phosphate Pathway 589
- 21 Glycogen Metabolism 617
- 22 Fatty Acid Metabolism 643
- 23 Protein Turnover and Amino Acid Catabolism 681

## Part III SYNTHESIZING THE MOLECULES OF LIFE

- 24 The Biosynthesis of Amino Acids 713
- 25 Nucleotide Biosynthesis 743
- 26 The Biosynthesis of Membrane Lipids and Steroids 767
- 27 The Integration of Metabolism 801
- 28 DNA Replication, Repair, and Recombination 827
- 29 RNA Synthesis and Processing 859
- 30 Protein Synthesis 893
- 31 The Control of Gene Expression in Prokaryotes 925
- 32 The Control of Gene Expression in Eukaryotes 941

## Part IV RESPONDING TO ENVIRONMENTAL CHANGES

- 33 Sensory Systems 961
- 34 The Immune System 981
- 35 Molecular Motors 1011
- 36 Drug Development 1033

# CONTENTS

- Preface v

## Part I THE MOLECULAR DESIGN OF LIFE 1

### CHAPTER 1 Biochemistry: An Evolving Science 1

- 1.1 Biochemical Unity Underlies Biological Diversity 1
- 1.2 DNA Illustrates the Interplay Between Form and Function 4
  - DNA is constructed from four building blocks 4
  - Two single strands of DNA combine to form a double helix 5
  - DNA structure explains heredity and the storage of information 5
- 1.3 Concepts from Chemistry Explain the Properties of Biological Molecules 6
  - The formation of the DNA double helix as a key example 6
  - The double helix can form from its component strands 6
  - Covalent and noncovalent bonds are important for the structure and stability of biological molecules 6
  - The double helix is an expression of the rules of chemistry 9
  - The laws of thermodynamics govern the behavior of biochemical systems 10
  - Heat is released in the formation of the double helix 12
  - Acid–base reactions are central in many biochemical processes 13
  - Acid–base reactions can disrupt the double helix 14
  - Buffers regulate pH in organisms and in the laboratory 15
- 1.4 The Genomic Revolution Is Transforming Biochemistry, Medicine, and Other Fields 17
  - Genome sequencing has transformed biochemistry and other fields 17
  - Environmental factors influence human biochemistry 20
  - Genome sequences encode proteins and patterns of expression 21
- APPENDIX: Visualizing Molecular Structures I: Small Molecules 22

### CHAPTER 2 Protein Composition and Structure 27

- 2.1 Proteins Are Built from a Repertoire of 20 Amino Acids 29
- 2.2 Primary Structure: Amino Acids Are Linked by Peptide Bonds to Form Polypeptide Chains 35
  - Proteins have unique amino acid sequences specified by genes 37
  - Polypeptide chains are flexible yet conformationally restricted 38
- 2.3 Secondary Structure: Polypeptide Chains Can Fold into Regular Structures Such As the Alpha Helix, the Beta Sheet, and Turns and Loops 40
  - The alpha helix is a coiled structure stabilized by intrachain hydrogen bonds 40
  - Beta sheets are stabilized by hydrogen bonding between polypeptide strands 42

Polypeptide chains can change direction by making reverse turns and loops	44	<b>3.3 Mass Spectrometry Is a Powerful Technique for the Identification of Peptides and Proteins</b>	<b>85</b>
Fibrous proteins provide structural support for cells and tissues	44	Peptides can be sequenced by mass spectrometry	87
<b>2.4 Tertiary Structure: Water-Soluble Proteins Fold into Compact Structures with Nonpolar Cores</b>	<b>46</b>	Proteins can be specifically cleaved into small peptides to facilitate analysis	88
<b>2.5 Quaternary Structure: Polypeptide Chains Can Assemble into Multisubunit Structures</b>	<b>48</b>	Genomic and proteomic methods are complementary	89
<b>2.6 The Amino Acid Sequence of a Protein Determines Its Three-Dimensional Structure</b>	<b>49</b>	The amino acid sequence of a protein provides valuable information	90
Amino acids have different propensities for forming $\alpha$ helices, $\beta$ sheets, and turns	51	Individual proteins can be identified by mass spectrometry	91
Protein folding is a highly cooperative process	52	<b>3.4 Peptides Can Be Synthesized by Automated Solid-Phase Methods</b>	<b>92</b>
Proteins fold by progressive stabilization of intermediates rather than by random search	53	<b>3.5 Three-Dimensional Protein Structure Can Be Determined by X-ray Crystallography and NMR Spectroscopy</b>	<b>95</b>
Prediction of three-dimensional structure from sequence remains a great challenge	54	X-ray crystallography reveals three-dimensional structure in atomic detail	95
Some proteins are inherently unstructured and can exist in multiple conformations	55	Nuclear magnetic resonance spectroscopy can reveal the structures of proteins in solution	97
Protein misfolding and aggregation are associated with some neurological diseases	56	<b>CHAPTER 4 DNA, RNA, and the Flow of Genetic Information</b>	<b>105</b>
Protein modification and cleavage confer new capabilities	57	<b>4.1 A Nucleic Acid Consists of Four Kinds of Bases Linked to a Sugar–Phosphate Backbone</b>	<b>106</b>
APPENDIX: Visualizing Molecular Structures II: Proteins	61	RNA and DNA differ in the sugar component and one of the bases	106
<b>CHAPTER 3 Exploring Proteins and Proteomes</b>	<b>65</b>	Nucleotides are the monomeric units of nucleic acids	107
The proteome is the functional representation of the genome	66	DNA molecules are very long and have directionality	108
<b>3.1 The Purification of Proteins Is an Essential First Step in Understanding Their Function</b>	<b>66</b>	<b>4.2 A Pair of Nucleic Acid Strands with Complementary Sequences Can Form a Double-Helical Structure</b>	<b>109</b>
The assay: How do we recognize the protein that we are looking for?	67	The double helix is stabilized by hydrogen bonds and van der Waals interactions	109
Proteins must be released from the cell to be purified	67	DNA can assume a variety of structural forms	111
Proteins can be purified according to solubility, size, charge, and binding affinity	68	Z-DNA is a left-handed double helix in which backbone phosphates zigzag	112
Proteins can be separated by gel electrophoresis and displayed	71	Some DNA molecules are circular and supercoiled	113
A protein purification scheme can be quantitatively evaluated	75	Single-stranded nucleic acids can adopt elaborate structures	113
Ultracentrifugation is valuable for separating biomolecules and determining their masses	76	<b>4.3 The Double Helix Facilitates the Accurate Transmission of Hereditary Information</b>	<b>114</b>
Protein purification can be made easier with the use of recombinant DNA technology	78	Differences in DNA density established the validity of the semiconservative replication hypothesis	115
<b>3.2 Immunology Provides Important Techniques with Which to Investigate Proteins</b>	<b>79</b>	The double helix can be reversibly melted	116
Antibodies to specific proteins can be generated	79	<b>4.4 DNA Is Replicated by Polymerases That Take Instructions from Templates</b>	<b>117</b>
Monoclonal antibodies with virtually any desired specificity can be readily prepared	80	DNA polymerase catalyzes phosphodiester-bridge formation	117
Proteins can be detected and quantified by using an enzyme-linked immunosorbent assay	82	The genes of some viruses are made of RNA	118
Western blotting permits the detection of proteins separated by gel electrophoresis	83	<b>4.5 Gene Expression Is the Transformation of DNA Information into Functional Molecules</b>	<b>119</b>
Fluorescent markers make the visualization of proteins in the cell possible	84	Several kinds of RNA play key roles in gene expression	119

All cellular RNA is synthesized by RNA polymerases	120	Next-generation sequencing methods enable the rapid determination of a complete genome sequence	155
RNA polymerases take instructions from DNA templates	121	Comparative genomics has become a powerful research tool	156
Transcription begins near promoter sites and ends at terminator sites	122	<b>5.4 Eukaryotic Genes Can Be Quantitated and Manipulated with Considerable Precision</b>	<b>157</b>
Transfer RNAs are the adaptor molecules in protein synthesis	123	Gene-expression levels can be comprehensively examined	157
<b>4.6 Amino Acids Are Encoded by Groups of Three Bases Starting from a Fixed Point</b>	<b>124</b>	New genes inserted into eukaryotic cells can be efficiently expressed	159
Major features of the genetic code	125	Transgenic animals harbor and express genes introduced into their germ lines	160
Messenger RNA contains start and stop signals for protein synthesis	126	Gene disruption and genome editing provide clues to gene function and opportunities for new therapies	160
The genetic code is nearly universal	126	RNA interference provides an additional tool for disrupting gene expression	162
<b>4.7 Most Eukaryotic Genes Are Mosaics of Introns and Exons</b>	<b>127</b>	Tumor-inducing plasmids can be used to introduce new genes into plant cells	163
RNA processing generates mature RNA	127	Human gene therapy holds great promise for medicine	164
Many exons encode protein domains	128		
<b>CHAPTER 5 Exploring Genes and Genomes</b>	<b>135</b>		
<b>5.1 The Exploration of Genes Relies on Key Tools</b>	<b>136</b>	<b>CHAPTER 6 Exploring Evolution and Bioinformatics</b>	<b>169</b>
Restriction enzymes split DNA into specific fragments	137	<b>6.1 Homologs Are Descended from a Common Ancestor</b>	<b>170</b>
Restriction fragments can be separated by gel electrophoresis and visualized	137	<b>6.2 Statistical Analysis of Sequence Alignments Can Detect Homology</b>	<b>171</b>
DNA can be sequenced by controlled termination of replication	138	The statistical significance of alignments can be estimated by shuffling	173
DNA probes and genes can be synthesized by automated solid-phase methods	139	Distant evolutionary relationships can be detected through the use of substitution matrices	174
Selected DNA sequences can be greatly amplified by the polymerase chain reaction	141	Databases can be searched to identify homologous sequences	177
PCR is a powerful technique in medical diagnostics, forensics, and studies of molecular evolution	142	<b>6.3 Examination of Three-Dimensional Structure Enhances Our Understanding of Evolutionary Relationships</b>	<b>177</b>
The tools for recombinant DNA technology have been used to identify disease-causing mutations	143	Tertiary structure is more conserved than primary structure	178
<b>5.2 Recombinant DNA Technology Has Revolutionized All Aspects of Biology</b>	<b>143</b>	Knowledge of three-dimensional structures can aid in the evaluation of sequence alignments	179
Restriction enzymes and DNA ligase are key tools in forming recombinant DNA molecules	143	Repeated motifs can be detected by aligning sequences with themselves	180
Plasmids and $\lambda$ phage are choice vectors for DNA cloning in bacteria	144	Convergent evolution illustrates common solutions to biochemical challenges	181
Bacterial and yeast artificial chromosomes	147	Comparison of RNA sequences can be a source of insight into RNA secondary structures	182
Specific genes can be cloned from digests of genomic DNA	147	<b>6.4 Evolutionary Trees Can Be Constructed on the Basis of Sequence Information</b>	<b>183</b>
Complementary DNA prepared from mRNA can be expressed in host cells	149	Horizontal gene transfer events may explain unexpected branches of the evolutionary tree	184
Proteins with new functions can be created through directed changes in DNA	150	<b>6.5 Modern Techniques Make the Experimental Exploration of Evolution Possible</b>	<b>185</b>
Recombinant methods enable the exploration of the functional effects of disease-causing mutations	152	Ancient DNA can sometimes be amplified and sequenced	185
<b>5.3 Complete Genomes Have Been Sequenced and Analyzed</b>	<b>152</b>	Molecular evolution can be examined experimentally	185
The genomes of organisms ranging from bacteria to multicellular eukaryotes have been sequenced	153		
The sequence of the human genome has been completed	154		

**CHAPTER 7 Hemoglobin: Portrait of a Protein in Action****191****7.1 Myoglobin and Hemoglobin Bind Oxygen at Iron Atoms in Heme****192**

Changes in heme electronic structure upon oxygen binding are the basis for functional imaging studies 193

The structure of myoglobin prevents the release of reactive oxygen species 194

Human hemoglobin is an assembly of four myoglobin-like subunits 195

**7.2 Hemoglobin Binds Oxygen Cooperatively****195**

Oxygen binding markedly changes the quaternary structure of hemoglobin 197

Hemoglobin cooperativity can be potentially explained by several models 198

Structural changes at the heme groups are transmitted to the  $\alpha_1\beta_1$ - $\alpha_2\beta_2$  interface 200

2,3-Bisphosphoglycerate in red cells is crucial in determining the oxygen affinity of hemoglobin 200

Carbon monoxide can disrupt oxygen transport by hemoglobin 201

**7.3 Hydrogen Ions and Carbon Dioxide Promote the Release of Oxygen: The Bohr Effect****202****7.4 Mutations in Genes Encoding Hemoglobin Subunits Can Result in Disease****204**

Sickle-cell anemia results from the aggregation of mutated deoxyhemoglobin molecules 205

Thalassemia is caused by an imbalanced production of hemoglobin chains 207

The accumulation of free alpha-hemoglobin chains is prevented 207

Additional globins are encoded in the human genome 208

APPENDIX: Binding Models Can Be Formulated in Quantitative Terms: The Hill Plot and the Concerted Model 210

**CHAPTER 8 Enzymes: Basic Concepts and Kinetics****215****8.1 Enzymes are Powerful and Highly Specific Catalysts****216**

Many enzymes require cofactors for activity 217

Enzymes can transform energy from one form into another 217

**8.2 Gibbs Free Energy Is a Useful Thermodynamic Function for Understanding Enzymes****218**

The free-energy change provides information about the spontaneity but not the rate of a reaction 218

The standard free-energy change of a reaction is related to the equilibrium constant 219

Enzymes alter only the reaction rate and not the reaction equilibrium 220

**8.3 Enzymes Accelerate Reactions by Facilitating the Formation of the Transition State****221**

The formation of an enzyme–substrate complex is the first step in enzymatic catalysis 222

The active sites of enzymes have some common features 223

The binding energy between enzyme and substrate is important for catalysis 225

**8.4 The Michaelis–Menten Model Accounts for the Kinetic Properties of Many Enzymes****225**

Kinetics is the study of reaction rates 225

The steady-state assumption facilitates a description of enzyme kinetics 226

Variations in  $K_M$  can have physiological consequences 228 $K_M$  and  $V_{max}$  values can be determined by several means 228 $K_M$  and  $V_{max}$  values are important enzyme characteristics 229 $k_{cat}/K_M$  is a measure of catalytic efficiency 230

Most biochemical reactions include multiple substrates 231

Allosteric enzymes do not obey Michaelis–Menten kinetics 233

**8.5 Enzymes Can Be Inhibited by Specific Molecules****234**

The different types of reversible inhibitors are kinetically distinguishable 235

Irreversible inhibitors can be used to map the active site 237

Penicillin irreversibly inactivates a key enzyme in bacterial cell-wall synthesis 239

Transition-state analogs are potent inhibitors of enzymes 240

Catalytic antibodies demonstrate the importance of selective binding of the transition state to enzymatic activity 241

**8.6 Enzymes Can Be Studied One Molecule at a Time****242**

APPENDIX: Enzymes are Classified on the Basis of the Types of Reactions That They Catalyze 245

**CHAPTER 9 Catalytic Strategies****251**

A few basic catalytic principles are used by many enzymes 252

**9.1 Proteases Facilitate a Fundamentally Difficult Reaction****253**

Chymotrypsin possesses a highly reactive serine residue 253

Chymotrypsin action proceeds in two steps linked by a covalently bound intermediate 254

Serine is part of a catalytic triad that also includes histidine and aspartate 255

Catalytic triads are found in other hydrolytic enzymes 258

The catalytic triad has been dissected by site-directed mutagenesis 260

Cysteine, aspartyl, and metalloproteases are other major classes of peptide-cleaving enzymes 260

Protease inhibitors are important drugs 263

<b>9.2 Carbonic Anhydrases Make a Fast Reaction Faster</b>	<b>264</b>		
Carbonic anhydrase contains a bound zinc ion essential for catalytic activity	265		
Catalysis entails zinc activation of a water molecule	265		
A proton shuttle facilitates rapid regeneration of the active form of the enzyme	267		
<b>9.3 Restriction Enzymes Catalyze Highly Specific DNA-Cleavage Reactions</b>	<b>269</b>		
Cleavage is by in-line displacement of 3'-oxygen from phosphorus by magnesium-activated water	269		
Restriction enzymes require magnesium for catalytic activity	271		
The complete catalytic apparatus is assembled only within complexes of cognate DNA molecules, ensuring specificity	272		
Host-cell DNA is protected by the addition of methyl groups to specific bases	274		
Type II restriction enzymes have a catalytic core in common and are probably related by horizontal gene transfer	275		
<b>9.4 Myosins Harness Changes in Enzyme Conformation to Couple ATP Hydrolysis to Mechanical Work</b>	<b>275</b>		
ATP hydrolysis proceeds by the attack of water on the gamma-phosphoryl group	276		
Formation of the transition state for ATP hydrolysis is associated with a substantial conformational change	277		
The altered conformation of myosin persists for a substantial period of time	278		
Scientists can watch single molecules of myosin move	279		
Myosins are a family of enzymes containing P-loop structures	280		
<b>CHAPTER 10 Regulatory Strategies</b>	<b>285</b>		
<b>10.1 Aspartate Transcarbamoylase Is Allosterically Inhibited by the End Product of Its Pathway</b>	<b>286</b>		
Allosterically regulated enzymes do not follow Michaelis–Menten kinetics	287		
ATCase consists of separable catalytic and regulatory subunits	287		
Allosteric interactions in ATCase are mediated by large changes in quaternary structure	288		
Allosteric regulators modulate the T-to-R equilibrium	291		
<b>10.2 Isozymes Provide a Means of Regulation Specific to Distinct Tissues and Developmental Stages</b>	<b>292</b>		
<b>10.3 Covalent Modification Is a Means of Regulating Enzyme Activity</b>	<b>293</b>		
Kinases and phosphatases control the extent of protein phosphorylation	294		
Phosphorylation is a highly effective means of regulating the activities of target proteins	296		
		Cyclic AMP activates protein kinase A by altering the quaternary structure	297
		ATP and the target protein bind to a deep cleft in the catalytic subunit of protein kinase A	298
		<b>10.4 Many Enzymes Are Activated by Specific Proteolytic Cleavage</b>	<b>299</b>
		Chymotrypsinogen is activated by specific cleavage of a single peptide bond	299
		Proteolytic activation of chymotrypsinogen leads to the formation of a substrate-binding site	300
		The generation of trypsin from trypsinogen leads to the activation of other zymogens	301
		Some proteolytic enzymes have specific inhibitors	302
		Blood clotting is accomplished by a cascade of zymogen activations	303
		Prothrombin requires a vitamin K-dependent modification for activation	304
		Fibrinogen is converted by thrombin into a fibrin clot	304
		Vitamin K is required for the formation of $\gamma$ -carboxyglutamate	306
		The clotting process must be precisely regulated	307
		Hemophilia revealed an early step in clotting	308
		<b>CHAPTER 11 Carbohydrates</b>	<b>315</b>
		<b>11.1 Monosaccharides Are the Simplest Carbohydrates</b>	<b>316</b>
		Many common sugars exist in cyclic forms	318
		Pyranose and furanose rings can assume different conformations	320
		Glucose is a reducing sugar	321
		Monosaccharides are joined to alcohols and amines through glycosidic bonds	322
		Phosphorylated sugars are key intermediates in energy generation and biosyntheses	322
		<b>11.2 Monosaccharides Are Linked to Form Complex Carbohydrates</b>	<b>323</b>
		Sucrose, lactose, and maltose are the common disaccharides	323
		Glycogen and starch are storage forms of glucose	324
		Cellulose, a structural component of plants, is made of chains of glucose	324
		<b>11.3 Carbohydrates Can Be Linked to Proteins to Form Glycoproteins</b>	<b>325</b>
		Carbohydrates can be linked to proteins through asparagine ( <i>N</i> -linked) or through serine or threonine ( <i>O</i> -linked) residues	326
		The glycoprotein erythropoietin is a vital hormone	327
		Glycosylation functions in nutrient sensing	327
		Proteoglycans, composed of polysaccharides and protein, have important structural roles	327
		Proteoglycans are important components of cartilage	328
		Mucins are glycoprotein components of mucus	329
		Protein glycosylation takes place in the lumen of the endoplasmic reticulum and in the Golgi complex	330

Specific enzymes are responsible for oligosaccharide assembly	331	<b>12.6 Eukaryotic Cells Contain Compartments Bounded by Internal Membranes</b>	<b>359</b>
Blood groups are based on protein glycosylation patterns	331		
Errors in glycosylation can result in pathological conditions	332	<b>CHAPTER 13 Membrane Channels and Pumps</b>	<b>367</b>
Oligosaccharides can be “sequenced”	332	The expression of transporters largely defines the metabolic activities of a given cell type	368
<b>11.4 Lectins Are Specific Carbohydrate-Binding Proteins</b>	<b>333</b>	<b>13.1 The Transport of Molecules Across a Membrane May Be Active or Passive</b>	<b>368</b>
Lectins promote interactions between cells	334	Many molecules require protein transporters to cross membranes	368
Lectins are organized into different classes	334	Free energy stored in concentration gradients can be quantified	369
Influenza virus binds to sialic acid residues	335	<b>13.2 Two Families of Membrane Proteins Use ATP Hydrolysis to Pump Ions and Molecules Across Membranes</b>	<b>370</b>
<b>CHAPTER 12 Lipids and Cell Membranes</b>	<b>341</b>	P-type ATPases couple phosphorylation and conformational changes to pump calcium ions across membranes	370
Many common features underlie the diversity of biological membranes	342	Digitalis specifically inhibits the Na <sup>+</sup> –K <sup>+</sup> pump by blocking its dephosphorylation	373
<b>12.1 Fatty Acids Are Key Constituents of Lipids</b>	<b>342</b>	P-type ATPases are evolutionarily conserved and play a wide range of roles	374
Fatty acid names are based on their parent hydrocarbons	342	Multidrug resistance highlights a family of membrane pumps with ATP-binding cassette domains	374
Fatty acids vary in chain length and degree of unsaturation	343	<b>13.3 Lactose Permease Is an Archetype of Secondary Transporters That Use One Concentration Gradient to Power the Formation of Another</b>	<b>376</b>
<b>12.2 There Are Three Common Types of Membrane Lipids</b>	<b>344</b>	<b>13.4 Specific Channels Can Rapidly Transport Ions Across Membranes</b>	<b>378</b>
Phospholipids are the major class of membrane lipids	344	Action potentials are mediated by transient changes in Na <sup>+</sup> and K <sup>+</sup> permeability	378
Membrane lipids can include carbohydrate moieties	345	Patch-clamp conductance measurements reveal the activities of single channels	379
Cholesterol is a lipid based on a steroid nucleus	346	The structure of a potassium ion channel is an archetype for many ion-channel structures	379
Archaeal membranes are built from ether lipids with branched chains	346	The structure of the potassium ion channel reveals the basis of ion specificity	380
A membrane lipid is an amphipathic molecule containing a hydrophilic and a hydrophobic moiety	347	The structure of the potassium ion channel explains its rapid rate of transport	383
<b>12.3 Phospholipids and Glycolipids Readily Form Bimolecular Sheets in Aqueous Media</b>	<b>348</b>	Voltage gating requires substantial conformational changes in specific ion-channel domains	383
Lipid vesicles can be formed from phospholipids	348	A channel can be inactivated by occlusion of the pore: the ball-and-chain model	384
Lipid bilayers are highly impermeable to ions and most polar molecules	349	The acetylcholine receptor is an archetype for ligand-gated ion channels	385
<b>12.4 Proteins Carry Out Most Membrane Processes</b>	<b>350</b>	Action potentials integrate the activities of several ion channels working in concert	387
Proteins associate with the lipid bilayer in a variety of ways	351	Disruption of ion channels by mutations or chemicals can be potentially life-threatening	388
Proteins interact with membranes in a variety of ways	351	<b>13.5 Gap Junctions Allow Ions and Small Molecules to Flow Between Communicating Cells</b>	<b>389</b>
Some proteins associate with membranes through covalently attached hydrophobic groups	354	<b>13.6 Specific Channels Increase the Permeability of Some Membranes to Water</b>	<b>390</b>
Transmembrane helices can be accurately predicted from amino acid sequences	354		
<b>12.5 Lipids and Many Membrane Proteins Diffuse Rapidly in the Plane of the Membrane</b>	<b>356</b>		
The fluid mosaic model allows lateral movement but not rotation through the membrane	357		
Membrane fluidity is controlled by fatty acid composition and cholesterol content	357		
Lipid rafts are highly dynamic complexes formed between cholesterol and specific lipids	358		
All biological membranes are asymmetric	358		

<b>CHAPTER 14 Signal-Transduction Pathways</b>	<b>397</b>		
Signal transduction depends on molecular circuits	398		
<b>14.1 Heterotrimeric G Proteins Transmit Signals and Reset Themselves</b>	<b>399</b>		
Ligand binding to 7TM receptors leads to the activation of heterotrimeric G proteins	400		
Activated G proteins transmit signals by binding to other proteins	402		
Cyclic AMP stimulates the phosphorylation of many target proteins by activating protein kinase A	403		
G proteins spontaneously reset themselves through GTP hydrolysis	403		
Some 7TM receptors activate the phosphoinositide cascade	404		
Calcium ion is a widely used second messenger	405		
Calcium ion often activates the regulatory protein calmodulin	407		
<b>14.2 Insulin Signaling: Phosphorylation Cascades Are Central to Many Signal-Transduction Processes</b>	<b>407</b>		
The insulin receptor is a dimer that closes around a bound insulin molecule	408		
Insulin binding results in the cross-phosphorylation and activation of the insulin receptor	408		
The activated insulin-receptor kinase initiates a kinase cascade	409		
Insulin signaling is terminated by the action of phosphatases	411		
<b>14.3 EGF Signaling: Signal-Transduction Pathways Are Poised to Respond</b>	<b>411</b>		
EGF binding results in the dimerization of the EGF receptor	411		
The EGF receptor undergoes phosphorylation of its carboxyl-terminal tail	413		
EGF signaling leads to the activation of Ras, a small G protein	413		
Activated Ras initiates a protein kinase cascade	414		
EGF signaling is terminated by protein phosphatases and the intrinsic GTPase activity of Ras	414		
<b>14.4 Many Elements Recur with Variation in Different Signal-Transduction Pathways</b>	<b>415</b>		
<b>14.5 Defects in Signal-Transduction Pathways Can Lead to Cancer and Other Diseases</b>	<b>416</b>		
Monoclonal antibodies can be used to inhibit signal-transduction pathways activated in tumors	416		
Protein kinase inhibitors can be effective anticancer drugs	417		
Cholera and whooping cough are the result of altered G-protein activity	417		
<b>Part II TRANSDUCING AND STORING ENERGY</b>			
<b>CHAPTER 15 Metabolism: Basic Concepts and Design</b>	<b>423</b>		
<b>15.1 Metabolism Is Composed of Many Coupled, Interconnecting Reactions</b>	<b>424</b>		
Metabolism consists of energy-yielding and energy-requiring reactions	424		
		A thermodynamically unfavorable reaction can be driven by a favorable reaction	425
		<b>15.2 ATP Is the Universal Currency of Free Energy in Biological Systems</b>	<b>426</b>
		ATP hydrolysis is exergonic	426
		ATP hydrolysis drives metabolism by shifting the equilibrium of coupled reactions	427
		The high phosphoryl potential of ATP results from structural differences between ATP and its hydrolysis products	429
		Phosphoryl-transfer potential is an important form of cellular energy transformation	430
		<b>15.3 The Oxidation of Carbon Fuels Is an Important Source of Cellular Energy</b>	<b>432</b>
		Compounds with high phosphoryl-transfer potential can couple carbon oxidation to ATP synthesis	432
		Ion gradients across membranes provide an important form of cellular energy that can be coupled to ATP synthesis	433
		Phosphates play a prominent role in biochemical processes	434
		Energy from foodstuffs is extracted in three stages	434
		<b>15.4 Metabolic Pathways Contain Many Recurring Motifs</b>	<b>435</b>
		Activated carriers exemplify the modular design and economy of metabolism	435
		Many activated carriers are derived from vitamins	438
		Key reactions are reiterated throughout metabolism	440
		Metabolic processes are regulated in three principal ways	442
		Aspects of metabolism may have evolved from an RNA world	444
		<b>CHAPTER 16 Glycolysis and Gluconeogenesis</b>	<b>449</b>
		Glucose is generated from dietary carbohydrates	450
		Glucose is an important fuel for most organisms	451
		<b>16.1 Glycolysis Is an Energy-Conversion Pathway in Many Organisms</b>	<b>451</b>
		Hexokinase traps glucose in the cell and begins glycolysis	451
		Fructose 1,6-bisphosphate is generated from glucose 6-phosphate	453
		The six-carbon sugar is cleaved into two three-carbon fragments	454
		Mechanism: Triose phosphate isomerase salvages a three-carbon fragment	455
		The oxidation of an aldehyde to an acid powers the formation of a compound with high phosphoryl-transfer potential	457
		Mechanism: Phosphorylation is coupled to the oxidation of glyceraldehyde 3-phosphate by a thioester intermediate	458
		ATP is formed by phosphoryl transfer from 1,3-bisphosphoglycerate	459
		Additional ATP is generated with the formation of pyruvate	460
		Two ATP molecules are formed in the conversion of glucose into pyruvate	461

NAD <sup>+</sup> is regenerated from the metabolism of pyruvate	462	Flexible linkages allow lipoamide to move between different active sites	500
Fermentations provide usable energy in the absence of oxygen	464	<b>17.2 The Citric Acid Cycle Oxidizes Two-Carbon Units</b>	<b>501</b>
The binding site for NAD <sup>+</sup> is similar in many dehydrogenases	465	Citrate synthase forms citrate from oxaloacetate and acetyl coenzyme A	502
Fructose is converted into glycolytic intermediates by fructokinase	465	Mechanism: The mechanism of citrate synthase prevents undesirable reactions	502
Excessive fructose consumption can lead to pathological conditions	466	Citrate is isomerized into isocitrate	504
Galactose is converted into glucose 6-phosphate	466	Isocitrate is oxidized and decarboxylated to alpha-ketoglutarate	504
Many adults are intolerant of milk because they are deficient in lactase	467	Succinyl coenzyme A is formed by the oxidative decarboxylation of alpha-ketoglutarate	505
Galactose is highly toxic if the transferase is missing	468	A compound with high phosphoryl-transfer potential is generated from succinyl coenzyme A	505
<b>16.2 The Glycolytic Pathway Is Tightly Controlled</b>	<b>469</b>	Mechanism: Succinyl coenzyme A synthetase transforms types of biochemical energy	506
Glycolysis in muscle is regulated to meet the need for ATP	469	Oxaloacetate is regenerated by the oxidation of succinate	507
The regulation of glycolysis in the liver illustrates the biochemical versatility of the liver	472	The citric acid cycle produces high-transfer-potential electrons, ATP, and CO <sub>2</sub>	508
A family of transporters enables glucose to enter and leave animal cells	473	<b>17.3 Entry to the Citric Acid Cycle and Metabolism Through It Are Controlled</b>	<b>510</b>
Aerobic glycolysis is a property of rapidly growing cells	474	The pyruvate dehydrogenase complex is regulated allosterically and by reversible phosphorylation	511
Cancer and endurance training affect glycolysis in a similar fashion	476	The citric acid cycle is controlled at several points	512
<b>16.3 Glucose Can Be Synthesized from Noncarbohydrate Precursors</b>	<b>476</b>	Defects in the citric acid cycle contribute to the development of cancer	513
Gluconeogenesis is not a reversal of glycolysis	478	<b>17.4 The Citric Acid Cycle Is a Source of Biosynthetic Precursors</b>	<b>514</b>
The conversion of pyruvate into phosphoenolpyruvate begins with the formation of oxaloacetate	478	The citric acid cycle must be capable of being rapidly replenished	514
Oxaloacetate is shuttled into the cytoplasm and converted into phosphoenolpyruvate	480	The disruption of pyruvate metabolism is the cause of beriberi and poisoning by mercury and arsenic	515
The conversion of fructose 1,6-bisphosphate into fructose 6-phosphate and orthophosphate is an irreversible step	480	The citric acid cycle may have evolved from preexisting pathways	516
The generation of free glucose is an important control point	481	<b>17.5 The Glyoxylate Cycle Enables Plants and Bacteria to Grow on Acetate</b>	<b>516</b>
Six high-transfer-potential phosphoryl groups are spent in synthesizing glucose from pyruvate	481	<b>CHAPTER 18 Oxidative Phosphorylation</b>	<b>523</b>
<b>16.4 Gluconeogenesis and Glycolysis Are Reciprocally Regulated</b>	<b>482</b>	<b>18.1 Eukaryotic Oxidative Phosphorylation Takes Place in Mitochondria</b>	<b>524</b>
Energy charge determines whether glycolysis or gluconeogenesis will be most active	482	Mitochondria are bounded by a double membrane	524
The balance between glycolysis and gluconeogenesis in the liver is sensitive to blood-glucose concentration	483	Mitochondria are the result of an endosymbiotic event	525
Substrate cycles amplify metabolic signals and produce heat	485	<b>18.2 Oxidative Phosphorylation Depends on Electron Transfer</b>	<b>526</b>
Lactate and alanine formed by contracting muscle are used by other organs	485	The electron-transfer potential of an electron is measured as redox potential	526
Glycolysis and gluconeogenesis are evolutionarily intertwined	487	A 1.14-volt potential difference between NADH and molecular oxygen drives electron transport through the chain and favors the formation of a proton gradient	528
<b>CHAPTER 17 The Citric Acid Cycle</b>	<b>495</b>	<b>18.3 The Respiratory Chain Consists of Four Complexes: Three Proton Pumps and a Physical Link to the Citric Acid Cycle</b>	<b>529</b>
The citric acid cycle harvests high-energy electrons	496	Iron-sulfur clusters are common components of the electron transport chain	531
<b>17.1 The Pyruvate Dehydrogenase Complex Links Glycolysis to the Citric Acid Cycle</b>	<b>497</b>		
Mechanism: The synthesis of acetyl coenzyme A from pyruvate requires three enzymes and five coenzymes	498		

The high-potential electrons of NADH enter the respiratory chain at NADH-Q oxidoreductase	532	Chloroplasts arose from an endosymbiotic event	568
Ubiquinol is the entry point for electrons from FADH <sub>2</sub> of flavoproteins	533	<b>19.2 Light Absorption by Chlorophyll Induces Electron Transfer</b>	<b>568</b>
Electrons flow from ubiquinol to cytochrome <i>c</i> through Q-cytochrome <i>c</i> oxidoreductase	533	A special pair of chlorophylls initiate charge separation	569
The Q cycle funnels electrons from a two-electron carrier to a one-electron carrier and pumps protons	535	Cyclic electron flow reduces the cytochrome of the reaction center	572
Cytochrome <i>c</i> oxidase catalyzes the reduction of molecular oxygen to water	535	<b>19.3 Two Photosystems Generate a Proton Gradient and NADPH in Oxygenic Photosynthesis</b>	<b>572</b>
Toxic derivatives of molecular oxygen such as superoxide radicals are scavenged by protective enzymes	538	Photosystem II transfers electrons from water to plastoquinone and generates a proton gradient	572
Electrons can be transferred between groups that are not in contact	540	Cytochrome <i>bf</i> links photosystem II to photosystem I	575
The conformation of cytochrome <i>c</i> has remained essentially constant for more than a billion years	541	Photosystem I uses light energy to generate reduced ferredoxin, a powerful reductant	575
<b>18.4 A Proton Gradient Powers the Synthesis of ATP</b>	<b>541</b>	Ferredoxin–NADP <sup>+</sup> reductase converts NADP <sup>+</sup> into NADPH	576
ATP synthase is composed of a proton-conducting unit and a catalytic unit	543	<b>19.4 A Proton Gradient across the Thylakoid Membrane Drives ATP Synthesis</b>	<b>578</b>
Proton flow through ATP synthase leads to the release of tightly bound ATP: The binding-change mechanism	544	The ATP synthase of chloroplasts closely resembles those of mitochondria and prokaryotes	578
Rotational catalysis is the world's smallest molecular motor	546	The activity of chloroplast ATP synthase is regulated	579
Proton flow around the <i>c</i> ring powers ATP synthesis	546	Cyclic electron flow through photosystem I leads to the production of ATP instead of NADPH	580
ATP synthase and G proteins have several common features	548	The absorption of eight photons yields one O <sub>2</sub> , two NADPH, and three ATP molecules	581
<b>18.5 Many Shuttles Allow Movement Across Mitochondrial Membranes</b>	<b>549</b>	<b>19.5 Accessory Pigments Funnel Energy into Reaction Centers</b>	<b>581</b>
Electrons from cytoplasmic NADH enter mitochondria by shuttles	549	Resonance energy transfer allows energy to move from the site of initial absorbance to the reaction center	582
The entry of ADP into mitochondria is coupled to the exit of ATP by ATP-ADP translocase	550	The components of photosynthesis are highly organized	583
Mitochondrial transporters for metabolites have a common tripartite structure	551	Many herbicides inhibit the light reactions of photosynthesis	584
<b>18.6 The Regulation of Cellular Respiration Is Governed Primarily by the Need for ATP</b>	<b>552</b>	<b>19.6 The Ability to Convert Light into Chemical Energy Is Ancient</b>	<b>584</b>
The complete oxidation of glucose yields about 30 molecules of ATP	552	Artificial photosynthetic systems may provide clean, renewable energy	585
The rate of oxidative phosphorylation is determined by the need for ATP	553	<b>CHAPTER 20 The Calvin Cycle and the Pentose Phosphate Pathway</b>	<b>589</b>
ATP synthase can be regulated	554	<b>20.1 The Calvin Cycle Synthesizes Hexoses from Carbon Dioxide and Water</b>	<b>590</b>
Regulated uncoupling leads to the generation of heat	554	Carbon dioxide reacts with ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate	591
Oxidative phosphorylation can be inhibited at many stages	556	Rubisco activity depends on magnesium and carbamate	592
Mitochondrial diseases are being discovered	557	Rubisco activase is essential for rubisco activity	593
Mitochondria play a key role in apoptosis	557	Rubisco also catalyzes a wasteful oxygenase reaction: Catalytic imperfection	593
Power transmission by proton gradients is a central motif of bioenergetics	558	Hexose phosphates are made from phosphoglycerate, and ribulose 1,5-bisphosphate is regenerated	594
<b>CHAPTER 19 The Light Reactions of Photosynthesis</b>	<b>565</b>	Three ATP and two NADPH molecules are used to bring carbon dioxide to the level of a hexose	597
Photosynthesis converts light energy into chemical energy	566	Starch and sucrose are the major carbohydrate stores in plants	597
<b>19.1 Photosynthesis Takes Place in Chloroplasts</b>	<b>567</b>	<b>20.2 The Activity of the Calvin Cycle Depends on Environmental Conditions</b>	<b>598</b>
The primary events of photosynthesis take place in thylakoid membranes	567		

Rubisco is activated by light-driven changes in proton and magnesium ion concentrations	598	Muscle phosphorylase is regulated by the intracellular energy charge	625
Thioredoxin plays a key role in regulating the Calvin cycle	599	Biochemical characteristics of muscle fiber types differ	625
The C <sub>4</sub> pathway of tropical plants accelerates photosynthesis by concentrating carbon dioxide	599	Phosphorylation promotes the conversion of phosphorylase <i>b</i> to phosphorylase <i>a</i>	626
Crassulacean acid metabolism permits growth in arid ecosystems	601	Phosphorylase kinase is activated by phosphorylation and calcium ions	626
<b>20.3 The Pentose Phosphate Pathway Generates NADPH and Synthesizes Five-Carbon Sugars</b>	<b>601</b>	<b>21.3 Epinephrine and Glucagon Signal the Need for Glycogen Breakdown</b>	<b>627</b>
Two molecules of NADPH are generated in the conversion of glucose 6-phosphate into ribulose 5-phosphate	602	G proteins transmit the signal for the initiation of glycogen breakdown	627
The pentose phosphate pathway and glycolysis are linked by transketolase and transaldolase	602	Glycogen breakdown must be rapidly turned off when necessary	629
Mechanism: Transketolase and transaldolase stabilize carbanionic intermediates by different mechanisms	605	The regulation of glycogen phosphorylase became more sophisticated as the enzyme evolved	629
<b>20.4 The Metabolism of Glucose 6-Phosphate by the Pentose Phosphate Pathway Is Coordinated with Glycolysis</b>	<b>607</b>	<b>21.4 Glycogen Is Synthesized and Degraded by Different Pathways</b>	<b>630</b>
The rate of the pentose phosphate pathway is controlled by the level of NADP <sup>+</sup>	607	UDP-glucose is an activated form of glucose	630
The flow of glucose 6-phosphate depends on the need for NADPH, ribose 5-phosphate, and ATP	608	Glycogen synthase catalyzes the transfer of glucose from UDP-glucose to a growing chain	630
The pentose phosphate pathway is required for rapid cell growth	610	A branching enzyme forms $\alpha$ -1,6 linkages	631
Through the looking-glass: The Calvin cycle and the pentose phosphate pathway are mirror images	610	Glycogen synthase is the key regulatory enzyme in glycogen synthesis	632
<b>20.5 Glucose 6-Phosphate Dehydrogenase Plays a Key Role in Protection Against Reactive Oxygen Species</b>	<b>610</b>	Glycogen is an efficient storage form of glucose	632
Glucose 6-phosphate dehydrogenase deficiency causes a drug-induced hemolytic anemia	610	<b>21.5 Glycogen Breakdown and Synthesis Are Reciprocally Regulated</b>	<b>632</b>
A deficiency of glucose 6-phosphate dehydrogenase confers an evolutionary advantage in some circumstances	612	Protein phosphatase 1 reverses the regulatory effects of kinases on glycogen metabolism	633
<b>CHAPTER 21 Glycogen Metabolism</b>	<b>617</b>	Insulin stimulates glycogen synthesis by inactivating glycogen synthase kinase	635
Glycogen metabolism is the regulated release and storage of glucose	618	Glycogen metabolism in the liver regulates the blood-glucose level	635
<b>21.1 Glycogen Breakdown Requires the Interplay of Several Enzymes</b>	<b>619</b>	A biochemical understanding of glycogen-storage diseases is possible	637
Phosphorylase catalyzes the phosphorolytic cleavage of glycogen to release glucose 1-phosphate	619	<b>CHAPTER 22 Fatty Acid Metabolism</b>	<b>643</b>
Mechanism: Pyridoxal phosphate participates in the phosphorolytic cleavage of glycogen	620	Fatty acid degradation and synthesis mirror each other in their chemical reactions	644
A debranching enzyme also is needed for the breakdown of glycogen	621	<b>22.1 Triacylglycerols Are Highly Concentrated Energy Stores</b>	<b>645</b>
Phosphoglucomutase converts glucose 1-phosphate into glucose 6-phosphate	622	Dietary lipids are digested by pancreatic lipases	645
The liver contains glucose 6-phosphatase, a hydrolytic enzyme absent from muscle	622	Dietary lipids are transported in chylomicrons	646
<b>21.2 Phosphorylase Is Regulated by Allosteric Interactions and Reversible Phosphorylation</b>	<b>623</b>	<b>22.2 The Use of Fatty Acids as Fuel Requires Three Stages of Processing</b>	<b>647</b>
Liver phosphorylase produces glucose for use by other tissues	623	Triacylglycerols are hydrolyzed by hormone-stimulated lipases	647
		Free fatty acids and glycerol are released into the blood	648
		Fatty acids are linked to coenzyme A before they are oxidized	648
		Carnitine carries long-chain activated fatty acids into the mitochondrial matrix	649
		Acetyl CoA, NADH, and FADH <sub>2</sub> are generated in each round of fatty acid oxidation	650

The complete oxidation of palmitate yields 106 molecules of ATP	652	<b>23.2 Protein Turnover Is Tightly Regulated</b>	<b>683</b>
<b>22.3 Unsaturated and Odd-Chain Fatty Acids Require Additional Steps for Degradation</b>	<b>652</b>	Ubiquitin tags proteins for destruction	683
An isomerase and a reductase are required for the oxidation of unsaturated fatty acids	652	The proteasome digests the ubiquitin-tagged proteins	685
Odd-chain fatty acids yield propionyl CoA in the final thiolysis step	654	The ubiquitin pathway and the proteasome have prokaryotic counterparts	686
Vitamin B <sub>12</sub> contains a corrin ring and a cobalt atom	654	Protein degradation can be used to regulate biological function	687
Mechanism: Methylmalonyl CoA mutase catalyzes a rearrangement to form succinyl CoA	655	<b>23.3 The First Step in Amino Acid Degradation Is the Removal of Nitrogen</b>	<b>687</b>
Fatty acids are also oxidized in peroxisomes	656	Alpha-amino groups are converted into ammonium ions by the oxidative deamination of glutamate	687
Ketone bodies are formed from acetyl CoA when fat breakdown predominates	657	Mechanism: Pyridoxal phosphate forms Schiff-base intermediates in aminotransferases	689
Ketone bodies are a major fuel in some tissues	658	Aspartate aminotransferase is an archetypal pyridoxal-dependent transaminase	690
Animals cannot convert fatty acids into glucose	660	Blood levels of aminotransferases serve a diagnostic function	691
Some fatty acids may contribute to the development of pathological conditions	661	Pyridoxal phosphate enzymes catalyze a wide array of reactions	691
<b>22.4 Fatty Acids Are Synthesized by Fatty Acid Synthase</b>	<b>661</b>	Serine and threonine can be directly deaminated	692
Fatty acids are synthesized and degraded by different pathways	661	Peripheral tissues transport nitrogen to the liver	692
The formation of malonyl CoA is the committed step in fatty acid synthesis	662	<b>23.4 Ammonium Ion Is Converted into Urea in Most Terrestrial Vertebrates</b>	<b>693</b>
Intermediates in fatty acid synthesis are attached to an acyl carrier protein	662	The urea cycle begins with the formation of carbamoyl phosphate	693
Fatty acid synthesis consists of a series of condensation, reduction, dehydration, and reduction reactions	662	Carbamoyl phosphate synthetase is the key regulatory enzyme for urea synthesis	694
Fatty acids are synthesized by a multifunctional enzyme complex in animals	664	Carbamoyl phosphate reacts with ornithine to begin the urea cycle	694
The synthesis of palmitate requires 8 molecules of acetyl CoA, 14 molecules of NADPH, and 7 molecules of ATP	666	The urea cycle is linked to gluconeogenesis	696
Citrate carries acetyl groups from mitochondria to the cytoplasm for fatty acid synthesis	666	Urea-cycle enzymes are evolutionarily related to enzymes in other metabolic pathways	696
Several sources supply NADPH for fatty acid synthesis	667	Inherited defects of the urea cycle cause hyperammonemia and can lead to brain damage	697
Fatty acid metabolism is altered in tumor cells	667	Urea is not the only means of disposing of excess nitrogen	698
<b>22.5 The Elongation and Unsaturation of Fatty Acids are Accomplished by Accessory Enzyme Systems</b>	<b>668</b>	<b>23.5 Carbon Atoms of Degraded Amino Acids Emerge as Major Metabolic Intermediates</b>	<b>698</b>
Membrane-bound enzymes generate unsaturated fatty acids	668	Pyruvate is an entry point into metabolism for a number of amino acids	699
Eicosanoid hormones are derived from polyunsaturated fatty acids	669	Oxaloacetate is an entry point into metabolism for aspartate and asparagine	700
Variations on a theme: Polyketide and nonribosomal peptide synthetases resemble fatty acid synthase	670	Alpha-ketoglutarate is an entry point into metabolism for five-carbon amino acids	700
<b>22.6 Acetyl CoA Carboxylase Plays a Key Role in Controlling Fatty Acid Metabolism</b>	<b>670</b>	Succinyl coenzyme A is a point of entry for several nonpolar amino acids	701
Acetyl CoA carboxylase is regulated by conditions in the cell	671	Methionine degradation requires the formation of a key methyl donor, S-adenosylmethionine	701
Acetyl CoA carboxylase is regulated by a variety of hormones	671	The branched-chain amino acids yield acetyl CoA, acetoacetate, or propionyl CoA	701
<b>CHAPTER 23 Protein Turnover and Amino Acid Catabolism</b>	<b>681</b>	Oxygenases are required for the degradation of aromatic amino acids	703
<b>23.1 Proteins are Degraded to Amino Acids</b>	<b>682</b>	<b>23.6 Inborn Errors of Metabolism Can Disrupt Amino Acid Degradation</b>	<b>705</b>
The digestion of dietary proteins begins in the stomach and is completed in the intestine	682	Phenylketonuria is one of the most common metabolic disorders	706
Cellular proteins are degraded at different rates	682	Determining the basis of the neurological symptoms of phenylketonuria is an active area of research	706

## Part III SYNTHESIZING THE MOLECULES OF LIFE

## CHAPTER 24 The Biosynthesis of Amino Acids 713

Amino acid synthesis requires solutions to three key biochemical problems 714

### 24.1 Nitrogen Fixation: Microorganisms Use ATP and a Powerful Reductant to Reduce Atmospheric Nitrogen to Ammonia 714

The iron–molybdenum cofactor of nitrogenase binds and reduces atmospheric nitrogen 715

Ammonium ion is assimilated into an amino acid through glutamate and glutamine 717

### 24.2 Amino Acids Are Made from Intermediates of the Citric Acid Cycle and Other Major Pathways 719

Human beings can synthesize some amino acids but must obtain others from their diet 719

Aspartate, alanine, and glutamate are formed by the addition of an amino group to an alpha-ketoacid 720

A common step determines the chirality of all amino acids 721

The formation of asparagine from aspartate requires an adenylated intermediate 721

Glutamate is the precursor of glutamine, proline, and arginine 722

3-Phosphoglycerate is the precursor of serine, cysteine, and glycine 722

Tetrahydrofolate carries activated one-carbon units at several oxidation levels 723

S-Adenosylmethionine is the major donor of methyl groups 724

Cysteine is synthesized from serine and homocysteine 726

High homocysteine levels correlate with vascular disease 726

Shikimate and chorismate are intermediates in the biosynthesis of aromatic amino acids 727

Tryptophan synthase illustrates substrate channeling in enzymatic catalysis 729

### 24.3 Feedback Inhibition Regulates Amino Acid Biosynthesis 730

Branched pathways require sophisticated regulation 731

The sensitivity of glutamine synthetase to allosteric regulation is altered by covalent modification 732

### 24.4 Amino Acids Are Precursors of Many Biomolecules 734

Glutathione, a gamma-glutamyl peptide, serves as a sulfhydryl buffer and an antioxidant 734

Nitric oxide, a short-lived signal molecule, is formed from arginine 735

Porphyryns are synthesized from glycine and succinyl coenzyme A 736

Porphyryns accumulate in some inherited disorders of porphyrin metabolism 737

## CHAPTER 25 Nucleotide Biosynthesis 743

Nucleotides can be synthesized by de novo or salvage pathways 744

### 25.1 The Pyrimidine Ring Is Assembled de Novo or Recovered by Salvage Pathways 744

Bicarbonate and other oxygenated carbon compounds are activated by phosphorylation 745

The side chain of glutamine can be hydrolyzed to generate ammonia 745

Intermediates can move between active sites by channeling 745

Orotate acquires a ribose ring from PRPP to form a pyrimidine nucleotide and is converted into uridylylate 746

Nucleotide mono-, di-, and triphosphates are interconvertible 747

CTP is formed by amination of UTP 747

Salvage pathways recycle pyrimidine bases 748

### 25.2 Purine Bases Can Be Synthesized de Novo or Recycled by Salvage Pathways 748

The purine ring system is assembled on ribose phosphate 749

The purine ring is assembled by successive steps of activation by phosphorylation followed by displacement 749

AMP and GMP are formed from IMP 751

Enzymes of the purine synthesis pathway associate with one another in vivo 752

Salvage pathways economize intracellular energy expenditure 752

### 25.3 Deoxyribonucleotides Are Synthesized by the Reduction of Ribonucleotides Through a Radical Mechanism 753

Mechanism: A tyrosyl radical is critical to the action of ribonucleotide reductase 753

Stable radicals other than tyrosyl radical are employed by other ribonucleotide reductases 755

Thymidylate is formed by the methylation of deoxyuridylylate 755

Dihydrofolate reductase catalyzes the regeneration of tetrahydrofolate, a one-carbon carrier 756

Several valuable anticancer drugs block the synthesis of thymidylate 757

### 25.4 Key Steps in Nucleotide Biosynthesis Are Regulated by Feedback Inhibition 758

Pyrimidine biosynthesis is regulated by aspartate transcarbamoylase 758

The synthesis of purine nucleotides is controlled by feedback inhibition at several sites 758

The synthesis of deoxyribonucleotides is controlled by the regulation of ribonucleotide reductase 759

### 25.5 Disruptions in Nucleotide Metabolism Can Cause Pathological Conditions 760

The loss of adenosine deaminase activity results in severe combined immunodeficiency 760

Gout is induced by high serum levels of urate 761

Lesch–Nyhan syndrome is a dramatic consequence of mutations in a salvage-pathway enzyme 761

Folic acid deficiency promotes birth defects such as spina bifida 762

**CHAPTER 26 The Biosynthesis of Membrane Lipids and Steroids 767****26.1 Phosphatidate Is a Common Intermediate in the Synthesis of Phospholipids and Triacylglycerols 768**

The synthesis of phospholipids requires an activated intermediate	769
Some phospholipids are synthesized from an activated alcohol	770
Phosphatidylcholine is an abundant phospholipid	770
Excess choline is implicated in the development of heart disease	771
Base-exchange reactions can generate phospholipids	771
Sphingolipids are synthesized from ceramide	772
Gangliosides are carbohydrate-rich sphingolipids that contain acidic sugars	772
Sphingolipids confer diversity on lipid structure and function	773
Respiratory distress syndrome and Tay–Sachs disease result from the disruption of lipid metabolism	774
Ceramide metabolism stimulates tumor growth	774
Phosphatidic acid phosphatase is a key regulatory enzyme in lipid metabolism	775

**26.2 Cholesterol Is Synthesized from Acetyl Coenzyme A in Three Stages 776**

The synthesis of mevalonate, which is activated as isopentenyl pyrophosphate, initiates the synthesis of cholesterol	776
Squalene (C <sub>30</sub> ) is synthesized from six molecules of isopentenyl pyrophosphate (C <sub>5</sub> )	777
Squalene cyclizes to form cholesterol	778

**26.3 The Complex Regulation of Cholesterol Biosynthesis Takes Place at Several Levels 779**

Lipoproteins transport cholesterol and triacylglycerols throughout the organism	782
Low-density lipoproteins play a central role in cholesterol metabolism	784
The absence of the LDL receptor leads to hypercholesterolemia and atherosclerosis	784
Mutations in the LDL receptor prevent LDL release and result in receptor destruction	785
Cycling of the LDL receptor is regulated	787
HDL appears to protect against atherosclerosis	787
The clinical management of cholesterol levels can be understood at a biochemical level	788

**26.4 Important Derivatives of Cholesterol Include Bile Salts and Steroid Hormones 788**

Letters identify the steroid rings and numbers identify the carbon atoms	790
Steroids are hydroxylated by cytochrome P450 monooxygenases that use NADPH and O <sub>2</sub>	790
The cytochrome P450 system is widespread and performs a protective function	791
Pregnenolone, a precursor of many other steroids, is formed from cholesterol by cleavage of its side chain	792

Pregesterone and corticosteroids are synthesized from pregnenolone	792
Androgens and estrogens are synthesized from pregnenolone	792
Vitamin D is derived from cholesterol by the ring-splitting activity of light	794

**CHAPTER 27 The Integration of Metabolism 801****27.1 Caloric Homeostasis Is a Means of Regulating Body Weight 802****27.2 The Brain Plays a Key Role in Caloric Homeostasis 804**

Signals from the gastrointestinal tract induce feelings of satiety	804
Leptin and insulin regulate long-term control over caloric homeostasis	805
Leptin is one of several hormones secreted by adipose tissue	806
Leptin resistance may be a contributing factor to obesity	806
DiETING is used to combat obesity	807

**27.3 Diabetes Is a Common Metabolic Disease Often Resulting from Obesity 807**

Insulin initiates a complex signal-transduction pathway in muscle	808
Metabolic syndrome often precedes type 2 diabetes	809
Excess fatty acids in muscle modify metabolism	810
Insulin resistance in muscle facilitates pancreatic failure	810
Metabolic derangements in type 1 diabetes result from insulin insufficiency and glucagon excess	812

**27.4 Exercise Beneficially Alters the Biochemistry of Cells 813**

Mitochondrial biogenesis is stimulated by muscular activity	813
Fuel choice during exercise is determined by the intensity and duration of activity	813

**27.5 Food Intake and Starvation Induce Metabolic Changes 816**

The starved–fed cycle is the physiological response to a fast	816
Metabolic adaptations in prolonged starvation minimize protein degradation	818

**27.6 Ethanol Alters Energy Metabolism in the Liver 819**

Ethanol metabolism leads to an excess of NADH	820
Excess ethanol consumption disrupts vitamin metabolism	821

**CHAPTER 28 DNA Replication, Repair, and Recombination 827****28.1 DNA Replication Proceeds by the Polymerization of Deoxyribonucleoside Triphosphates Along a Template 828**

DNA polymerases require a template and a primer	829	<b>CHAPTER 29 RNA Synthesis and Processing</b>	<b>859</b>
All DNA polymerases have structural features in common	829	RNA synthesis comprises three stages: Initiation, elongation, and termination	860
Two bound metal ions participate in the polymerase reaction	829	<b>29.1 RNA Polymerases Catalyze Transcription</b>	<b>861</b>
The specificity of replication is dictated by complementarity of shape between bases	830	RNA chains are formed de novo and grow in the 5'-to-3' direction	862
An RNA primer synthesized by primase enables DNA synthesis to begin	831	RNA polymerases backtrack and correct errors	863
One strand of DNA is made continuously, whereas the other strand is synthesized in fragments	831	RNA polymerase binds to promoter sites on the DNA template to initiate transcription	864
DNA ligase joins ends of DNA in duplex regions	832	Sigma subunits of RNA polymerase recognize promoter sites	865
The separation of DNA strands requires specific helicases and ATP hydrolysis	832	RNA polymerases must unwind the template double helix for transcription to take place	865
<b>28.2 DNA Unwinding and Supercoiling Are Controlled by Topoisomerases</b>	<b>833</b>	Elongation takes place at transcription bubbles that move along the DNA template	866
The linking number of DNA, a topological property, determines the degree of supercoiling	835	Sequences within the newly transcribed RNA signal termination	866
Topoisomerases prepare the double helix for unwinding	836	Some messenger RNAs directly sense metabolite concentrations	867
Type I topoisomerases relax supercoiled structures	836	The <i>rho</i> protein helps to terminate the transcription of some genes	868
Type II topoisomerases can introduce negative supercoils through coupling to ATP hydrolysis	837	Some antibiotics inhibit transcription	869
<b>28.3 DNA Replication Is Highly Coordinated</b>	<b>839</b>	Precursors of transfer and ribosomal RNA are cleaved and chemically modified after transcription in prokaryotes	870
DNA replication requires highly processive polymerases	839	<b>29.2 Transcription in Eukaryotes Is Highly Regulated</b>	<b>871</b>
The leading and lagging strands are synthesized in a coordinated fashion	840	Three types of RNA polymerase synthesize RNA in eukaryotic cells	872
DNA replication in <i>Escherichia coli</i> begins at a unique site	842	Three common elements can be found in the RNA polymerase II promoter region	874
DNA synthesis in eukaryotes is initiated at multiple sites	843	The TFIID protein complex initiates the assembly of the active transcription complex	874
Telomeres are unique structures at the ends of linear chromosomes	844	Multiple transcription factors interact with eukaryotic promoters	875
Telomeres are replicated by telomerase, a specialized polymerase that carries its own RNA template	845	Enhancer sequences can stimulate transcription at start sites thousands of bases away	876
<b>28.4 Many Types of DNA Damage Can Be Repaired</b>	<b>845</b>	<b>29.3 The Transcription Products of Eukaryotic Polymerases Are Processed</b>	<b>876</b>
Errors can arise in DNA replication	846	RNA polymerase I produces three ribosomal RNAs	877
Bases can be damaged by oxidizing agents, alkylating agents, and light	846	RNA polymerase III produces transfer RNA	877
DNA damage can be detected and repaired by a variety of systems	847	The product of RNA polymerase II, the pre-mRNA transcript, acquires a 5' cap and a 3' poly(A) tail	878
The presence of thymine instead of uracil in DNA permits the repair of deaminated cytosine	849	Small regulatory RNAs are cleaved from larger precursors	879
Some genetic diseases are caused by the expansion of repeats of three nucleotides	850	RNA editing changes the proteins encoded by mRNA	879
Many cancers are caused by the defective repair of DNA	850	Sequences at the ends of introns specify splice sites in mRNA precursors	880
Many potential carcinogens can be detected by their mutagenic action on bacteria	852	Splicing consists of two sequential transesterification reactions	881
<b>28.5 DNA Recombination Plays Important Roles in Replication, Repair, and Other Processes</b>	<b>852</b>	Small nuclear RNAs in spliceosomes catalyze the splicing of mRNA precursors	882
RecA can initiate recombination by promoting strand invasion	853	Transcription and processing of mRNA are coupled	883
Some recombination reactions proceed through Holliday-junction intermediates	854	Mutations that affect pre-mRNA splicing cause disease	884
		Most human pre-mRNAs can be spliced in alternative ways to yield different proteins	885
		<b>29.4 The Discovery of Catalytic RNA was Revealing in Regard to Both Mechanism and Evolution</b>	<b>886</b>

<b>CHAPTER 30 Protein Synthesis</b>	<b>893</b>		
<b>30.1 Protein Synthesis Requires the Translation of Nucleotide Sequences into Amino Acid Sequences</b>	<b>894</b>		
The synthesis of long proteins requires a low error frequency	894		
Transfer RNA molecules have a common design	895		
Some transfer RNA molecules recognize more than one codon because of wobble in base-pairing	897		
<b>30.2 Aminoacyl Transfer RNA Synthetases Read the Genetic Code</b>	<b>898</b>		
Amino acids are first activated by adenylation	898		
Aminoacyl-tRNA synthetases have highly discriminating amino acid activation sites	899		
Proofreading by aminoacyl-tRNA synthetases increases the fidelity of protein synthesis	900		
Synthetases recognize various features of transfer RNA molecules	901		
Aminoacyl-tRNA synthetases can be divided into two classes	901		
<b>30.3 The Ribosome Is the Site of Protein Synthesis</b>	<b>902</b>		
Ribosomal RNAs (5S, 16S, and 23S rRNA) play a central role in protein synthesis	903		
Ribosomes have three tRNA-binding sites that bridge the 30s and 50s subunits	905		
The start signal is usually AUG preceded by several bases that pair with 16S rRNA	905		
Bacterial protein synthesis is initiated by formylmethionyl transfer RNA	906		
Formylmethionyl-tRNA <sub>f</sub> is placed in the P site of the ribosome in the formation of the 70S initiation complex	907		
Elongation factors deliver aminoacyl-tRNA to the ribosome	907		
Peptidyl transferase catalyzes peptide-bond synthesis	908		
The formation of a peptide bond is followed by the GTP-driven translocation of tRNAs and mRNA	909		
Protein synthesis is terminated by release factors that read stop codons	910		
<b>30.4 Eukaryotic Protein Synthesis Differs from Bacterial Protein Synthesis Primarily in Translation Initiation</b>	<b>911</b>		
Mutations in initiation factor 2 cause a curious pathological condition	913		
<b>30.5 A Variety of Antibiotics and Toxins Can Inhibit Protein Synthesis</b>	<b>913</b>		
Some antibiotics inhibit protein synthesis	914		
Diphtheria toxin blocks protein synthesis in eukaryotes by inhibiting translocation	914		
Ricin fatally modifies 28S ribosomal RNA	915		
<b>30.6 Ribosomes Bound to the Endoplasmic Reticulum Manufacture Secretory and Membrane Proteins</b>	<b>915</b>		
Protein synthesis begins on ribosomes that are free in the cytoplasm	916		
Signal sequences mark proteins for translocation across the endoplasmic reticulum membrane	916		
		Transport vesicles carry cargo proteins to their final destination	918
<b>CHAPTER 31 The Control of Gene Expression in Prokaryotes</b>	<b>925</b>		
<b>31.1 Many DNA-Binding Proteins Recognize Specific DNA Sequences</b>	<b>926</b>		
The helix-turn-helix motif is common to many prokaryotic DNA-binding proteins	927		
<b>31.2 Prokaryotic DNA-Binding Proteins Bind Specifically to Regulatory Sites in Operons</b>	<b>927</b>		
An operon consists of regulatory elements and protein-encoding genes	928		
The <i>lac</i> repressor protein in the absence of lactose binds to the operator and blocks transcription	929		
Ligand binding can induce structural changes in regulatory proteins	930		
The operon is a common regulatory unit in prokaryotes	930		
Transcription can be stimulated by proteins that contact RNA polymerase	931		
<b>31.3 Regulatory Circuits Can Result in Switching Between Patterns of Gene Expression</b>	<b>932</b>		
The $\lambda$ repressor regulates its own expression	932		
A circuit based on the $\lambda$ repressor and Cro forms a genetic switch	933		
Many prokaryotic cells release chemical signals that regulate gene expression in other cells	933		
Biofilms are complex communities of prokaryotes	934		
<b>31.4 Gene Expression Can Be Controlled at Posttranscriptional Levels</b>	<b>935</b>		
Attenuation is a prokaryotic mechanism for regulating transcription through the modulation of nascent RNA secondary structure	935		
<b>CHAPTER 32 The Control of Gene Expression in Eukaryotes</b>	<b>941</b>		
<b>32.1 Eukaryotic DNA Is Organized into Chromatin</b>	<b>943</b>		
Nucleosomes are complexes of DNA and histones	943		
DNA wraps around histone octamers to form nucleosomes	943		
<b>32.2 Transcription Factors Bind DNA and Regulate Transcription Initiation</b>	<b>945</b>		
A range of DNA-binding structures are employed by eukaryotic DNA-binding proteins	945		
Activation domains interact with other proteins	946		
Multiple transcription factors interact with eukaryotic regulatory regions	946		
Enhancers can stimulate transcription in specific cell types	946		
Induced pluripotent stem cells can be generated by introducing four transcription factors into differentiated cells	947		
<b>32.3 The Control of Gene Expression Can Require Chromatin Remodeling</b>	<b>948</b>		

The methylation of DNA can alter patterns of gene expression	949	Mechanosensory channels have been identified in <i>Drosophila</i> and vertebrates	976
Steroids and related hydrophobic molecules pass through membranes and bind to DNA-binding receptors	949	<b>33.5 Touch Includes the Sensing of Pressure, Temperature, and Other Factors</b>	<b>977</b>
Nuclear hormone receptors regulate transcription by recruiting coactivators to the transcription complex	950	Studies of capsaicin reveal a receptor for sensing high temperatures and other painful stimuli	977
Steroid-hormone receptors are targets for drugs	951	<b>CHAPTER 34 The Immune System</b>	<b>981</b>
Chromatin structure is modulated through covalent modifications of histone tails	952	Innate immunity is an evolutionarily ancient defense system	982
Histone deacetylases contribute to transcriptional repression	953	The adaptive immune system responds by using the principles of evolution	984
<b>32.4 Eukaryotic Gene Expression Can Be Controlled at Posttranscriptional Levels</b>	<b>954</b>	<b>34.1 Antibodies Possess Distinct Antigen-Binding and Effector Units</b>	<b>985</b>
Genes associated with iron metabolism are translationally regulated in animals	954	<b>34.2 Antibodies Bind Specific Molecules Through Hypervariable Loops</b>	<b>988</b>
Small RNAs regulate the expression of many eukaryotic genes	956	The immunoglobulin fold consists of a beta-sandwich framework with hypervariable loops	988
<b>Part IV RESPONDING TO ENVIRONMENTAL CHANGES</b>		X-ray analyses have revealed how antibodies bind antigens	989
<b>CHAPTER 33 Sensory Systems</b>	<b>961</b>	Large antigens bind antibodies with numerous interactions	990
<b>33.1 A Wide Variety of Organic Compounds Are Detected by Olfaction</b>	<b>962</b>	<b>34.3 Diversity Is Generated by Gene Rearrangements</b>	<b>991</b>
Olfaction is mediated by an enormous family of seven-transmembrane-helix receptors	962	J (joining) genes and D (diversity) genes increase antibody diversity	991
Odorants are decoded by a combinatorial mechanism	964	More than $10^8$ antibodies can be formed by combinatorial association and somatic mutation	992
<b>33.2 Taste Is a Combination of Senses That Function by Different Mechanisms</b>	<b>966</b>	The oligomerization of antibodies expressed on the surfaces of immature B cells triggers antibody secretion	993
Sequencing of the human genome led to the discovery of a large family of 7TM bitter receptors	967	Different classes of antibodies are formed by the hopping of $V_H$ genes	994
A heterodimeric 7TM receptor responds to sweet compounds	968	<b>34.4 Major-Histocompatibility-Complex Proteins Present Peptide Antigens on Cell Surfaces for Recognition by T-Cell Receptors</b>	<b>995</b>
Umami, the taste of glutamate and aspartate, is mediated by a heterodimeric receptor related to the sweet receptor	969	Peptides presented by MHC proteins occupy a deep groove flanked by alpha helices	996
Salty tastes are detected primarily by the passage of sodium ions through channels	969	T-cell receptors are antibody-like proteins containing variable and constant regions	998
Sour tastes arise from the effects of hydrogen ions (acids) on channels	969	CD8 on cytotoxic T cells acts in concert with T-cell receptors	998
<b>33.3 Photoreceptor Molecules in the Eye Detect Visible Light</b>	<b>970</b>	Helper T cells stimulate cells that display foreign peptides bound to class II MHC proteins	1000
Rhodopsin, a specialized 7TM receptor, absorbs visible light	970	Helper T cells rely on the T-cell receptor and CD4 to recognize foreign peptides on antigen-presenting cells	1000
Light absorption induces a specific isomerization of bound 11- <i>cis</i> -retinal	971	MHC proteins are highly diverse	1002
Light-induced lowering of the calcium level coordinates recovery	972	Human immunodeficiency viruses subvert the immune system by destroying helper T cells	1003
Color vision is mediated by three cone receptors that are homologs of rhodopsin	973	<b>34.5 The Immune System Contributes to the Prevention and the Development of Human Diseases</b>	<b>1004</b>
Rearrangements in the genes for the green and red pigments lead to “color blindness”	974	T cells are subjected to positive and negative selection in the thymus	1004
<b>33.4 Hearing Depends on the Speedy Detection of Mechanical Stimuli</b>	<b>975</b>	Autoimmune diseases result from the generation of immune responses against self-antigens	1005
Hair cells use a connected bundle of stereocilia to detect tiny motions	975		

The immune system plays a role in cancer prevention	1005	Drugs must have suitable properties to reach their targets	1036
Vaccines are a powerful means to prevent and eradicate disease	1006	Toxicity can limit drug effectiveness	1040
<b>CHAPTER 35 Molecular Motors</b>	<b>1011</b>	<b>36.2 Drug Candidates Can Be Discovered by Serendipity, Screening, or Design</b>	<b>1041</b>
<b>35.1 Most Molecular-Motor Proteins Are Members of the P-Loop NTPase Superfamily</b>	<b>1012</b>	Serendipitous observations can drive drug development	1041
Molecular motors are generally oligomeric proteins with an ATPase core and an extended structure	1012	Natural products are a valuable source of drugs and drug leads	1043
ATP binding and hydrolysis induce changes in the conformation and binding affinity of motor proteins	1014	Screening libraries of synthetic compounds expands the opportunity for identification of drug leads	1044
<b>35.2 Myosins Move Along Actin Filaments</b>	<b>1016</b>	Drugs can be designed on the basis of three-dimensional structural information about their targets	1046

<b>36.1 The Development of Drugs Presents Huge Challenges</b>	<b>1034</b>		
Drug candidates must be potent and selective modulators of their targets	1035		

# Biochemistry: An Evolving Science

Chemistry in action. Human activities require energy. The interconversion of different forms of energy requires large biochemical machines comprising many thousands of atoms such as the complex shown above. Yet, the functions of these elaborate assemblies depend on simple chemical processes such as the protonation and deprotonation of the carboxylic acid groups shown on the right. The photograph is of Nobel Prize winners Peter Agre, M.D., and Carol Greider, Ph.D., who used, respectively, biochemical techniques to reveal key mechanisms of how water is transported into and out of cells, and how chromosomes are replicated faithfully. [Keith Weller for Johns Hopkins Medicine.]

**B**iochemistry is the study of the chemistry of life processes. Since the discovery that biological molecules such as urea could be synthesized from nonliving components in 1828, scientists have explored the chemistry of life with great intensity. Through these investigations, many of the most fundamental mysteries of how living things function at a biochemical level have now been solved. However, much remains to be investigated. As is often the case, each discovery raises at least as many new questions as it answers. Furthermore, we are now in an age of unprecedented opportunity for the application of our tremendous knowledge of biochemistry to problems in medicine, dentistry, agriculture, forensics, anthropology, environmental sciences, alternative energy, and many other fields. We begin our journey into biochemistry with one of the most startling discoveries of the past century: namely, the great unity of all living things at the biochemical level.

## OUTLINE

- 1.1 Biochemical Unity Underlies Biological Diversity
- 1.2 DNA Illustrates the Interplay Between Form and Function
- 1.3 Concepts from Chemistry Explain the Properties of Biological Molecules
- 1.4 The Genomic Revolution Is Transforming Biochemistry, Medicine, and Other Fields

### 1.1 Biochemical Unity Underlies Biological Diversity

The biological world is magnificently diverse. The animal kingdom is rich with species ranging from nearly microscopic insects to elephants and whales. The plant kingdom includes species as small and relatively

simple as algae and as large and complex as giant sequoias. This diversity extends further when we descend into the microscopic world. Organisms such as protozoa, yeast, and bacteria are present with great diversity in water, in soil, and on or within larger organisms. Some organisms can survive and even thrive in seemingly hostile environments such as hot springs and glaciers.

The development of the microscope revealed a key unifying feature that underlies this diversity. Large organisms are built up of *cells*, resembling, to some extent, single-celled microscopic organisms. The construction of animals, plants, and microorganisms from cells suggested that these diverse organisms might have more in common than is apparent from their outward appearance. With the development of biochemistry, this suggestion has been tremendously supported and expanded. At the biochemical level, all organisms have many common features (Figure 1.1).

As mentioned earlier, biochemistry is the study of the chemistry of life processes. These processes entail the interplay of two different classes of molecules: large molecules such as proteins and nucleic acids, referred to as *biological macromolecules*, and low-molecular-weight molecules such as glucose and glycerol, referred to as *metabolites*, that are chemically transformed in biological processes.

Members of both these classes of molecules are common, with minor variations, to all living things. For example, *deoxyribonucleic acid* (DNA) stores genetic information in all cellular organisms. *Proteins*, the macromolecules that are key participants in most biological processes, are built from the same set of 20 building blocks in all organisms. Furthermore, proteins that play similar roles in different organisms often have very similar three-dimensional structures (Figure 1.1).

*Sulfolobus archaea*

*Arabidopsis thaliana*

*Homo sapiens*

**FIGURE 1.1 Biological diversity and similarity.** The shape of a key molecule in gene regulation (the TATA-box-binding protein) is similar in three very different organisms that are separated from one another by billions of years of evolution. [(Left) Eye of Science/Science Source; (middle) Holt Studios/Photo Researchers; (right) Time Life Pictures/Getty Images.]

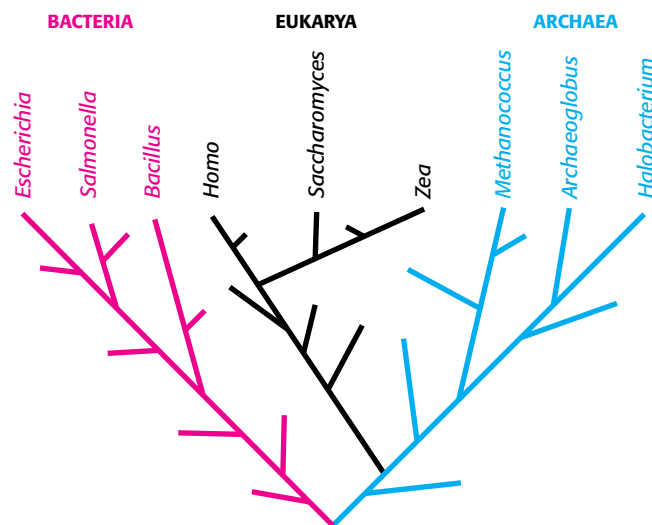

**FIGURE 1.2** A possible time line for biochemical evolution. Selected key events are indicated. Note that life on Earth began approximately 3.5 billion years ago, whereas human beings emerged quite recently.

Key metabolic processes also are common to many organisms. For example, the set of chemical transformations that converts glucose and oxygen into carbon dioxide and water is essentially identical in simple bacteria such as *Escherichia coli* (*E. coli*) and human beings. Even processes that appear to be quite distinct often have common features at the biochemical level. Remarkably, the biochemical processes by which plants capture light energy and convert it into more-useful forms are strikingly similar to steps used in animals to capture energy released from the breakdown of glucose.

These observations overwhelmingly suggest that all living things on Earth have a common ancestor and that modern organisms have evolved from this ancestor into their present forms. Geological and biochemical findings support a time line for this evolutionary path (Figure 1.2). On the basis of their biochemical characteristics, the diverse organisms of the modern world can be divided into three fundamental groups called *domains*: *Eukarya* (eukaryotes), *Bacteria*, and *Archaea*. Domain *Eukarya* comprises all multicellular organisms, including human beings as well as many microscopic unicellular organisms such as yeast. The defining characteristic of *eukaryotes* is the presence of a well-defined nucleus within each cell. Unicellular organisms such as bacteria, which lack a nucleus, are referred to as *prokaryotes*. The prokaryotes were reclassified as two separate domains in response to Carl Woese's discovery in 1977 that certain bacteria-like organisms are biochemically quite distinct from other previously characterized bacterial species. These organisms, now recognized as having diverged from bacteria early in evolution, are the *archaea*. Evolutionary paths from a common ancestor to modern organisms can be deduced on the basis of biochemical information. One such path is shown in Figure 1.3.

Much of this book will explore the chemical reactions and the associated biological macromolecules and metabolites that are found in biological processes common to all organisms. The unity of life at the biochemical level makes this approach possible. At the same time, different organisms have specific needs, depending on the particular biological niche in which they evolved and live. By comparing and contrasting details of particular biochemical pathways in different organisms, we can learn how biological challenges are solved at the biochemical level. In most cases, these challenges are addressed by the adaptation of existing macromolecules to new roles rather than by the evolution of entirely new ones.

Biochemistry has been greatly enriched by our ability to examine the three-dimensional structures of biological macromolecules in great detail. Some of these structures

**FIGURE 1.3** The tree of life. A possible evolutionary path from a common ancestor approximately 3.5 billion years ago at the bottom of the tree to organisms found in the modern world at the top.

are simple and elegant, whereas others are incredibly complicated. In any case, these structures provide an essential framework for understanding function. We begin our exploration of the interplay between structure and function with the genetic material, DNA.

## 1.2 DNA Illustrates the Interplay Between Form and Function

A fundamental biochemical feature common to all cellular organisms is the use of DNA for the storage of genetic information. The discovery that DNA plays this central role was first made in studies of bacteria in the 1940s. This discovery was followed by a compelling proposal for the three-dimensional structure of DNA in 1953, an event that set the stage for many of the advances in biochemistry and many other fields, extending to the present.

The structure of DNA powerfully illustrates a basic principle common to all biological macromolecules: the intimate relation between structure and function. The remarkable properties of this chemical substance allow it to function as a very efficient and robust vehicle for storing information. We start with an examination of the covalent structure of DNA and its extension into three dimensions.

### DNA is constructed from four building blocks

DNA is a *linear polymer* made up of four different types of monomers. It has a fixed backbone from which protrude variable substituents, referred to as bases (Figure 1.4). The backbone is built of repeating sugar–phosphate units. The sugars are molecules of *deoxyribose* from which DNA receives its name. Each sugar is connected to two phosphate groups through different linkages. Moreover, each sugar is oriented in the same way, and so each DNA strand has directionality, with one end distinguishable from the other. Joined to each deoxyribose is one of four possible bases: adenine (A), cytosine (C), guanine (G), and thymine (T).

These bases are connected to the sugar components in the DNA backbone through the bonds shown in black in Figure 1.4. All four bases are planar but differ significantly in other respects. Thus, each monomer of DNA consists of a sugar–phosphate unit and one of four bases attached to the sugar. These bases can be arranged in any order along a strand of DNA.

**FIGURE 1.4 Covalent structure of DNA.** Each unit of the polymeric structure is composed of a sugar (deoxyribose), a phosphate, and a variable base that protrudes from the sugar–phosphate backbone.

## Two single strands of DNA combine to form a double helix

Most DNA molecules consist of not one but two strands (Figure 1.5). In 1953, James Watson and Francis Crick deduced the arrangement of these strands and proposed a three-dimensional structure for DNA molecules. This structure is a *double helix* composed of two intertwined strands arranged such that the sugar–phosphate backbone lies on the outside and the bases on the inside. The key to this structure is that the bases form *specific base pairs* (bp) held together by *hydrogen bonds* (Section 1.3): adenine pairs with thymine (A–T) and guanine pairs with cytosine (G–C), as shown in Figure 1.6. Hydrogen bonds are much weaker than *covalent bonds* such as the carbon–carbon or carbon–nitrogen bonds that define the structures of the bases themselves. Such weak bonds are crucial to biochemical systems; they are weak enough to be reversibly broken in biochemical processes, yet they are strong enough, particularly when many form simultaneously, to help stabilize specific structures such as the double helix.

**FIGURE 1.5 The double helix.** The double-helical structure of DNA proposed by Watson and Crick. The sugar–phosphate backbones of the two chains are shown in red and blue, and the bases are shown in green, purple, orange, and yellow. The two strands are antiparallel, running in opposite directions with respect to the axis of the double helix, as indicated by the arrows.

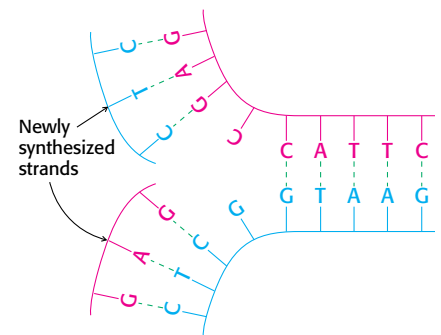

**FIGURE 1.6 Watson–Crick base pairs.** Adenine pairs with thymine (A–T), and guanine with cytosine (G–C). The dashed green lines represent hydrogen bonds.

## DNA structure explains heredity and the storage of information

The structure proposed by Watson and Crick has two properties of central importance to the role of DNA as the hereditary material. First, the structure is compatible with any sequence of bases. While the bases are distinct in structure, the base pairs have essentially the same shape (Figure 1.6) and thus fit equally well into the center of the double-helical structure of any sequence. Without any constraints, the sequence of bases along a DNA strand can act as an efficient means of storing information. Indeed, the sequence of bases along DNA strands is how genetic information is stored. The DNA sequence determines the sequences of the ribonucleic acid (RNA) and protein molecules that carry out most of the activities within cells.

Second, because of base-pairing, the sequence of bases along one strand completely determines the sequence along the other strand. As Watson and Crick so coyly wrote: “It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material.” Thus, if the DNA double helix is separated into two single strands, each strand can act as a template for the generation of its partner strand through specific base-pair formation (Figure 1.7). The three-dimensional structure of DNA beautifully illustrates the close connection between molecular form and function.

**FIGURE 1.7 DNA replication.** If a DNA molecule is separated into two strands, each strand can act as the template for the generation of its partner strand.

## 1.3 Concepts from Chemistry Explain the Properties of Biological Molecules

We have seen how a chemical insight into the hydrogen-bonding capabilities of the bases of DNA led to a deep understanding of a fundamental biological process. To lay the groundwork for the rest of the book, we begin our study of biochemistry by examining selected concepts from chemistry and showing how these concepts apply to biological systems. The concepts include the types of chemical bonds; the structure of water, the solvent in which most biochemical processes take place; the First and Second Laws of Thermodynamics; and the principles of acid–base chemistry.

### The formation of the DNA double helix as a key example

We will use these concepts to examine an archetypical biochemical process—namely, the formation of a DNA double helix from its two component strands. The process is but one of many examples that could have been chosen to illustrate these topics. Keep in mind that, although the specific discussion is about DNA and double-helix formation, the concepts considered are quite general and will apply to many other classes of molecules and processes that will be discussed in the remainder of the book. In the course of these discussions, we will touch on the properties of water and the concepts of  $pK_a$  and buffers that are of great importance to many aspects of biochemistry.

### The double helix can form from its component strands

The discovery that DNA from natural sources exists in a double-helical form with Watson–Crick base pairs suggested, but did not prove, that such double helices would form spontaneously outside biological systems. Suppose that two short strands of DNA were chemically synthesized to

**FIGURE 1.8 Formation of a double helix.** When two DNA strands with appropriate, complementary sequences are mixed, they spontaneously assemble to form a double helix.

have complementary sequences so that they could, in principle, form a double helix with Watson–Crick base pairs. Two such sequences are CGATTAAT and ATTAATCG. The structures of these molecules in solution can be examined by a variety of techniques. In isolation, each sequence exists almost exclusively as a single-stranded molecule. However, when the two sequences are mixed, a double helix with Watson–Crick base pairs does form (Figure 1.8). This reaction proceeds nearly to completion.

What forces cause the two strands of DNA to bind to each other? To analyze this binding reaction, we must consider several factors: the types of interactions and bonds in biochemical systems and the energetic favorability of the reaction. We must also consider the influence of the solution conditions—in particular, the consequences of acid–base reactions.

### Covalent and noncovalent bonds are important for the structure and stability of biological molecules

Atoms interact with one another through chemical bonds. These bonds include the covalent bonds that define the structure of molecules as well as a variety of noncovalent bonds that are of great importance to biochemistry.

**Covalent bonds.** The strongest bonds are covalent bonds, such as the bonds that hold the atoms together within the individual bases shown on page 4. A covalent bond is formed by the sharing of a pair of electrons between adjacent atoms. A typical carbon–carbon (C—C) covalent bond has

a bond length of 1.54 Å and bond energy of 355 kJ mol<sup>-1</sup> (85 kcal mol<sup>-1</sup>). Because covalent bonds are so strong, considerable energy must be expended to break them. More than one electron pair can be shared between two atoms to form a multiple covalent bond. For example, three of the bases in Figure 1.6 include carbon–oxygen (C=O) double bonds. These bonds are even stronger than C–C single bonds, with energies near 730 kJ mol<sup>-1</sup> (175 kcal mol<sup>-1</sup>) and are somewhat shorter.

For some molecules, more than one pattern of covalent bonding can be written. For example, adenine can be written in two nearly equivalent ways called *resonance structures*.

These adenine structures depict alternative arrangements of single and double bonds that are possible within the same structural framework. Resonance structures are shown connected by a double-headed arrow. Adenine's true structure is a composite of its two resonance structures. The composite structure is manifested in the bond lengths such as that for the bond joining carbon atoms C-4 and C-5. The observed bond length of 1.40 Å is between that expected for a C–C single bond (1.54 Å) and a C=C double bond (1.34 Å). A molecule that can be written as several resonance structures of approximately equal energies has greater stability than does a molecule without multiple resonance structures.

**Noncovalent bonds.** Noncovalent bonds are weaker than covalent bonds but are crucial for biochemical processes such as the formation of a double helix. Four fundamental noncovalent bond types are *ionic interactions*, *hydrogen bonds*, *van der Waals interactions*, and *hydrophobic interactions*. They differ in geometry, strength, and specificity. Furthermore, these bonds are affected in vastly different ways by the presence of water. Let us consider the characteristics of each type:

1. *Ionic Interactions.* A charged group on one molecule can attract an oppositely charged group on the same or another molecule. The energy of an ionic interaction (sometimes called an electrostatic interaction) is given by the *Coulomb energy*:

$$E = kq_1q_2/Dr$$

where  $E$  is the energy,  $q_1$  and  $q_2$  are the charges on the two atoms (in units of the electronic charge),  $r$  is the distance between the two atoms (in angstroms),  $D$  is the dielectric constant (which decreases the strength of the Coulomb depending on the intervening solvent or medium), and  $k$  is a proportionality constant ( $k = 1389$ , for energies in units of kilojoules per mole, or 332 for energies in kilocalories per mole).

By convention, an attractive interaction has a negative energy. The ionic interaction between two ions bearing single opposite charges separated by 3 Å in water (which has a dielectric constant of 80) has an energy of  $-5.8$  kJ mol<sup>-1</sup> ( $-1.4$  kcal mol<sup>-1</sup>). Note how important the dielectric constant of the medium is. For the same ions separated by 3 Å in a nonpolar solvent such as hexane (which has a dielectric constant of 2), the energy of this interaction is  $-232$  kJ mol<sup>-1</sup> ( $-55$  kcal mol<sup>-1</sup>).

#### Distance and energy units

Interatomic distances and bond lengths are usually measured in angstrom (Å) units:

$$1 \text{ \AA} = 10^{-10} \text{ m} = 10^{-8} \text{ cm} = 0.1 \text{ nm}$$

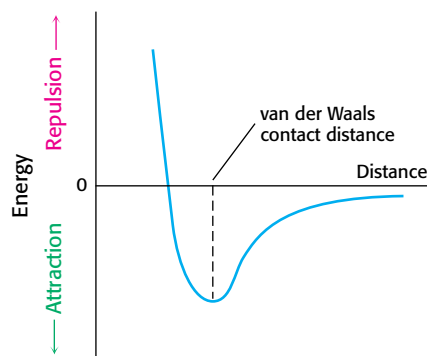

Several energy units are in common use. One joule (J) is the amount of energy required to move 1 meter against a force of 1 newton. A kilojoule (kJ) is 1000 joules. One calorie is the amount of energy required to raise the temperature of 1 gram of water 1 degree Celsius. A kilocalorie (kcal) is 1000 calories. One joule is equal to 0.239 cal.

**FIGURE 1.9 Hydrogen bonds.** Hydrogen bonds are depicted by dashed green lines. The positions of the partial charges ( $\delta^+$  and  $\delta^-$ ) are shown.

**FIGURE 1.10 Energy of a van der Waals interaction as two atoms approach each other.** The energy is most favorable at the van der Waals contact distance. Owing to electron–electron repulsion, the energy rises rapidly as the distance between the atoms becomes shorter than the contact distance.

2. *Hydrogen Bonds.* These interactions are largely ionic interactions, with partial charges on nearby atoms attracting one another. Hydrogen bonds are responsible for specific base-pair formation in the DNA double helix. The hydrogen atom in a hydrogen bond is partially shared by two electronegative atoms such as nitrogen or oxygen. The *hydrogen-bond donor* is the group that includes both the atom to which the hydrogen atom is more tightly linked and the hydrogen atom itself, whereas the *hydrogen-bond acceptor* is the atom less tightly linked to the hydrogen atom (Figure 1.9). The electronegative atom to which the hydrogen atom is covalently bonded pulls electron density away from the hydrogen atom, which thus develops a partial positive charge ( $\delta^+$ ). Thus, the hydrogen atom with a partial positive charge can interact with an atom having a partial negative charge ( $\delta^-$ ) through an ionic interaction.

Hydrogen bonds are much weaker than covalent bonds. They have energies ranging from 4 to 20 kJ mol<sup>-1</sup> (from 1 to 5 kcal mol<sup>-1</sup>). Hydrogen bonds are also somewhat longer than covalent bonds; their bond lengths (measured from the hydrogen atom) range from 1.5 Å to 2.6 Å; hence, a distance ranging from 2.4 Å to 3.5 Å separates the two nonhydrogen atoms in a hydrogen bond.

The strongest hydrogen bonds have a tendency to be approximately straight, such that the hydrogen-bond donor, the hydrogen atom, and the hydrogen-bond acceptor lie along a straight line. This tendency toward linearity can be important for orienting interacting molecules with respect to one another. Hydrogen-bonding interactions are responsible for many of the properties of water that make it such a special solvent, as will be described shortly.

3. *van der Waals Interactions.* The basis of a van der Waals interaction is that the distribution of electronic charge around an atom fluctuates with time. At any instant, the charge distribution is not perfectly symmetric. This transient asymmetry in the electronic charge about an atom acts through ionic interactions to induce a complementary asymmetry in the electron distribution within its neighboring atoms. The atom and its neighbors then attract one another. This attraction increases as two atoms come closer to each other, until they are separated by the van der Waals *contact distance* (Figure 1.10). At distances shorter than the van der Waals contact distance, very strong repulsive forces become dominant because the outer electron clouds of the two atoms overlap.

Energies associated with van der Waals interactions are quite small; typical interactions contribute from 2 to 4 kJ mol<sup>-1</sup> (from 0.5 to 1 kcal mol<sup>-1</sup>) per atom pair. When the surfaces of two large molecules come together, however, a large number of atoms are in van der Waals contact, and the net effect, summed over many atom pairs, can be substantial.

We will cover the fourth noncovalent interaction, the hydrophobic interaction, after we examine the characteristics of water; these characteristics are essential to understanding the hydrophobic interaction.

**Properties of water.** Water is the solvent in which most biochemical reactions take place, and its properties are essential to the formation of macromolecular structures and the progress of chemical reactions. Two properties of water are especially relevant:

1. *Water is a polar molecule.* The water molecule is bent, not linear, and so the distribution of charge is asymmetric. The oxygen nucleus draws electrons away from the two hydrogen nuclei, which leaves the region around

each hydrogen atom with a net positive charge. The water molecule is thus an electrically polar structure.

2. *Water is highly cohesive.* Water molecules interact strongly with one another through hydrogen bonds. These interactions are apparent in the structure of ice (Figure 1.11). Networks of hydrogen bonds hold the structure together; similar interactions link molecules in liquid water and account for many of the properties of water. In the liquid state, approximately one in four of the hydrogen bonds present in ice are broken. The polar nature of water is responsible for its high dielectric constant of 80. Molecules in aqueous solution interact with water molecules through the formation of hydrogen bonds and through ionic interactions. These interactions make water a versatile solvent, able to readily dissolve many species, especially polar and charged compounds that can participate in these interactions.

**The hydrophobic effect.** A final fundamental interaction called the *hydrophobic effect* is a manifestation of the properties of water. Some molecules (termed *nonpolar molecules*) cannot participate in hydrogen bonding or ionic interactions. The interactions of nonpolar molecules with water molecules are not as favorable as are interactions between the water molecules themselves. The water molecules in contact with these nonpolar molecules form “cages” around them, becoming more well ordered than water molecules free in solution. However, when two such nonpolar molecules come together, some of the water molecules are released, allowing them to interact freely with bulk water (Figure 1.12). The release of water from such cages is favorable for reasons to be considered shortly. The result is that nonpolar molecules show an increased tendency to associate with one another in water compared with other, less polar and less self-associating, solvents. This tendency is called the hydrophobic effect and the associated interactions are called *hydrophobic interactions*.

### The double helix is an expression of the rules of chemistry

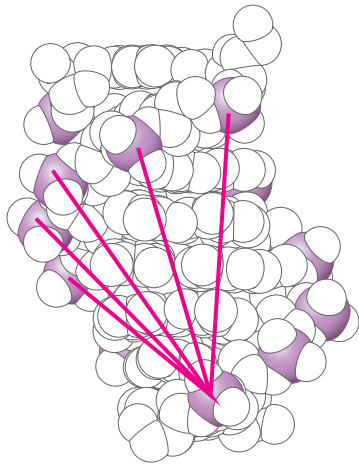

Let us now see how these four noncovalent interactions work together in driving the association of two strands of DNA to form a double helix. First, each phosphate group in a DNA strand carries a negative charge. These negatively charged groups interact unfavorably with one another over distances. Thus, unfavorable ionic interactions take place when two strands of

**FIGURE 1.11 Structure of ice.** Hydrogen bonds (shown as dashed green lines) are formed between water molecules to produce a highly ordered and open structure.

**FIGURE 1.12 The hydrophobic effect.** The aggregation of nonpolar groups in water leads to the release of water molecules, initially interacting with the nonpolar surface, into bulk water. The release of water molecules into solution makes the aggregation of nonpolar groups favorable.

**FIGURE 1.13 Ionic interactions in DNA.** Each unit within the double helix includes a phosphate group (the phosphorus atom being shown in purple) that bears a negative charge. The unfavorable interactions of one phosphate with several others are shown by red lines. These repulsive interactions oppose the formation of a double helix.

DNA come together. These phosphate groups are far apart in the double helix with distances greater than 10 Å, but many such interactions take place (Figure 1.13). Thus, ionic interactions oppose the formation of the double helix. The strength of these repulsive ionic interactions is diminished by the high dielectric constant of water and the presence of ionic species such as  $\text{Na}^+$  or  $\text{Mg}^{2+}$  ions in solution. These positively charged species interact with the phosphate groups and partly neutralize their negative charges.

Second, as already noted, hydrogen bonds are important in determining the formation of specific base pairs in the double helix. However, in single-stranded DNA, the hydrogen-bond donors and acceptors are exposed to solution and can form hydrogen bonds with water molecules.

When two single strands come together, these hydrogen bonds with water are broken and new hydrogen bonds between the bases are formed. Because the number of hydrogen bonds broken is the same as the number formed, these hydrogen bonds do not contribute substantially to driving the overall process of double-helix formation. However, they contribute greatly to the specificity of binding. Suppose two bases that cannot form Watson–Crick base pairs are brought together. Hydrogen bonds with water must be broken as the bases come into contact. Because the bases are not complementary in structure, not all of these bonds can be simultaneously replaced by hydrogen bonds between the bases. Thus, the formation of a double helix between noncomplementary sequences is disfavored.

Third, within a double helix, the base pairs are parallel and stacked nearly on top of one another. The typical separation between the planes of adjacent base pairs is 3.4 Å, and the distances between the most closely approaching atoms are approximately 3.6 Å. This separation distance corresponds nicely to the van der Waals contact distance (Figure 1.14). Bases tend to stack even in single-stranded DNA molecules. However, the base stacking and associated van der Waals interactions are nearly optimal in a double-helical structure.

Fourth, the hydrophobic effect also contributes to the favorability of base stacking. More-complete base stacking moves the nonpolar surfaces of the bases out of water into contact with each other.

The principles of double-helix formation between two strands of DNA apply to many other biochemical processes. Many weak interactions contribute to the overall energetics of the process, some favorably and some unfavorably. Furthermore, surface complementarity is a key feature: when complementary surfaces meet, hydrogen-bond donors align with hydrogen-bond acceptors and nonpolar surfaces come together to maximize van der Waals interactions and minimize nonpolar surface area exposed to the aqueous environment. The properties of water play a major role in determining the importance of these interactions.

**FIGURE 1.14 Base stacking.** In the DNA double helix, adjacent base pairs are stacked nearly on top of one another, and so many atoms in each base pair are separated by their van der Waals contact distance. The central base pair is shown in dark blue and the two adjacent base pairs in light blue. Several van der Waals contacts are shown in red.

### The laws of thermodynamics govern the behavior of biochemical systems

We can look at the formation of the double helix from a different perspective by examining the laws of thermodynamics. These laws are general

principles that apply to all physical (and biological) processes. They are of great importance because they determine the conditions under which specific processes can or cannot take place. We will consider these laws from a general perspective first and then apply the principles that we have developed to the formation of the double helix.

The laws of thermodynamics distinguish between a system and its surroundings. A *system* refers to the matter within a defined region of space. The matter in the rest of the universe is called the *surroundings*. *The First Law of Thermodynamics states that the total energy of a system and its surroundings is constant.* In other words, the energy content of the universe is constant; energy can be neither created nor destroyed. Energy can take different forms, however. Heat, for example, is one form of energy. Heat is a manifestation of the *kinetic energy* associated with the random motion of molecules. Alternatively, energy can be present as *potential energy*—energy that will be released on the occurrence of some process. Consider, for example, a ball held at the top of a tower. The ball has considerable potential energy because, when it is released, the ball will develop kinetic energy associated with its motion as it falls. Within chemical systems, potential energy is related to the likelihood that atoms can react with one another. For instance, a mixture of gasoline and oxygen has a large potential energy because these molecules may react to form carbon dioxide and water and release energy as heat. The First Law requires that any energy released in the formation of chemical bonds must be used to break other bonds, released as heat or light, or stored in some other form.

Another important thermodynamic concept is that of *entropy*, a measure of the degree of randomness or disorder in a system. *The Second Law of Thermodynamics states that the total entropy of a system plus that of its surroundings always increases.* For example, the release of water from nonpolar surfaces responsible for the hydrophobic effect is favorable because water molecules free in solution are more disordered than they are when they are associated with nonpolar surfaces. At first glance, the Second Law appears to contradict much common experience, particularly about biological systems. Many biological processes, such as the generation of a leaf from carbon dioxide gas and other nutrients, clearly increase the level of order and hence decrease entropy. Entropy may be decreased locally in the formation of such ordered structures only if the entropy of other parts of the universe is increased by an equal or greater amount. The local decrease in entropy is often accomplished by a release of heat, which increases the entropy of the surroundings.

We can analyze this process in quantitative terms. First, consider the system. The entropy ( $S$ ) of the system may change in the course of a chemical reaction by an amount  $\Delta S_{\text{system}}$ . If heat flows from the system to its surroundings, then the heat content, often referred to as the *enthalpy* ( $H$ ), of the system will be reduced by an amount  $\Delta H_{\text{system}}$ . To apply the Second Law, we must determine the change in entropy of the surroundings. If heat flows from the system to the surroundings, then the entropy of the surroundings will increase. The precise change in the entropy of the surroundings depends on the temperature; the change in entropy is greater when heat is added to relatively cold surroundings than when heat is added to surroundings at high temperatures that are already in a high degree of disorder. To be even more specific, the change in the entropy of the surroundings will be proportional to the amount of heat transferred from the system and inversely proportional to the temperature ( $T$ ) of the surroundings. In biological systems,  $T$  [in kelvins (K), absolute temperature] is

usually assumed to be constant. Thus, a change in the entropy of the surroundings is given by

$$\Delta S_{\text{surroundings}} = -\Delta H_{\text{system}}/T \quad (1)$$

The total entropy change is given by the expression

$$\Delta S_{\text{total}} = \Delta S_{\text{system}} + \Delta S_{\text{surroundings}} \quad (2)$$

Substituting equation 1 into equation 2 yields

$$\Delta S_{\text{total}} = \Delta S_{\text{system}} - \Delta H_{\text{system}}/T \quad (3)$$

Multiplying by  $-T$  gives

$$-T\Delta S_{\text{total}} = \Delta H_{\text{system}} - T\Delta S_{\text{system}} \quad (4)$$

The function  $-T\Delta S$  has units of energy and is referred to as *free energy* or *Gibbs free energy*, after Josiah Willard Gibbs, who developed this function in 1878:

$$\Delta G = \Delta H_{\text{system}} - T\Delta S_{\text{system}} \quad (5)$$

The free-energy change,  $\Delta G$ , will be used throughout this book to describe the energetics of biochemical reactions. The Gibbs free energy is essentially an accounting tool that keeps track of both the entropy of the system (directly) and the entropy of the surroundings (in the form of heat released from the system).

Recall that the Second Law of Thermodynamics states that, for a process to take place, the entropy of the universe must increase. Examination of equation 3 shows that the total entropy will increase if and only if

$$\Delta S_{\text{system}} > \Delta H_{\text{system}}/T \quad (6)$$

Rearranging gives  $T\Delta S_{\text{system}} > \Delta H$  or, in other words, entropy will increase if and only if

$$\Delta G = \Delta H_{\text{system}} - T\Delta S_{\text{system}} < 0 \quad (7)$$

Thus, the free-energy change must be negative for a process to take place spontaneously. *There is negative free-energy change when and only when the overall entropy of the universe is increased.* Again, the free energy represents a single term that takes into account both the entropy of the system and the entropy of the surroundings.

### Heat is released in the formation of the double helix

Let us see how the principles of thermodynamics apply to the formation of the double helix (Figure 1.15). Suppose solutions containing each of the two single strands are mixed. Before the double helix forms, each of the single strands is free to translate and rotate in solution, whereas each matched pair of strands in the double helix must move together. Furthermore, the free single strands exist in more conformations than possible when bound together in a double helix. Thus, the formation of a double helix from two single strands appears to result in an increase in order for the system, that is, a decrease in the entropy of the system.

On the basis of this analysis, we expect that the double helix cannot form without violating the Second Law of Thermodynamics unless heat is released to increase the entropy of the surroundings. Experimentally, we can measure the heat released by allowing the solutions containing the two single strands to come together within a water bath, which here corresponds to the surroundings. We then determine how much heat must be absorbed by the water bath or released from it to maintain it at a constant temperature. This experiment

reveals that a substantial amount of heat is released—namely, approximately  $250 \text{ kJ mol}^{-1}$  ( $60 \text{ kcal mol}^{-1}$ ). This experimental result reveals that the change in enthalpy for the process is quite large,  $-250 \text{ kJ mol}^{-1}$ , consistent with our expectation that significant heat would have to be released to the surroundings for the process not to violate the Second Law. We see in quantitative terms how order within a system can be increased by releasing sufficient heat to the surroundings to ensure that the entropy of the universe increases. We will encounter this general theme again and again throughout this book.

### Acid–base reactions are central in many biochemical processes

Throughout our consideration of the formation of the double helix, we have dealt only with the noncovalent bonds that are formed or broken in this process. Many biochemical processes entail the formation and cleavage of covalent bonds. A particularly important class of reactions prominent in biochemistry is *acid–base reactions*.

In acid and base reactions, hydrogen ions are added to molecules or removed from them. Throughout the book, we will encounter many processes in which the addition or removal of hydrogen atoms is crucial, such as the metabolic processes by which carbohydrates are degraded to release energy for other uses. Thus, a thorough understanding of the basic principles of these reactions is essential.

A hydrogen ion, often written as  $\text{H}^+$ , corresponds to a proton. In fact, hydrogen ions exist in solution bound to water molecules, thus forming what are known as *hydronium ions*,  $\text{H}_3\text{O}^+$ . For simplicity, we will continue to write  $\text{H}^+$ , but we should keep in mind that  $\text{H}^+$  is shorthand for the actual species present.

The concentration of hydrogen ions in solution is expressed as the pH. Specifically, the *pH* of a solution is defined as

$$\text{pH} = -\log[\text{H}^+]$$

where  $[\text{H}^+]$  is in units of molarity. Thus, pH 7.0 refers to a solution for which  $-\log[\text{H}^+] = 7.0$ , and so  $\log[\text{H}^+] = -7.0$  and  $[\text{H}^+] = 10^{\log[\text{H}^+]} = 10^{-7.0} = 1.0 \times 10^{-7} \text{ M}$ .

The pH also indirectly expresses the concentration of hydroxide ions,  $[\text{OH}^-]$ , in solution. To see how, we must realize that water molecules can dissociate to form  $\text{H}^+$  and  $\text{OH}^-$  ions in an equilibrium process.

The equilibrium constant ( $K$ ) for the dissociation of water is defined as

$$K = [\text{H}^+][\text{OH}^-]/[\text{H}_2\text{O}]$$

**FIGURE 1.15 Double-helix formation and entropy.** When solutions containing DNA strands with complementary sequences are mixed, the strands react to form double helices. This process results in a loss of entropy from the system, indicating that heat must be released to the surroundings to prevent a violation of the Second Law of Thermodynamics.

and has a value of  $K = 1.8 \times 10^{-16}$ . Note that an equilibrium constant does not formally have units. Nonetheless, the value of the equilibrium constant given assumes that particular units are used for concentration (sometimes referred to a standard states); in this case and in many others, units of molarity (M) are assumed.

The concentration of water,  $[\text{H}_2\text{O}]$ , in pure water is 55.5 M, and this concentration is constant under most conditions. Thus, we can define a new constant,  $K_{\text{W}}$ :

$$K_{\text{W}} = K[\text{H}_2\text{O}] = [\text{H}^+][\text{OH}^-]$$

$$\begin{aligned} K[\text{H}_2\text{O}] &= 1.8 \times 10^{-16} \times 55.5 \\ &= 1.0 \times 10^{-14} \end{aligned}$$

Because  $K_{\text{W}} = [\text{H}^+][\text{OH}^-] = 1.0 \times 10^{-14}$ , we can calculate

$$[\text{OH}^-] = 10^{-14}/[\text{H}^+] \text{ and } [\text{H}^+] = 10^{-14}/[\text{OH}^-]$$

With these relations in hand, we can easily calculate the concentration of hydroxide ions in an aqueous solution, given the pH. For example, at pH = 7.0, we know that  $[\text{H}^+] = 10^{-7}$  M and so  $[\text{OH}^-] = 10^{-14}/10^{-7} = 10^{-7}$  M. In acidic solutions, the concentration of hydrogen ions is higher than  $10^{-7}$  and, hence, the pH is below 7. For example, in 0.1 M HCl,  $[\text{H}^+] = 10^{-1}$  M and so pH = 1.0 and  $[\text{OH}^-] = 10^{-14}/10^{-1} = 10^{-13}$  M.

**FIGURE 1.16 DNA denaturation by the addition of a base.** The addition of a base to a solution of double-helical DNA initially at pH 7 causes the double helix to separate into single strands. The process is half complete at slightly above pH 9.

### Acid–base reactions can disrupt the double helix

The reaction that we have been considering between two strands of DNA to form a double helix takes place readily at pH 7.0. Suppose that we take the solution containing the double-helical DNA and treat it with a solution of concentrated base (i.e., with a high concentration of  $\text{OH}^-$ ). As the base is added, we monitor the pH and the fraction of DNA in double-helical form (Figure 1.16). When the first additions of base are made, the pH rises, but the concentration of the double-helical DNA does not change significantly. However, as the pH approaches 9, the DNA double helix begins to dissociate into its component single strands. As the pH continues to rise from 9 to 10, this dissociation becomes essentially complete. Why do the two strands dissociate? The hydroxide ions can react with bases in DNA base pairs to remove certain protons. The most susceptible proton is the one bound to the N-1 nitrogen atom in a guanine base.

Proton dissociation for a substance HA (such as that bound to N-1 on guanine) has an equilibrium constant defined by the expression

$$K_{\text{a}} = [\text{H}^+][\text{A}^-]/[\text{HA}]$$

The susceptibility of a proton to removal by reaction with a base is often described by its  $pK_{\text{a}}$  value:

$$pK_{\text{a}} = -\log(K_{\text{a}})$$

When the pH is equal to the  $pK_a$ , we have

$$pH = pK_a$$

and so

$$-\log[H^+] = -\log([H^+][A^-]/[HA])$$

and

$$[H^+] = [H^+][A^-]/[HA]$$

Dividing by  $[H^+]$  reveals that

$$1 = [A^-]/[HA]$$

and so

$$[A^-] = [HA]$$

Thus, when the pH equals the  $pK_a$ , the concentration of the deprotonated form of the group or molecule is equal to the concentration of the protonated form; the deprotonation process is halfway to completion.

The  $pK_a$  for the proton on N-1 of guanine is typically 9.7. When the pH approaches this value, the proton on N-1 is lost (Figure 1.16). Because this proton participates in an important hydrogen bond, its loss substantially destabilizes the DNA double helix. The DNA double helix is also destabilized by *low* pH. Below pH 5, some of the hydrogen bond *acceptors* that participate in base-pairing become protonated. In their protonated forms, these bases can no longer form hydrogen bonds and the double helix separates. Thus, acid–base reactions that remove or donate protons at specific positions on the DNA bases can disrupt the double helix.

### Buffers regulate pH in organisms and in the laboratory

These observations about DNA reveal that a significant change in pH can disrupt molecular structure. The same is true for many other biological macromolecules; changes in pH can protonate or deprotonate key groups, potentially disrupting structures and initiating harmful reactions. Thus, systems have evolved to mitigate changes in pH in biological systems. Solutions that resist such changes are called *buffers*. Specifically, when acid is added to an unbuffered aqueous solution, the pH drops in proportion to the amount of acid added. In contrast, when acid is added to a buffered solution, the pH drops more gradually. Buffers also mitigate the pH increase caused by the addition of base and changes in pH caused by dilution.

Compare the result of adding a 1 M solution of the strong acid HCl drop by drop to pure water with adding it to a solution containing 100 mM of the buffer sodium acetate ( $Na^+CH_3COO^-$ ; Figure 1.17). The process of gradually adding known amounts of reagent to a solution with which the reagent reacts while monitoring the results is called a *titration*. For pure water, the pH drops from 7 to close to 2 on the addition of the first few drops of acid. However, for the sodium acetate solution, the pH first falls rapidly from its initial value near 10, then changes more gradually until the pH reaches 3.5, and then falls more rapidly again. Why does the pH decrease so gradually in the middle of the titration? The answer is that, when hydrogen ions are added to this solution, they react with acetate ions to form acetic acid. This reaction consumes some of the added hydrogen ions so that the pH does not drop. Hydrogen ions continue reacting with acetate ions until essentially all of the acetate ion is converted into acetic acid. After this point, added protons remain free in solution and the pH begins to fall sharply again.

**FIGURE 1.17 Buffer action.** The addition of a strong acid, 1 M HCl, to pure water results in an immediate drop in pH to near 2. In contrast, the addition of the acid to a 0.1 M sodium acetate ( $Na^+CH_3COO^-$ ) solution results in a much more gradual change in pH until the pH drops below 3.5.

**FIGURE 1.18 Buffer protonation.** When acid is added to sodium acetate, the added hydrogen ions are used to convert acetate ion into acetic acid. Because the proton concentration does not increase significantly, the pH remains relatively constant until all of the acetate has been converted into acetic acid.

We can analyze the effect of the buffer in quantitative terms. The equilibrium constant for the deprotonation of an acid is

$$K_a = [\text{H}^+][\text{A}^-]/[\text{HA}]$$

Taking logarithms of both sides yields

$$\log(K_a) = \log([\text{H}^+]) + \log([\text{A}^-]/[\text{HA}])$$

Recalling the definitions of  $\text{p}K_a$  and  $\text{pH}$  and rearranging gives

$$\text{pH} = \text{p}K_a + \log([\text{A}^-]/[\text{HA}])$$

This expression is referred to as the *Henderson–Hasselbalch equation*.

We can apply the equation to our titration of sodium acetate. The  $\text{p}K_a$  of acetic acid is 4.75. We can calculate the ratio of the concentration of acetate ion to the concentration of acetic acid as a function of  $\text{pH}$  by using the Henderson–Hasselbalch equation, slightly rearranged.

$$[\text{Acetate ion}]/[\text{Acetic acid}] = [\text{A}^-]/[\text{HA}] = 10^{\text{pH} - \text{p}K_a}$$

At  $\text{pH}$  9, this ratio is  $10^{9-4.75} = 10^{4.25} = 17,800$ ; very little acetic acid has been formed. At  $\text{pH}$  4.75 (when the  $\text{pH}$  equals the  $\text{p}K_a$ ), the ratio is  $10^{4.75-4.75} = 10^0 = 1$ . At  $\text{pH}$  3, the ratio is  $10^{3-4.75} = 10^{-1.75} = 0.02$ ; almost all of the acetate ion has been converted into acetic acid. We can follow the conversion of acetate ion into acetic acid over the entire titration (Figure 1.18). The graph shows that the region of relatively constant  $\text{pH}$  corresponds precisely to the region in which acetate ion is being protonated to form acetic acid.

From this discussion, we see that a buffer functions best close to the  $\text{p}K_a$  value of its acid component. Physiological  $\text{pH}$  is typically about 7.4. An important buffer in biological systems is based on phosphoric acid ( $\text{H}_3\text{PO}_4$ ). The acid can be deprotonated in three steps to form a phosphate ion.

At about  $\text{pH}$  7.4, inorganic phosphate exists primarily as a nearly equal mixture of  $\text{H}_2\text{PO}_4^-$  and  $\text{HPO}_4^{2-}$ . Thus, phosphate solutions function as effective buffers near  $\text{pH}$  7.4. The concentration of inorganic phosphate in blood is typically approximately 1 mM, providing a useful buffer against processes that produce either acid or base. We can examine this utility in quantitative terms with the use of the Henderson–Hasselbalch equation. What concentration of acid must be added to change the  $\text{pH}$  of 1 mM phosphate buffer from 7.4 to 7.3? Without buffer, this change in  $[\text{H}^+]$  corresponds to a change of  $10^{-7.3} - 10^{-7.4} \text{ M} = (5.0 \times 10^{-8} - 4.0 \times 10^{-8}) \text{ M} = 1.0 \times 10^{-8} \text{ M}$ . Let us now consider what happens to the buffer components. At  $\text{pH}$  7.4,

$$[\text{HPO}_4^{2-}]/[\text{H}_2\text{PO}_4^-] = 10^{7.4-7.21} = 10^{0.19} = 1.55$$

The total concentration of phosphate,  $[\text{HPO}_4^{2-}] + [\text{H}_2\text{PO}_4^-]$ , is 1 mM. Thus,

$$[\text{HPO}_4^{2-}] = (1.55/2.55) \times 1 \text{ mM} = 0.608 \text{ mM}$$

and

$$[\text{H}_2\text{PO}_4^-] = (1/2.55) \times 1 \text{ mM} = 0.392 \text{ mM}$$

At pH 7.3,

$$[\text{HPO}_4^{2-}]/[\text{H}_2\text{PO}_4^-] = 10^{7.3-7.21} = 10^{0.09} = 1.23$$

and so

$$[\text{HPO}_4^{2-}] = (1.23/2.23) = 0.552 \text{ mM}$$

and

$$[\text{H}_2\text{PO}_4^-] = (1/2.23) = 0.448 \text{ mM}$$

Thus,  $(0.608 - 0.552) = 0.056 \text{ mM HPO}_4^{2-}$  is converted into  $\text{H}_2\text{PO}_4^-$ , consuming  $0.056 \text{ mM} = 5.6 \times 10^{-5} \text{ M [H}^+]$ . Thus, the buffer increases the amount of acid required to produce a drop in pH from 7.4 to 7.3 by a factor of  $5.6 \times 10^{-5}/1.0 \times 10^{-8} = 5600$  compared with pure water.

## 1.4 The Genomic Revolution Is Transforming Biochemistry, Medicine, and Other Fields

Watson and Crick's discovery of the structure of DNA suggested the hypothesis that hereditary information is stored as a sequence of bases along long strands of DNA. This remarkable insight provided an entirely new way of thinking about biology. However, at the time that it was made, Watson and Crick's discovery, though full of potential, remained to be confirmed and many features needed to be elucidated. How is the sequence information read and translated into action? What are the sequences of naturally occurring DNA molecules and how can such sequences be experimentally determined? Through advances in biochemistry and related sciences, we now have essentially complete answers to these questions. Indeed, in the past decade or so, scientists have determined the complete genome sequences of hundreds of different organisms, including simple microorganisms, plants, animals of varying degrees of complexity, and human beings. Comparisons of these genome sequences, with the use of methods introduced in Chapter 6, have been sources of many insights that have transformed biochemistry. In addition to its experimental and clinical aspects, biochemistry has now become an *information science*.

### Genome sequencing has transformed biochemistry and other fields

The sequencing of a human genome was a daunting task because it contains approximately 3 billion ( $3 \times 10^9$ ) base pairs. For example, the sequence

```
ACATTTGCTTCTGACACAACCTGTGTTCCTACTAGCAACCTC
AAACAGACACCATGGTGCATCTGACTCCTGAGGAGAAGT
CTGCCGTTACTGCCCTGTGGGGCAAGGTGAACGTGGA...
```

is a part of one of the genes that encodes hemoglobin, the oxygen carrier in our blood. This gene is found on the end of chromosome 9 of our 24 distinct chromosomes. If we were to include the complete sequence of our entire genome, this chapter would run to more than 500,000 pages. The sequencing of our genome is truly a landmark in human history. This sequence contains a vast amount of information, some of which we can now extract and interpret, but much of which we are only beginning to understand. For example, some human diseases have been linked to particular variations in genomic sequence. Sickle-cell anemia, discussed in detail in Chapter 7, is caused by a single base change of an A (noted in boldface type in the

**FIGURE 1.19 Decreasing costs of DNA sequencing.** Through the Human Genome Project, the cost of DNA sequencing dropped steadily. With the advent of new methods, these costs dropped dramatically and are now approaching \$1000 for a complete human genome sequence. [National Human Genome Research Institute. [www.genome.gov/sequencingcosts](http://www.genome.gov/sequencingcosts)]

preceding sequence) to a T. We will encounter many other examples of diseases that have been linked to specific DNA sequence changes.

Determining the first human genome sequences was a great challenge. It required the efforts of large teams of geneticists, molecular biologists, biochemists, and computer scientists, as well as billions of dollars, because there was no previous framework for aligning the sequences of various DNA fragments. One human genome sequence can serve as a reference for other sequences. The availability of such reference sequences enables much more rapid characterization of partial or complete genomes from other individuals. As we will discuss in Chapter 5, arrays containing millions of target single-stranded DNA molecules with sequences from the reference genome and known or potential variants are powerful tools. These arrays can be exposed to mixtures of DNA fragments for a particular individual and those single-stranded targets that bind to their complementary strands can be determined. This allows many positions within the genome of the individual to be simultaneously interrogated.

Methods for sequencing DNA have also been improving rapidly, driven by a deep understanding of the biochemistry of DNA replication and other processes. This has resulted in both dramatic increases in the DNA sequencing rate and decreases in cost (Figure 1.19). The availability of such powerful sequencing technology is transforming many fields, including medicine, dentistry, microbiology, pharmacology, and ecology, although a great deal remains to be done to improve the accuracy and precision of the interpretation of these large genomic and related data sets.

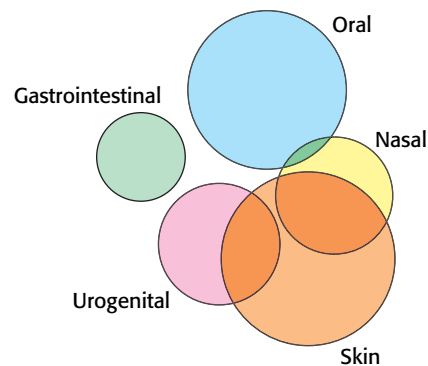

Each person has a unique sequence of DNA base pairs. How different are we from one another at the genomic level? Examination of genomic variation reveals that, on average, each pair of individuals has a different base in one position per 200 bases; that is, the difference is approximately 0.5%. This variation between individuals who are not closely related is quite substantial compared with differences in populations. The average difference between two people within one ethnic group is greater than the difference between the averages of two different ethnic groups.

The significance of much of this genetic variation is not understood. As noted earlier, variation in a single base within the genome can lead to a disease such as sickle-cell anemia. Scientists have now identified the genetic variations associated with hundreds of diseases for which the cause can be traced to a single gene. For other diseases and traits, we know that variation in many different genes contributes in significant and often complex ways. Many of the most prevalent human ailments such as heart disease are linked to variations in many genes. Furthermore, in most cases, the presence of a particular variation or set of variations does not inevitably result in the onset of a disease but, instead, leads to a *predisposition* to the development of the disease.

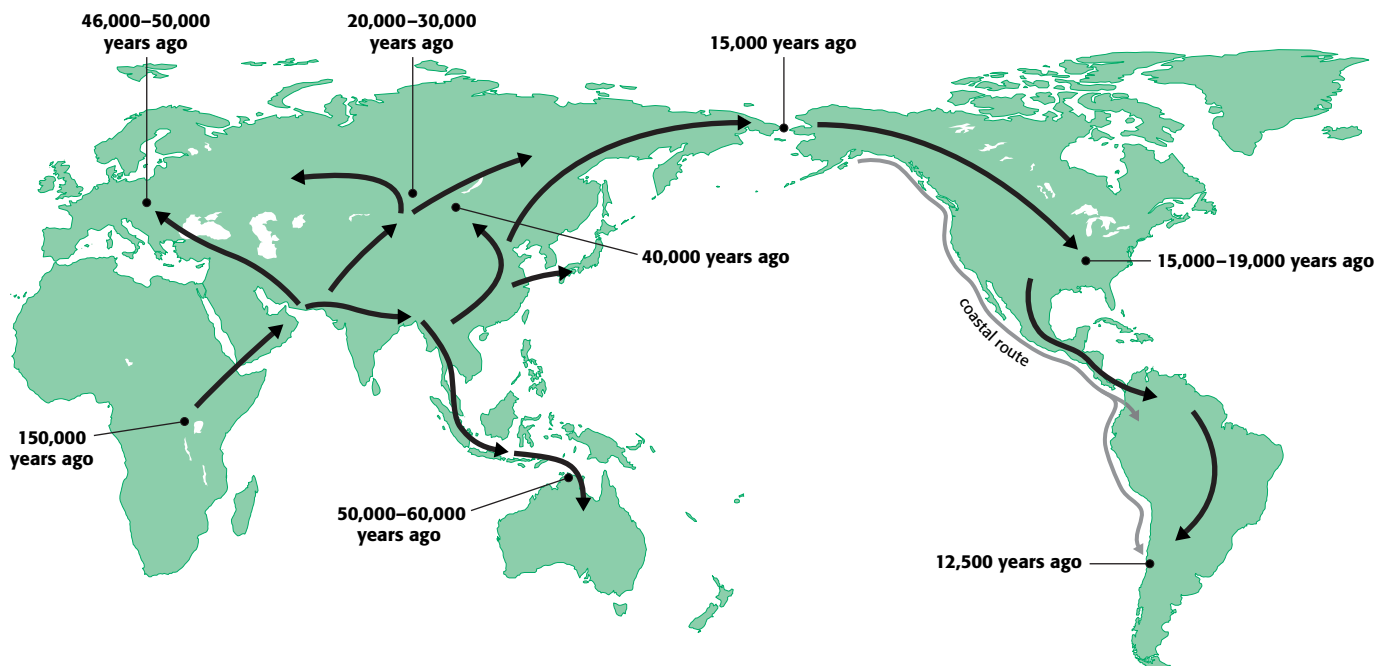

Our own genes are not the only ones that can contribute to health and disease. Our bodies, including our skin, mouth, digestive tract, genitourinary tract, respiratory tract, and other areas, contain large number of microorganisms. These complex communities have been characterized through powerful methods that allow DNA isolated from these biological samples to be sequenced without any previous knowledge of the

organisms present. Many of these organisms had not previously been discovered because they can only grow as part of complex communities and thus cannot be isolated through standard microbiological techniques. Remarkably, it appears that we are outnumbered in our own bodies! Each of us contains approximately ten times more microbial cells than human cells and these microbial cells include many more genes than do our own genomes. These *microbiomes* differ from site to site, from one person to another and over time in the same individual. They appear to play roles in health and in diseases such as obesity and dental caries (Figure 1.20).

In addition to the implications for understanding human health and disease, the genome sequence is a source of deep insight into other aspects of human biology and culture. For example, by comparing the sequences of different individuals and populations, we can learn a great deal about human history. On the basis of such analysis, a compelling case can be made that the human species originated in Africa, and the occurrence and even the timing of important migrations of groups of human beings can be demonstrated (Figure 1.21). Finally, comparisons of the human genome with the genomes of other organisms are confirming the tremendous unity that exists at the level of biochemistry and are revealing key steps in the course of evolution from relatively simple, single-celled organisms to complex, multicellular organisms such as human beings. For example, many genes that are key to the function of the human brain and nervous system have evolutionary and functional relatives in the genomes of bacteria. Because many studies that are possible in model organisms are difficult or unethical to conduct in human beings, these discoveries have many practical implications. *Comparative genomics* has become a powerful science, linking evolution and biochemistry.

**FIGURE 1.20 The human microbiome.** Microorganisms cover the human body. Examination of the microbial communities using DNA sequencing methods revealed many previously uncharacterized species. The Venn diagrams represent populations of related species as determined by DNA sequence comparisons. The populations present on different body surfaces are largely distinct. [Adapted from [www.nature.com/nature/journal/v486/n7402/fig\\_tab/nature11234\\_F1.html](http://www.nature.com/nature/journal/v486/n7402/fig_tab/nature11234_F1.html)]

**FIGURE 1.21 Human migrations supported by DNA sequence comparisons.** Modern human beings originated in Africa, migrated first to Asia, and then to Europe, Australia, and North and South America. [Adapted from S. Oppenheimer, "Out-of-Africa, the peopling of continents and islands: tracing uniparental gene trees across the map." *Philos. Trans. R. Soc. Lond. B. Biol. Sci.* 367(1590):770–784]

## Environmental factors influence human biochemistry

Although our genetic makeup (and that of our microbiomes) is an important factor that contributes to disease susceptibility and to other traits, factors in a person's environment also are significant. What are these environmental factors? Perhaps the most obvious are chemicals that we eat or are exposed to in some other way. The adage "you are what you eat" has considerable validity; it applies both to substances that we ingest in significant quantities and to those that we ingest in only trace amounts. Throughout our study of biochemistry, we will encounter *vitamins* and *trace elements* and their derivatives that play crucial roles in many processes. In many cases, the roles of these chemicals were first revealed through investigation of *deficiency disorders* observed in people who do not take in a sufficient quantity of a particular vitamin or trace element. Despite the fact that the most important essential dietary factors have been known for some time, new roles for them continue to be discovered.

**FIGURE 1.22 Nutrition.** Proper health depends on an appropriate combination of food groups (fruits, vegetables, protein, grains, dairy) (left) to provide an optimal mix of biochemicals (carbohydrates, proteins, fats, vitamins, and minerals) (right). [Adapted from [www.choosemyplate.gov](http://www.choosemyplate.gov)]

A healthful diet requires a balance of major food groups. In addition to providing vitamins and trace elements, food provides calories in the form of substances that can be broken down to release energy that drives other biochemical processes. Proteins, fats, and carbohydrates provide the building blocks used to construct the molecules of life (Figure 1.22). Finally, it is possible to get too much of a good thing. Human beings evolved under circumstances in which food, particularly rich foods such as meat, was scarce. With the development of agriculture and modern economies, rich foods are now plentiful in parts of the world. Some of the most prevalent diseases in the so-called developed world, such as

heart disease and diabetes, can be attributed to the large quantities of fats and carbohydrates present in modern diets. We are now developing a deeper understanding of the biochemical consequences of these diets and the interplay between diet and genetic factors.

Chemicals are only one important class of environmental factors. Our behaviors also have biochemical consequences. Through physical activity, we consume the calories that we take in, ensuring an appropriate balance between food intake and energy expenditure. Activities ranging from exercise to emotional responses such as fear and love may activate specific biochemical pathways, leading to changes in levels of gene expression, the release of hormones, and other consequences. Furthermore, the interplay between biochemistry and behavior is bidirectional. Just as our biochemistry is affected by our behavior, so, too, our behavior is affected, although certainly not completely determined, by our genetic makeup and other aspects of our biochemistry. Genetic factors associated with a range of behavioral characteristics have been at least tentatively identified.

Just as vitamin deficiencies and genetic diseases have revealed fundamental principles of biochemistry and biology, investigations of variations in behavior and their linkage to genetic and biochemical factors are potential sources of great insight into mechanisms within the brain. For example, studies of drug addiction have revealed neural circuits and biochemical pathways that greatly influence aspects of behavior. Unraveling the interplay between biology and behavior is one of the great challenges in modern science, and biochemistry is providing some of the most important concepts and tools for this endeavor.

## Genome sequences encode proteins and patterns of expression

The structure of DNA revealed how information is stored in the base sequence along a DNA strand. But what information is stored and how is it expressed? The most fundamental role of DNA is to encode the sequences of proteins. Like DNA, proteins are linear polymers. However, proteins differ from DNA in two important ways. First, proteins are built from 20 building blocks, called *amino acids*, rather than just four, as in DNA. The chemical complexity provided by this variety of building blocks enables proteins to perform a wide range of functions. Second, proteins spontaneously fold into elaborate three-dimensional structures, determined only by their amino acid sequences (Figure 1.23). We have explored in depth how solutions containing two appropriate strands of DNA come together to form a solution of double-helical molecules. A similar spontaneous folding process gives proteins their three-dimensional structure. A balance of hydrogen bonding, van der Waals interactions, and hydrophobic interactions overcomes the entropy lost in going from an unfolded ensemble of proteins to a homogenous set of well-folded molecules. Proteins and protein folding will be discussed extensively in Chapter 2.

The fundamental unit of hereditary information, the *gene*, is becoming increasingly difficult to precisely define as our knowledge of the complexities of genetics and genomics increases. The genes that are simplest to define encode the sequences of proteins. For these protein-encoding genes, a block of DNA bases encodes the amino acid sequence of a specific protein molecule. A set of three bases along the DNA strand, called a *codon*, determines the identity of one amino acid within the protein sequence. The set of rules that links the DNA sequence to the encoded protein sequence is called the *genetic code*. One of the biggest surprises from the sequencing of the human genome is the small number of protein-encoding genes. Before the genome-sequencing project began, the consensus view was that the human genome would include approximately 100,000 protein-encoding genes. The current analysis suggests that the actual number is between 20,000 and 25,000. We shall use an estimate of 21,000 throughout this book. However, additional mechanisms allow many genes to encode more than one protein. For example, the genetic information in some genes is translated in more than one way to produce a set of proteins that differ from one another in parts of their amino acid sequences. In other cases, proteins are modified after they have been synthesized through the addition of accessory chemical groups. Through these indirect mechanisms, much more complexity is encoded in our genomes than would be expected from the number of protein-encoding genes alone.

On the basis of current knowledge, the protein-encoding regions account for only about 3% of the human genome. What is the function of the rest of the DNA? Some of it contains information that regulates the expression of specific genes (i.e., the production of specific proteins) in particular cell types and physiological conditions. Essentially every human

**FIGURE 1.23 Protein folding.** Proteins are linear polymers of amino acids that fold into elaborate structures. The sequence of amino acids determines the three-dimensional structure. Thus, amino acid sequence 1 gives rise only to a protein with the shape depicted in blue, *not* the shape depicted in red.

cell contains the same DNA genome, yet cell types differ considerably in the proteins that they produce. For example, hemoglobin is expressed only in precursors of red blood cells, even though the genes for hemoglobin are present in essentially every cell. Specific sets of genes are expressed in response to hormones, even though these genes are not expressed in the same cell in the absence of the hormones. The control regions that regulate such differences account for only a small amount of the remainder of our genomes. The truth is that we do not yet understand all of the function of much of the remainder of the DNA. Some of it is sometimes referred to as “junk”—stretches of DNA that were inserted at some stage of evolution and have remained. In some cases, this DNA may, in fact, serve important functions. In others, it may serve no function but, because it does not cause significant harm, it has remained.

## APPENDIX: Visualizing Molecular Structures I: Small Molecules

The authors of a biochemistry textbook face the problem of trying to present three-dimensional molecules in the two dimensions available on the printed page. The interplay between the three-dimensional structures of biomolecules and their biological functions will be discussed extensively throughout this book. Toward this end, we will frequently use representations that, although of necessity are rendered in two dimensions, emphasize the three-dimensional structures of molecules.

### Stereochemical Renderings

Most of the chemical formulas in this book are drawn to depict the geometric arrangement of atoms, crucial to chemical bonding and reactivity, as accurately as possible. For example, the carbon atom of methane is tetrahedral, with H–C–H angles of 109.5 degrees, whereas the carbon atom in formaldehyde has bond angles of 120 degrees.

To illustrate the correct *stereochemistry* about tetrahedral carbon atoms, wedges will be used to depict the direction of a bond into or out of the plane of the page. A solid wedge with the broad end away from the carbon atom denotes a bond coming toward the viewer out of the plane. A dashed wedge, with its broad end at the carbon atom, represents a bond going away from the viewer behind the plane of the page. The remaining two bonds are depicted as straight lines.

### Fischer Projections

Although representative of the actual structure of a compound, stereochemical structures are often difficult to draw quickly. An alternative, less-representative method of depicting structures with tetrahedral carbon centers relies on the use of *Fischer projections*.

In a Fischer projection, the bonds to the central carbon are represented by horizontal and vertical lines from the substituent atoms to the carbon atom, which is assumed to be at the center of the cross. By convention, the horizontal bonds are assumed to project out of the page toward the viewer, whereas the vertical bonds are assumed to project behind the page away from the viewer.

### Molecular Models for Small Molecules

For depicting the molecular architecture of small molecules in more detail, two types of models will often be used: space filling and ball and stick. These models show structures at the atomic level.

1. *Space-Filling Models.* The space-filling models are the most realistic. The size and position of an atom in a space-filling model are determined by its bonding properties and van der Waals radius, or contact distance. A van der Waals radius describes how closely two atoms can approach each other when they are not linked by a covalent bond. The colors of the model are set by convention.

Carbon, black	Hydrogen, white	Nitrogen, blue
Oxygen, red	Sulfur, yellow	Phosphorus, purple

Space-filling models of several simple molecules are shown in Figure 1.24.

2. *Ball-and-Stick Models.* Ball-and-stick models are not as realistic as space-filling models, because the atoms are depicted as spheres of radii smaller than their van der Waals radii. However, the bonding arrangement is easier to see because the bonds are explicitly represented as sticks. In an illustration, the taper of a stick, representing parallax, tells which of a pair of bonded atoms is closer to the reader. A ball-and-stick

model reveals a complex structure more clearly than a space-filling model does. Ball-and-stick models of several simple molecules are shown in Figure 1.24.

Molecular models for depicting large molecules will be discussed in the appendix to Chapter 2.

**FIGURE 1.24 Molecular representations.** Structural formulas (bottom), ball-and-stick models (top), and space-filling representations (middle) of selected molecules are shown. Black = carbon, red = oxygen, white = hydrogen, yellow = sulfur, blue = nitrogen.

## KEY TERMS

## PROBLEMS

1. *Donors and acceptors.* Identify the hydrogen-bond donors and acceptors in each of the four bases on page 4.

2. *Resonance structures.* The structure of an amino acid, tyrosine, is shown here. Draw an alternative resonance structure.

3. *It takes all types.* What types of noncovalent bonds hold together the following solids?

- Table salt (NaCl), which contains  $\text{Na}^+$  and  $\text{Cl}^-$  ions.
- Graphite (C), which consists of sheets of covalently bonded carbon atoms.

4. *Don't break the law.* Given the following values for the changes in enthalpy ( $\Delta H$ ) and entropy ( $\Delta S$ ), which of the following processes can take place at 298 K without violating the Second Law of Thermodynamics?

- $\Delta H = -84 \text{ kJ mol}^{-1}$  ( $-20 \text{ kcal mol}^{-1}$ ),  
 $\Delta S = +125 \text{ J mol}^{-1} \text{ K}^{-1}$  ( $+30 \text{ cal mol}^{-1} \text{ K}^{-1}$ )

(b)  $\Delta H = -84 \text{ kJ mol}^{-1}$  ( $-20 \text{ kcal mol}^{-1}$ ),  
 $\Delta S = -125 \text{ J mol}^{-1} \text{ K}^{-1}$  ( $-30 \text{ cal mol}^{-1} \text{ K}^{-1}$ )

(c)  $\Delta H = +84 \text{ kJ mol}^{-1}$  ( $+20 \text{ kcal mol}^{-1}$ ),  
 $\Delta S = +125 \text{ J mol}^{-1} \text{ K}^{-1}$  ( $+30 \text{ cal mol}^{-1} \text{ K}^{-1}$ )

(d)  $\Delta H = +84 \text{ kJ mol}^{-1}$  ( $+20 \text{ kcal mol}^{-1}$ ),  
 $\Delta S = -125 \text{ J mol}^{-1} \text{ K}^{-1}$  ( $-30 \text{ cal mol}^{-1} \text{ K}^{-1}$ )

5. *Double-helix-formation entropy.* For double-helix formation,  $\Delta G$  can be measured to be  $-54 \text{ kJ mol}^{-1}$  ( $-13 \text{ kcal mol}^{-1}$ ) at pH 7.0 in 1 M NaCl at  $25^\circ\text{C}$  (298 K). The heat released indicates an enthalpy change of  $-251 \text{ kJ mol}^{-1}$  ( $-60 \text{ kcal mol}^{-1}$ ). For this process, calculate the entropy change for the system and the entropy change for the surroundings.

6. *Find the pH.* What are the pH values for the following solutions?

(a) 0.1 M HCl

(b) 0.1 M NaOH

(c) 0.05 M HCl

(d) 0.05 M NaOH

7. *A weak acid.* What is the pH of a 0.1 M solution of acetic acid ( $\text{p}K_a = 4.75$ )?

(Hint: Let  $x$  be the concentration of  $\text{H}^+$  ions released from acetic acid when it dissociates. The solutions to a quadratic equation of the form  $ax^2 + bx + c = 0$  are  $x = (-b \pm \sqrt{b^2 - 4ac})/2a$ .)

8. *Substituent effects.* What is the pH of a 0.1 M solution of chloroacetic acid ( $\text{ClCH}_2\text{COOH}$ ,  $\text{p}K_a = 2.86$ )?

9. *Water in water.* Given a density of 1 g/ml and a molecular weight of 18 g/mol, calculate the concentration of water in water.

10. *Basic fact.* What is the pH of a 0.1 M solution of ethylamine, given that the  $\text{p}K_a$  of ethylammonium ion ( $\text{CH}_3\text{CH}_2\text{NH}_3^+$ ) is 10.70?

11. *Comparison.* A solution is prepared by adding 0.01 M acetic acid and 0.01 M ethylamine to water and adjusting the pH to 7.4. What is the ratio of acetate to acetic acid? What is the ratio of ethylamine to ethylammonium ion?

12. *Concentrate.* Acetic acid is added to water until the pH value reaches 4.0. What is the total concentration of the added acetic acid?

13. *Dilution.* 100 mL of a solution of hydrochloric acid with pH 5.0 is diluted to 1 L. What is the pH of the diluted solution?

14. *Buffer dilution.* 100 mL of a 0.1 mM buffer solution made from acetic acid and sodium acetate with pH 5.0 is diluted to 1 L. What is the pH of the diluted solution?

15. *Find the  $\text{p}K_a$ .* For an acid HA, the concentrations of HA and  $\text{A}^-$  are 0.075 and 0.025, respectively, at pH 6.0. What is the  $\text{p}K_a$  value for HA?

16. *pH indicator.* A dye that is an acid and that appears as different colors in its protonated and deprotonated forms can be used as a pH indicator. Suppose that you have a 0.001 M solution of a dye with a  $\text{p}K_a$  of 7.2. From the color, the concentration of the protonated form is found to be 0.0002 M. Assume that the remainder of the dye is in the deprotonated form. What is the pH of the solution?

17. *What's the ratio?* An acid with a  $\text{p}K_a$  of 8.0 is present in a solution with a pH of 6.0. What is the ratio of the protonated to the deprotonated form of the acid?

18. *Phosphate buffer.* What is the ratio of the concentrations of  $\text{H}_2\text{PO}_4^-$  and  $\text{HPO}_4^{2-}$  at (a) pH 7.0; (b) pH 7.5; (c) pH 8.0?

19. *Neutralization of phosphate.* Given that phosphoric acid ( $\text{H}_3\text{PO}_4$ ) can give up three protons with different  $\text{p}K_a$  values, sketch a plot of pH as a function of added drops of sodium hydroxide solution, starting with a solution of phosphoric acid at pH 1.0.

20. *Buffer capacity.* Two solutions of sodium acetate are prepared, one with a concentration of 0.1 M and the other with a concentration of 0.01 M. Calculate the pH values when the following concentrations of HCl have been added to each of these solutions: 0.0025 M, 0.005 M, 0.01 M, and 0.05 M.

21. *Buffer preparation.* You wish to prepare a buffer consisting of acetic acid and sodium acetate with a total acetic acid plus acetate concentration of 250 mM and a pH of 5.0. What concentrations of acetic acid and sodium acetate should you use? Assuming you wish to make 2 liters of this buffer, how many moles of acetic acid and sodium acetate will you need? How many grams of each will you need (molecular weights: acetic acid  $60.05 \text{ g mol}^{-1}$ , sodium acetate,  $82.03 \text{ g mol}^{-1}$ )?

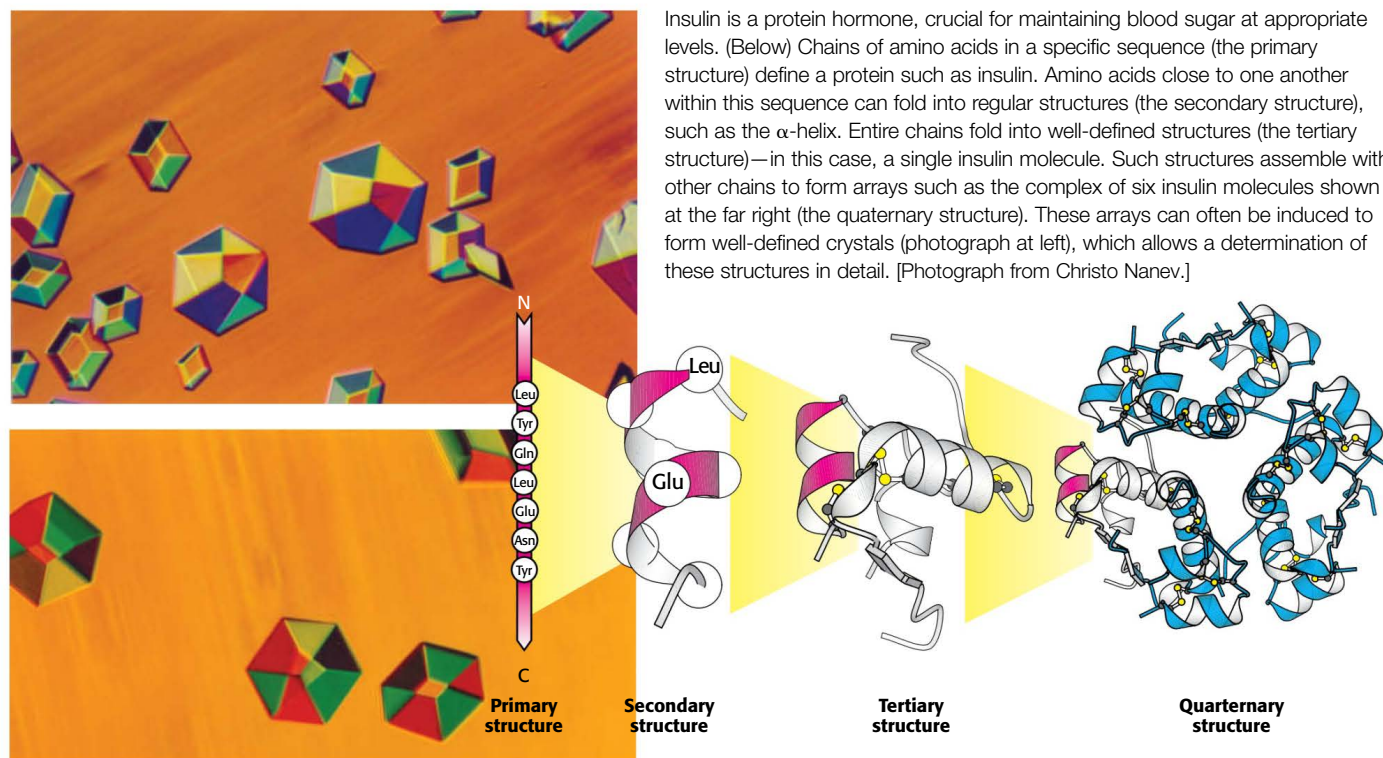

22. *An alternative approach.* When you go to prepare the buffer described in Problem 21, you discover that your laboratory is out of sodium acetate, but you do have sodium hydroxide. How much (in moles and grams) acetic acid and sodium hydroxide do you need to make the buffer?

23. *Another alternative.* Your friend from another laboratory was out of acetic acid, so tries to prepare the buffer in Problem 21 by dissolving 41.02 g of sodium acetate in water, carefully adding 180.0 ml of 1 M HCl, and adding more water to reach a total volume of 2 liters. What is the total concentration of acetate plus acetic acid in the solution? Will this solution have pH 5.0? Will it be identical with the desired buffer? If not, how will it differ?

24. *Blood substitute.* As noted in this chapter, blood contains a total concentration of phosphate of approximately 1 mM and typically has a pH of 7.4. You wish to make 100 liters of phosphate buffer with a pH of 7.4 from  $\text{NaH}_2\text{PO}_4$  (molecular weight,  $119.98 \text{ g mol}^{-1}$ ) and  $\text{Na}_2\text{HPO}_4$  (molecular weight,  $141.96 \text{ g mol}^{-1}$ ). How much of each (in grams) do you need?
25. *A potential problem.* You wish to make a buffer with pH 7.0. You combine 0.060 grams of acetic acid and 14.59 grams of sodium acetate and add water to yield a total volume of 1 liter. What is the pH? Will this be the useful pH 7.0 buffer you seek?
26. *Charge!* Suppose two phosphate groups in DNA (each with a charge of  $-1$ ) are separated by  $12 \text{ \AA}$ . What is the energy of the ionic interaction between these two phosphates assuming a dielectric constant of 80? Repeat the calculation assuming a dielectric constant of 2.
27. *Vive la différence.* On average, estimate how many base differences there are between two human beings.
28. *Epigenomics.* The human body contains many distinct cell types yet almost all human cells contain the same genome with 21,000 genes. The distinct cell types are primarily due to differences in gene expression. Assume that one set of 1000 genes is expressed in all cell types and that the remaining 20,000 genes can be divided into sets of 1000 genes that are either all expressed or all not expressed in a given cell type. How many different cell types are possible if each cell type expresses 10 sets of these genes? Note that the number of combinations of  $n$  objects into  $m$  sets is given by  $n!/(m!(n-m)!)$  where  $n! = 1*2*\dots*(n-1)*n$ .
29. *Predispositions in populations.* Assume that 10% of the members of a population will get a particular disease over the course of their lifetime. Genomic studies reveal that 5% of the population have sequences in their genomes such that their probability of getting the disease over the course of their lifetimes is 50%. What is the average lifetime risk of this disease for the remaining 95% of the population without these sequences?

# Protein Composition and Structure

Proteins are the most versatile macromolecules in living systems and serve crucial functions in essentially all biological processes. They function as catalysts, transport and store other molecules such as oxygen, provide mechanical support and immune protection, generate movement, transmit nerve impulses, and control growth and differentiation. Indeed, much of this book will focus on understanding what proteins do and how they perform these functions.

Several key properties enable proteins to participate in a wide range of functions.

1. *Proteins are linear polymers built of monomer units called amino acids, which are linked end to end. The sequence of linked amino acids is called the primary structure. Remarkably, proteins spontaneously fold up into three-dimensional structures that are determined by the sequence of amino acids in the protein polymer. Three-dimensional structure formed by hydrogen bonds between amino acids near one another is called secondary structure, whereas tertiary structure is formed by long-range interactions between amino acids. Protein function depends directly on this three-dimensional structure (Figure 2.1). Thus, proteins are the embodiment of the transition from the one-dimensional world of sequences to the three-dimensional world of molecules capable of diverse activities. Many proteins also display*

## OUTLINE

- 2.1 Proteins Are Built from a Repertoire of 20 Amino Acids
- 2.2 Primary Structure: Amino Acids Are Linked by Peptide Bonds to Form Polypeptide Chains
- 2.3 Secondary Structure: Polypeptide Chains Can Fold into Regular Structures Such As the Alpha Helix, the Beta Sheet, and Turns and Loops
- 2.4 Tertiary Structure: Water-Soluble Proteins Fold into Compact Structures with Nonpolar Cores
- 2.5 Quaternary Structure: Polypeptide Chains Can Assemble into Multisubunit Structures
- 2.6 The Amino Acid Sequence of a Protein Determines Its Three-Dimensional Structure

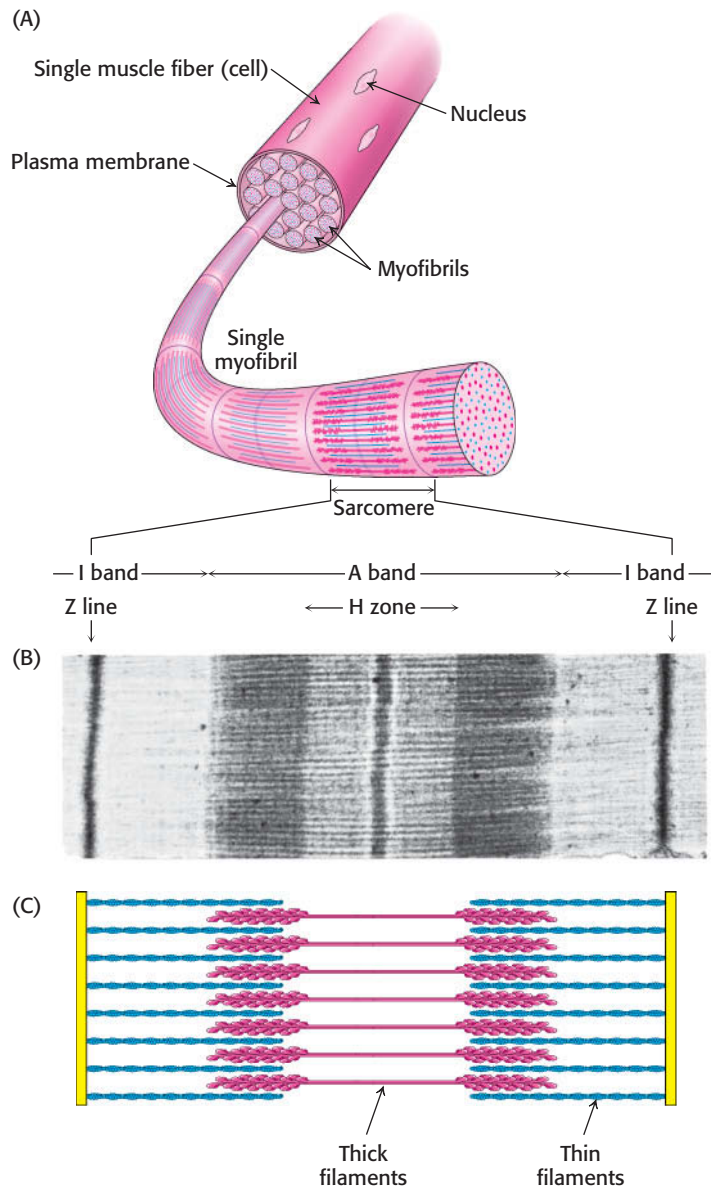

**FIGURE 2.1 Structure dictates function.** A protein component of the DNA replication machinery surrounds a section of DNA double helix depicted as a cylinder. The protein, which consists of two identical subunits (shown in red and yellow), acts as a clamp that allows large segments of DNA to be copied without the replication machinery dissociating from the DNA. [Drawn from 2POL.pdb.]

quaternary structure, in which the functional protein is composed of several distinct polypeptide chains.

2. *Proteins contain a wide range of functional groups.* These functional groups include alcohols, thiols, thioethers, carboxylic acids, carboxamides, and a variety of basic groups. Most of these groups are chemically reactive. When combined in various sequences, this array of functional groups accounts for the broad spectrum of protein function. For instance, their reactive properties are essential to the function of *enzymes*, the proteins that catalyze specific chemical reactions in biological systems (Chapters 8 through 10).

3. *Proteins can interact with one another and with other biological macromolecules to form complex assemblies.* The proteins within these assemblies can act synergistically to generate capabilities that individual proteins may lack. Examples of these assemblies include macromolecular machines that replicate DNA, transmit signals within cells, and enable muscle cells to contract (Figure 2.2).

**FIGURE 2.2 A complex protein assembly.** (A) A single muscle cell contains multiple myofibrils, each of which is comprised of numerous repeats of a complex protein assembly known as the sarcomere. (B) The banding pattern of a sarcomere, evident by electron microscopy, is caused by (C) the interdigitation of filaments made up of many individual proteins. [(B) Courtesy of Dr. Hugh Huxley.]

4. Some proteins are quite rigid, whereas others display considerable flexibility. Rigid units can function as structural elements in the cytoskeleton (the internal scaffolding within cells) or in connective tissue. Proteins with some flexibility may act as hinges, springs, or levers. In addition, conformational changes within proteins enable the regulated assembly of larger protein complexes as well as the transmission of information within and between cells (Figure 2.3).

**FIGURE 2.3 Flexibility and function.** On binding iron, the protein lactoferrin undergoes a substantial change in conformation that allows other molecules to distinguish between the iron-free and the iron-bound forms. [Drawn from 1LFH.pdb and 1LFG.pdb.]

## 2.1 Proteins Are Built from a Repertoire of 20 Amino Acids

Amino acids are the building blocks of proteins. An  $\alpha$ -amino acid consists of a central carbon atom, called the  $\alpha$  carbon, linked to an amino group, a carboxylic acid group, a hydrogen atom, and a distinctive R group. The R group is often referred to as the *side chain*. With four different groups connected to the tetrahedral  $\alpha$ -carbon atom,  $\alpha$ -amino acids are *chiral*: they may exist in one or the other of two mirror-image forms, called the L isomer and the D isomer (Figure 2.4).

 Only L amino acids are constituents of proteins. For almost all amino acids, the L isomer has S (rather than R) absolute configuration (Figure 2.5). What is the basis for the preference for L amino acids? The answer has been lost to evolutionary history. It is possible that the preference for L over D amino acids was a consequence of a chance selection. However, there is evidence that L amino acids are slightly more soluble than a racemic mixture of D and L amino acids, which tend to form crystals. This small solubility difference could have been amplified over time so that the L isomer became dominant in solution.

Amino acids in solution at neutral pH exist predominantly as *dipolar ions* (also called *zwitterions*). In the dipolar form, the amino group is protonated

**FIGURE 2.4 The L and D isomers of amino acids.** The letter R refers to the side chain. The L and D isomers are mirror images of each other.

### Notation for distinguishing stereoisomers

The four different substituents of an asymmetric carbon atom are assigned a priority according to atomic number. The lowest-priority substituent, often hydrogen, is pointed away from the viewer. The configuration about the carbon atom is called S (from the Latin *sinister*, "left") if the progression from the highest to the lowest priority is counterclockwise. The configuration is called R (from the Latin *rectus*, "right") if the progression is clockwise.

**FIGURE 2.5 Only L amino acids are found in proteins.** Almost all L amino acids have an S absolute configuration. The counterclockwise direction of the arrow from highest- to lowest-priority substituents indicates that the chiral center is of the S configuration.

( $-\text{NH}_3^+$ ) and the carboxyl group is deprotonated ( $-\text{COO}^-$ ). The ionization state of an amino acid varies with pH (Figure 2.6). In acid solution (e.g., pH 1), the amino group is protonated ( $-\text{NH}_3^+$ ) and the carboxyl group is not dissociated ( $-\text{COOH}$ ). As the pH is raised, the carboxylic acid is the first group to give up a proton, inasmuch as its  $\text{pK}_a$  is near 2. The dipolar form persists until the pH approaches 9, when the protonated amino group loses a proton.

**FIGURE 2.6 Ionization state as a**

**function of pH.** The ionization state of amino acids is altered by a change in pH. The zwitterionic form predominates near physiological pH.

Twenty kinds of side chains varying in *size*, *shape*, *charge*, *hydrogen-bonding capacity*, *hydrophobic character*, and *chemical reactivity* are commonly found in proteins. Indeed, all proteins in all species—bacterial, archaeal, and eukaryotic—are constructed from the same set of 20 amino acids with only a few exceptions. This fundamental alphabet for the construction of proteins is several billion years old. The remarkable range of functions mediated by proteins results from the diversity and versatility of these 20 building blocks. Understanding how this alphabet is used to create the intricate three-dimensional structures that enable proteins to carry out so many biological processes is an exciting area of biochemistry and one that we will return to in Section 2.6.

Although there are many ways to classify amino acids, we will sort these molecules into four groups, on the basis of the general chemical characteristics of their R groups:

1. Hydrophobic amino acids with nonpolar R groups
2. Polar amino acids with neutral R groups but the charge is not evenly distributed
3. Positively charged amino acids with R groups that have a positive charge at physiological pH
4. Negatively charged amino acids with R groups that have a negative charge at physiological pH

**Hydrophobic amino acids.** The simplest amino acid is *glycine*, which has a single hydrogen atom as its side chain. With two hydrogen atoms bonded to the  $\alpha$ -carbon atom, glycine is unique in being *achiral*. *Alanine*, the next simplest amino acid, has a methyl group ( $-\text{CH}_3$ ) as its side chain (Figure 2.7).

**FIGURE 2.7 Structures of hydrophobic amino acids.** For each amino acid, a ball-and-stick model (top) shows the arrangement of atoms and bonds in space. A stereochemically realistic formula (middle) shows the geometric arrangement of bonds around atoms, and a Fischer projection (bottom) shows all bonds as being perpendicular for a simplified representation (see the Appendix to Chapter 1). The additional chiral center in isoleucine is indicated by an asterisk.

**FIGURE 2.8 Structures of the polar amino acids.** The additional chiral center in threonine is indicated by an asterisk.

Larger hydrocarbon side chains are found in *valine*, *leucine*, and *isoleucine*. *Methionine* contains a largely aliphatic side chain that includes a *thioether* ( $\text{—S—}$ ) group. The side chain of *isoleucine* includes an additional chiral center; only the isomer shown in Figure 2.7 is found in proteins. The larger aliphatic side chains are especially hydrophobic; that is, they tend to cluster together rather than contact water. The three-dimensional structures of water-soluble proteins are stabilized by this tendency of hydrophobic groups to come together, which is called *the hydrophobic effect* (p. 9). The different sizes and shapes of these hydrocarbon side chains enable them to pack together to form compact structures with little empty space. *Proline* also has an aliphatic side chain, but it differs from other members of the set of 20 in that its side chain is bonded to both the nitrogen and the  $\alpha$ -carbon atoms, yielding a *pyrrolidine* ring. Proline markedly influences protein architecture because its cyclic structure makes it more conformationally restricted than the other amino acids.

Two amino acids with relatively simple *aromatic side chains* are part of the fundamental repertoire. *Phenylalanine*, as its name indicates, contains a phenyl ring attached in place of one of the hydrogen atoms of alanine. *Tryptophan* has an *indole* group joined to a methylene ( $\text{—CH}_2\text{—}$ ) group; the indole group comprises two fused rings containing an NH group. Phenylalanine is purely hydrophobic, whereas tryptophan is less so because of its NH group.

**Polar amino acids.** Six amino acids are polar but uncharged. Three amino acids, *serine*, *threonine*, and *tyrosine*, contain *hydroxyl groups* ( $\text{—OH}$ ) attached to a hydrophobic side chain (Figure 2.8). Serine can be thought of as a version of alanine with a hydroxyl group attached, threonine resembles valine with a

hydroxyl group in place of one of valine's methyl groups, and tyrosine is a version of phenylalanine with the hydroxyl group replacing a hydrogen atom on the aromatic ring. The hydroxyl group makes these amino acids much more *hydrophilic* (water loving) and *reactive* than their hydrophobic analogs. Threonine, like isoleucine, contains an additional asymmetric center; again, only one isomer is present in proteins.

In addition, the set includes *asparagine* and *glutamine*, two amino acids that contain a terminal *carboxamide*. The side chain of glutamine is one methylene group longer than that of asparagine.

*Cysteine* is structurally similar to serine but contains a *sulfhydryl*, or *thiol* ( $-\text{SH}$ ), group in place of the hydroxyl ( $-\text{OH}$ ) group. The sulfhydryl group is much more reactive. Pairs of sulfhydryl groups may come together to form disulfide bonds, which are particularly important in stabilizing some proteins, as will be discussed shortly.

**Positively charged amino acids.** We turn now to amino acids with complete positive charges that render them highly hydrophilic. *Lysine* and *arginine* have long side chains that terminate with groups that are *positively charged* at neutral pH. Lysine is capped by a primary amino group and arginine by a guanidinium group. *Histidine* contains an imidazole group, an aromatic ring that also can be positively charged (Figure 2.9).

With a  $\text{pK}_a$  value near 6, the imidazole group can be uncharged or positively charged near neutral pH, depending on its local environment (Figure 2.10). Histidine is often found in the active sites of enzymes, where the imidazole ring can bind and release protons in the course of enzymatic reactions.

**Negatively charged amino acids.** This set of amino acids contains two with *acidic side chains*: *aspartic acid* and *glutamic acid* (Figure 2.11). These amino acids are charged derivatives of asparagine and glutamine (Figure 2.8), with a carboxylic acid in place of a carboxamide. Aspartic acid and glutamic acid are often called *aspartate* and *glutamate* to emphasize that, at physiological pH, their side chains usually lack a proton that is present in the acid form and hence are negatively charged. Nonetheless, these side chains can accept protons in some proteins, often with functionally important consequences.

Seven of the 20 amino acids have readily ionizable side chains. These 7 amino acids are able to donate or accept protons to facilitate reactions as well as to form ionic bonds. Table 2.1 gives equilibria and typical  $\text{pK}_a$  values for ionization of the side chains of tyrosine, cysteine, arginine, lysine,

FIGURE 2.9 Positively charged amino acids lysine, arginine, and histidine.

FIGURE 2.10 Histidine ionization. Histidine can bind or release protons near physiological pH.

**FIGURE 2.11** Negatively charged amino acids.

**TABLE 2.1** Typical  $pK_a$  values of ionizable groups in proteins

Group	Acid	$\rightleftharpoons$	Base	Typical $pK_a^*$
Terminal $\alpha$ -carboxyl group		$\rightleftharpoons$		3.1
Aspartic acid Glutamic acid		$\rightleftharpoons$		4.1
Histidine		$\rightleftharpoons$		6.0
Terminal $\alpha$ -amino group		$\rightleftharpoons$		8.0
Cysteine		$\rightleftharpoons$		8.3
Tyrosine		$\rightleftharpoons$		10.9
Lysine		$\rightleftharpoons$		10.8
Arginine		$\rightleftharpoons$		12.5

\* $pK_a$  values depend on temperature, ionic strength, and the microenvironment of the ionizable group

histidine, and aspartic and glutamic acids in proteins. Two other groups in proteins—the terminal  $\alpha$ -amino group and the terminal  $\alpha$ -carboxyl group—can be ionized, and typical  $pK_a$  values for these groups also are included in Table 2.1.

Amino acids are often designated by either a three-letter abbreviation or a one-letter symbol (Table 2.2). The abbreviations for amino acids are the first three letters of their names, except for asparagine (Asn), glutamine (Gln), isoleucine (Ile), and tryptophan (Trp). The symbols for many amino acids are the first letters of their names (e.g., G for glycine and L for leucine);

**TABLE 2.2** Abbreviations for amino acids

Amino acid	Three-letter abbreviation	One-letter abbreviation	Amino acid	Three-letter abbreviation	One-letter abbreviation
Alanine	Ala	A	Methionine	Met	M
Arginine	Arg	R	Phenylalanine	Phe	F
Asparagine	Asn	N	Proline	Pro	P
Aspartic acid	Asp	D	Serine	Ser	S
Cysteine	Cys	C	Threonine	Thr	T
Glutamine	Gln	Q	Tryptophan	Trp	W
Glutamic acid	Glu	E	Tyrosine	Tyr	Y
Glycine	Gly	G	Valine	Val	V
Histidine	His	H	Asparagine or aspartic acid	Asx	B
Isoleucine	Ile	I	Glutamine or glutamic acid	Glx	Z
Leucine	Leu	L			
Lysine	Lys	K			

**FIGURE 2.12 Undesirable reactivity in amino acids.** Some amino acids are unsuitable for proteins because of undesirable cyclization. Homoserine can cyclize to form a stable, five-membered ring, potentially resulting in peptide-bond cleavage. The cyclization of serine would form a strained, four-membered ring and is thus disfavored. X can be an amino group from a neighboring amino acid or another potential leaving group.

the other symbols have been agreed on by convention. These abbreviations and symbols are an integral part of the vocabulary of biochemists.

How did this particular set of amino acids become the building blocks of proteins? First, as a set, they are diverse: their structural and chemical properties span a wide range, endowing proteins with the versatility to assume many functional roles. Second, many of these amino acids were probably available from prebiotic reactions; that is, from reactions that took place before the origin of life. Finally, other possible amino acids may have simply been too reactive. For example, amino acids such as homoserine and homocysteine tend to form five-membered cyclic forms that limit their use in proteins; the alternative amino acids that are found in proteins—serine and cysteine—do not readily cyclize, because the rings in their cyclic forms are too small (Figure 2.12).

## 2.2 Primary Structure: Amino Acids Are Linked by Peptide Bonds to Form Polypeptide Chains

Proteins are *linear polymers* formed by linking the  $\alpha$ -carboxyl group of one amino acid to the  $\alpha$ -amino group of another amino acid. This type of linkage is called a *peptide bond* or an *amide bond*. The formation of a dipeptide from two amino acids is accompanied by the loss of a water molecule (Figure 2.13). The equilibrium of this reaction lies on the side of hydrolysis rather than synthesis under most conditions. Hence, the biosynthesis of peptide bonds requires an input of free energy. Nonetheless, peptide bonds are quite *stable kinetically* because the rate of hydrolysis is extremely slow; the lifetime of a peptide bond in aqueous solution in the absence of a catalyst approaches 1000 years.

A series of amino acids joined by peptide bonds form a *polypeptide chain*, and each amino acid unit in a polypeptide is called a *residue*. A *polypeptide chain has directionality because its ends are different*: an  $\alpha$ -amino group

**FIGURE 2.13 Peptide-bond formation.** The linking of two amino acids is accompanied by the loss of a molecule of water.

**FIGURE 2.14 Amino acid sequences have direction.** This illustration of the pentapeptide Tyr-Gly-Gly-Phe-Leu (YGGFL) shows the sequence from the amino terminus to the carboxyl terminus. This pentapeptide, Leu-enkephalin, is an opioid peptide that modulates the perception of pain. The reverse pentapeptide, Leu-Phe-Gly-Gly-Tyr (LFGGY), is a different molecule and has no such effects.

is present at one end and an  $\alpha$ -carboxyl group at the other. *The amino end is taken to be the beginning of a polypeptide chain*; by convention, the sequence of amino acids in a polypeptide chain is written starting with the amino-terminal residue. Thus, in the polypeptide Tyr-Gly-Gly-Phe-Leu (YGGFL), tyrosine is the amino-terminal (N-terminal) residue and leucine is the carboxyl-terminal (C-terminal) residue (Figure 2.14). Leu-Phe-Gly-Gly-Tyr (LFGGY) is a different polypeptide, with different chemical properties.

A polypeptide chain consists of a regularly repeating part, called the *main chain* or *backbone*, and a variable part, comprising the distinctive *side chains* (Figure 2.15). The polypeptide backbone is rich in hydrogen-bonding potential. Each residue contains a carbonyl group ( $C=O$ ), which is a good hydrogen-bond acceptor, and, with the exception of proline, an NH group, which is a good hydrogen-bond donor. These groups interact with each other and with functional groups from side chains to stabilize particular structures, as will be discussed in Section 2.3.

Most natural polypeptide chains contain between 50 and 2000 amino acid residues and are commonly referred to as *proteins*. The largest single polypeptide known is the muscle protein *titin*, which consists of more than 27,000 amino acids. Polypeptide chains made of small numbers of amino acids are called *oligopeptides* or simply *peptides*. The mean molecular weight of an amino acid residue is about  $110 \text{ g mol}^{-1}$ , and so the molecular weights of most proteins are between 5500 and  $220,000 \text{ g mol}^{-1}$ . We can also refer

to the mass of a protein, which is expressed in units of daltons; one *dalton* is equal to one atomic mass unit. A protein with a molecular weight of  $50,000 \text{ g mol}^{-1}$  has a mass of 50,000 daltons, or 50 kDa (kilodaltons).

In some proteins, the linear polypeptide chain is cross-linked. The most common cross-links are *disulfide bonds*, formed by the oxidation of a pair of cysteine residues (Figure 2.16). The resulting unit of two linked cysteines is called *cystine*. Extracellular proteins

#### Dalton

A unit of mass very nearly equal to that of a hydrogen atom. Named after John Dalton (1766–1844), who developed the atomic theory of matter.

#### Kilodalton (kDa)

A unit of mass equal to 1000 daltons

**FIGURE 2.15 Components of a polypeptide chain.** A polypeptide chain consists of a constant backbone (shown in black) and variable side chains (shown in green).

often have several disulfide bonds, whereas intracellular proteins usually lack them. Rarely, nondisulfide cross-links derived from other side chains are present in proteins. For example, collagen fibers in connective tissue are strengthened in this way, as are fibrin blood clots (Section 10.4).

### Proteins have unique amino acid sequences specified by genes

In 1953, Frederick Sanger determined the amino acid sequence of insulin, a protein hormone (Figure 2.17). *This work is a landmark in biochemistry because it showed for the first time that a protein has a precisely defined amino acid sequence consisting only of L amino acids linked by peptide bonds.* This accomplishment stimulated other scientists to carry out sequence studies of a wide variety of proteins. Currently, the complete amino acid sequences of more than 2,000,000 proteins are known. *The striking fact is that each protein has a unique, precisely defined amino acid sequence.* The amino acid sequence of a protein is referred to as its *primary structure*.

**FIGURE 2.16 Cross-links.** The formation of a disulfide bond from two cysteine residues is an oxidation reaction.

**FIGURE 2.17 Amino acid sequence of bovine insulin.**

A series of incisive studies in the late 1950s and early 1960s revealed that the amino acid sequences of proteins are determined by the nucleotide sequences of genes. The sequence of nucleotides in DNA specifies a complementary sequence of nucleotides in RNA, which in turn specifies the amino acid sequence of a protein. In particular, each of the 20 amino acids of the repertoire is encoded by one or more specific sequences of three nucleotides (Section 4.6).

Knowing amino acid sequences is important for several reasons. First, knowledge of the sequence of a protein is usually essential to elucidating its function (e.g., the catalytic mechanism of an enzyme). In fact, proteins with novel properties can be generated by varying the sequence of known proteins. Second, amino acid sequences determine the three-dimensional structures of proteins. The amino acid sequence is the link between the genetic message in DNA and the three-dimensional structure that performs a protein's biological function. Analyses of relations between amino acid sequences and three-dimensional structures of proteins are uncovering the rules that govern the folding of polypeptide chains. Third, alterations in amino acid sequence can lead to abnormal protein function and disease. Severe and sometimes fatal diseases, such as sickle-cell anemia (Chapter 7) and cystic fibrosis, can result from a change in a single amino acid within a protein. Fourth, the sequence of a protein reveals much about its evolutionary history (Chapter 6). Proteins resemble one another in amino acid sequence only if they have a common ancestor. Consequently, molecular events in evolution can be traced from amino acid sequences; molecular paleontology is a flourishing area of research.

## Polypeptide chains are flexible yet conformationally restricted

Examination of the geometry of the protein backbone reveals several important features. First, *the peptide bond is essentially planar* (Figure 2.18). Thus, for a pair of amino acids linked by a peptide bond, six atoms lie in the same plane: the  $\alpha$ -carbon atom and CO group of the first amino acid and the NH group and  $\alpha$ -carbon atom of the second amino acid. The nature of the chemical bonding within a peptide accounts for the bond's planarity. The bond resonates between a single bond and a double bond. Because of this *partial double-bond character*, rotation about this bond is prevented and thus the conformation of the peptide backbone is constrained.

**FIGURE 2.18 Peptide bonds are planar.** In a pair of linked amino acids, six atoms ( $C_{\alpha}$ , C, O, N, H, and  $C_{\alpha}$ ) lie in a plane. Side chains are shown as green balls.

The partial double-bond character is also expressed in the length of the bond between the CO and the NH groups. As shown in Figure 2.19, the C—N distance in a peptide bond is typically 1.32 Å, which is between the values expected for a C—N single bond (1.49 Å) and a C=N double bond (1.27 Å). Finally, the peptide bond is uncharged, allowing polymers of amino acids linked by peptide bonds to form tightly packed globular structures.

Two configurations are possible for a planar peptide bond. In the *trans* configuration, the two  $\alpha$ -carbon atoms are on opposite sides of the peptide bond. In the *cis* configuration, these groups are on the same side of the peptide bond. *Almost all peptide bonds in proteins are trans*. This preference for trans over cis can be explained by the fact that steric clashes between groups attached to the  $\alpha$ -carbon atoms hinder the formation of the cis configuration (Figure 2.20). By far the most common cis peptide bonds are X—Pro linkages. Such bonds show less preference for the trans configuration because the nitrogen of proline is bonded to two tetrahedral carbon atoms, limiting the steric differences between the trans and cis forms (Figure 2.21).

**FIGURE 2.19 Typical bond lengths within a peptide unit.** The peptide unit is shown in the trans configuration.

In contrast with the peptide bond, the bonds between the amino group and the  $\alpha$ -carbon atom and between the  $\alpha$ -carbon atom and the carbonyl group are pure single bonds. The two adjacent rigid peptide units can rotate about these bonds, taking on various orientations. *This freedom of rotation about two bonds of each amino acid allows proteins to fold in many different ways*. The rotations about these bonds can be specified by

**FIGURE 2.20 Trans and cis peptide bonds.** The trans form is strongly favored because of steric clashes, indicated by the orange semicircles, that arise in the cis form.

**FIGURE 2.21 Trans and cis X-Pro bonds.** The energies of these forms are similar to one another because steric clashes, indicated by the orange semicircles, arise in both forms.

**FIGURE 2.22 Rotation about bonds in a polypeptide.** The structure of each amino acid in a polypeptide can be adjusted by rotation about two single bonds. (A) Phi ( $\phi$ ) is the angle of rotation about the bond between the nitrogen and the  $\alpha$ -carbon atoms, whereas psi ( $\psi$ ) is the angle of rotation about the bond between the  $\alpha$ -carbon and the carbonyl carbon atoms. (B) A view down the bond between the nitrogen and the  $\alpha$ -carbon atoms, showing how  $\phi$  is measured. (C) A view down the bond between the  $\alpha$ -carbon and the carbonyl carbon atoms, showing how  $\psi$  is measured.

*torsion angles* (Figure 2.22). The angle of rotation about the bond between the nitrogen and the  $\alpha$ -carbon atoms is called phi ( $\phi$ ). The angle of rotation about the bond between the  $\alpha$ -carbon and the carbonyl carbon atoms is called psi ( $\psi$ ). A clockwise rotation about either bond as viewed from the nitrogen atom toward the  $\alpha$ -carbon atom or from the  $\alpha$ -carbon atom toward the carbonyl group corresponds to a positive value. The  $\phi$  and  $\psi$  angles determine the path of the polypeptide chain.

Are all combinations of  $\phi$  and  $\psi$  possible? Gopalasamudram Ramachandran recognized that many combinations are forbidden because of steric collisions between atoms. The allowed values can be visualized on a two-dimensional plot called a *Ramachandran plot* (Figure 2.23). Three-quarters of the possible ( $\phi$ ,  $\psi$ ) combinations are excluded simply by local steric clashes. *Steric exclusion, the fact that two atoms cannot be in the same place at the same time, can be a powerful organizing principle.*

The ability of biological polymers such as proteins to fold into well-defined structures is remarkable thermodynamically. An unfolded polymer exists as a random coil: each copy of an unfolded polymer will have a different conformation, yielding a mixture of many possible conformations. The favorable entropy associated with a mixture of many conformations opposes folding and must be overcome by interactions favoring the folded form. Thus, highly flexible polymers with a large number of possible conformations do not fold into unique structures. *The rigidity of the peptide unit and the restricted set of allowed  $\phi$  and  $\psi$  angles limits the number of structures accessible to the unfolded form sufficiently to allow protein folding to take place.*

#### Torsion angle

A measure of the rotation about a bond, usually taken to lie between  $-180$  and  $+180$  degrees. Torsion angles are sometimes called dihedral angles.

**FIGURE 2.23** A Ramachandran plot showing the values of  $\phi$  and  $\psi$ . Not all  $\phi$  and  $\psi$  values are possible without collisions between atoms. The most favorable regions are shown in dark green; borderline regions are shown in light green. The structure on the right is disfavored because of steric clashes.

### 2.3 Secondary Structure: Polypeptide Chains Can Fold into Regular Structures Such As the Alpha Helix, the Beta Sheet, and Turns and Loops

Can a polypeptide chain fold into a regularly repeating structure? In 1951, Linus Pauling and Robert Corey proposed two periodic structures called the  $\alpha$  *helix* (alpha helix) and the  $\beta$  *pleated sheet* (beta pleated sheet). Subsequently, other structures such as the  $\beta$  *turn* and  $\omega$  ( $\Omega$ ) *loop* were identified. Although not periodic, these common turn or loop structures are well defined and contribute with  $\alpha$  helices and  $\beta$  sheets to form the final protein structure. Alpha helices,  $\beta$  strands, and turns are formed by a regular pattern of hydrogen bonds between the peptide N—H and C=O groups of amino acids that are *near one another in the linear sequence*. Such folded segments are called *secondary structure*.

#### The alpha helix is a coiled structure stabilized by intrachain hydrogen bonds

In evaluating potential structures, Pauling and Corey considered which conformations of peptides were sterically allowed and which most fully exploited the hydrogen-bonding capacity of the backbone NH and CO groups. The first of their proposed structures, the  $\alpha$  *helix*, is a rodlike structure (Figure 2.24). A tightly coiled backbone forms the inner part of the rod and the side chains extend outward in a helical array. The  $\alpha$  helix is stabilized by hydrogen bonds between the NH and CO groups of the main chain. In particular, the CO group of each amino acid forms a hydrogen bond with the NH group of the amino acid that is situated four residues ahead in the sequence (Figure 2.25). Thus, except for amino acids near the ends of an  $\alpha$  helix, *all the main-chain CO and NH groups are hydrogen bonded*. Each residue is related to the next one by a rise, also called *translation*, of 1.5 Å along the helix axis and a rotation of 100 degrees, which gives 3.6 amino acid residues per turn of helix. Thus, amino acids spaced three and four apart in the sequence are spatially quite close to one another in an  $\alpha$  helix. In contrast, amino acids spaced two apart in the sequence are situated on opposite sides of the helix and so are unlikely to make contact. The *pitch* of the  $\alpha$  helix is the length of one complete turn along the helix axis and is equal to the product of the rise (1.5 Å) and the number of residues per turn (3.6), or 5.4 Å. The *screw*

#### Screw sense

Describes the direction in which a helical structure rotates with respect to its axis. If, viewed down the axis of a helix, the chain turns in a clockwise direction, it has a right-handed screw sense. If the turning is counterclockwise, the screw sense is left-handed.

**FIGURE 2.24 Structure of the  $\alpha$  helix.** (A) A ribbon depiction shows the  $\alpha$ -carbon atoms and side chains (green). (B) A side view of a ball-and-stick version depicts the hydrogen bonds (dashed lines) between NH and CO groups. (C) An end view shows the coiled backbone as the inside of the helix and the side chains (green) projecting outward. (D) A space-filling view of part C shows the tightly packed interior core of the helix.

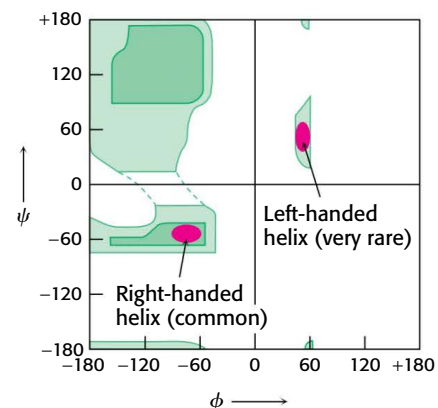

**FIGURE 2.25 Hydrogen-bonding scheme for an  $\alpha$  helix.** In the  $\alpha$  helix, the CO group of residue  $i$  forms a hydrogen bond with the NH group of residue  $i + 4$ .

sense of an  $\alpha$  helix can be right-handed (clockwise) or left-handed (counterclockwise). The Ramachandran plot reveals that both the right-handed and the left-handed helices are among allowed conformations (Figure 2.26). However, right-handed helices are energetically more favorable because there is less steric clash between the side chains and the backbone. *Essentially all  $\alpha$  helices found in proteins are right-handed.* In schematic representations of proteins,  $\alpha$  helices are depicted as twisted ribbons or rods (Figure 2.27).

Not all amino acids can be readily accommodated in an  $\alpha$  helix. Branching at the  $\beta$ -carbon atom, as in valine, threonine, and isoleucine, tends to destabilize  $\alpha$  helices because of steric clashes. Serine, aspartate, and asparagine also tend to disrupt  $\alpha$  helices because their side chains contain hydrogen-bond donors or acceptors in close proximity to the main chain, where they compete for main-chain NH and CO groups. Proline also is a helix breaker because it lacks an NH group and because its ring structure prevents it from assuming the  $\phi$  value to fit into an  $\alpha$  helix.

The  $\alpha$ -helical content of proteins ranges widely, from none to almost 100%. For example, about 75% of the residues in ferritin, a protein that helps store iron, are in  $\alpha$  helices (Figure 2.28). Indeed, about 25% of all soluble proteins are composed of  $\alpha$  helices connected by loops and turns of the polypeptide chain. Single  $\alpha$  helices are usually less than 45 Å long. Many proteins that span biological membranes also contain  $\alpha$  helices.

**FIGURE 2.26 Ramachandran plot for helices.** Both right- and left-handed helices lie in regions of allowed conformations in the Ramachandran plot. However, essentially all  $\alpha$  helices in proteins are right-handed.

**FIGURE 2.27 Schematic views of  $\alpha$  helices.** (A) A ribbon depiction. (B) A cylindrical depiction.

**FIGURE 2.28 A largely  $\alpha$ -helical protein.** Ferritin, an iron-storage protein, is built from a bundle of  $\alpha$  helices. [Drawn from 1AEW.pdb.]

**FIGURE 2.29 Ramachandran plot for  $\beta$  strands.** The red area shows the sterically allowed conformations of extended,  $\beta$ -strand-like structures.

### Beta sheets are stabilized by hydrogen bonding between polypeptide strands

Pauling and Corey proposed another periodic structural motif, which they named the  $\beta$  *pleated sheet* ( $\beta$  because it was the second structure that they elucidated, the  $\alpha$  helix having been the first). The  $\beta$  pleated sheet (or, more simply, the  $\beta$  sheet) differs markedly from the rodlike  $\alpha$  helix. It is composed of two or more polypeptide chains called  $\beta$  strands. A  $\beta$  strand is almost fully extended rather than being tightly coiled as in the  $\alpha$  helix. A range of extended structures are sterically allowed (Figure 2.29).

The distance between adjacent amino acids along a  $\beta$  strand is approximately  $3.5 \text{ \AA}$ , in contrast with a distance of  $1.5 \text{ \AA}$  along an  $\alpha$  helix. The side chains of adjacent amino acids point in opposite directions (Figure 2.30).

**FIGURE 2.30 Structure of a  $\beta$  strand.** The side chains (green) are alternately above and below the plane of the strand.

A  $\beta$  sheet is formed by linking two or more  $\beta$  strands lying next to one another through hydrogen bonds. Adjacent strands in a  $\beta$  sheet can run in opposite directions (antiparallel  $\beta$  sheet) or in the same direction (parallel  $\beta$  sheet). In the antiparallel arrangement, the NH group and the CO group of each amino acid are respectively hydrogen bonded to the CO group and the NH group of a partner on the adjacent chain (Figure 2.31). In the parallel arrangement, the hydrogen-bonding scheme is slightly more complicated. For each amino acid, the NH group is hydrogen bonded to the CO group of one amino acid on the adjacent strand, whereas the CO group is hydrogen bonded to the NH group on the amino acid two residues farther along the chain (Figure 2.32). Many strands, typically 4 or 5 but as many as 10 or more, can come together in  $\beta$  sheets. Such  $\beta$  sheets can be purely antiparallel, purely parallel, or mixed (Figure 2.33).

**FIGURE 2.31 An antiparallel  $\beta$  sheet.** Adjacent  $\beta$  strands run in opposite directions, as indicated by the arrows. Hydrogen bonds between NH and CO groups connect each amino acid to a single amino acid on an adjacent strand, stabilizing the structure.

**FIGURE 2.32 A parallel  $\beta$  sheet.** Adjacent  $\beta$  strands run in the same direction, as indicated by the arrows. Hydrogen bonds connect each amino acid on one strand with two different amino acids on the adjacent strand.

**FIGURE 2.33 Structure of a mixed  $\beta$  sheet.** The arrows indicate directionality of each strand.

In schematic representations,  $\beta$  strands are usually depicted by broad arrows pointing in the direction of the carboxyl-terminal end to indicate the type of  $\beta$  sheet formed—parallel or antiparallel. More structurally diverse than  $\alpha$  helices,  $\beta$  sheets can be almost flat but most adopt a somewhat twisted shape (Figure 2.34). The  $\beta$  sheet is an important structural element in many proteins. For example, fatty acid-binding proteins, important for lipid metabolism, are built almost entirely from  $\beta$  sheets (Figure 2.35).

**FIGURE 2.34 A schematic twisted  $\beta$  sheet.** (A) A schematic model. (B) The schematic view rotated by 90 degrees to illustrate the twist more clearly.

**FIGURE 2.36 Structure of a reverse turn.** The CO group of residue  $i$  of the polypeptide chain is hydrogen bonded to the NH group of residue  $i + 3$  to stabilize the turn.

**FIGURE 2.37 Loops on a protein surface.** A part of an antibody molecule has surface loops (shown in red) that mediate interactions with other molecules. [Drawn from 7FAB.pdb.]

## Polypeptide chains can change direction by making reverse turns and loops

Most proteins have compact, globular shapes owing to reversals in the direction of their polypeptide chains. Many of these reversals are accomplished by a common structural element called the *reverse turn* (also known as the  $\beta$  turn or *hairpin turn*), illustrated in Figure 2.36. In many reverse turns, the CO group of residue  $i$  of a polypeptide is hydrogen bonded to the NH group of residue  $i + 3$ . This interaction stabilizes abrupt changes in direction of the polypeptide chain. In other cases, more-elaborate structures are responsible for chain reversals. These structures are called *loops* or sometimes  $\Omega$  loops (omega loops) to suggest their overall shape. Unlike  $\alpha$  helices and  $\beta$  strands, loops do not have regular, periodic structures. Nonetheless, loop structures are often rigid and well defined (Figure 2.37). Turns and loops invariably lie on the surfaces of proteins and thus often participate in interactions between proteins and other molecules.

## Fibrous proteins provide structural support for cells and tissues

Special types of helices are present in the two proteins  $\alpha$ -keratin and collagen. These proteins form long fibers that serve a structural role.

$\alpha$ -Keratin, which is an essential component of wool, hair, and skin, consists of two right-handed  $\alpha$  helices intertwined to form a type of left-handed superhelix called an  $\alpha$ -*helical coiled coil*.  $\alpha$ -Keratin is a member of a superfamily of proteins referred to as *coiled-coil proteins* (Figure 2.38). In these proteins, two or more  $\alpha$  helices can entwine to form a very stable structure, which can have a length of 1000 Å (100 nm, or 0.1  $\mu$ m) or more. There are approximately 60 members of this family in humans, including intermediate filaments, proteins that contribute to the cell cytoskeleton (internal scaffolding in a cell), and the muscle proteins myosin and tropomyosin (Section 35.2). Members of this family are characterized by a central region of 300 amino acids that contains imperfect repeats of a sequence of seven amino acids called a *heptad repeat*.

The two helices in  $\alpha$ -keratin associate with each other by weak interactions such as van der Waals forces and ionic interactions. The left-handed supercoil alters the two right-handed  $\alpha$  helices such that there are 3.5 residues per turn instead of 3.6. Thus, the pattern of side-chain interactions can be repeated every seven residues, forming the heptad repeats. Two helices with such repeats are able to interact with one another if the repeats are complementary (Figure 2.39). For example, the repeating residues may be hydrophobic, allowing van der Waals interactions, or have opposite charge, allowing ionic interactions. In addition, the two helices may be linked by disulfide bonds formed by neighboring cysteine residues. The bonding of the helices accounts for the physical properties of wool, an example of an  $\alpha$ -keratin. Wool is extensible and can be stretched to nearly twice its length because the  $\alpha$  helices stretch, breaking

**FIGURE 2.38 An  $\alpha$ -helical coiled coil.** (A) Space-filling model. (B) Ribbon diagram. The two helices wind around one another to form a superhelix. Such structures are found in many proteins, including keratin in hair, quills, claws, and horns. [Drawn from 1C1G.pdb.]

the weak interactions between neighboring helices. However, the covalent disulfide bonds resist breakage and return the fiber to its original state once the stretching force is released. The number of disulfide bond cross-links further defines the fiber's properties. Hair and wool, having fewer cross-links, are flexible. Horns, claws, and hooves, having more cross-links, are much harder.

A different type of helix is present in collagen, the most abundant protein of mammals. Collagen is the main fibrous component of skin, bone, tendon, cartilage, and teeth. This extracellular protein is a rod-shaped molecule, about 3000 Å long and only 15 Å in diameter. It contains three helical polypeptide chains, each nearly 1000 residues long. Glycine appears at every third residue in the amino acid sequence, and the sequence glycine-proline-hydroxyproline recurs frequently (Figure 2.40). Hydroxyproline is a derivative of proline that has a hydroxyl group in place of one of the hydrogen atoms on the pyrrolidine ring.

The collagen helix has properties different from those of the  $\alpha$  helix. Hydrogen bonds within a strand are absent. Instead, *the helix is stabilized by steric repulsion of the pyrrolidine rings of the proline and hydroxyproline residues* (Figure 2.41). The pyrrolidine rings keep out of each other's way when the polypeptide chain assumes its helical form, which has about three residues per turn. Three strands wind around one another to form a *superhelical cable* that is stabilized by hydrogen bonds between strands. The hydrogen bonds form between the peptide NH groups of glycine residues and the CO groups of residues on the other chains. The hydroxyl groups of hydroxyproline residues also participate in hydrogen bonding.

FIGURE 2.41 Conformation of a single strand of a collagen triple helix.

The inside of the triple-stranded helical cable is very crowded and accounts for the requirement that glycine be present at every third position on each strand (Figure 2.42A). *The only residue that can fit in an interior position is glycine.* The amino acid residue on either side of glycine is located on the outside of the cable, where there is room for the bulky rings of proline and hydroxyproline residues (Figure 2.42B).

FIGURE 2.42 Structure of the protein collagen. (A) Space-filling model of collagen. Each strand is shown in a different color. (B) Cross section of a model of collagen. Each strand is hydrogen bonded to the other two strands. The  $\alpha$ -carbon atom of a glycine residue is identified by the letter G. Every third residue must be glycine because there is no space in the center of the helix. Notice that the pyrrolidine rings of the proline residues are on the outside.

FIGURE 2.39 Heptad repeats in a coiled-coil protein. Every seventh residue in each helix is leucine. The two helices are held together by van der Waals interactions primarily between the leucine residues. [Drawn from 2ZTA.pdb.]

FIGURE 2.40 Amino acid sequence of a part of a collagen chain. Every third residue is a glycine. Proline and hydroxyproline (Hyp) also are abundant.

The importance of the positioning of glycine inside the triple helix is illustrated in the disorder osteogenesis imperfecta, also known as brittle bone disease. In this condition, which can vary from mild to very severe, other amino acids replace the internal glycine residue. This replacement leads to a delayed and improper folding of collagen. The most serious symptom is severe bone fragility. Defective collagen in the eyes causes the whites of the eyes to have a blue tint (blue sclera).

## 2.4 Tertiary Structure: Water-Soluble Proteins Fold into Compact Structures with Nonpolar Cores

Let us now examine how amino acids are grouped together in a complete protein. X-ray crystallographic and nuclear magnetic resonance (NMR) studies (Section 3.5) have revealed the detailed three-dimensional structures of thousands of proteins. We begin here with an examination of *myoglobin*, the first protein to be seen in atomic detail.

Myoglobin, the oxygen storage protein in muscle, is a single polypeptide chain of 153 amino acids (Chapter 7). The capacity of myoglobin to bind oxygen depends on the presence of *heme*, a nonpolypeptide *prosthetic (helper) group* consisting of protoporphyrin IX and a central iron atom. *Myoglobin is an extremely compact molecule*. Its overall dimensions are  $45 \times 35 \times 25 \text{ \AA}$ , an order of magnitude less than if it were fully stretched out (Figure 2.43). About 70% of the main chain is folded into eight  $\alpha$  helices, and much of the rest of the chain forms turns and loops between helices.

The folding of the main chain of myoglobin, like that of most other proteins, is complex and devoid of symmetry. The overall course of the polypeptide chain of a protein is referred to as its *tertiary structure*. A unifying principle emerges from the distribution of side chains. Strikingly, *the interior consists almost entirely of nonpolar residues* such as leucine, valine, methionine, and phenylalanine (Figure 2.44). Charged residues such as aspartate, glutamate, lysine, and arginine are absent from the inside of myoglobin. The only polar residues inside are two histidine residues, which play critical roles in binding iron and oxygen. The outside of myoglobin, on the

**FIGURE 2.43** Three-dimensional structure of myoglobin. (A) A ribbon diagram shows that the protein consists largely of  $\alpha$  helices. (B) A space-filling model in the same orientation shows how tightly packed the folded protein is. Notice that the heme group is nestled into a crevice in the compact protein with only an edge exposed. One helix is blue to allow comparison of the two structural depictions. [Drawn from 1A6N.pdb.]

**FIGURE 2.44** Distribution of amino acids in myoglobin. (A) A space-filling model of myoglobin with hydrophobic amino acids shown in yellow, charged amino acids shown in blue, and others shown in white. Notice that the surface of the molecule has many charged amino acids, as well as some hydrophobic amino acids. (B) In this cross-sectional view, notice that mostly hydrophobic amino acids are found on the inside of the structure, whereas the charged amino acids are found on the protein surface. [Drawn from 1MBD.pdb.]

other hand, consists of both polar and nonpolar residues. The space-filling model shows that there is very little empty space inside.

This contrasting distribution of polar and nonpolar residues reveals a key facet of protein architecture. In an aqueous environment, protein folding is driven by the strong tendency of hydrophobic residues to be excluded from water. Recall that a system is more thermodynamically stable when hydrophobic groups are clustered rather than extended into the aqueous surroundings (p. 9). *The polypeptide chain therefore folds so that its hydrophobic side chains are buried and its polar, charged chains are on the surface.* Many  $\alpha$  helices and  $\beta$  strands are amphipathic; that is, the  $\alpha$  helix or  $\beta$  strand has a hydrophobic face, which points into the protein interior, and a more polar face, which points into solution. The fate of the main chain accompanying the hydrophobic side chains is important, too. An unpaired peptide NH or CO group markedly prefers water to a nonpolar milieu. The secret of burying a segment of main chain in a hydrophobic environment is to pair all the NH and CO groups by hydrogen bonding. This pairing is neatly accomplished in an  $\alpha$  helix or  $\beta$  sheet. Van der Waals interactions between tightly packed hydrocarbon side chains also contribute to the stability of proteins. We can now understand why the set of 20 amino acids contains several that differ subtly in size and shape. They provide a palette from which to choose to fill the interior of a protein neatly and thereby maximize van der Waals interactions, which require intimate contact.

Some proteins that span biological membranes are “the exceptions that prove the rule” because they have the reverse distribution of hydrophobic and hydrophilic amino acids. For example, consider porins, proteins found in the outer membranes of many bacteria (Figure 2.45). Membranes are built largely of hydrophobic alkane chains (Section 12.2). Thus, porins are covered on the outside largely with hydrophobic residues that interact with the neighboring alkane chains. In contrast, the center of the protein contains many charged and polar amino acids that surround a water-filled channel running through the middle of the protein. Thus, because porins function in hydrophobic environments, they are “inside out” relative to proteins that function in aqueous solution.

**FIGURE 2.45** “Inside out” amino acid distribution in porin. The outside of porin (which contacts hydrophobic groups in membranes) is covered largely with hydrophobic residues, whereas the center includes a water-filled channel lined with charged and polar amino acids. [Drawn from 1PRN.pdb.]

**FIGURE 2.46** The helix-turn-helix motif, a supersecondary structural element. Helix-turn-helix motifs are found in many DNA-binding proteins. [Drawn from 1LMB.pdb.]

Certain combinations of secondary structure are present in many proteins and frequently exhibit similar functions. These combinations are called *motifs* or *supersecondary structures*. For example, an  $\alpha$  helix separated from another  $\alpha$  helix by a turn, called a *helix-turn-helix* unit, is found in many proteins that bind DNA (Figure 2.46).

Some polypeptide chains fold into two or more compact regions that may be connected by a flexible segment of polypeptide chain, rather like pearls on a string. These compact globular units, called *domains*, range in size from about 30 to 400 amino acid residues. For example, the extracellular part of CD4, a protein on the surface of certain cells of the immune system (Section 34.4), comprises four similar domains of approximately 100 amino acids each (Figure 2.47). Proteins may have domains in common even if their overall tertiary structures are different.

**FIGURE 2.47** Protein domains. The cell-surface protein CD4 consists of four similar domains. [Drawn from 1WIO.pdb.]

## 2.5 Quaternary Structure: Polypeptide Chains Can Assemble into Multisubunit Structures

Four levels of structure are frequently cited in discussions of protein architecture. So far, we have considered three. *Primary structure* is the amino acid sequence. *Secondary structure* refers to the spatial arrangement of amino acid residues that are nearby in the sequence. Some of these arrangements give rise to periodic structures. The  $\alpha$  helix and  $\beta$  strand are elements of secondary structure. *Tertiary structure* refers to the

spatial arrangement of amino acid residues that are far apart in the sequence and to the pattern of disulfide bonds. We now turn to proteins containing more than one polypeptide chain. Such proteins exhibit a fourth level of structural organization. Each polypeptide chain in such a protein is called a *subunit*. *Quaternary structure* refers to the spatial arrangement of subunits and the nature of their interactions. The simplest sort of quaternary structure is a *dimer*, consisting of two identical subunits. This organization is present in the DNA-binding protein Cro, found in a bacterial virus called  $\lambda$  (Figure 2.48). More-complicated quaternary structures also are common. More than one type of subunit can be present, often in variable numbers. For example, human hemoglobin, the oxygen-carrying protein in blood, consists of two subunits of one type (designated  $\alpha$ )

and two subunits of another type (designated  $\beta$ ), as illustrated in Figure 2.49. Thus, the hemoglobin molecule exists as an  $\alpha_2\beta_2$  tetramer. Subtle changes in the arrangement of subunits within the hemoglobin molecule allow it to carry oxygen from the lungs to tissues with great efficiency (Chapter 7).

**FIGURE 2.48** Quaternary structure. The Cro protein of bacteriophage  $\lambda$  is a dimer of identical subunits. [Drawn from 5CRO.pdb.]

**FIGURE 2.49 The  $\alpha_2\beta_2$  tetramer of human hemoglobin.** The structure of the two  $\alpha$  subunits (red) is similar to but not identical with that of the two  $\beta$  subunits (yellow). The molecule contains four heme groups (gray with the iron atom shown in purple). (A) The ribbon diagram highlights the similarity of the subunits and shows that they are composed mainly of  $\alpha$  helices. (B) The space-filling model illustrates how the heme groups occupy crevices in the protein. [Drawn from 1A3N.pdb.]

Viruses make the most of a limited amount of genetic information by forming coats that use the same kind of subunit repetitively in a symmetric array. The coat of rhinovirus, the virus that causes the common cold, includes 60 copies of each of four subunits (Figure 2.50). The subunits come together to form a nearly spherical shell that encloses the viral genome.

**FIGURE 2.50 Complex quaternary structure.** The coat of human rhinovirus, the cause of the common cold, comprises 60 copies of each of four subunits. The three most prominent subunits are shown as different colors.

## 2.6 The Amino Acid Sequence of a Protein Determines Its Three-Dimensional Structure

How is the elaborate three-dimensional structure of proteins attained? The classic work of Christian Anfinsen in the 1950s on the enzyme ribonuclease revealed the relation between the amino acid sequence of a protein and its conformation. Ribonuclease is a single polypeptide chain consisting of 124 amino acid residues cross-linked by four disulfide bonds (Figure 2.51). Anfinsen's plan was to destroy the three-dimensional structure of the enzyme and to then determine what conditions were required to restore the structure.

Agents such as *urea* or *guanidinium chloride* effectively disrupt a protein's noncovalent bonds. Although the mechanism of action of these agents is not fully understood, computer simulations suggest that they replace water as the molecule solvating the protein and are then able to disrupt the van der Waals interactions stabilizing the protein structure. The disulfide bonds can be cleaved reversibly by reducing them with a reagent such as  $\beta$ -mercaptoethanol (Figure 2.52). In the presence of a large excess of  $\beta$ -mercaptoethanol, the disulfides (cystines) are fully converted into sulfhydryls (cysteines).

**FIGURE 2.51 Amino acid sequence of bovine ribonuclease.** The four disulfide bonds are shown in color. [After C. H. W. Hirs, S. Moore, and W. H. Stein, *J. Biol. Chem.* 235:633–647, 1960.]

**FIGURE 2.52 Role of  $\beta$ -mercaptoethanol in reducing disulfide bonds.** Note that, as the disulfides are reduced, the  $\beta$ -mercaptoethanol is oxidized and forms dimers.

**FIGURE 2.53** Reduction and denaturation of ribonuclease.

Most polypeptide chains devoid of cross-links assume a *random-coil conformation* in 8 M urea or 6 M guanidinium chloride. When ribonuclease was treated with  $\beta$ -mercaptoethanol in 8 M urea, the product was a fully reduced, randomly coiled polypeptide chain *devoid of enzymatic activity*. When a protein is converted into a randomly coiled peptide without its normal activity, it is said to be *denatured* (Figure 2.53).

Anfinsen then made the critical observation that the denatured ribonuclease, freed of urea and  $\beta$ -mercaptoethanol by dialysis (Section 3.1), slowly regained enzymatic activity. He perceived the significance of this chance finding: the sulfhydryl groups of the denatured enzyme became oxidized by air, and the enzyme spontaneously refolded into a catalytically active form. Detailed studies then showed that nearly all the original enzymatic activity was regained if the sulfhydryl groups were oxidized under suitable conditions. All the measured physical and chemical properties of the refolded enzyme were virtually identical with those of the native enzyme. These experiments showed that *the information needed to specify the catalytically active structure of ribonuclease is contained in its amino acid sequence*. Subsequent studies have established the generality of this central principle of biochemistry: *sequence specifies conformation*. The dependence of conformation on sequence is especially significant because of the intimate connection between conformation and function.

A quite different result was obtained when reduced ribonuclease was reoxidized while it was still in 8 M urea and the preparation was then dialyzed to remove the urea. Ribonuclease reoxidized in this way had only 1% of the enzymatic activity of the native protein. Why were the outcomes so different when reduced ribonuclease was reoxidized in the presence and absence of urea? The reason is that the wrong disulfides formed pairs in urea. There are 105 different ways of pairing eight cysteine molecules to form four disulfides; only one of these combinations is enzymatically active. The 104 wrong pairings have been picturesquely termed “scrambled” ribonuclease. Anfinsen found that scrambled ribonuclease spontaneously converted into fully active, native ribonuclease when trace amounts of  $\beta$ -mercaptoethanol were added to an aqueous solution of the protein (Figure 2.54). The added  $\beta$ -mercaptoethanol catalyzed the rearrangement of disulfide pairings until the native structure was regained in about 10 hours. *This process was driven by the decrease in free energy as the scrambled conformations were converted into the stable, native conformation of the enzyme*. The native disulfide pairings of ribonuclease thus contribute to the stabilization of the thermodynamically preferred structure.

Similar refolding experiments have been performed on many other proteins. In many cases, the native structure can be generated under suitable conditions. For other proteins, however, refolding does not proceed efficiently. In these cases, the unfolded protein molecules usually become tangled up with one another to form aggregates. Inside cells, proteins called *chaperones* block such undesirable interactions. Additionally, it is now

**FIGURE 2.54** Reestablishing correct disulfide pairing. Native ribonuclease can be re-formed from scrambled ribonuclease in the presence of a trace of  $\beta$ -mercaptoethanol.

evident that some proteins do not assume a defined structure until they interact with molecular partners, as we will see shortly.

### Amino acids have different propensities for forming $\alpha$ helices, $\beta$ sheets, and turns

How does the amino acid sequence of a protein specify its three-dimensional structure? How does an unfolded polypeptide chain acquire the form of the native protein? These fundamental questions in biochemistry can be approached by first asking a simpler one: What determines whether a particular sequence in a protein forms an  $\alpha$  helix, a  $\beta$  strand, or a turn? One source of insight is to examine the frequency of occurrence of particular amino acid residues in these secondary structures (Table 2.3). Residues such as alanine, glutamate, and leucine tend to be present in  $\alpha$  helices, whereas valine and isoleucine tend to be present in  $\beta$  strands. Glycine, asparagine, and proline are more commonly observed in turns.

Studies of proteins and synthetic peptides have revealed some reasons for these preferences. Branching at the  $\beta$ -carbon atom, as in valine, threonine, and isoleucine, tends to destabilize  $\alpha$  helices because of steric clashes. These residues are readily accommodated in  $\beta$  strands, where their side chains project out of the plane containing the main chain. Serine and asparagine tend to disrupt  $\alpha$  helices because their side chains contain hydrogen-bond donors or acceptors in close proximity to the main chain, where they compete for main-chain NH and CO groups. Proline tends to disrupt both  $\alpha$  helices and  $\beta$  strands because it lacks an NH group and because its ring structure restricts its  $\phi$  value to near 60 degrees. Glycine readily fits into all structures, but its conformational flexibility renders it well-suited to reverse turns.

Can we predict the secondary structure of a protein by using this knowledge of the conformational preferences of amino acid residues?

**TABLE 2.3** Relative frequencies of amino acid residues in secondary structures

Amino acid	$\alpha$ helix	$\beta$ sheet	Reverse turn
Glu	1.59	0.52	1.01
Ala	1.41	0.72	0.82

Note: The amino acids are grouped according to their preference for  $\alpha$  helices (top group),  $\beta$  sheets (middle group), or turns (bottom group).

Source: T. E. Creighton, *Proteins: Structures and Molecular Properties*, 2d ed. (W. H. Freeman and Company, 1992), p. 256.

**FIGURE 2.55 Alternative conformations of a peptide sequence.** Many sequences can adopt alternative conformations in different proteins. Here the sequence VDLLKN shown in red assumes an  $\alpha$  helix in one protein context (left) and a  $\beta$  strand in another (right). [Drawn from (left) 3WRP.pdb and (right) 2HLA.pdb.]

Accurate predictions of secondary structure adopted by even a short stretch of residues have proved to be difficult. What stands in the way of more-accurate prediction? Note that the conformational preferences of amino acid residues are not tipped all the way to one structure (Table 2.3). For example, glutamate, one of the strongest helix formers, prefers  $\alpha$  helix to  $\beta$  strand by only a factor of three. The preference ratios of most other residues are smaller. Indeed, some penta- and hexapeptide sequences have been found to adopt one structure in one protein and an entirely different structure in another (Figure 2.55). Hence, some amino acid sequences do not uniquely determine secondary structure. Tertiary interactions—interactions between residues that are far apart in the sequence—may be decisive in specifying the secondary structure of some segments. Context is often crucial: the conformation of a protein has evolved to work in a particular environment. Nevertheless, substantial improvements in secondary structure prediction have been achieved by using families of related sequences, each of which adopts the same structure.

**FIGURE 2.56 Transition from folded to unfolded state.** Most proteins show a sharp transition from the folded to the unfolded form on treatment with increasing concentrations of denaturants.

### Protein folding is a highly cooperative process

Proteins can be denatured by any treatment that disrupts the weak bonds stabilizing tertiary structure, such as heating, or by chemical denaturants such as urea or guanidinium chloride. For many proteins, a comparison of the degree of unfolding as the concentration of denaturant increases reveals a sharp transition from the folded, or native, form to the unfolded, or denatured form, suggesting that only these two conformational states are present to any significant extent (Figure 2.56). A similar sharp transition is observed if denaturants are removed from unfolded proteins, allowing the proteins to fold.

The sharp transition seen in Figure 2.56 suggests that protein folding and unfolding is an “*all or none*” process that results from a *cooperative transition*. For example, suppose that a protein is placed in conditions under which some part of the protein structure is thermodynamically unstable. As this part of the folded structure is disrupted, the interactions between it and the remainder of the protein will be lost. The loss of these interactions, in turn, will destabilize the remainder of the structure. Thus, conditions that lead to the disruption of any part of a protein structure are likely to unravel the protein completely. The structural properties of proteins provide a clear rationale for the cooperative transition.

**FIGURE 2.57 Components of a partly denatured protein solution.** In a half-unfolded protein solution, half the molecules are fully folded and half are fully unfolded.

The consequences of cooperative folding can be illustrated by considering the contents of a protein solution under conditions corresponding to the middle of the transition between the folded and the unfolded forms. Under these conditions, the protein is “half folded.” Yet the solution will appear to have no partly folded molecules but, instead, look as if it is a 50/50 mixture of fully folded and fully unfolded molecules (Figure 2.57). Although the protein may appear to behave as if it exists in only two states, this simple two-state existence is an impossibility at a molecular level. Even simple reactions go through reaction intermediates, and so a complex molecule such as a protein cannot simply switch from a completely unfolded state to the native state in one step. Unstable, transient

intermediate structures must exist between the native and denatured state (p. 54). Determining the nature of these intermediate structures is an area of intense biochemical research.

### Proteins fold by progressive stabilization of intermediates rather than by random search

How does a protein make the transition from an unfolded structure to a unique conformation in the native form? One possibility a priori would be that all possible conformations are sampled to find the energetically most favorable one. How long would such a random search take? Consider a small protein with 100 residues. Cyrus Levinthal calculated that, if each residue can assume three different conformations, the total number of structures would be  $3^{100}$ , which is equal to  $5 \times 10^{47}$ . If it takes  $10^{-13}$  s to convert one structure into another, the total search time would be  $5 \times 10^{47} \times 10^{-13}$  s, which is equal to  $5 \times 10^{34}$  s, or  $1.6 \times 10^{27}$  years. In reality, small proteins can fold in less than a second. Clearly, it would take much too long for even a small protein to fold properly by randomly trying out all possible conformations. The enormous difference between calculated and actual folding times is called *Levinthal's paradox*. This paradox clearly reveals that proteins do not fold by trying every possible conformation; instead, they must follow at least a partly defined folding pathway consisting of intermediates between the fully denatured protein and its native structure.

The way out of this paradox is to recognize the power of *cumulative selection*. Richard Dawkins, in *The Blind Watchmaker*, asked how long it would take a monkey poking randomly at a typewriter to reproduce Hamlet's remark to Polonius, "Methinks it is like a weasel" (Figure 2.58). An astronomically large number of keystrokes, on the order of  $10^{40}$ , would be required. However, suppose that we preserved each correct character and allowed the monkey to retype only the wrong ones. In this case, only a few thousand keystrokes, on average, would be needed. The crucial difference between these cases is that the first employs a completely random search, whereas, in the second, *partly correct intermediates are retained*.

*The essence of protein folding is the tendency to retain partly correct intermediates.* However, the protein-folding problem is much more difficult than the one presented to our simian Shakespeare. First, the criterion of correctness is not a residue-by-residue scrutiny of conformation by an omniscient observer but rather the total free energy of the transient species. Second, proteins are only marginally stable. The free-energy difference between the folded and the unfolded states of a typical 100-residue protein is  $42 \text{ kJ mol}^{-1}$  ( $10 \text{ kcal mol}^{-1}$ ), and thus each residue contributes on average only  $0.42 \text{ kJ mol}^{-1}$  ( $0.1 \text{ kcal mol}^{-1}$ ) of energy to maintain the folded state. This amount is less than the amount of thermal energy, which is  $2.5 \text{ kJ mol}^{-1}$  ( $0.6 \text{ kcal mol}^{-1}$ ) at room temperature. This meager stabilization energy means that correct intermediates, especially those formed early in folding, can be lost. The analogy is that the monkey would be somewhat free to undo its correct keystrokes. Nonetheless, the interactions that lead to cooperative folding can stabilize intermediates as structure builds up. Thus, local regions that have significant structural preference, though not necessarily stable on their own, will tend to adopt their favored structures and, as they form, can interact with one other, leading to increasing stabilization. This conceptual framework is often referred to as the *nucleation-condensation model*.

A simulation of the folding of a protein, based on the nucleation-condensation model, is shown in Figure 2.59. This model suggests that

**FIGURE 2.58 Typing-monkey analogy.** A monkey randomly poking a typewriter could write a line from Shakespeare's *Hamlet*, provided that correct keystrokes were retained. In the two computer simulations shown, the cumulative number of keystrokes is given at the left of each line.

**FIGURE 2.59 Proposed folding pathway of chymotrypsin inhibitor.** Local regions with sufficient structural preference tend to adopt their favored structures initially (1). These structures come together to form a nucleus with a nativelike, but still mobile, structure (4). This structure then fully condenses to form the native, more rigid structure (5). [From A. R. Fersht and V. Daggett. *Cell* 108:573–582, 2002; with permission from Elsevier.]

certain pathways may be preferred. Although Figure 2.59 suggests a discrete pathway, each of the intermediates shown represents an ensemble of similar structures, and thus a protein follows a general rather than a precise pathway in its transition from the unfolded to the native state. The energy surface for the overall process of protein folding can be visualized as a funnel (Figure 2.60). The wide rim of the funnel represents the wide range of structures accessible to the ensemble of denatured protein molecules. As the free energy of the population of protein molecules decreases, the proteins move down into narrower parts of the funnel and fewer conformations are accessible. At the bottom of the funnel is the folded state with its well-defined conformation. Many paths can lead to this same energy minimum.

**FIGURE 2.60 Folding funnel.** The folding funnel depicts the thermodynamics of protein folding. The top of the funnel represents all possible denatured conformations—that is, maximal conformational entropy. Depressions on the sides of the funnel represent semistable intermediates that can facilitate or hinder the formation of the native structure, depending on their depth. Secondary structures, such as helices, form and collapse onto one another to initiate folding. [After D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry*, 5th ed. (W. H. Freeman and Company, 2008), p. 143.]

### Prediction of three-dimensional structure from sequence remains a great challenge

The prediction of three-dimensional structure from sequence has proved to be extremely difficult. The local sequence appears to determine only between 60 and 70% of the secondary structure; long-range interactions are required to stabilize the full secondary structure and the tertiary structure.

Investigators are exploring two fundamentally different approaches to predicting three-dimensional structure from amino acid sequence. The first is *ab initio* (Latin, “from the beginning”) *prediction*, which attempts to predict the folding of an amino acid sequence without prior knowledge about similar sequences in known protein structures. Computer-based calculations are employed that attempt to minimize the free energy of a structure with a given amino acid sequence or to simulate the folding process. The utility of these methods is limited by the vast number of possible conformations, the marginal stability of proteins, and the subtle energetics of weak interactions in aqueous solution. The second approach takes advantage of our growing knowledge of the three-dimensional structures of many proteins. In these *knowledge-based methods*, an amino acid sequence of unknown structure is examined for compatibility with known protein structures or fragments therefrom. If a significant match is detected, the known structure can be used as an initial model. Knowledge-based methods have been a source of many insights into the three-dimensional conformation of proteins of known sequence but unknown structure.

### Some proteins are inherently unstructured and can exist in multiple conformations

The discussion of protein folding thus far is based on the paradigm that a given protein amino acid sequence will fold into a particular three-dimensional structure. This paradigm holds well for many proteins. However, it has been known for some time that some proteins can adopt two different structures, only one of which results in protein aggregation and pathological conditions (p. 56). Such alternate structures originating from a unique amino acid sequence were thought to be rare, the exception to the paradigm. Recent work has called into question the universality of the idea that each amino acid sequence gives rise to one structure for certain proteins, even under normal cellular conditions.

Our first example is a class of proteins referred to as *intrinsically unstructured proteins* (IUPs). As the name suggests, these proteins, completely or in part, do not have a discrete three-dimensional structure under physiological conditions. Indeed, an estimated 50% of eukaryotic proteins have at least one unstructured region greater than 30 amino acids in length. Unstructured regions are rich in charged and polar amino acids with few hydrophobic residues. These proteins assume a defined structure on interaction with other proteins. This molecular versatility means that one protein can assume different structures and interact with the different partners, yielding different biochemical functions. IUPs appear to be especially important in signaling and regulatory pathways.

Another class of proteins that do not adhere to the paradigm is *metamorphic proteins*. These proteins appear to exist in an ensemble of structures of approximately equal energy that are in equilibrium. Small molecules or other proteins may bind to different members of the ensemble, resulting in various complexes, each having a different biochemical function. An especially clear example of a metamorphic protein is the chemokine lymphotactin. Chemokines are small signaling proteins in the immune system that bind to receptor proteins on the surface of immune-system cells, instigating an immunological response. Lymphotactin exists in two very different structures that are in equilibrium (Figure 2.61). One structure is characteristic of chemokines, consisting of a three-stranded  $\beta$  sheet and a carboxyl-terminal helix. This structure binds to its receptor and activates it. The alternative structure is an identical dimer of all  $\beta$  sheets. When in this structure, lymphotactin binds to glycosaminoglycan, a complex carbohydrate (Chapter 11). The biochemical activities of each structure are mutually exclusive: the chemokine structure cannot bind the glycosaminoglycan, and the  $\beta$ -sheet structure cannot activate the receptor. Yet, remarkably, both activities are required for full biological activity of the chemokine.

**FIGURE 2.61** Lymphotactin exists in two conformations, which are in equilibrium.

[R. L. Tuinstra, F. C. Peterson, S. Kutlesa, E. S. Elgin, M. A. Kron, and B. F. Volkman. *Proc. Natl. Sci. U.S.A.* 105:5057–5062, 2008, Fig. 2A.]

Note that IUPs and metamorphic proteins effectively expand the protein-encoding capacity of the genome. In some cases, a gene can encode a single protein that has more than one structure and function. These examples also illustrate the dynamic nature of the study of biochemistry and its inherent excitement: even well-established ideas are often subject to modifications.

### Protein misfolding and aggregation are associated with some neurological diseases

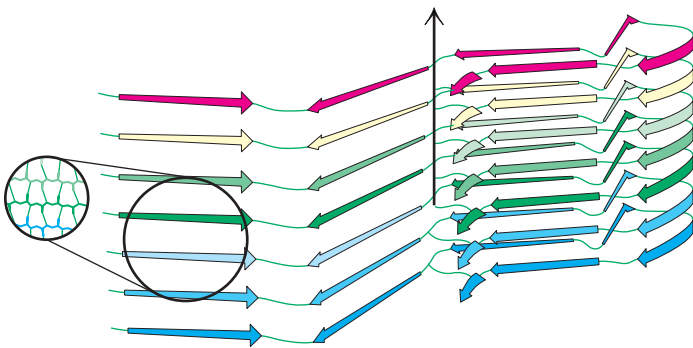

Understanding protein folding and misfolding is of more than academic interest. A host of diseases, including Alzheimer disease, Parkinson disease, Huntington disease, and transmissible spongiform encephalopathies (prion disease), are associated with improperly folded proteins. All of these diseases result in the deposition of protein aggregates, called *amyloid fibrils* or *plaques*. These diseases are consequently referred to as *amyloidoses*. A common feature of amyloidoses is that normally soluble proteins are converted into insoluble fibrils rich in  $\beta$  sheets. The correctly folded protein is only marginally more stable than the incorrect form. But the incorrect form aggregates, pulling more correct forms into the incorrect form. We will focus on the transmissible spongiform encephalopathies.

One of the great surprises in modern medicine was that certain infectious neurological diseases were found to be transmitted by agents that were similar in size to viruses but consisted only of protein. These diseases include *bovine spongiform encephalopathy* (commonly referred to as *mad cow disease*) and the analogous diseases in other organisms, including *Creutzfeldt–Jakob disease* (CJD) in human beings, *scrapie* in sheep, and chronic wasting disease in deer and elk. The agents causing these diseases are termed *prions*. Prions are composed largely, if not exclusively, of a cellular protein called PrP, which is normally present in the brain; its function is still the focus of active research. The infectious prions are aggregated forms of the PrP protein termed PrP<sup>SC</sup>.

How does the structure of the protein in the aggregated form differ from that of the protein in its normal state in the brain? The normal cellular protein PrP contains extensive regions of  $\alpha$  helix and relatively little  $\beta$  strand. The structure of the form of PrP present in infected brains, termed PrP<sup>SC</sup>, has not yet been determined because of challenges posed by its insoluble and heterogeneous nature. However, a variety of evidence indicates that some parts of the protein that had been in  $\alpha$ -helical or turn conformations have been converted into  $\beta$ -strand conformations (Figure 2.62). The  $\beta$  strands of largely planar monomers stack on one another with their side chains tightly interwoven. A side view shows the extensive network of hydrogen bonds between the monomers. These fibrous protein aggregates are often referred to as *amyloid forms*.

With the realization that the infectious agent in prion diseases is an aggregated form of a protein that is already present in the brain, a model for disease transmission emerges (Figure 2.63). Protein aggregates built of abnormal forms of PrP<sup>SC</sup> act as sites of nucleation to which other PrP molecules attach. Prion diseases can thus be transferred from one individual organism to another through the transfer of an aggregated nucleus, as likely happened in the mad cow disease outbreak in the United Kingdom that emerged in the late 1980s. Cattle fed on animal feed containing material from diseased cows developed the disease in turn.

**FIGURE 2.62** A model of the human prion protein amyloid.

A detailed model of a human prion amyloid fibril deduced from spin labeling and electron paramagnetic resonance (EPR) spectroscopy studies shows that protein aggregation is due to the formation of large parallel  $\beta$  sheets. The black arrow indicates the long axis of the fibril.

[N. J. Cobb, F. D. Sönnichsen, H. Mchaourab, and W. K. Surewicz. *Proc. Natl. Acad. Sci. U.S.A.* 104: 18946–18951, 2007, Fig. 4E.]

**FIGURE 2.63** The protein-only model for prion-disease transmission. A nucleus consisting of proteins in an abnormal conformation grows by the addition of proteins from the normal pool.

Amyloid fibers are also seen in the brains of patients with certain noninfectious neurodegenerative disorders such as Alzheimer and Parkinson diseases. For example, the brains of patients with Alzheimer disease contain protein aggregates called *amyloid plaques* that consist primarily of a single polypeptide termed  $A\beta$ . This polypeptide is derived from a cellular protein called *amyloid precursor protein* (APP) through the action of specific proteases. Polypeptide  $A\beta$  is prone to form insoluble aggregates. Despite the difficulties posed by the protein's insolubility, a detailed structural model for  $A\beta$  has been derived through the use of NMR techniques that can be applied to solids rather than to materials in solution. As expected, the structure is rich in  $\beta$  strands, which come together to form extended parallel  $\beta$ -sheet structures (Figure 2.62).

How do such aggregates lead to the death of the cells that harbor them? The answer is still controversial. One hypothesis is that the large aggregates themselves are not toxic but, instead, smaller aggregates of the same proteins may be the culprits, perhaps damaging cell membranes.

### Protein modification and cleavage confer new capabilities

Proteins are able to perform numerous functions that rely solely on the versatility of their 20 amino acids. In addition, many proteins are covalently modified, through the attachment of groups other than amino acids, to augment their functions (Figure 2.64). For example, *acetyl groups* are attached to the amino termini of many proteins, a modification that makes these proteins more resistant to degradation. As discussed earlier (p. 45), the addition of *hydroxyl groups* to many proline residues stabilizes fibers of newly synthesized collagen. The biological significance of this modification is evident in the disease scurvy: a deficiency of vitamin C results in insufficient hydroxylation of collagen, and the abnormal collagen fibers that result are unable to maintain normal tissue strength (Section 27.6). Another specialized amino acid is  *$\gamma$ -carboxyglutamate*. In vitamin K deficiency, insufficient

**FIGURE 2.64** Finishing touches. Some common and important covalent modifications of amino acid side chains are shown.

carboxylation of glutamate in prothrombin, a clotting protein, can lead to hemorrhage (Section 10.4). Many proteins, especially those that are present on the surfaces of cells or are secreted, acquire *carbohydrate units* on specific asparagine, serine, or threonine residues (Chapter 11). The addition of sugars makes the proteins more hydrophilic and able to participate in interactions with other proteins. Conversely, the addition of a *fatty acid* to an  $\alpha$ -amino group or a cysteine sulfhydryl group produces a more hydrophobic protein.

Many hormones, such as epinephrine (adrenaline), alter the activities of enzymes by stimulating the phosphorylation of the hydroxyl amino acids serine and threonine; *phosphoserine* and *phosphothreonine* are the most ubiquitous modified amino acids in proteins. Growth factors such as insulin act by triggering the phosphorylation of the hydroxyl group of tyrosine residues to form *phosphotyrosine*. The phosphoryl groups on these three modified amino acids are readily removed; thus the modified amino acids are able to act as reversible switches in regulating cellular processes. The roles of phosphorylation in signal transduction will be discussed extensively in Chapter 14.

The preceding modifications consist of the addition of special groups to amino acids. Other special groups are generated by chemical rearrangements of side chains and, sometimes, the peptide backbone. For example, the jellyfish *Aequorea victoria* produces green fluorescent protein (GFP), which emits green light when stimulated with blue light. The source of the fluorescence is a group formed by the spontaneous rearrangement and oxidation of the sequence Ser-Tyr-Gly within the center of the protein (Figure 2.65A). Since the discovery

**FIGURE 2.65 Chemical rearrangement in GFP.** (A) The structure of green fluorescent protein (GFP). The rearrangement and oxidation of the sequence Ser-Tyr-Gly is the source of fluorescence. (B) Mutants of GFP emit light across the visible spectrum. (C) A melanoma cell line engineered to express one of these GFP mutants, red fluorescent protein (RFP), was then injected into a mouse whose blood vessels express GFP. In this fluorescence micrograph, the formation of new blood vessels (green) in the tumor (red) is readily apparent. [(A) Drawn from 1GFL.pdb; (B) R.Y. Tsien. *Integr. Biol.* 2:77–93, 2010, Fig. 12; (C) M. Yang, et al. *Proc. Natl. Acad. Sci. U.S.A.* 100:14259–14262, 2003, Fig. 2B]

of GFP, a number of mutants have been engineered which absorb and emit light across the entire visible spectrum (Figure 2.65B). These proteins are of great utility to researchers as markers within cells (Figure 2.65C).

Finally, many proteins are cleaved and trimmed after synthesis. For example, digestive enzymes are synthesized as inactive precursors that can be stored safely in the pancreas. After release into the intestine, these precursors become activated by peptide-bond cleavage (Section 10.4). In blood clotting, peptide-bond cleavage converts soluble fibrinogen into insoluble fibrin. A number of polypeptide hormones, such as adrenocorticotrophic hormone, arise from the splitting of a single large precursor protein. Likewise, many viral proteins are produced by the cleavage of large polyprotein precursors. We shall encounter many more examples of modification and cleavage as essential features of protein formation and function. Indeed, these finishing touches account for much of the versatility, precision, and elegance of protein action and regulation.

## SUMMARY

Protein structure can be described at four levels. The primary structure refers to the amino acid sequence. The secondary structure refers to the conformation adopted by local regions of the polypeptide chain. Tertiary structure describes the overall folding of the polypeptide chain. Finally, quaternary structure refers to the specific association of multiple polypeptide chains to form multisubunit complexes.

### 2.1 Proteins Are Built from a Repertoire of 20 Amino Acids

Proteins are linear polymers of amino acids. Each amino acid consists of a central tetrahedral carbon atom linked to an amino group, a carboxylic acid group, a distinctive side chain, and a hydrogen atom. These tetrahedral centers, with the exception of that of glycine, are chiral; only the L isomer exists in natural proteins. Nearly all natural proteins are constructed from the same set of 20 amino acids. The side chains of these 20 building blocks vary tremendously in size, shape, and the presence of functional groups. They can be grouped as follows: (1) hydrophobic side chains, including the aliphatic amino acids—glycine, alanine, valine, leucine, isoleucine, methionine, and proline—and aromatic side chains—phenylalanine, and tryptophan; (2) polar side chains, including hydroxyl-containing side chains—serine, threonine and tyrosine; the sulfhydryl-containing cysteine; and carboxamide-containing side chains—asparagine and glutamine; (3) basic side chains—lysine, arginine, and histidine; and (4) acidic side chains—aspartic acid and glutamic acid. These groupings are somewhat arbitrary and many other sensible groupings are possible.

### 2.2 Primary Structure: Amino Acids Are Linked by Peptide Bonds to Form Polypeptide Chains

The amino acids in a polypeptide are linked by amide bonds formed between the carboxyl group of one amino acid and the amino group of the next. This linkage, called a peptide bond, has several important properties. First, it is resistant to hydrolysis, and so proteins are remarkably stable kinetically. Second, the peptide group is planar because the C—N bond has considerable double-bond character. Third, each peptide bond has both a hydrogen-bond donor (the NH group) and a hydrogen-bond acceptor (the CO group). Hydrogen bonding between these backbone groups is a distinctive feature of protein structure. Finally, the peptide bond is uncharged, which allows proteins to form

tightly packed globular structures having significant amounts of the backbone buried within the protein interior. Because they are linear polymers, proteins can be described as sequences of amino acids. Such sequences are written from the amino to the carboxyl terminus.

### 2.3 Secondary Structure: Polypeptide Chains Can Fold into Regular Structures Such As the Alpha Helix, the Beta Sheet, and Turns and Loops

Two major elements of secondary structure are the  $\alpha$  helix and the  $\beta$  strand. In the  $\alpha$  helix, the polypeptide chain twists into a tightly packed rod. Within the helix, the CO group of each amino acid is hydrogen bonded to the NH group of the amino acid four residues farther along the polypeptide chain. In the  $\beta$  strand, the polypeptide chain is nearly fully extended. Two or more  $\beta$  strands connected by NH-to-CO hydrogen bonds come together to form  $\beta$  sheets. The strands in  $\beta$  sheets can be antiparallel, parallel, or mixed.

### 2.4 Tertiary Structure: Water-Soluble Proteins Fold into Compact Structures with Nonpolar Cores

The compact, asymmetric structure that individual polypeptides attain is called tertiary structure. The tertiary structures of water-soluble proteins have features in common: (1) an interior formed of amino acids with hydrophobic side chains and (2) a surface formed largely of hydrophilic amino acids that interact with the aqueous environment. The hydrophobic interactions between the interior residues are the driving force for the formation of the tertiary structure of water-soluble proteins. Some proteins that exist in a hydrophobic environment, such as in membranes, display the inverse distribution of hydrophobic and hydrophilic amino acids. In these proteins, the hydrophobic amino acids are on the surface to interact with the environment, whereas the hydrophilic groups are shielded from the environment in the interior of the protein.

### 2.5 Quaternary Structure: Polypeptide Chains Can Assemble into Multisubunit Structures

Proteins consisting of more than one polypeptide chain display quaternary structure; each individual polypeptide chain is called a subunit. Quaternary structure can be as simple as two identical subunits or as complex as dozens of different subunits. In most cases, the subunits are held together by noncovalent bonds.

### 2.6 The Amino Acid Sequence of a Protein Determines Its Three-Dimensional Structure

The amino acid sequence determines the three-dimensional structure and, hence, all other properties of a protein. Some proteins can be unfolded completely yet refold efficiently when placed under conditions in which the folded form of the protein is stable. The amino acid sequence of a protein is determined by the sequences of bases in a DNA molecule. This one-dimensional sequence information is extended into the three-dimensional world by the ability of proteins to fold spontaneously. Protein folding is a highly cooperative process; structural intermediates between the unfolded and folded forms do not accumulate.

Some proteins, such as intrinsically unstructured proteins and metamorphic proteins, do not strictly adhere to the one-sequence-one-structure paradigm. Because of this versatility, these proteins expand the protein encoding capacity of the genome.

The versatility of proteins is further enhanced by covalent modifications. Such modifications can incorporate functional groups not present in the 20 amino acids. Other modifications are important to the

regulation of protein activity. Through their structural stability, diversity, and chemical reactivity, proteins make possible most of the key processes associated with life.

## APPENDIX: Visualizing Molecular Structures II: Proteins

Scientists have developed powerful techniques for the determination of protein structures, as will be considered in Chapter 3. In most cases, these techniques allow the positions of the thousands of atoms within a protein structure to be determined. The final results from such an experiment include the  $x$ ,  $y$ , and  $z$  coordinates for each atom in the structure. These coordinate files are compiled in the Protein Data Bank (<http://www.pdb.org>) from which they can be readily downloaded. These structures comprise thousands or even tens of thousands of atoms. The complexity of proteins with thousands of atoms presents a challenge for the depiction of their structure. Several different types of representations are used to portray proteins, each with its own strengths and weaknesses. The types that you will see most often in this book are space-filling models, ball-and-stick models, backbone models, and ribbon diagrams. Where appropriate, structural features of particular importance or relevance are noted in an illustration's legend.

### Space-Filling Models

Space-filling models are the most realistic type of representation. Each atom is shown as a sphere with a size corresponding to the van der Waals radius of the atom (Section 1.3). Bonds are not shown explicitly but are represented by the intersection of the spheres shown when atoms are closer together than the sum of their van der Waals radii. All atoms are shown, including those that make up the backbone and those in the side chains. A space-filling model of lysozyme is depicted in Figure 2.66.

Space-filling models convey a sense of how little open space there is in a protein's structure, which always has many atoms in van der Waals contact with one another. These models are particularly useful in showing conformational changes in a protein from one set of circumstances to another. A disadvantage of space-filling models is that the secondary and tertiary structures of the protein are difficult to see. Thus, these models are not very effective in distinguishing one protein from another—many space-filling models of proteins look very much alike.

### Ball-and-Stick Models

Ball-and-stick models are not as realistic as space-filling models. Realistically portrayed atoms occupy more space, determined by their van der Waals radii, than do the atoms depicted in ball-and-stick models. However, the bonding arrangement is easier to see because the bonds are explicitly represented as sticks (Figure 2.67). A ball-and-stick model reveals a complex structure more clearly than a space-filling model does. However, the depiction is so complicated that structural features such as  $\alpha$  helices or potential binding sites are difficult to discern.

Because space-filling and ball-and-stick models depict protein structures at the atomic level, the large number of

atoms in a complex structure makes it difficult to distinguish the relevant structural features. Thus, representations that are more schematic—such as backbone models and ribbon diagrams—have been developed for the depiction of macromolecular structures. In these representations, most or all atoms are not shown explicitly.

### Backbone Models

Backbone models show only the backbone atoms of a polypeptide chain or even only the  $\alpha$ -carbon atom of each

**FIGURE 2.66** Space-filling model of lysozyme. Notice how tightly packed the atoms are, with little unfilled space. All atoms are shown with the exception of hydrogen atoms. Hydrogen atoms are often omitted because their positions are not readily determined by x-ray crystallographic methods and because their omission somewhat improves the clarity of the structure's depiction.

**FIGURE 2.67** Ball-and-stick model of lysozyme. Again, hydrogen atoms are omitted.

FIGURE 2.68 Backbone model of lysozyme.

amino acid. Atoms are linked by lines representing bonds; if only  $\alpha$ -carbon atoms are depicted, lines connect  $\alpha$ -carbon atoms of amino acids that are adjacent in the amino acid sequence (Figure 2.68). In this book, backbone models show only the lines connecting the  $\alpha$ -carbon atoms; other carbon atoms are not depicted.

A backbone model shows the overall course of the polypeptide chain much better than a space-filling or ball-and-stick model does. However, secondary structural elements are still difficult to see.

### Ribbon Diagrams

Ribbon diagrams are highly schematic and most commonly used to accent a few dramatic aspects of protein structure, such as the  $\alpha$  helix (depicted as a coiled ribbon or a cylinder), the  $\beta$  strand (a broad arrow), and loops (thin tubes), to provide clear views of the folding patterns of proteins (Figure 2.69). The ribbon diagram allows the course of a polypeptide chain to be traced and readily shows the secondary structural elements. Thus, ribbon diagrams of proteins that are related to one another by evolutionary divergence appear similar (Figure 6.15), whereas unrelated proteins are clearly distinct.

In this book, coiled ribbons will be generally used to depict  $\alpha$  helices. However, for membrane proteins, which are often quite complex, cylinders will be used rather than coiled ribbons. This convention will also make membrane proteins with their membrane-spanning  $\alpha$  helices easy to recognize (Figure 12.18).

FIGURE 2.69 Ribbon diagram of lysozyme. The  $\alpha$  helices are shown as coiled ribbons;  $\beta$  strands are depicted as arrows. More irregular structures are shown as thin tubes.

Bear in mind that the open appearance of ribbon diagrams is deceptive. As noted earlier, protein structures are tightly packed and have little open space. The openness of ribbon diagrams makes them particularly useful as frameworks in which to highlight additional aspects of protein structure. Active sites, substrates, bonds, and other structural fragments can be included in ball-and-stick or space-filling form within a ribbon diagram (Figure 2.70).

FIGURE 2.70 Ribbon diagram of lysozyme with highlights. Four disulfide bonds and a functionally important aspartate residue are shown in ball-and-stick form.

## KEY TERMS

side chain (R group) (p. 29)

L amino acid (p. 29)

dipolar ion (zwitterion) (p. 29)

peptide bond (amide bond) (p. 35)

disulfide bond (p. 36)

primary structure (p. 37)

torsion angle (p. 39)

phi ( $\phi$ ) angle (p. 39)

psi ( $\psi$ ) angle (p. 39)

Ramachandran plot (p. 39)

secondary structure (p. 40)

$\alpha$  helix (p. 40)

rise (translation) (p. 40)

$\beta$  pleated sheet (p. 42)

$\beta$  strand (p. 42)

reverse turn ( $\beta$  turn; hairpin turn)  
(p. 44)  
coiled coil (p. 44)  
heptad repeat (p. 44)  
tertiary structure (p. 46)

motif (supersecondary structure)

## PROBLEMS

1. *Identify.* Examine the following four amino acids (A–D):

What are their names, three-letter abbreviations, and one-letter symbols?

2. *Properties.* In reference to the amino acids shown in Problem 1, which are associated with the following characteristics?

- Hydrophobic side chain \_\_\_\_\_
- Basic side chain \_\_\_\_\_
- Three ionizable groups \_\_\_\_\_
- $pK_a$  of approximately 10 in proteins \_\_\_\_\_
- Modified form of phenylalanine \_\_\_\_\_

3. *Match 'em.* Match each amino acid in the left-hand column with the appropriate side-chain type in the right-hand column.

- |         |                         |
|---------|-------------------------|
| (a) Leu | (1) hydroxyl-containing |
| (b) Glu | (2) acidic              |
| (c) Lys | (3) basic               |
| (d) Ser | (4) sulfur-containing   |
| (e) Cys | (5) nonpolar aromatic   |
| (f) Trp | (6) nonpolar aliphatic  |

4. *Solubility.* In each of the following pairs of amino acids, identify which amino acid would be more soluble in water: (a) Ala, Leu; (b) Tyr, Phe; (c) Ser, Ala; (d) Trp, His.

5. *Bonding is good.* Which of the following amino acids have R groups that have hydrogen-bonding potential? Ala, Gly, Ser, Phe, Glu, Tyr, Ile, and Thr.

6. *Name those components.* Examine the segment of a protein shown here.

- What three amino acids are present?
- Of the three, which is the N-terminal amino acid?
- Identify the peptide bonds.
- Identify the  $\alpha$ -carbon atoms.

7. *Who's charged?* Draw the structure of the dipeptide Gly-His. What is the charge on the peptide at pH 5.5? pH 7.5?

8. *Alphabet soup.* How many different polypeptides of 50 amino acids in length can be made from the 20 common amino acids?

9. *Sweet tooth, but calorie conscious.* Aspartame (NutraSweet), an artificial sweetener, is a dipeptide composed of Asp-Phe in which the carboxyl terminus is modified by the attachment of a methyl group. Draw the structure of Aspartame at pH 7.

10. *Vertebrate proteins?* What is meant by the term *polypeptide backbone*?

11. *Not a sidecar.* Define the term *side chain* in the context of amino acid or protein structure.

12. *One from many.* Differentiate between *amino acid composition* and *amino acid sequence*.

13. *Shape and dimension.* (a) Tropomyosin, a 70-kDa muscle protein, is a two-stranded  $\alpha$ -helical coiled coil. Estimate the length of the molecule. (b) Suppose that a 40-residue segment of a protein folds into a two-stranded antiparallel  $\beta$  structure with a 4-residue hairpin turn. What is the longest dimension of this motif?

14. *Contrasting isomers.* Poly-L-leucine in an organic solvent such as dioxane is  $\alpha$  helical, whereas poly-L-isoleucine is not. Why do these amino acids with the same number and kinds of atoms have different helix-forming tendencies?

15. *Exceptions to the rule.* Ramachandran plots for two amino acids differ significantly from that shown in Figure 2.23. Which two, and why?

16. *Active again.* A mutation that changes an alanine residue in the interior of a protein to valine is found to lead to a loss of activity. However, activity is regained when a second

mutation at a different position changes an isoleucine residue to glycine. How might this second mutation lead to a restoration of activity?

17. *Exposure issues.* Many of the loops on proteins are composed of hydrophilic amino acids. Why might this be the case?

18. *Shuffle test.* An enzyme that catalyzes disulfide–sulfhydryl exchange reactions, called protein disulfide isomerase (PDI), has been isolated. PDI rapidly converts inactive scrambled ribonuclease into enzymatically active ribonuclease. In contrast, insulin is rapidly inactivated by PDI. What does this important observation imply about the relation between the amino acid sequence of insulin and its three-dimensional structure?

19. *Stretching a target.* A protease is an enzyme that catalyzes the hydrolysis of the peptide bonds of target proteins. How might a protease bind a target protein so that its main chain becomes fully extended in the vicinity of the vulnerable peptide bond?

20. *Often irreplaceable.* Glycine is a highly conserved amino acid residue in the evolution of proteins. Why?

21. *Potential partners.* Identify the groups in a protein that can form hydrogen bonds or electrostatic bonds with an arginine side chain at pH 7.

22. *Permanent waves.* The shape of hair is determined in part by the pattern of disulfide bonds in keratin, its major protein. How can curls be induced?

23. *Location is everything 1.* Most proteins have hydrophilic exteriors and hydrophobic interiors. Would you expect this structure to apply to proteins embedded in the hydrophobic interior of a membrane? Explain.

24. *Location is everything 2.* Proteins that span biological membranes often contain  $\alpha$  helices. Given that the insides of membranes are highly hydrophobic (Section 12.2), predict what type of amino acids would be in such an  $\alpha$  helix. Why is an  $\alpha$  helix particularly suited to existence in the hydrophobic environment of the interior of a membrane?

25. *Neighborhood peer pressure?* Table 2.1 shows the typical  $pK_a$  values for ionizable groups in proteins. However, more than 500  $pK_a$  values have been determined for individual groups in folded proteins. Account for this discrepancy.

26. *Greasy patches.* The  $\alpha$  and  $\beta$  subunits of hemoglobin bear a remarkable structural similarity to myoglobin. However, in the subunits of hemoglobin, certain residues that are hydrophilic in myoglobin are hydrophobic. Why might this be the case?

27. *Maybe size does matter.* Osteogenesis imperfecta displays a wide range of symptoms, from mild to severe. On

the basis of your knowledge of amino acid and collagen structure, propose a biochemical basis for the variety of symptoms.

28. *Issues of stability.* Proteins are quite stable. The lifetime of a peptide bond in aqueous solution is nearly 1000 years. However, the free energy of hydrolysis of proteins is negative and quite large. How can you account for the stability of the peptide bond in light of the fact that hydrolysis releases much energy?

29. *Minor species.* For an amino acid such as alanine, the major species in solution at pH 7 is the zwitterionic form. Assume a  $pK_a$  value of 8 for the amino group and a  $pK_a$  value of 3 for the carboxylic acid. Estimate the ratio of the concentration of the neutral amino acid species (with the carboxylic acid protonated and the amino group neutral) to that of the zwitterionic species at pH 7 (Section 1.3).

30. *A matter of convention.* All L amino acids have an S absolute configuration except L-cysteine, which has the R configuration. Explain why L-cysteine is designated as having the R absolute configuration.

31. *Hidden message.* Translate the following amino acid sequence into one-letter code: Glu-Leu-Val-Ile-Ser-Ile-Ser-Leu-Ile-Val-Ile-Asn-Gly-Ile-Asn-Leu-Ala-Ser-Val-Glu-Gly-Ala-Ser.

32. *Who goes first?* Would you expect Pro—X peptide bonds to tend to have cis conformations like those of X—Pro bonds? Why or why not?

33. *Matching.* For each of the amino acid derivatives shown here (A–E), find the matching set of  $\phi$  and  $\psi$  values (a–e).

34. *Scrambled ribonuclease.* When performing his experiments on protein refolding, Christian Anfinsen obtained a quite different result when reduced ribonuclease was reoxidized while it was still in 8 M urea and the preparation was then dialyzed to remove the urea. Ribonuclease reoxidized in this way had only 1% of the enzymatic activity of the native protein. Why were the outcomes so different when reduced ribonuclease was reoxidized in the presence and absence of urea?

# Exploring Proteins and Proteomes

Milk, a source of nourishment for all mammals, is composed, in part, of a variety of proteins. The protein components of milk are revealed by the technique of MALDI-TOF mass spectrometry, which separates molecules on the basis of their mass-to-charge ratio. [(Left) Okea/istockphoto.com. (Right) Courtesy of Dr. Brian Chait.]

Proteins play crucial roles in nearly all biological processes—in catalysis, signal transmission, and structural support. This remarkable range of functions arises from the existence of thousands of proteins, each folded into a distinctive three-dimensional structure that enables it to interact with one or more of a highly diverse array of molecules. A major goal of biochemistry is to determine how amino acid sequences specify the conformations, and hence functions, of proteins. Other goals are to learn how individual proteins bind specific substrates and other molecules, mediate catalysis, and transduce energy and information.

It is often preferable to study a protein of interest after it has been separated from other components within the cell so that the structure and function of this protein can be probed without any confounding effects from contaminants. Hence, the first step in these studies is the purification of the protein of interest. Proteins can be separated from one another on the basis of solubility, size, charge, and binding ability. After a protein has been purified, its amino acid sequence can be determined. Many protein sequences, often deduced from genome sequences, are available in vast sequence databases. If the sequence of a purified protein has been archived in a publicly searchable database, the job of the investigator becomes much easier. The investigator need determine only a small stretch of amino acid sequence of the protein to find its match in the database. Alternatively, such a protein might be identified by matching its mass to those deduced for proteins in the database. Mass spectrometry provides a powerful method for determining the mass and sequence of a protein.

## OUTLINE

- 3.1 The Purification of Proteins Is an Essential First Step in Understanding Their Function
- 3.2 Immunology Provides Important Techniques with Which to Investigate Proteins
- 3.3 Mass Spectrometry Is a Powerful Technique for the Identification of Peptides and Proteins
- 3.4 Peptides Can Be Synthesized by Automated Solid-Phase Methods
- 3.5 Three-Dimensional Protein Structure Can Be Determined by X-ray Crystallography and NMR Spectroscopy

After a protein has been purified and its identity confirmed, the challenge remains to determine its function within a physiologically relevant context. Antibodies are choice probes for locating proteins *in vivo* and measuring their quantities. Monoclonal antibodies, able to recognize specific proteins, can be obtained in large amounts and used to detect and quantify the protein both in isolation and in cells. Peptides and proteins can be chemically synthesized, providing tools for research and, in some cases, highly pure material for use as drugs. Finally, x-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy are the principal techniques for elucidating three-dimensional structure, the key determinant of function.

The exploration of proteins by this array of physical and chemical techniques has greatly enriched our understanding of the molecular basis of life. These techniques make it possible to tackle some of the most challenging questions of biology in molecular terms.

### The proteome is the functional representation of the genome

As will be discussed in Chapter 5, the complete DNA base sequences, or *genomes*, of many organisms are now available. For example, the roundworm *Caenorhabditis elegans* has a genome of 97 million bases and about 19,000 protein-encoding genes, whereas that of the fruit fly *Drosophila melanogaster* contains 180 million bases and about 14,000 genes. The completely sequenced human genome contains 3 billion bases and about 23,000 genes. However, these genomes are simply inventories of the genes that *could* be expressed within a cell under specific conditions. Only a subset of the proteins encoded by these genes will actually be present in a given biological context. The *proteome*—derived from *proteins* expressed by the *genome*—of an organism signifies a more complex level of information content, encompassing the types, functions, and interactions of proteins within its biological environment.

The proteome is not a fixed characteristic of the cell. Because it represents the functional expression of information, it varies with cell type, developmental stage, and environmental conditions, such as the presence of hormones. The proteome is much larger than the genome because almost all gene products are proteins that can be chemically modified in a variety of ways. Furthermore, these proteins do not exist in isolation; they often interact with one another to form complexes with specific functional properties. Whereas the genome is “hard wired,” the proteome is highly dynamic. An understanding of the proteome is acquired by investigating, characterizing, and cataloging proteins. In some, but not all, cases, this process begins by separating a particular protein from all other biomolecules in the cell.

---

## 3.1 The Purification of Proteins Is an Essential First Step in Understanding Their Function

An adage of biochemistry is “Never waste pure thoughts on an impure protein.” Starting from pure proteins, we can determine amino acid sequences and investigate biochemical functions. From the amino acid sequences, we can map evolutionary relationships between proteins in diverse organisms (Chapter 6). By using crystals grown from pure protein, we can obtain x-ray data that will provide us with a picture of the protein’s tertiary structure—the shape that determines function.

### The assay: How do we recognize the protein that we are looking for?

Purification should yield a sample containing only one type of molecule—the protein in which the biochemist is interested. This protein sample may be only a fraction of 1% of the starting material, whether that starting material consists of one type of cell in culture or a particular organ from a plant or animal. How is the biochemist able to isolate a particular protein from a complex mixture of proteins?

A protein can be purified by subjecting the impure mixture of the starting material to a series of separations based on physical properties such as size and charge. To monitor the success of this purification, the biochemist needs a test, called an *assay*, for some unique identifying property of the protein. A positive result on the assay indicates that the protein is present. Although assay development can be a challenging task, the more specific the assay, the more effective the purification. For enzymes, which are protein catalysts (Chapter 8), the assay usually measures *enzyme activity*—that is, the ability of the enzyme to promote a particular chemical reaction. This activity is often measured indirectly. Consider the enzyme lactate dehydrogenase, which catalyzes the following reaction in the synthesis of glucose:

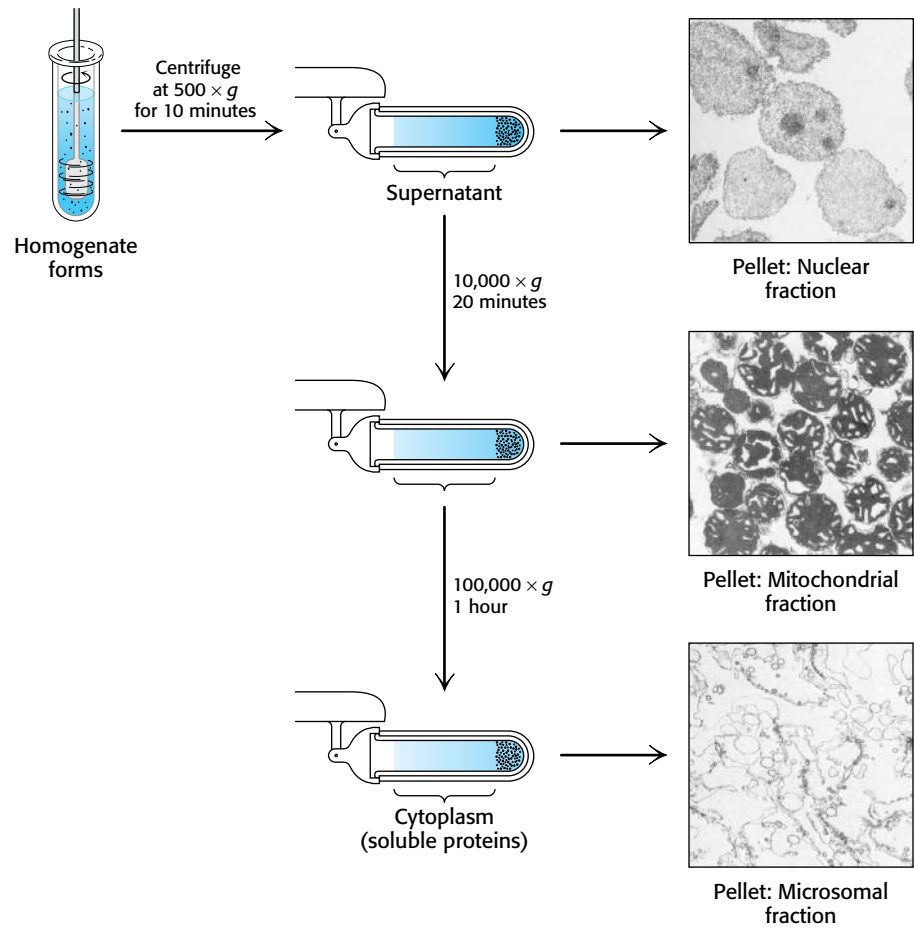

Reduced nicotinamide adenine dinucleotide (NADH, Figure 15.13) absorbs light at 340 nm, whereas oxidized nicotinamide adenine dinucleotide (NAD<sup>+</sup>) does not. Consequently, we can follow the progress of the reaction by examining how much light-absorbing ability is developed by a sample in a given period of time—for instance, within 1 minute after the addition of the enzyme. Our assay for enzyme activity during the purification of lactate dehydrogenase is thus the increase in the absorbance of light at 340 nm observed in 1 minute.

To analyze how our purification scheme is working, we need one additional piece of information—the amount of protein present in the mixture being assayed. There are various rapid and reasonably accurate means of determining protein concentration. With these two experimentally determined numbers—enzyme activity and protein concentration—we then calculate the *specific activity*, the ratio of enzyme activity to the amount of protein in the mixture. Ideally, the specific activity will rise as the purification proceeds and the protein mixture will contain the protein of interest to a greater extent. In essence, the overall goal of the purification is to maximize the specific activity. For a pure enzyme, the specific activity will have a constant value.

### Proteins must be released from the cell to be purified

Having found an assay and chosen a source of protein, we now fractionate the cell into components and determine which component is enriched in the protein of interest. In the first step, a *homogenate* is formed by disrupting the cell membrane, and the mixture is fractionated by centrifugation, yielding a dense pellet of heavy material at the bottom of the centrifuge tube and a lighter supernatant above (Figure 3.1). The supernatant is again centrifuged

**FIGURE 3.1 Differential centrifugation.**

Cells are disrupted in a homogenizer and the resulting mixture, called the homogenate, is centrifuged in a step-by-step fashion of increasing centrifugal force. The denser material will form a pellet at lower centrifugal force than will the less-dense material. The isolated fractions can be used for further purification.

[Photographs courtesy of Dr. S. Fleischer and Dr. B. Fleischer.]

at a greater force to yield yet another pellet and supernatant. This procedure, called *differential centrifugation*, yields several fractions of decreasing density, each still containing hundreds of different proteins. The fractions are each separately assayed for the desired activity. Usually, one fraction will be enriched for such activity, and it then serves as the source of material to which more-discriminating purification techniques are applied.

### Proteins can be purified according to solubility, size, charge, and binding affinity

Several thousand proteins have been purified in active form on the basis of such characteristics as *solubility*, *size*, *charge*, and *specific binding affinity*. Usually, protein mixtures are subjected to a series of separations, each based on a different property. At each step in the purification, the preparation is assayed and its specific activity is determined. A variety of purification techniques are available.

**Salting out.** Most proteins are less soluble at high salt concentrations, an effect called *salting out*. The salt concentration at which a protein precipitates differs from one protein to another. Hence, salting out can be used to fractionate proteins. For example, 0.8 M ammonium sulfate precipitates fibrinogen, a blood-clotting protein, whereas a concentration of 2.4 M is needed to precipitate serum albumin. Salting out is also useful for concentrating dilute solutions of proteins, including active fractions obtained from other purification steps. Dialysis can be used to remove the salt if necessary.

**Dialysis.** Proteins can be separated from small molecules such as salt by *dialysis* through a semipermeable membrane, such as a cellulose membrane with pores (Figure 3.2). The protein mixture is placed inside the dialysis bag, which is then submerged in a buffer solution that is devoid of the small molecules to be separated away. Molecules having dimensions significantly greater than the pore diameter are retained inside the dialysis bag. Smaller molecules and ions capable of passing through the pores of the membrane diffuse down their concentration gradients and emerge in the solution outside the bag. This technique is useful for removing a salt or other small molecule from a cell fractionate, but it will not distinguish between proteins effectively.

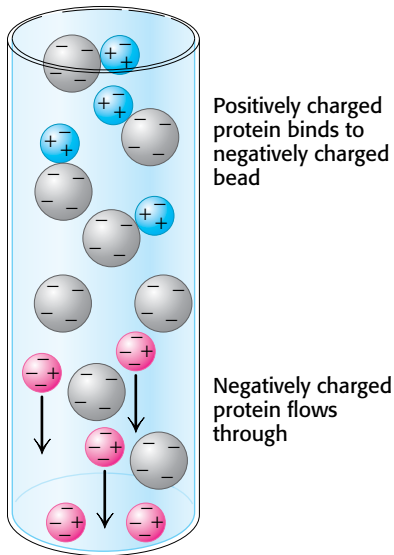

**FIGURE 3.2 Dialysis.** Protein molecules (red) are retained within the dialysis bag, whereas small molecules (blue) diffuse down their concentration gradient into the surrounding medium.

**Gel-filtration chromatography.** More-discriminating separations on the basis of size can be achieved by the technique of *gel-filtration chromatography*, also known as molecular exclusion chromatography (Figure 3.3). The sample is applied to the top of a column consisting of porous beads made of an insoluble but highly hydrated polymer such as dextran or agarose (which are carbohydrates) or polyacrylamide. Sephadex, Sepharose, and Biogel are commonly used commercial preparations of these beads, which are typically 100  $\mu\text{m}$  (0.1 mm) in diameter. Small molecules can enter these beads, but large ones cannot. The result is that small molecules are distributed in the aqueous solution both inside the beads and between them, whereas large molecules are located only in the solution between the beads. *Large molecules flow more rapidly through this column and emerge first because a smaller volume is accessible to them.* Molecules of medium size occasionally enter the beads and will flow from the column at an intermediate position, while small molecules, which take a longer, tortuous path, will exit last.

**Ion-exchange chromatography.** To obtain a protein of high purity, one chromatography step is usually not sufficient, because other proteins in the crude mixture will likely co-elute with the desired material. Additional

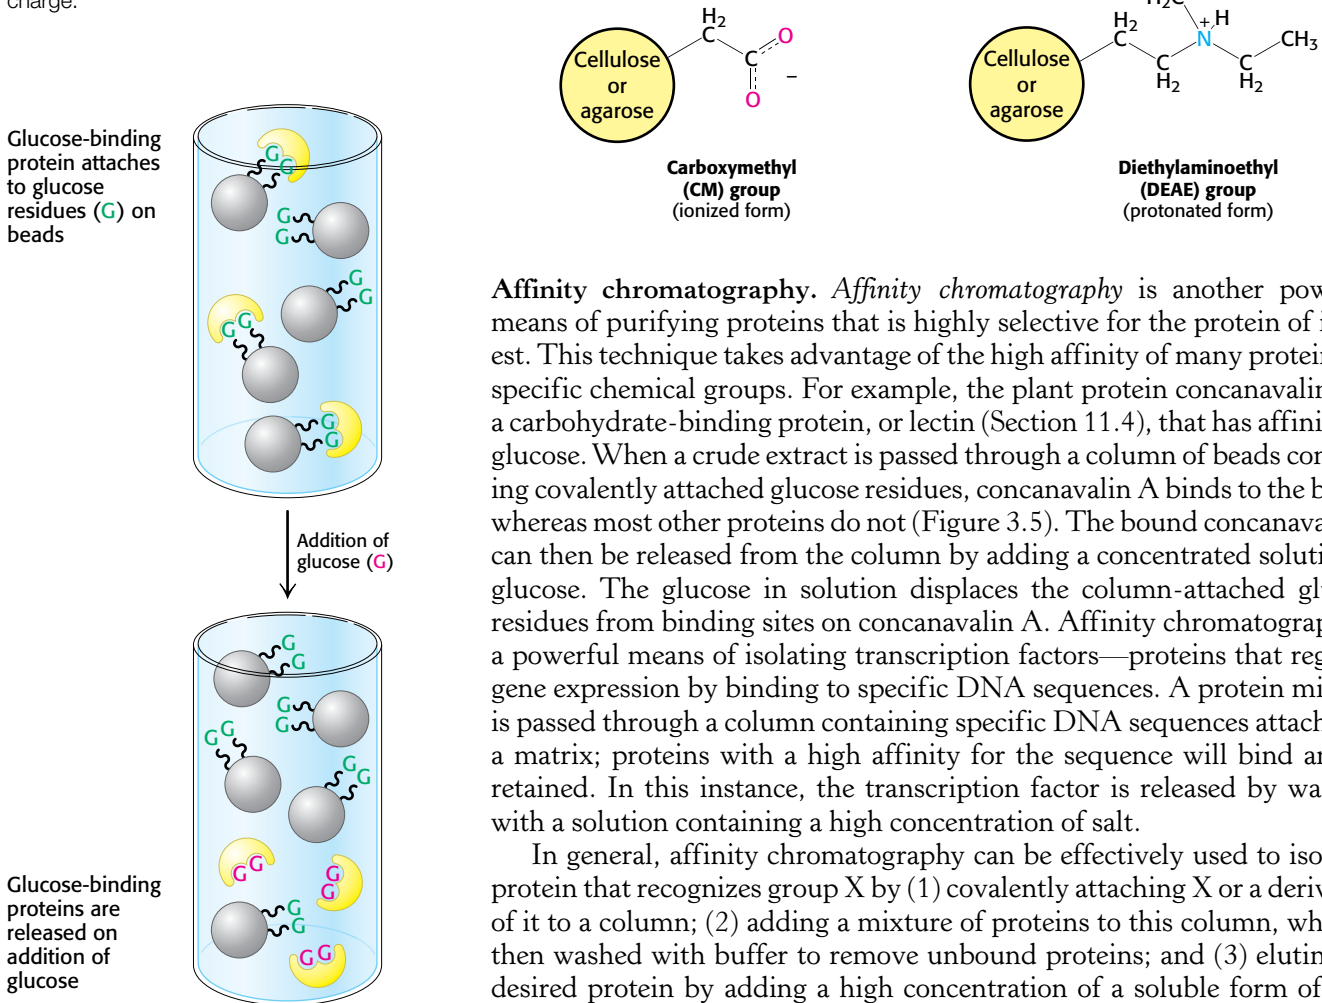

**FIGURE 3.3 Gel-filtration chromatography.** A mixture of proteins in a small volume is applied to a column filled with porous beads. Because large proteins cannot enter the internal volume of the beads, they emerge sooner than do small ones.

**FIGURE 3.4 Ion-exchange chromatography.** This technique separates proteins mainly according to their net charge.

purity can be achieved by performing sequential separations that are based on distinct molecular properties. For example, in addition to size, proteins can be separated on the basis of their net charge by *ion-exchange chromatography*. If a protein has a net positive charge at pH 7, it will usually bind to a column of beads containing carboxylate groups, whereas a negatively charged protein will not (Figure 3.4). The bound protein can then be eluted (released) by increasing the concentration of sodium chloride or another salt in the eluting buffer; sodium ions compete with positively charged groups on the protein for binding to the column. Proteins that have a low density of net positive charge will tend to emerge first, followed by those having a higher charge density. This procedure is also referred to as *cation exchange* to indicate that positively charged groups will bind to the anionic beads. Positively charged proteins (cationic proteins) can be separated by chromatography on negatively charged carboxymethylcellulose (CM-cellulose) columns. Conversely, negatively charged proteins (anionic proteins) can be separated by *anion exchange* on positively charged diethylaminoethylcellulose (DEAE-cellulose) columns.

**FIGURE 3.5 Affinity chromatography.** Affinity chromatography of concanavalin A (shown in yellow) using a solid support containing covalently attached glucose residues (G).

**Affinity chromatography.** *Affinity chromatography* is another powerful means of purifying proteins that is highly selective for the protein of interest. This technique takes advantage of the high affinity of many proteins for specific chemical groups. For example, the plant protein concanavalin A is a carbohydrate-binding protein, or lectin (Section 11.4), that has affinity for glucose. When a crude extract is passed through a column of beads containing covalently attached glucose residues, concanavalin A binds to the beads, whereas most other proteins do not (Figure 3.5). The bound concanavalin A can then be released from the column by adding a concentrated solution of glucose. The glucose in solution displaces the column-attached glucose residues from binding sites on concanavalin A. Affinity chromatography is a powerful means of isolating transcription factors—proteins that regulate gene expression by binding to specific DNA sequences. A protein mixture is passed through a column containing specific DNA sequences attached to a matrix; proteins with a high affinity for the sequence will bind and be retained. In this instance, the transcription factor is released by washing with a solution containing a high concentration of salt.

In general, affinity chromatography can be effectively used to isolate a protein that recognizes group X by (1) covalently attaching X or a derivative of it to a column; (2) adding a mixture of proteins to this column, which is then washed with buffer to remove unbound proteins; and (3) eluting the desired protein by adding a high concentration of a soluble form of X or altering the conditions to decrease binding affinity. Affinity chromatography is most effective when the interaction of the protein and the molecule that is used as the bait is highly specific.

Affinity chromatography can be used to isolate proteins expressed from cloned genes (Section 5.2). Extra amino acids are encoded in the cloned gene

that, when expressed, serve as an affinity tag that can be readily trapped. For example, repeats of the codon for histidine may be added such that the expressed protein has a string of histidine residues (called a *His tag*) on one end. The tagged proteins are then passed through a column of beads containing covalently attached, immobilized nickel(II) or other metal ions. The His tags bind tightly to the immobilized metal ions, binding the desired protein, while other proteins flow through the column. The protein can then be eluted from the column by the addition of imidazole or some other chemical that binds to the metal ions and displaces the protein.

**High-performance liquid chromatography.** A technique called *high-performance liquid chromatography* (HPLC) is an enhanced version of the column techniques already discussed. The column materials are much more finely divided and, as a consequence, possess more interaction sites and thus greater resolving power. Because the column is made of finer material, pressure must be applied to the column to obtain adequate flow rates. The net result is both high resolution and rapid separation. In a typical HPLC setup, a detector that monitors the absorbance of the eluate at a particular wavelength is placed immediately after the column. In the sample HPLC elution profile shown in Figure 3.6, proteins are detected by setting the detector to 220 nm (the characteristic absorbance wavelength of the peptide bond). In a short span of 10 minutes, a number of sharp peaks representing individual proteins can be readily identified.

#### Proteins can be separated by gel electrophoresis and displayed

How can we tell that a purification scheme is effective? One way is to ascertain that the specific activity rises with each purification step. Another is to determine that the number of different proteins in each sample declines at each step. The technique of electrophoresis makes the latter method possible.

**Gel electrophoresis.** A molecule with a net charge will move in an electric field. This phenomenon, termed *electrophoresis*, offers a powerful means of separating proteins and other macromolecules, such as DNA and RNA. The velocity of migration ( $v$ ) of a protein (or any molecule) in an electric field depends on the electric field strength ( $E$ ), the net charge on the protein ( $z$ ), and the frictional coefficient ( $f$ ).

$$v = Ez/f \quad (1)$$

The electric force  $Ez$  driving the charged molecule toward the oppositely charged electrode is opposed by the viscous drag  $fv$  arising from friction between the moving molecule and the medium. The frictional coefficient  $f$  depends on both the mass and shape of the migrating molecule and the viscosity ( $\eta$ ) of the medium. For a sphere of radius  $r$ ,

$$f = 6\pi\eta r \quad (2)$$

Electrophoretic separations are nearly always carried out in porous gels (or on solid supports such as paper) because the gel serves as a molecular sieve that enhances separation (Figure 3.7). Molecules that are small compared with the pores in the gel readily move through the gel, whereas molecules much larger than the pores are almost immobile. Intermediate-size molecules move through the gel with various degrees of facility. The electric field is applied such that proteins migrate from the negative to the positive electrodes, typically from top to bottom. Electrophoresis is performed in a thin, vertical slab of polyacrylamide gel. Polyacrylamide gels are choice

**FIGURE 3.6 High-performance liquid chromatography (HPLC).** Gel filtration by HPLC clearly defines the individual proteins because of its greater resolving power: (1) thyroglobulin (669 kDa), (2) catalase (232 kDa), (3) bovine serum albumin (67 kDa), (4) ovalbumin (43 kDa), and (5) ribonuclease (13.4 kDa). [Data from K. J. Wilson and T. D. Schlabach. In *Current Protocols in Molecular Biology*, vol. 2, suppl. 41, F. M. Ausubel, R. Brent, R. E. Kingston, D. D. Moore, J. G. Seidman, J. A. Smith, and K. Struhl, Eds. (Wiley, 1998), p. 10.14.1.]

**FIGURE 3.7**  
**Polyacrylamide gel electrophoresis.**

(A) Gel-electrophoresis apparatus. Typically, several samples undergo electrophoresis on one flat polyacrylamide gel. A microliter pipette is used to place solutions of proteins in the wells of the slab. A cover is then placed over the gel chamber and voltage is applied. The negatively charged SDS (sodium dodecyl sulfate)-protein complexes migrate in the direction of the anode, at the bottom of the gel. (B) The sieving action of a porous polyacrylamide gel separates proteins according to size, with the smallest moving most rapidly.

supporting media for electrophoresis because they are chemically inert and readily formed by the polymerization of acrylamide with a small amount of the cross-linking agent methylenebisacrylamide to make a three-dimensional mesh (Figure 3.8). Electrophoresis is distinct from gel filtration in that, because of the electric field, all of the molecules, regardless of size, are forced to move through the same matrix.

**FIGURE 3.8** Formation of a polyacrylamide gel. A three-dimensional mesh is formed by copolymerizing activated monomer (blue) and cross-linker (red).

Proteins can be separated largely on the basis of mass by electrophoresis in a polyacrylamide gel under denaturing conditions. The mixture of proteins is first dissolved in a solution of sodium dodecyl sulfate (SDS), an anionic detergent that disrupts nearly all noncovalent interactions in native proteins.  $\beta$ -Mercaptoethanol (2-thioethanol) or dithiothreitol is added to reduce disulfide bonds. Anions of SDS bind to main chains at a ratio of about one SDS anion for every two amino acid residues. The negative charge acquired on binding SDS is usually much greater than the charge on the native protein; the contribution of the protein to the total charge of the

SDS–protein complex is thus rendered insignificant. As a result, this complex of SDS with a denatured protein has a large net negative charge that is roughly proportional to the mass of the protein. The SDS–protein complexes are then subjected to electrophoresis. When the electrophoresis is complete, the proteins in the gel can be visualized by staining them with silver nitrate or a dye such as Coomassie blue, which reveals a series of bands (Figure 3.9). Radioactive labels, if they have been incorporated into proteins, can be detected by placing a sheet of x-ray film over the gel, a procedure called *autoradiography*.

*Small proteins move rapidly through the gel, whereas large proteins stay at the top, near the point of application of the mixture.* The mobility of most polypeptide chains under these conditions is linearly proportional to the logarithm of their mass (Figure 3.10). Some carbohydrate-rich proteins and membrane proteins do not obey this empirical relation, however. SDS–polyacrylamide gel electrophoresis (often referred to as SDS–PAGE) is rapid, sensitive, and capable of a high degree of resolution. As little as 0.1  $\mu\text{g}$  ( $\sim 2$  pmol) of a protein gives a distinct band when stained with Coomassie blue, and even less ( $\sim 0.02$   $\mu\text{g}$ ) can be detected with a silver stain. Proteins that differ in mass by about 2% (e.g., 50 and 51 kDa, arising from a difference of about 10 amino acids) can usually be distinguished with SDS–PAGE.

We can examine the efficacy of our purification scheme by analyzing a part of each fraction by electrophoresis. The initial fractions will display dozens to hundreds of proteins. As the purification progresses, the number of bands will diminish, and the prominence of one of the bands should increase. This band should correspond to the protein of interest.

**Isoelectric focusing.** Proteins can also be separated electrophoretically on the basis of their relative contents of acidic and basic residues. The *isoelectric point* (pI) of a protein is the pH at which its net charge is zero. At this pH, its electrophoretic mobility is zero because  $z$  in equation 1 is equal to zero. For example, the pI of cytochrome *c*, a highly basic electron-transport protein, is 10.6, whereas that of serum albumin, an acidic protein in blood, is 4.8. Suppose that a mixture of proteins undergoes electrophoresis in a pH gradient in a gel in the absence of SDS. Each protein will move until it reaches a position in the gel at which the pH is equal to the pI of the protein. This method of separating proteins according to their isoelectric point is called *isoelectric focusing*. The pH gradient in the gel is formed first by subjecting a mixture of *polyampholytes* (small multi-charged polymers) having many different pI values to electrophoresis. Isoelectric focusing can readily resolve proteins that differ in pI by as little as 0.01, which means that proteins differing by one net charge can be separated (Figure 3.11).

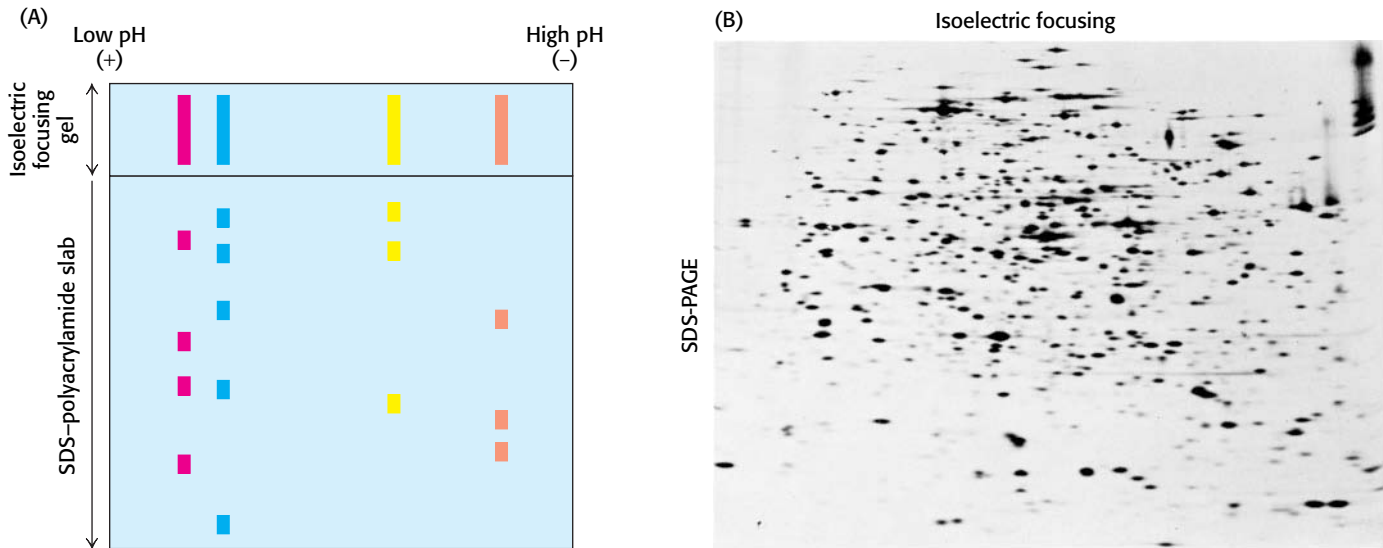

**FIGURE 3.11 The principle of isoelectric focusing.** A pH gradient is established in a gel before loading the sample. (A) Each protein, represented by the different colored circles, will possess a net positive charge in the regions of the gel where the pH is lower than its respective pI value and a net negative charge where the pH is greater than its pI. When voltage is applied to the gel, each protein will migrate to its pI, the location at which it has no net charge. (B) The proteins form bands that can be excised and used for further experimentation.

**FIGURE 3.9 Staining of proteins after electrophoresis.** Mixtures of proteins from cellular extracts subjected to electrophoresis on an SDS–polyacrylamide gel can be visualized by staining with Coomassie blue. The first lane contains a mixture of proteins of known molecular weights, which can be used to estimate the sizes of the bands in the samples. [©Dr. Robert Farrell.]

**FIGURE 3.10 Electrophoresis can determine mass.** The electrophoretic mobility of many proteins in SDS–polyacrylamide gels is inversely proportional to the logarithm of their mass. [Data from K. Weber and M. Osborn, *The Proteins*, vol. 1, 3d ed. (Academic Press, 1975), p. 179.]

**FIGURE 3.12 Two-dimensional gel electrophoresis.** (A) A protein sample is initially fractionated in one dimension by isoelectric focusing as described in Figure 3.11. The isoelectric focusing gel is then attached to an SDS-polyacrylamide gel, and electrophoresis is performed in the second dimension, perpendicular to the original separation. Proteins with the same pI are now separated on the basis of mass. (B) Proteins from *E. coli* were separated by two-dimensional gel electrophoresis, resolving more than a thousand different proteins. [(B) Courtesy of Dr. Patrick H. O'Farrell.]

**Two-dimensional electrophoresis.** Isoelectric focusing can be combined with SDS-PAGE to obtain very high resolution separations. A single sample is first subjected to isoelectric focusing. This single-lane gel is then placed horizontally on top of an SDS-polyacrylamide slab. The proteins are thus spread across the top of the polyacrylamide gel according to how far they migrated during isoelectric focusing. They then undergo electrophoresis again in a perpendicular direction (vertically) to yield a two-dimensional pattern of spots. In such a gel, proteins have been separated in the horizontal direction on the basis of isoelectric point and in the vertical direction on the basis of mass. Remarkably, more than a thousand different proteins in the bacterium *Escherichia coli* can be resolved in a single experiment by two-dimensional electrophoresis (Figure 3.12).

Proteins isolated from cells under different physiological conditions can be subjected to two-dimensional electrophoresis. The intensities of individual spots on the gels can then be compared, which indicates that the concentrations of specific proteins have changed in response to the physiological state (Figure 3.13). How can we discover the identity of a protein that is showing such responses? Although many proteins are displayed on a two-dimensional gel, they are not identified. It is now possible to identify proteins by coupling two-dimensional gel electrophoresis with mass

**FIGURE 3.13 Alterations in protein levels detected by two-dimensional gel electrophoresis.** Samples of (A) normal colon mucosa and (B) colorectal tumor tissue from the same person were analyzed by two-dimensional gel electrophoresis. In the gel section shown, changes in the intensity of several spots are evident, including a dramatic increase in levels of the protein indicated by the arrow, corresponding to the enzyme glyceraldehyde-3-phosphate dehydrogenase. **TABLE 3.1** Quantification of a purification protocol for a fictitious protein

Step	Total protein (mg)	Total activity (units)	Specific activity (units mg <sup>-1</sup> )	Yield (%)	Purification level
Homogenization	15,000	150,000	10	100	1
Salt fractionation	4,600	138,000	30	92	3
Ion-exchange chromatography	1,278	115,500	90	77	9
Gel-filtration chromatography	68.8	75,000	1,100	50	110
Affinity chromatography	1.75	52,500	30,000	35	3,000

## 3.1 The Purification of Proteins

spectrometric techniques. We will examine these powerful techniques shortly (Section 3.3).

### A protein purification scheme can be quantitatively evaluated

To determine the success of a protein purification scheme, we monitor each step of the procedure by determining the specific activity of the protein mixture and by subjecting it to SDS-PAGE analysis. Consider the results for the purification of a fictitious protein, summarized in Table 3.1 and Figure 3.14. At each step, the following parameters are measured:

*Total Protein.* The quantity of protein present in a fraction is obtained by determining the protein concentration of a part of each fraction and multiplying by the fraction's total volume.

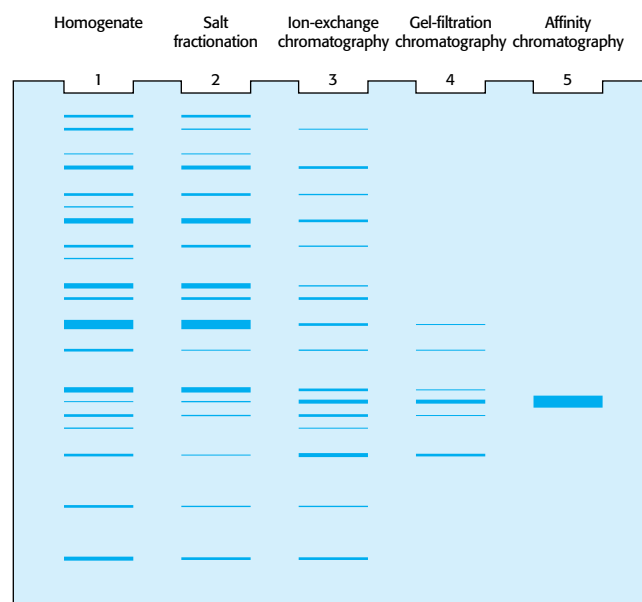

*Total Activity.* The enzyme activity for the fraction is obtained by measuring the enzyme activity in the volume of fraction used in the assay and multiplying by the fraction's total volume.

*Specific Activity.* This parameter is obtained by dividing total activity by total protein.

*Yield.* This parameter is a measure of the activity retained after each purification step as a percentage of the activity in the crude extract. The amount of activity in the initial extract is taken to be 100%.

*Purification Level.* This parameter is a measure of the increase in purity and is obtained by dividing the specific activity, calculated after each purification step, by the specific activity of the initial extract.

As we see in Table 3.1, the first purification step, salt fractionation, leads to an increase in purity of only 3-fold, but we recover nearly all the target protein in the original extract, given that the yield is 92%. After dialysis to lower the high concentration of salt remaining from the salt fractionation, the fraction is passed through an ion-exchange column. The purification now increases to 9-fold compared with the original extract, whereas the yield falls to 77%. Gel-filtration chromatography brings the level of purification to 110-fold, but the yield is now at 50%. The final step is affinity chromatography with the use of a ligand specific for the target enzyme. This step, the most powerful of these purification procedures, results in a purification level of 3000-fold but lowers the yield to 35%. The SDS-PAGE

**FIGURE 3.14** Electrophoretic analysis of a protein purification. The purification scheme in Table 3.1 was analyzed by SDS-PAGE. Each lane contained 50  $\mu\text{g}$  of sample. The effectiveness of the purification can be seen as the band for the protein of interest becomes more prominent relative to other bands.

analysis in Figure 3.14 shows that, if we load a constant amount of protein onto each lane after each step, the number of bands decreases in proportion to the level of purification, and the amount of protein of interest increases as a proportion of the total protein present.

A good purification scheme takes into account both purification levels and yield. A high degree of purification and a poor yield leave little protein with which to experiment. A high yield with low purification leaves many contaminants (proteins other than the one of interest) in the fraction and complicates the interpretation of subsequent experiments.

### Ultracentrifugation is valuable for separating biomolecules and determining their masses

We have already seen that centrifugation is a powerful and generally applicable method for separating a crude mixture of cell components. This technique is also valuable for the analysis of the physical properties of biomolecules. Using centrifugation, we can determine such parameters as mass and density, learn about the shape of a molecule, and investigate the interactions between molecules. To deduce these properties from the centrifugation data, we require a mathematical description of how a particle behaves when a centrifugal force is applied.

A particle will move through a liquid medium when subjected to a centrifugal force. A convenient means of quantifying the rate of movement is to calculate the sedimentation coefficient,  $s$ , of a particle by using the following equation:

$$s = m(1 - \bar{v}\rho)/f$$

where  $m$  is the mass of the particle,  $\bar{v}$  is the partial specific volume (the reciprocal of the particle density),  $\rho$  is the density of the medium, and  $f$  is the frictional coefficient (a measure of the shape of the particle). The  $(1 - \bar{v}\rho)$  term is the buoyant force exerted by liquid medium.

*Sedimentation coefficients* are usually expressed in *Svedberg units* (S), equal to  $10^{-13}$  s. The smaller the S value, the more slowly a molecule moves in a centrifugal field. The S values for a number of biomolecules and cellular components are listed in Table 3.2 and Figure 3.15.

Several important conclusions can be drawn from the preceding equation:

1. The sedimentation velocity of a particle depends in part on its mass. A more massive particle sediments more rapidly than does a less massive particle of the same shape and density.
2. Shape, too, influences the sedimentation velocity because it affects the viscous drag. The frictional coefficient  $f$  of a compact particle is smaller than that of an extended particle of the same mass. Hence, elongated particles sediment more slowly than do spherical ones of the same mass.

**TABLE 3.2** S values and molecular weights of sample proteins

Protein	S value (Svedberg units)	Molecular weight
Pancreatic trypsin inhibitor	1	6,520
Cytochrome <i>c</i>	1.83	12,310
Ribonuclease A	1.78	13,690
Myoglobin	1.97	17,800
Trypsin	2.5	23,200
Carbonic anhydrase	3.23	28,800
Concanavalin A	3.8	51,260
Malate dehydrogenase	5.76	74,900
Lactate dehydrogenase	7.54	146,200

Source: T. Creighton, *Proteins*, 2d ed. (W. H. Freeman and Company, 1993), Table 7.1.

**FIGURE 3.15** Density and sedimentation coefficients of cellular components. [Data from L. J. Kleinsmith and V. M. Kish, *Principles of Cell and Molecular Biology*, 2d ed. (HarperCollins, 1995), p. 138.]

3. A dense particle moves more rapidly than does a less dense one because the opposing buoyant force ( $1 - \bar{v}\rho$ ) is smaller for the denser particle.

4. The sedimentation velocity also depends on the density of the solution ( $\rho$ ). Particles sink when  $\bar{v}\rho < 1$ , float when  $\bar{v}\rho > 1$ , and do not move when  $\bar{v}\rho = 1$ .

A technique called *zonal*, *band*, or most commonly *gradient* centrifugation can be used to separate proteins with different sedimentation coefficients. The first step is to form a density gradient in a centrifuge tube. Differing proportions of a low-density solution (such as 5% sucrose) and a high-density solution (such as 20% sucrose) are mixed to create a linear gradient of sucrose concentration ranging from 20% at the bottom of the tube to 5% at the top (Figure 3.16). The role of the gradient is to prevent convective flow. A small volume of a solution containing the mixture of proteins to be separated is placed on top of the density gradient. When the rotor is spun, proteins move through the gradient and separate according to their sedimentation coefficients. The time and speed of the centrifugation is determined empirically. The separated bands, or zones, of protein can be harvested by making a hole in the bottom of the tube and collecting drops. The drops can be measured for protein content and catalytic activity or another functional property. This sedimentation-velocity technique readily separates proteins differing in sedimentation coefficient by a factor of two or more.

**FIGURE 3.16** Zonal centrifugation. The steps are as follows: (A) form a density gradient, (B) layer the sample on top of the gradient, (C) place the tube in a swinging-bucket rotor and centrifuge it, and (D) collect the samples. [Information from D. Freifelder, *Physical Biochemistry*, 2d ed. (W. H. Freeman and Company, 1982), p. 397.]

The mass of a protein can be directly determined by *sedimentation equilibrium*, in which a sample is centrifuged at low speed such that a concentration gradient of the sample is formed. However, this sedimentation is counterbalanced by the diffusion of the sample from regions of high to low concentration. When equilibrium has been achieved, the shape of the final gradient depends solely on the mass of the sample. *The sedimentation-equilibrium technique for determining mass is very accurate and can be applied without denaturing the protein. Thus the native quaternary structure of multimeric proteins is preserved.* In contrast, SDS–polyacrylamide gel electrophoresis provides an *estimate* of the mass of dissociated polypeptide chains under *denaturing* conditions. Note that, if we know the mass of the dissociated components of a multimeric protein as determined by SDS–polyacrylamide analysis and the mass of the intact multimer as determined by sedimentation-equilibrium analysis, we can determine the number of copies of each polypeptide chain present in the protein complex.

### Protein purification can be made easier with the use of recombinant DNA technology

In Chapter 5, we shall consider the widespread effect of recombinant DNA technology on all areas of biochemistry and molecular biology. The application of recombinant methods to the overproduction of proteins has enabled dramatic advances in our understanding of their structure and function. Before the advent of this technology, proteins were isolated solely from their native sources, often requiring a large amount of tissue to obtain a sufficient amount of protein for analytical study. For example, the purification of bovine deoxyribonuclease in 1946 required nearly ten pounds of beef pancreas to yield one gram of protein. As a result, biochemical studies on purified material were often limited to abundant proteins.

Armed with the tools of recombinant technology, the biochemist is now able to enjoy a number of significant advantages:

1. *Proteins can be expressed in large quantities.* The homogenate serves as the starting point in a protein purification scheme. For recombinant systems, a host organism that is amenable to genetic manipulation, such as the bacterium *Escherichia coli* or the yeast *Pichia pastoris*, is utilized to express a protein of interest. The biochemist can exploit the short doubling times and ease of genetic manipulation of such organisms to produce large amounts of protein from manageable amounts of culture. As a result, purification can begin with a homogenate that is often highly enriched with the desired molecule. Moreover, a protein can be easily obtained regardless of its natural abundance or its species of origin.
2. *Affinity tags can be fused to proteins.* As described above, affinity chromatography can be a highly selective step within a protein purification scheme. Recombinant DNA technology enables the attachment of any one of a number of possible affinity tags to a protein (such as the “His tag” mentioned earlier). Hence, the benefits of affinity chromatography can be realized even for those proteins for which a binding partner is unknown or not easily determined.
3. *Proteins with modified primary structures can be readily generated.* A powerful aspect of recombinant DNA technology as applied to protein purification is the ability to manipulate genes to generate variants of a native protein sequence (Section 5.2). We learned in Section 2.4 that many proteins consist of compact domains connected by flexible linker regions. With the use of genetic-manipulation strategies, fragments of a protein that encompass single domains can be generated, an advantageous approach when expression of the

entire protein is limited by its size or solubility. Additionally, as we will see in Section 9.1, amino acid substitutions can be introduced into the active site of an enzyme to precisely probe the roles of specific residues within its catalytic cycle.

### 3.2 Immunology Provides Important Techniques with Which to Investigate Proteins

The purification of a protein enables the biochemist to explore its function and structure within a precisely controlled environment. However, the isolation of a protein removes it from its native context within the cell, where its activity is most physiologically relevant. Advances in the field of immunology (Chapter 34) have enabled the use of antibodies as critical reagents for exploring the functions of proteins within the cell. The exquisite specificity of antibodies for their target proteins provides a means to tag a specific protein so that it can be isolated, quantified, or visualized.

#### Antibodies to specific proteins can be generated

Immunological techniques begin with the generation of antibodies to a particular protein. An *antibody* (also called an *immunoglobulin*, Ig) is itself a protein (Figure 3.17); it is synthesized by vertebrates in response to the presence of a foreign substance, called an *antigen*. Antibodies have specific and high affinity for the antigens that elicited their synthesis. The binding of antibody to antigen is a step in the immune response that protects the animal from infection (Chapter 34). Foreign proteins, polysaccharides, and nucleic acids can be antigens. Small foreign molecules, such as synthetic peptides, also can elicit antibodies, provided that the small molecule is attached to a macromolecular carrier. An antibody recognizes a specific group or cluster of amino acids on the target molecule called an *antigenic determinant* or *epitope*. The specificity of the antibody–antigen interaction is a consequence of the shape complementarity between the two surfaces (Figure 3.18). Animals have a very large repertoire of antibody-producing cells, each producing an antibody that contains a unique surface for antigen recognition. When an antigen is introduced into an animal, it is recognized by a select few cells from this population, stimulating the proliferation of these cells. This process ensures that more antibodies of the appropriate specificity are produced.

**FIGURE 3.17 Antibody structure.**

(A) Immunoglobulin G (IgG) consists of four chains, two heavy chains (blue) and two light chains (red), linked by disulfide bonds. The heavy and light chains come together to form  $F_{ab}$  domains, which have the antigen-binding sites at the ends. The two heavy chains form the  $F_c$  domain. Notice that the  $F_{ab}$  domains are linked to the  $F_c$  domain by flexible linkers. (B) A more schematic representation of an IgG molecule. [Drawn from 1IGT.pdb.]

**FIGURE 3.18 Antigen–antibody interactions.** A protein antigen, in this case lysozyme, binds to the end of an  $F_{ab}$  domain of an antibody. Notice that the end of the antibody and the antigen have complementary shapes, allowing a large amount of surface to be buried on binding. [Drawn from 1YQV.pdb.]

**FIGURE 3.19 Polyclonal and monoclonal antibodies.** Most antigens have several epitopes. Polyclonal antibodies are heterogeneous mixtures of antibodies, each specific for one of the various epitopes on an antigen. Monoclonal antibodies are all identical, produced by clones of a single antibody-producing cell. They recognize one specific epitope. [Information from R. A. Goldsby, T. J. Kindt, and B. A. Osborne, *Kuby Immunology*, 4th ed. (W. H. Freeman and Company, 2000), p. 154.]

Immunological techniques depend on the ability to generate antibodies to a specific antigen. To obtain antibodies that recognize a particular protein, a biochemist injects the protein into a rabbit twice, 3 weeks apart. The injected protein acts as an antigen, stimulating the reproduction of cells producing antibodies that recognize it. Blood is drawn from the immunized rabbit several weeks later and centrifuged to separate blood cells from the supernatant, or serum. The serum, called an *antiserum*, contains antibodies to all antigens to which the rabbit has been exposed. Only some of them will be antibodies to the injected protein. Moreover, antibodies that recognize a particular antigen are not a single molecular species. For instance, 2,4-dinitrophenol (DNP) was used as an antigen to generate antibodies. Analyses of anti-DNP antibodies revealed a wide range of binding affinities; the dissociation constants ranged from about 0.1 nM to 1  $\mu$ M. Correspondingly, a large number of bands were evident when anti-DNP antibody was subjected to isoelectric focusing. These results indicate that cells are producing many different antibodies, each recognizing a different surface feature of the same antigen. These antibodies are termed *polyclonal*, referring to the fact that they are derived from multiple antibody-producing cell populations (Figure 3.19). The heterogeneity of polyclonal antibodies can be advantageous for certain applications, such as the detection of a protein of low abundance, because each protein molecule can be bound by more than one antibody at multiple distinct antigenic sites.

### Monoclonal antibodies with virtually any desired specificity can be readily prepared

The discovery of a means of producing *monoclonal antibodies* of virtually any desired specificity was a major breakthrough that intensified the power of immunological approaches. As with impure proteins, working with an impure mixture of antibodies makes it difficult to interpret data. Ideally, one would

isolate a clone of cells producing a single, identical antibody. The problem is that antibody-producing cells isolated from an organism have short life spans.

Immortal cell lines that produce monoclonal antibodies do exist. These cell lines are derived from a type of cancer, *multiple myeloma*, which is a malignant disorder of antibody-producing cells. In this cancer, a single transformed plasma cell divides uncontrollably, generating a very large number of *cells of a single kind*. Such a group of cells is a *clone* because the cells are descended from the same cell and have identical properties. The identical cells of the myeloma secrete large amounts of *a single immunoglobulin* generation after generation. While these antibodies have proven useful for elucidating antibody structure, nothing is known about their specificity. Hence, they have little utility for the immunological methods described in the next pages.

César Milstein and Georges Köhler discovered that large amounts of antibodies of nearly any desired specificity can be obtained by fusing a short-lived antibody-producing cell with an immortal myeloma cell. An antigen is injected into a mouse, and its spleen is removed several weeks later (Figure 3.20). A mixture of plasma cells from this spleen is fused *in vitro* with myeloma cells. Each of the resulting hybrid cells, called hybridoma cells, indefinitely produces the identical antibody specified by the parent cell from the spleen. Hybridoma cells can then be screened by a specific assay for the antigen–antibody interaction to determine which ones produce antibodies of the preferred specificity. Collections of cells shown to produce the desired antibody are subdivided and reassayed. This process is repeated until a pure cell line, a clone producing a single antibody, is isolated. These positive cells can be grown in

**FIGURE 3.20 Preparation of monoclonal antibodies.** Hybridoma cells are formed by the fusion of antibody-producing cells and myeloma cells. The hybrid cells are allowed to proliferate by growing them in selective medium. They are then screened to determine which ones produce antibody of the desired specificity. [Information from C. Milstein. *Monoclonal antibodies*. Copyright © 1980 by Scientific American, Inc. All rights reserved.]

**FIGURE 3.21** Fluorescence micrograph of a developing *Drosophila* embryo. The embryo was stained with a fluorescence-labeled monoclonal antibody for the DNA-binding protein encoded by *engrailed*, an essential gene in specifying the body plan. [Courtesy of Dr. Nipam Patel and Dr. Corey Goodman.]

culture medium or injected into mice to induce myelomas. Alternatively, the cells can be frozen and stored for long periods.

The hybridoma method of producing monoclonal antibodies has opened new vistas in biology and medicine. Large amounts of identical antibodies with tailor-made specificities can be readily prepared. They are sources of insight into relations between antibody structure and specificity. Moreover, monoclonal antibodies can serve as precise analytical and preparative reagents. Proteins that guide development have been identified with the use of monoclonal antibodies as tags (Figure 3.21). Monoclonal antibodies attached to solid supports can be used as affinity columns to purify scarce proteins. This method has been used to purify interferon (an antiviral protein) 5000-fold from a crude mixture. Clinical laboratories use monoclonal antibodies in many assays. For example, the detection in blood of isozymes that are normally localized in the heart points to a myocardial infarction (heart attack). Blood transfusions have been made safer by antibody screening of donor blood for viruses that cause AIDS (acquired immune deficiency syndrome), hepatitis, and other infectious diseases. Monoclonal antibodies can be used as therapeutic agents. For example, trastuzumab (Herceptin) is a monoclonal antibody useful for treating some forms of breast cancer.

### Proteins can be detected and quantified by using an enzyme-linked immunosorbent assay

Antibodies can be used as exquisitely specific analytic reagents to quantify the amount of a protein or other antigen present in a biological sample. The *enzyme-linked immunosorbent assay* (ELISA) makes use of an enzyme that reacts with a colorless substrate to produce a colored product. The enzyme is covalently linked to a specific antibody that recognizes a target antigen. If the antigen is present, the antibody–enzyme complex will bind to it and, on addition of the substrate, the enzyme will catalyze the reaction, generating the colored product. Thus, the presence of the colored product indicates the presence of the antigen. Rapid and convenient, ELISAs can detect less than a nanogram ( $10^{-9}$  g) of a specific protein. ELISAs can be performed with either polyclonal or monoclonal antibodies, but the use of monoclonal antibodies yields more-reliable results.

We will consider two among the several types of ELISA. The *indirect ELISA* is used to detect the presence of antibody and is the basis of the test for HIV infection. The HIV test detects the presence of antibodies that recognize viral core protein antigens. Viral core proteins are adsorbed to the bottom of a well. Antibodies from the person being tested are then added to the coated well. Only someone infected with HIV will have antibodies that bind to the antigen. Finally, enzyme-linked antibodies to human antibodies (e.g., enzyme-linked goat antibodies that recognize human antibodies) are allowed to react in the well, and unbound antibodies are removed by washing. Substrate is then applied. An enzyme reaction yielding a colored product suggests that the enzyme-linked antibodies were bound to human antibodies, which in turn implies that the patient has antibodies to the viral antigen (Figure 3.22A). This assay is quantitative: the rate of the color-formation reaction is proportional to the amount of antibody originally present.

The *sandwich ELISA* is used to detect antigen rather than antibody. Antibody to a particular antigen is first adsorbed to the bottom of a well. Next, solution containing the antigen (such as blood or urine, in medical diagnostic tests) is added to the well and binds to the antibody. Finally, a

**FIGURE 3.22 Indirect ELISA and sandwich ELISA.** (A) In indirect ELISA, the production of color indicates the amount of an antibody to a specific antigen. (B) In sandwich ELISA, the production of color indicates the quantity of antigen. [Information from R. A. Goldsby, T. J. Kindt, and B. A. Osborne, *Kuby Immunology*, 4th ed. (W. H. Freeman and Company, 2000), p. 162.]

second, different antibody to the antigen is added. This antibody is enzyme linked and is processed as described for indirect ELISA. In this case, the rate of color formation is directly proportional to the amount of antigen present. Consequently, it permits the measurement of small quantities of antigen (Figure 3.22B).

### Western blotting permits the detection of proteins separated by gel electrophoresis

Very small quantities of a protein of interest in a cell or in body fluid can be detected by an immunoassay technique called *western blotting* (Figure 3.23). A sample is subjected to electrophoresis on an SDS–polyacrylamide gel. A polymer sheet is pressed against the gel, transferring the resolved proteins on the gel to the sheet, which makes the proteins more accessible for reaction. An antibody that is specific for the protein of interest, called the *primary*

**FIGURE 3.23 Western blotting.** Proteins on an SDS–polyacrylamide gel are transferred to a polymer sheet. The sheet is first treated with a primary antibody, which is specific for the protein of interest, and then washed to remove unbound antibody. Next, the sheet is treated with a secondary antibody, which recognizes the primary antibody, and washed again. Since the secondary antibody is labeled (here, with a fluorescent tag indicated by the yellow circle), the band containing the protein of interest can be identified.

**FIGURE 3.24 Actin filaments.** Fluorescence micrograph of a cell shows actin filaments stained green using an antibody specific to actin. [David Becker/Science Source.]

*antibody*, is added to the sheet and reacts with the antigen. The antibody–antigen complex on the sheet can then be detected by rinsing the sheet with a second antibody, called the *secondary antibody*, that is specific for the primary antibody (e.g., a goat antibody that recognizes mouse antibodies). Typically, the secondary antibody is fused to an enzyme that produces a chemiluminescent or colored product or contains a fluorescent tag, enabling the identification and quantitation of the protein of interest. Western blotting makes it possible to find a protein in a complex mixture, the proverbial needle in a haystack. It is the basis for the test for infection by hepatitis C, where it is used to detect a core protein of the virus. This technique is also very useful in monitoring protein purification and in the cloning of genes.

### Fluorescent markers make the visualization of proteins in the cell possible

Biochemistry is often performed in test tubes or polyacrylamide gels. However, most proteins function in the context of a cell. Fluorescent markers provide a powerful means of examining proteins in their biological context. Cells can be stained with fluorescence-labeled antibodies and examined by *fluorescence microscopy* to reveal the location of a protein of interest. For example, arrays of parallel bundles are evident in cells stained with antibody specific for actin, a protein that polymerizes into filaments (Figure 3.24). Actin filaments are constituents of the cytoskeleton, the internal scaffolding of cells that controls their shape and movement. By tracking protein location, fluorescent markers also provide clues to protein function. For instance, the mineralocorticoid receptor protein binds to steroid hormones (Section 26.4), including cortisol. The receptor was linked to a yellow variant of *green fluorescent protein* (GFP), a naturally fluorescent protein isolated from the jellyfish *Aequorea victoria* (Chapter 2). Fluorescence microscopy revealed that, in the absence of the hormone, the receptor is located in the cytoplasm (Figure 3.25A). On addition of the steroid, the receptor is translocated to the nucleus, where it binds to DNA (Figure 3.25B). These results indicate that the mineralocorticoid receptor protein is a transcription factor that controls gene expression.

**FIGURE 3.26 Immunoelectron microscopy.** The opaque particles (150-Å, or 15-nm, diameter) in this electron micrograph are clusters of gold atoms bound to antibody molecules. A gold-labeled antibody against a channel protein (Section 13.4) identifies membrane vesicles at the termini of neurons that contain this protein. [Courtesy of Dr. Peter Sargent.]

**FIGURE 3.25 Nuclear localization of a steroid receptor.** (A) The mineralocorticoid receptor, made visible by attachment to a yellow variant of GFP, is located predominantly in the cytoplasm of the cultured cell. (B) Subsequent to the addition of corticosterone (a glucocorticoid steroid that also binds to the mineralocorticoid receptor), the receptor moves into the nucleus. [M. Nishi, M. Tanaka, K.-i. Matsuda, M. Sunaguchi, and M. Kawata. *J. Neurosci.* 24:4918–4927, 2004, Fig. 7A.]

The highest resolution of fluorescence microscopy is about  $0.2\ \mu\text{m}$  (200 nm, or 2000 Å), the wavelength of visible light. Finer spatial resolution can be achieved by electron microscopy if the antibodies are tagged with electron-dense markers. For example, antibodies conjugated to clusters of gold or to ferritin (which has an electron-dense core rich in iron) are highly visible under the electron microscope. *Immunoelectron microscopy* can define the position of antigens to a resolution of 10 nm (100 Å) or finer (Figure 3.26).

### 3.3 Mass Spectrometry is a Powerful Technique for the Identification of Peptides and Proteins

In many instances, the study of a particular biological process in its native context is advantageous. For example, if we are interested in a pathway that is localized to the nucleus of a cell, we might conduct studies on an isolated nuclear extract. In these experiments, identification of the proteins present in the sample is often critical. Antibody-based techniques, such as the ELISA method described in the previous section, can be very helpful toward this goal. However, these techniques are limited to the detection of proteins for which an antibody is already available. Mass spectrometry enables the highly precise and sensitive measurement of the atomic composition of a particular molecule, or *analyte*, without prior knowledge of its identity. Originally, this method was relegated to the study of the chemical composition and molecular mass of gases or volatile liquids. However, technological advances in the past two decades have dramatically expanded the utility of mass spectrometry to the study of proteins, even those found at very low concentrations within highly complex mixtures, such as the contents of a particular cell type.

Mass spectrometry enables the highly accurate and sensitive detection of the mass of an analyte. This information can be used to determine the identity and chemical state of the molecule of interest. Mass spectrometers operate by converting analyte molecules into gaseous, charged forms (*gas-phase ions*). Through the application of electrostatic potentials, the ratio of the mass of each ion to its charge (the *mass-to-charge ratio*, or  $m/z$ ) can be measured. Although a wide variety of techniques employed by mass spectrometers are used in current practice, each of them comprises three essential components: the ion source, the mass analyzer, and the detector. Let us consider the first two in greater detail, because improvements in them have contributed most significantly to the analysis of biological samples.

The *ion source* achieves the first critical step in mass spectrometric analysis: conversion of the analyte into gas-phase ions (*ionization*). Until recently, proteins could not be ionized efficiently because of their high molecular weights and low volatility. However, the development of techniques such as *matrix-assisted laser desorption/ionization* (MALDI) and *electrospray ionization* (ESI) has enabled the clearing of this significant hurdle. In MALDI, the analyte is evaporated to dryness in the presence of a volatile, aromatic compound (the *matrix*) that can absorb light at specific wavelengths. A laser pulse tuned to one of these wavelengths excites and vaporizes the matrix, converting some of the analyte into the gas phase. Subsequent gaseous collisions enable the intermolecular transfer of charge, ionizing the analyte. In ESI, a solution of the analyte is passed through an electrically charged nozzle. Droplets of the analyte, now charged, emerge from the nozzle into a chamber of very low pressure, evaporating the solvent and ultimately yielding the ionized analyte.

The newly formed analyte ions then enter the *mass analyzer*, where they are distinguished on the basis of their mass-to-charge ratios. There are a number of different types of mass analyzers. For this discussion, we will consider one of the simplest, the *time-of-flight* (TOF) *mass analyzer*, in which ions are accelerated through an elongated chamber under a fixed electrostatic potential. Given two ions of identical net charge, the smaller ion will require less time to traverse the chamber than will the larger ion. The mass of each ion can be determined by measuring the time required for each ion to pass through the chamber.

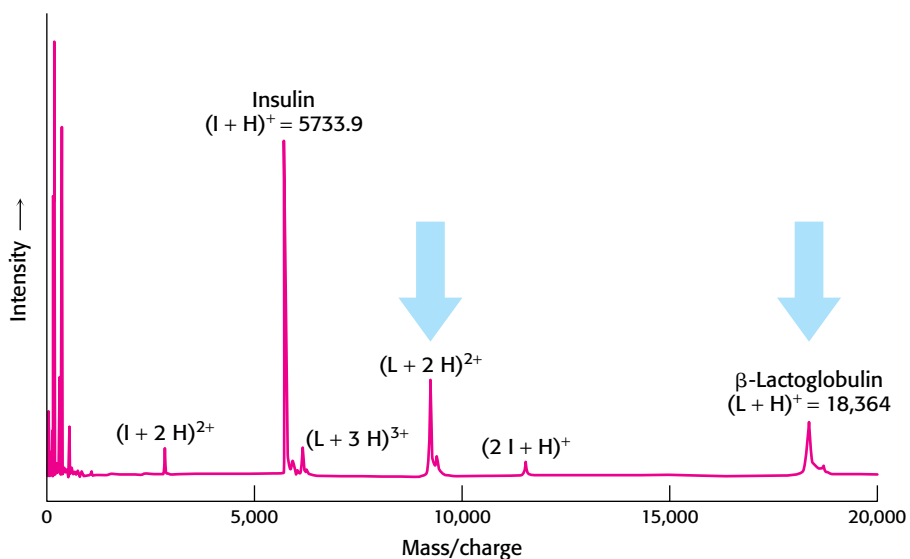

**FIGURE 3.27 MALDI-TOF mass spectrometry.** (1) The protein sample, embedded in an appropriate matrix, is ionized by the application of a laser beam. (2) An electric field accelerates the ions through the flight tube toward the detector. (3) The lightest ions arrive first. (4) The ionizing laser pulse also triggers a clock that measures the time of flight (TOF) for the ions. [Information from J. T. Watson, *Introduction to Mass Spectrometry*, 3d ed. (Lippincott-Raven, 1997), p. 279.]

The sequential action of the ion source and the mass analyzer enables the highly sensitive measurement of the mass of potentially massive ions, such as those of proteins. Consider an example of a MALDI ion source coupled to a TOF mass analyzer: the MALDI-TOF mass spectrometer (Figure 3.27). Gas-phase ions generated by the MALDI ion source pass directly into the TOF analyzer, where the mass-to-charge ratios are recorded. In Figure 3.28, the MALDI-TOF mass spectrum of a mixture of 5 pmol each of insulin and lactoglobulin is shown. The masses determined by MALDI-TOF are 5733.9 and 18,364, respectively. A comparison with the calculated values of 5733.5 and 18,388 reveals that MALDI-TOF is clearly an accurate means of determining protein mass.

In the ionization process, a family of ions, each of the same mass but carrying different total net charges, is formed from a single analyte. Because the mass spectrometer detects ions on the basis of their mass-to-charge ratio, these ions will appear as separate peaks in the mass spectrum. For example, in the mass spectrum of  $\beta$ -lactoglobulin shown in Figure 3.28, peaks near  $m/z = 18,364$  (corresponding to the +1 charged ion) and  $m/z = 9,183$

**FIGURE 3.28 MALDI-TOF mass spectrum of insulin and  $\beta$ -lactoglobulin.** A mixture of 5 pmol each of insulin (I) and  $\beta$ -lactoglobulin (L) was ionized by MALDI, which produces predominantly singly charged molecular ions from peptides and proteins—the insulin ion  $(I+H)^+$  and the lactoglobulin ion  $(L+H)^+$ . Molecules with multiple charges, such as those for  $\beta$ -lactoglobulin indicated by the blue arrows, as well as small quantities of a singly charged dimer of insulin  $(2I+H)^+$  also are produced. [Data from J. T. Watson, *Introduction to Mass Spectrometry*, 3d ed. (Lippincott-Raven, 1997), p. 282.]

(corresponding to the +2 charged ion) are visible (indicated by the blue arrows). Although multiple peaks for the same ion may appear to be a nuisance, they enable the spectrometrists to measure the mass of an analyte ion more than once in a single experiment, improving the overall precision of the calculated result.

### Peptides can be sequenced by mass spectrometry

Mass spectrometry is one of several techniques for the determination of the amino acid sequence of a protein. As we shall discuss shortly, this sequence data can be a valuable source of information. For many years, chemical methods were the primary means for peptide sequencing. In the most common of these methods, *Edman degradation*, the N-terminal amino acid of a polypeptide is labeled with *phenyl isothiocyanate*. Subsequent cleavage yields the phenylthiohydantoin (PTH)-amino acid derivative, which can be identified by spectroscopic methods, and the polypeptide chain, now shortened by one residue (Figure 3.29). This procedure can then be repeated on the shortened peptide, yielding another PTH-amino acid, which can again be identified by chromatography.

While technological advancements have improved the speed and sensitivity of the Edman degradation, these parameters have largely been surpassed by the application of mass spectrometric methods. The use of mass spectrometry for protein sequencing takes advantage of the fact that ions of proteins that have been analyzed by a mass spectrometer, the *precursor ions*, can be broken into smaller peptide chains by bombardment with atoms of an inert gas such as helium or argon. These new fragments, or *product ions*, can be passed through a second mass analyzer for further mass characterization. The utilization of two mass analyzers arranged in this manner is referred to as *tandem mass spectrometry*. Importantly, the product-ion fragments are formed in chemically predictable ways that can provide clues to the amino acid sequence of the precursor ion. For polypeptide analytes, disruption of individual peptide bonds will yield two smaller peptide ions, containing the

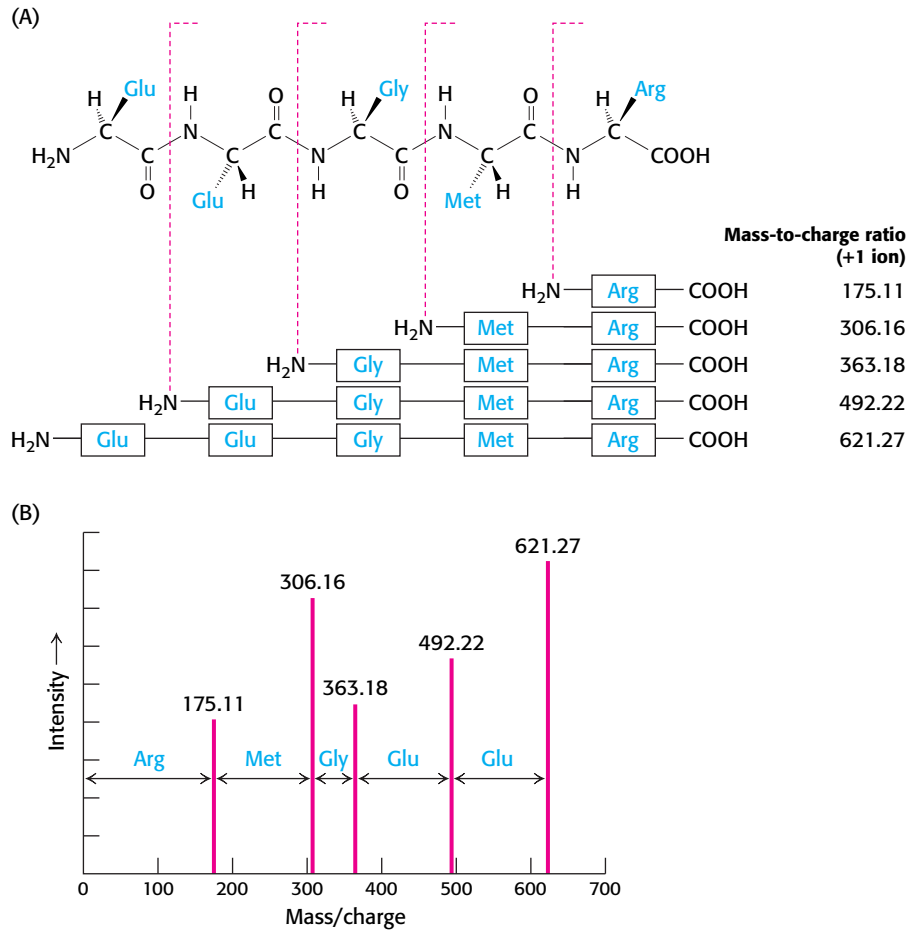

**FIGURE 3.29 The Edman degradation.** The labeled amino-terminal residue (PTH-alanine in the first round) can be released without hydrolyzing the rest of the peptide. Hence, the amino-terminal residue of the shortened peptide (Gly-Asp-Phe-Arg-Gly) can be determined in the second round. Three more rounds of the Edman degradation reveal the complete sequence of the original peptide.

**FIGURE 3.30 Peptide sequencing by tandem mass spectrometry.**

(A) Within the mass spectrometer, peptides can be fragmented by bombardment with inert gaseous ions to generate a family of product ions in which individual amino acids have been removed from one end. In this example, the carboxyl fragment of the cleaved peptide bond is ionized. (B) The product ions are detected in the second mass analyzer. The mass differences between the peaks indicate the sequence of amino acids in the precursor ion. [Data from H. Steen and M. Mann. *Nat. Rev. Mol. Cell Biol.* 5:699–711, 2004.]

sequences before and after the cleavage site. Hence, a family of ions can be detected; each ion represents a fragment of the original peptide with one or more amino acids removed from one end (Figure 3.30A). For simplicity, only the carboxyl-terminal peptide fragments are shown in Figure 3.30A. Figure 3.30B depicts a representative mass spectrum from a fragmented peptide. The mass differences between the peaks in this fragmentation experiment indicate the amino acid sequence of the precursor peptide ion.

### Proteins can be specifically cleaved into small peptides to facilitate analysis

In principle, it should be possible to sequence an entire protein using the Edman degradation or mass spectrometric methods. In practice, the Edman degradation is limited to peptides of 50 residues, because not all peptides in the reaction mixture release the amino acid derivative at each step. For instance, if the efficiency of release for each round were 98%, the proportion of “correct” amino acid released after 60 rounds would be  $(0.98^{60})$ , or 0.3—a hopelessly impure mix. Similarly, sequencing of long peptides by mass spectrometry yields a mass spectrum that can be complex and difficult to interpret. This obstacle can be circumvented by cleaving a protein into smaller peptides that can be sequenced. Protein cleavage can be achieved by chemical reagents, such as cyanogen bromide, or proteolytic enzymes, such as trypsin. Table 3.3 gives several other ways of specifically cleaving polypeptide chains. Note that these methods are sequence specific: they disrupt the protein backbone at particular amino acid residues in a predictable manner.

The peptides obtained by specific chemical or enzymatic cleavage are separated by some type of chromatography. The sequence of each purified

**Table 3.3** Specific cleavage of polypeptides

Reagent	Cleavage site
<b>Chemical cleavage</b>	
Cyanogen bromide	Carboxyl side of methionine residues
O-Iodosobenzoate	Carboxyl side of tryptophan residues
Hydroxylamine	Asparagine–glycine bonds
2-Nitro-5-thiocyanobenzoate	Amino side of cysteine residues
<b>Enzymatic cleavage</b>	
Trypsin	Carboxyl side of lysine and arginine residues
Clostripain	Carboxyl side of arginine residues
Staphylococcal protease	Carboxyl side of aspartate and glutamate residues (glutamate only under certain conditions)
Thrombin	Carboxyl side of arginine
Chymotrypsin	Carboxyl side of tyrosine, tryptophan, phenylalanine, leucine, and methionine
Carboxypeptidase A	Amino side of C-terminal amino acid (not arginine, lysine, or proline)

peptide is then determined by the methods described above. At this point, the amino acid sequences of segments of the protein are known, but the order of these segments is not yet defined. How can we order the peptides to obtain the primary structure of the original protein? The necessary additional information is obtained from *overlap peptides* (Figure 3.31). A second enzyme is used to split the polypeptide chain at different linkages. For example, chymotrypsin cleaves preferentially on the carboxyl side of aromatic and some other bulky nonpolar residues (Chapter 9). Because these chymotryptic peptides overlap two or more tryptic peptides, they can be used to establish the order of the peptides. The entire amino acid sequence of the polypeptide chain is then known.

Additional steps are necessary if the initial protein sample is actually several polypeptide chains. SDS–gel electrophoresis under reducing conditions should display the number of chains. Alternatively, the number of distinct N-terminal amino acids could be determined. After a protein has been identified as being made up of two or more polypeptide chains, denaturing agents, such as urea or guanidine hydrochloride, are used to dissociate chains held together by noncovalent bonds. The dissociated chains must be separated from one another before sequence determination can begin. Polypeptide chains linked by disulfide bonds are separated by reduction with thiols such as  $\beta$ -mercaptoethanol or dithiothreitol. To prevent the cysteine residues from recombining, they are alkylated with iodoacetate to form stable S-carboxymethyl derivatives (Figure 3.32). Sequencing can then be performed as already described.

### Genomic and proteomic methods are complementary

Despite the technological advancements in both chemical and mass spectrometric methods of peptide sequencing, heroic effort is required to elucidate the sequence of large proteins, those with more than 1000 residues. For sequencing such proteins, a complementary experimental approach based on recombinant DNA technology is often more efficient. As will be discussed in Chapter 5, long stretches of DNA can be cloned and sequenced, and the nucleotide sequence can be translated to reveal the amino acid sequence of the protein encoded by the gene (Figure 3.33). Recombinant

**FIGURE 3.31** **Overlap peptides.** The peptide obtained by chymotryptic digestion overlaps two tryptic peptides, establishing their order.

**FIGURE 3.32 Disulfide-bond reduction.** Polypeptides linked by disulfide bonds can be separated by reduction with dithiothreitol followed by alkylation to prevent them from re-forming.

DNA technology is producing a wealth of amino acid sequence information at a remarkable rate.

Nevertheless, even with the use of the DNA base sequence to determine primary structure, there is still a need to work with isolated proteins. The amino acid sequence deduced by reading the DNA sequence is that of the nascent protein, the direct product of the translational machinery. However, many proteins undergo *posttranslational modifications* after their syntheses. Some have their ends trimmed, and others arise by cleavage of a larger initial polypeptide chain. Cysteine residues in some proteins are oxidized to form disulfide links, connecting either parts within a chain or separate polypeptide chains. Specific side chains of some proteins are altered. Amino acid sequences derived from DNA sequences are rich in information, but they do not disclose these modifications. Chemical analyses of proteins in their mature form are needed to delineate the nature of these changes, which are critical for the biological activities of most proteins. *Thus, genomic and proteomic analyses are complementary approaches to elucidating the structural basis of protein function.*

### The amino acid sequence of a protein provides valuable information

Regardless of the method used for its determination, the amino acid sequence of a protein can provide the biochemist with a wealth of information as to the protein's structure, function, and history.

1. *The sequence of a protein of interest can be compared with all other known sequences to ascertain whether significant similarities exist.* A search for kinship between a newly sequenced protein and the millions of previously sequenced ones takes only a few seconds on a personal computer (Chapter 6). If the newly isolated protein is a member of an established class of protein, we can begin to infer information about the protein's structure and function. For instance, chymotrypsin and trypsin are members of the serine protease family, a clan of proteolytic enzymes that have a common catalytic mechanism based on a reactive serine residue (Chapter 9). If the sequence of the newly isolated protein shows sequence similarity with trypsin or chymotrypsin, the result suggests that it may be a serine protease.

2. *Comparison of sequences of the same protein in different species yields a wealth of information about evolutionary pathways.* Genealogical relationships between species can be inferred from sequence differences between their proteins. If we assume that the random mutation rate of proteins over time is constant, then careful sequence comparison of related proteins between two organisms can provide an estimate for when these two evolutionary lines diverged. For example, a comparison of serum albumins found in primates indicates that human beings and African apes diverged 5 million years ago, not 30 million years ago as was once thought. Sequence analyses have opened a new perspective on the fossil record and the pathway of human evolution.

<b>DNA sequence</b>	GGG	TTC	TTG	GGA	GCA	GCA	GGA	AGC	ACT	ATG	GGC	GCA
<b>Amino acid sequence</b>	Gly	Phe	Leu	Gly	Ala	Ala	Gly	Ser	Thr	Met	Gly	Ala

**FIGURE 3.33 DNA sequence yields the amino acid sequence.** The complete nucleotide sequence of HIV-1 (human immunodeficiency virus), the cause of AIDS (acquired immune deficiency syndrome), was determined within a year after the isolation of the virus. A part of the DNA sequence specified by the RNA genome of the virus is shown here with the corresponding amino acid sequence (deduced from a knowledge of the genetic code).

3. *Amino acid sequences can be searched for the presence of internal repeats.* Such internal repeats can reveal the history of an individual protein itself. Many proteins apparently have arisen by duplication of primordial genes followed by their diversification. For example, calmodulin, a ubiquitous calcium sensor in eukaryotes, contains four similar calcium-binding modules that arose by gene duplication (Figure 3.34).

4. *Many proteins contain amino acid sequences that serve as signals designating their destinations or controlling their processing.* For example, a protein destined for export from a cell or for location in a membrane contains a *signal sequence*, a stretch of about 20 hydrophobic residues near the amino terminus that directs the protein to the appropriate membrane. Another protein may contain a stretch of amino acids that functions as a *nuclear localization signal*, directing the protein to the nucleus.

5. *Sequence data provide a basis for preparing antibodies specific for a protein of interest.* One or more parts of the amino acid sequence of a protein will elicit an antibody when injected into a mouse or rabbit. These specific antibodies can be very useful in determining the amount of a protein present in solution or in the blood, ascertaining its distribution within a cell, or cloning its gene (Section 3.2).

6. *Amino acid sequences are valuable for making DNA probes that are specific for the genes encoding the corresponding proteins.* Knowledge of a protein's primary structure permits the use of reverse genetics. DNA sequences that correspond to a part of the amino acid sequence can be constructed on the basis of the genetic code. These DNA sequences can be used as probes to isolate the gene encoding the protein so that the entire sequence of the protein can be determined. The gene in turn can provide valuable information about the physiological regulation of the protein. Protein sequencing is an integral part of molecular genetics, just as DNA cloning is central to the analysis of protein structure and function. We will revisit some of these topics in more detail in Chapter 5.

### Individual proteins can be identified by mass spectrometry

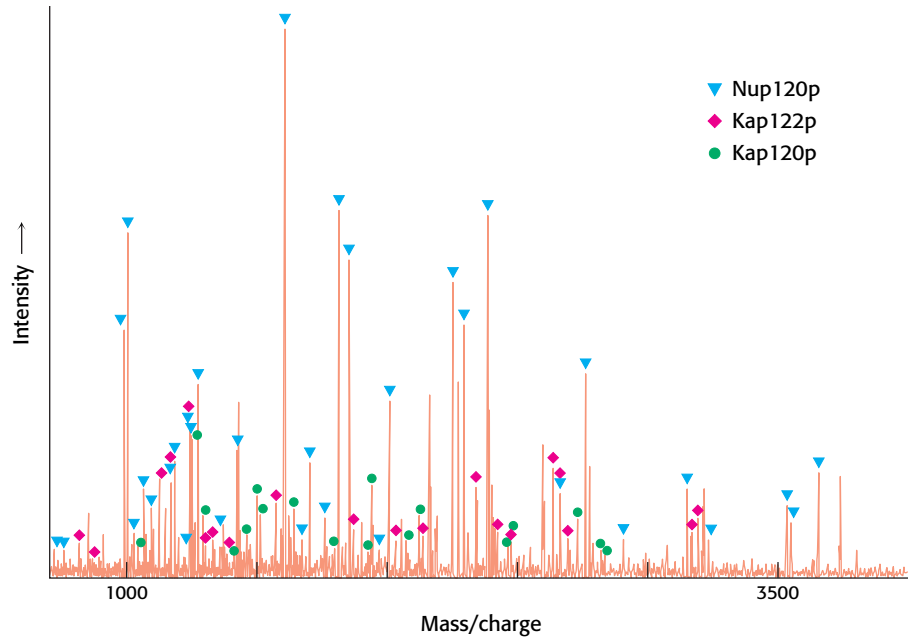

The combination of mass spectrometry with chromatographic and peptide-cleavage techniques enables highly sensitive protein identification in complex biological mixtures. When a protein is cleaved by chemical or enzymatic methods (Table 3.3), a specific and predictable family of peptide fragments is formed. We learned in Chapter 2 that each protein has a unique, precisely defined amino acid sequence. Hence, the identity of the individual peptides formed from this cleavage reaction—and, importantly, their corresponding masses—is a distinctive signature for that particular protein. Protein cleavage, followed by chromatographic separation and mass spectrometry, enables rapid identification and quantitation of these signatures, even if they are present at very low concentrations. This technique for protein identification is referred to as *peptide mass fingerprinting*.

The speed and sensitivity of mass spectrometry has made this technology critical for the study of proteomics. Let us consider the analysis of the nuclear-pore complex from yeast, which facilitates the transport of large molecules into and out of the nucleus. This huge macromolecular complex was purified from yeast cells by careful procedures. The purified complex was fractionated by HPLC followed by gel electrophoresis. Individual bands from the gel were isolated, cleaved with trypsin, and analyzed by MALDI-TOF mass spectrometry. The fragments produced were compared with amino acid sequences deduced from the DNA sequence of the yeast genome as shown in Figure 3.35. A total of 174 nuclear-pore proteins were identified

**FIGURE 3.34 Repeating motifs in a protein chain.** Calmodulin, a calcium sensor, contains four similar units (shown in red, yellow, blue, and orange) in a single polypeptide chain. Notice that each unit binds a calcium ion (shown in green). [Drawn from 1CLL.pdb.]

**FIGURE 3.35 Proteomic analysis by mass spectrometry.** This mass spectrum was obtained by analyzing a trypsin-treated band in a gel derived from a yeast nuclear-pore sample. Many of the peaks were found to match the masses predicted for peptide fragments from three proteins (Nup120p, Kap122p, and Kap120p) within the yeast genome. The band corresponded to an apparent molecular mass of 100 kDa. [Data from M. P. Rout, J. D. Aitchison, A. Suprpto, K. Hjertaas, Y. Zhao, and B. T. Chait. *J. Cell Biol.* 148:635–651, 2000.]

in this manner. Many of these proteins had not previously been identified as being associated with the nuclear pore despite years of study. Furthermore, mass spectrometric methods are sensitive enough to detect essentially all components of the pore if they are present in the samples used. Thus, a complete list of the components constituting this macromolecular complex could be obtained in a straightforward manner. Proteomic analysis of this type is growing in power as mass spectrometric and biochemical fractionation methods are refined.

### 3.4 Peptides Can Be Synthesized by Automated Solid-Phase Methods

Peptides of defined sequence can be synthesized to assist in biochemical analysis. These peptides are valuable tools for several purposes.

1. *Synthetic peptides can serve as antigens to stimulate the formation of specific antibodies.* Suppose we want to isolate the protein expressed by a specific gene. Peptides can be synthesized that match the translation of part of the gene's nucleic acid sequence, and antibodies can be generated that target these peptides. These antibodies can then be used to isolate the intact protein or localize it within the cell.

2. *Synthetic peptides can be used to isolate receptors for many hormones and other signal molecules.* For example, white blood cells are attracted to bacteria by formylmethionyl (fMet) peptides released in the breakdown of bacterial proteins. Synthetic formylmethionyl peptides have been useful in identifying the cell-surface receptor for this class of peptide. Moreover, synthetic peptides can be attached to agarose beads to prepare affinity chromatography columns for the purification of receptor proteins that specifically recognize the peptides.

3. *Synthetic peptides can serve as drugs.* Vasopressin is a peptide hormone that stimulates the reabsorption of water in the distal tubules of the kidney, leading to the formation of more-concentrated urine. Patients with diabetes insipidus are deficient in vasopressin (also called *antidiuretic hormone*), and so they excrete large volumes of dilute urine (more than 5 liters per day)

**FIGURE 3.36 Vasopressin and a synthetic vasopressin analog.** Structural formulas of (A) vasopressin, a peptide hormone that stimulates water resorption, and (B) 1-desamino-8-D-arginine vasopressin, a more stable synthetic analog of this antidiuretic hormone.

and are continually thirsty. This defect can be treated by administering 1-desamino-8-D-arginine vasopressin, a synthetic analog of the missing hormone (Figure 3.36). This synthetic peptide is degraded *in vivo* much more slowly than vasopressin and does not increase blood pressure.

4. Finally, *studying synthetic peptides can help define the rules governing the three-dimensional structure of proteins.* We can ask whether a particular sequence by itself tends to fold into an  $\alpha$  helix, a  $\beta$  strand, or a hairpin turn or behaves as a random coil. The peptides created for such studies can incorporate amino acids not normally found in proteins, allowing more variation in chemical structure than is possible with the use of only 20 amino acids.

How are these peptides constructed? The amino group of one amino acid is linked to the carboxyl group of another. However, a unique product is formed only if a single amino group and a single carboxyl group are available for reaction. Therefore, it is necessary to block some groups and to activate others to prevent unwanted reactions. First, the carboxyl-terminal amino acid is attached to an insoluble resin by its carboxyl group, effectively protecting it from further peptide-bond-forming reactions (Figure 3.37). The  $\alpha$ -amino group of this amino acid is blocked with a protecting group such as a *tert*-butyloxycarbonyl (*t*-Boc) group. The *t*-Boc protecting group of this amino acid is then removed with trifluoroacetic acid.

The next amino acid (in the protected *t*-Boc form) and *dicyclohexylcarbodiimide* (DCC) are added together. At this stage, only the carboxyl group of the incoming amino acid and the amino group of the resin-bound amino acid are free to form a peptide bond. DCC reacts with the carboxyl group of the incoming amino acid, activating it for the peptide-bond-forming reaction. After the peptide bond has formed, excess reagents are washed away, leaving the desired dipeptide product attached to the beads. Additional amino acids are linked by the same sequence of reactions. At the end of the synthesis, the peptide is released from the beads by the

**FIGURE 3.37 Solid-phase peptide synthesis.**

The sequence of steps in solid-phase synthesis is: (1) anchoring of the C-terminal amino acid to a solid resin, (2) deprotection of the amino terminus, and (3) coupling of the free amino terminus with the DCC-activated carboxyl group of the next amino acid. Steps 2 and 3 are repeated for each added amino acid. Finally, in step 4, the completed peptide is released from the resin.

addition of hydrofluoric acid (HF), which cleaves the carboxyl ester anchor without disrupting peptide bonds. Protecting groups on potentially reactive side chains, such as that of lysine, also are removed at this time.

A major advantage of this *solid-phase method*, first developed by R. Bruce Merrifield, is that the desired product at each stage is bound to beads that can be rapidly filtered and washed. Hence, there is no need to purify intermediates. All reactions are carried out in a single vessel, eliminating losses caused by repeated transfers of products. This cycle of reactions can be readily automated, which makes it feasible to routinely synthesize peptides containing about 50 residues in good yield and purity. In fact, the solid-phase method has been used to synthesize interferons (155 residues) that have antiviral activity and ribonuclease (124 residues) that is catalytically active. The protecting groups and cleavage agents may be varied for increased flexibility or convenience.

Synthetic peptides can be linked to create even longer molecules. With the use of specially developed *peptide-ligation* methods, proteins of 100 amino acids or more can be synthesized in very pure form. These methods enable the construction of even sharper tools for examining protein structure and function.

### 3.5 Three-Dimensional Protein Structure Can Be Determined by X-ray Crystallography and NMR Spectroscopy

Elucidation of the three-dimensional structure of a protein is often the source of a tremendous amount of insight into its corresponding function, inasmuch as the specificity of active sites and binding sites is defined by the precise atomic arrangement within these regions. For example, knowledge of the structure of a protein enables the biochemist to predict its mechanism of action, the effects of mutations on its function, and the desired features of drugs that may inhibit or augment its activity. X-ray crystallography and nuclear magnetic resonance spectroscopy are the two most important techniques for elucidating the conformation of proteins.

#### X-ray crystallography reveals three-dimensional structure in atomic detail

*X-ray crystallography* was the first method developed to determine protein structure in atomic detail. This technique provides the clearest visualization of the precise three-dimensional positions of most atoms within a protein. Of all forms of radiation, x-rays provide the best resolution for the determination of molecular structures because their wavelength approximately corresponds to the length of a covalent bond. The three components in an x-ray crystallographic analysis are a *protein crystal*, a *source of x-rays*, and a *detector* (Figure 3.38).

X-ray crystallography first requires the preparation of a protein or protein complex in crystal form, in which all protein molecules are oriented in a fixed, repeated arrangement with respect to one another. Slowly adding ammonium sulfate or another salt to a concentrated solution of protein to reduce its solubility favors the formation of highly ordered crystals—the process of salting out discussed on page 68. For example, myoglobin crystallizes in 3 M ammonium sulfate. Protein crystallization can be quite challenging: a concentrated solution of highly pure material is required and it is often difficult to predict which experimental conditions will yield the most effective crystals. Methods for screening many different crystallization conditions using a small amount of protein sample have been developed. Typically, hundreds of conditions must be tested to obtain crystals fully suitable for crystallographic studies. Nevertheless, increasingly large and complex proteins have been crystallized. For example, poliovirus, an 8500-kDa assembly of 240 protein subunits surrounding an RNA core, has been crystallized and its structure solved by x-ray methods. Crucially, proteins frequently crystallize in their biologically active configuration. Enzyme crystals may display catalytic activity if the crystals are suffused with substrate.

After a suitably pure crystal of protein has been obtained, a source of x-rays is required. A beam of x-rays of wavelength 1.54 Å is produced by accelerating electrons against a copper target. Equipment suitable for generating x-rays in this manner is available in many laboratories. Alternatively, x-rays can be produced by *synchrotron radiation*, the acceleration of electrons in circular orbits at speeds close to the speed of light. Synchrotron-generated x-ray beams are much more intense than those generated by electrons hitting copper. The higher intensity enables the acquisition of high quality data from smaller crystals over a shorter exposure times. Several facilities throughout

**FIGURE 3.38** An x-ray crystallographic experiment. An x-ray source generates a beam, which is diffracted by a crystal. The resulting diffraction pattern is collected on a detector.

the world generate synchrotron radiation, such as the Advanced Light Source at Argonne National Laboratory outside Chicago and the Photon Factory in Tsukuba City, Japan.

When a narrow beam of x-rays is directed at the protein crystal, most of the beam passes directly through the crystal while a small part is scattered in various directions. These scattered, or *diffracted*, x-rays can be detected by x-ray film or by a solid-state electronic detector. The scattering pattern provides abundant information about protein structure. The basic physical principles underlying the technique are:

**FIGURE 3.39 An x-ray diffraction pattern.** A protein crystal diffracts x-rays to produce a pattern of spots, or reflections, on the detector surface. The white silhouette in the center of the image is from a beam stop which protects the detector from the intense, undiffracted x-rays. [S. Lansky, O. Alalouf, V. Solomon, A. Alhassid, L. Govada, N. E. Chayan, H. Belhali, Y. Shoham, and G. Shoham. *Acta Cryst.* F69:430–434, 2013, Fig. 2.]

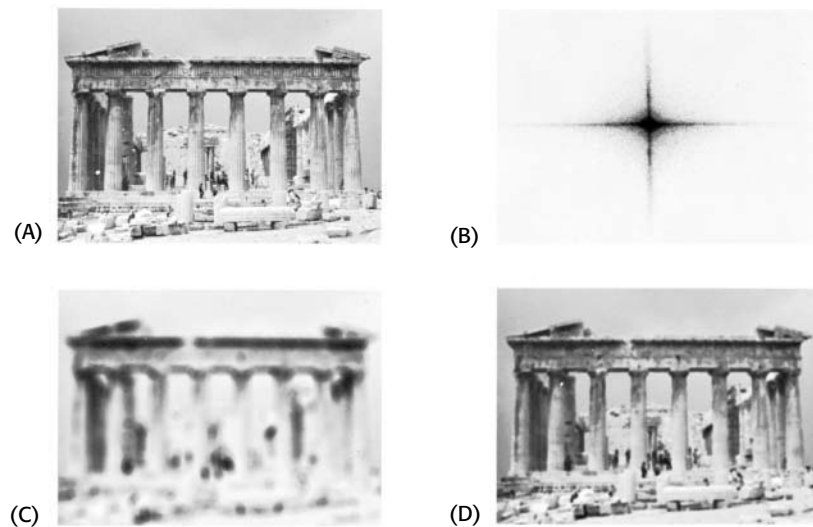

1. *Electrons scatter x-rays.* The amplitude of the wave scattered by an atom is proportional to its number of electrons. Thus, a carbon atom scatters six times as strongly as a hydrogen atom does.
2. *The scattered waves recombine.* Each diffracted beam comprises waves scattered by each atom in the crystal. The scattered waves reinforce one another at the film or detector if they are in phase (in step) there, and they cancel one another if they are out of phase.
3. *The way in which the scattered waves recombine depends only on the atomic arrangement.*

The protein crystal is mounted and positioned in a precise orientation with respect to the x-ray beam and the film. The crystal is rotated so that the beam can strike the crystal from many directions. This rotational motion results in an x-ray photograph consisting of a regular array of spots called *reflections*. The x-ray photograph shown in Figure 3.39 is a two-dimensional section through a three-dimensional array of 72,000 reflections. The intensities and positions of these reflections are the basic experimental data of an x-ray crystallographic analysis. Each reflection is formed from a wave with an amplitude proportional to the square root of the observed intensity of the spot. Each wave also has a *phase*—that is, the timing of its crests and troughs relative to those of other waves. Additional experiments or calculations must be performed to determine the phases corresponding to each reflection.

The next step is to reconstruct an image of the protein from the observed reflections. In light microscopy or electron microscopy, the diffracted beams are focused by lenses to directly form an image. However, appropriate lenses for focusing x-rays do not exist. Instead, the image is formed by applying a mathematical relation called a *Fourier transform* to the measured amplitudes and calculated phases of every observed reflection. The image obtained is referred to as the *electron-density map*. It is a three-dimensional graphic representation of where the electrons are most densely localized and is used to determine the positions of the atoms in the crystallized molecule (Figure 3.40). Critical to the interpretation of the map is its *resolution*, which is determined by the number of scattered intensities used in the Fourier transform. The fidelity of the image depends on this resolution, as shown by the optical analogy in Figure 3.41.

**Figure 3.40 Interpretation of an electron-density map.** (A) A segment of an electron-density map is drawn as a three-dimensional contour plot, in which the regions inside the “cage” represent the regions of highest electron density. (B) A model of the protein is built into this map so as to maximize the placement of atoms within this density. [Drawn from 1FCH.pdb.]

**FIGURE 3.41 Resolution affects the quality of an image.** The effect of resolution on the quality of a reconstructed image is shown by an optical analog of x-ray diffraction: (A) a photograph of the Parthenon; (B) an optical diffraction pattern of the Parthenon; (C and D) images reconstructed from the pattern in part B. More data were used to obtain image D than image C, which accounts for the higher quality of image D. [Courtesy of Dr. Thomas Steitz (part A) and Dr. David DeRosier (part B).]

A resolution of 6 Å reveals the course of the polypeptide chain but few other structural details. The reason is that polypeptide chains pack together so that their centers are between 5 Å and 10 Å apart. Maps at higher resolution are needed to delineate groups of atoms, which lie between 2.8 Å and 4.0 Å apart, and individual atoms, which are between 1.0 Å and 1.5 Å apart (Figure 3.42). The ultimate resolution of an x-ray analysis is determined by the degree of perfection of the crystal. For proteins, this limiting resolution is often about 2 Å; however, in exceptional cases, resolutions of 1.0 Å have been obtained.

### Nuclear magnetic resonance spectroscopy can reveal the structures of proteins in solution

X-ray crystallography is the most powerful method for determining protein structures. However, some proteins do not readily crystallize. Furthermore, although structures of crystallized proteins very closely represent those of proteins free of the constraints imposed by the crystalline environment, structures in solution can be sources of additional insights. *Nuclear magnetic resonance (NMR) spectroscopy* is unique in being able to reveal the atomic structure of macromolecules *in solution*, provided that highly concentrated solutions

**FIGURE 3.42 Resolution affects the quality of the electron density map.** The electron density maps of a tyrosine residue at four different resolution levels (1.0 Å, 2.0 Å, 2.7 Å, and 3.0 Å) are shown. At the lower resolution levels (2.7 Å and 3.0 Å), only a group of atoms corresponding to the side chain is visible, whereas at the highest resolution (1.0 Å), individual atoms within the side chain are distinguishable. [Data from [www.rcsb.org/pdb/101/static101.do?p=education\\_discussion/Looking-at-Structures/resolution.html](http://www.rcsb.org/pdb/101/static101.do?p=education_discussion/Looking-at-Structures/resolution.html)]

**TABLE 3.4** Biologically important nuclei giving NMR signals

Nucleus	Natural abundance (% by weight of the element)
$^1\text{H}$	99.984
$^2\text{H}$	0.016
$^{13}\text{C}$	1.108
$^{14}\text{N}$	99.635
$^{15}\text{N}$	0.365
$^{17}\text{O}$	0.037
$^{23}\text{Na}$	100.0
$^{25}\text{Mg}$	10.05
$^{31}\text{P}$	100.0
$^{35}\text{Cl}$	75.4
$^{39}\text{K}$	93.1

**FIGURE 3.43** Basis of NMR spectroscopy. The energies of the two orientations of a nucleus of spin  $1/2$  (such as  $^{31}\text{P}$  and  $^1\text{H}$ ) depend on the strength of the applied magnetic field. Absorption of electromagnetic radiation of appropriate frequency induces a transition from the lower to the upper level.

( $\sim 1$  mM, or  $15 \text{ mg ml}^{-1}$  for a 15-kDa protein) can be obtained. This technique depends on the fact that certain atomic nuclei are intrinsically magnetic. Only a limited number of isotopes display this property, called *spin*, and those most important to biochemistry are listed in Table 3.4. The simplest example is the hydrogen nucleus ( $^1\text{H}$ ), which is a proton. The spinning of a proton generates a magnetic moment. This moment can take either of two orientations, or spin states (called  $\alpha$  and  $\beta$ ), when an external magnetic field is applied (Figure 3.43). The energy difference between these states is proportional to the strength of the imposed magnetic field. The  $\alpha$  state has a slightly lower energy because it is aligned with this applied field. Hence, in a given population of nuclei, slightly more will occupy the  $\alpha$  state (by a factor of the order of 1.00001 in a typical experiment). A spinning proton in an  $\alpha$  state can be raised to an excited state ( $\beta$  state) by applying a pulse of electromagnetic radiation (a radio-frequency, or RF, pulse), provided that the frequency corresponds to the energy difference between the  $\alpha$  and the  $\beta$  states. In these circumstances, the spin will change from  $\alpha$  to  $\beta$ ; in other words, *resonance* will be obtained.

These properties can be used to examine the chemical surroundings of the hydrogen nucleus. The flow of electrons around a magnetic nucleus generates a small local magnetic field that opposes the applied field. The degree of such shielding depends on the surrounding electron density. Consequently, nuclei in different environments will change states, or resonate, at slightly different field strengths or radiation frequencies. A resonance spectrum for a molecule is obtained by keeping the magnetic field constant and varying the frequency of the electromagnetic radiation. The nuclei of the perturbed sample absorb electromagnetic radiation at a frequency that can be measured. The different frequencies, termed *chemical shifts*, are expressed in fractional units  $\delta$  (parts per million, or ppm) relative to the shifts of a standard compound, such as a water-soluble derivative of tetramethylsilane, that is added with the sample. For example, a  $-\text{CH}_3$  proton typically exhibits a chemical shift ( $\delta$ ) of 1 ppm, compared with a chemical shift of 7 ppm for an aromatic proton. The chemical shifts of most protons in protein molecules fall between 0 and 9 ppm (Figure 3.44). Most protons in many proteins can be resolved by using this technique of *one-dimensional NMR*. With this information, we can then deduce changes to a particular chemical group under different conditions, such as the conformational change of a protein from a disordered structure to an  $\alpha$  helix in response to a change in pH.

**FIGURE 3.44** One-dimensional NMR spectra. (A)  $^1\text{H}$ -NMR spectrum of ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ) shows that the chemical shifts for the hydrogen are clearly resolved. (B)  $^1\text{H}$ -NMR spectrum of a 55 amino acid fragment of a protein having a role in RNA splicing shows a greater degree of complexity. A large number of peaks are present and many overlap. [(A) Data from C. Branden and J. Tooze, *Introduction to Protein Structure* (Garland, 1991), p. 280; (B) courtesy of Dr. Barbara Amann and Dr. Wesley McDermott.]

**FIGURE 3.45 The nuclear Overhauser effect.** The nuclear Overhauser effect (NOE) identifies pairs of protons that are in close proximity. (A) Schematic representation of a polypeptide chain highlighting five particular protons. Protons 2 and 5 are in close proximity ( $\sim 4$  Å apart), whereas other pairs are farther apart. (B) A highly simplified NOESY spectrum. The diagonal shows five peaks corresponding to the five protons in part A. The peak above the diagonal and the symmetrically related one below reveal that proton 2 is close to proton 5.

We can garner even more information by examining how the spins on different protons affect their neighbors. By inducing a transient magnetization in a sample through the application of a radio-frequency pulse, we can alter the spin on one nucleus and examine the effect on the spin of a neighboring nucleus. Especially revealing is a *two-dimensional spectrum obtained by nuclear Overhauser enhancement spectroscopy (NOESY), which graphically displays pairs of protons that are in close proximity*, even if they are not close together in the primary structure. The basis for this technique is the *nuclear Overhauser effect (NOE)*, an interaction between nuclei that is proportional to the inverse sixth power of the distance between them. Magnetization is transferred from an excited nucleus to an unexcited one if the two nuclei are less than about 5 Å apart (Figure 3.45A). In other words, the effect provides a means of detecting the location of atoms relative to one another in the three-dimensional structure of the protein. The peaks that lie along the diagonal of a NOESY spectrum (shown in white in Figure 3.45B) correspond to those present in a one-dimensional NMR experiment. The peaks apart from the diagonal (shown in red in Figure 3.45B), referred to as *off-diagonal peaks* or *cross-peaks*, provide crucial new information: *they identify pairs of protons that are less than 5 Å apart*. A two-dimensional NOESY spectrum for a protein comprising 55 amino acids is shown in Figure 3.46. The large number of off-diagonal peaks reveals short proton–proton distances. The three-dimensional structure of a protein can be

**FIGURE 3.46 Detecting short proton–proton distances.** A NOESY spectrum for a 55 amino acid domain from a protein having a role in RNA splicing. Each off-diagonal peak corresponds to a short proton–proton separation. This spectrum reveals hundreds of such short proton–proton distances, which can be used to determine the three-dimensional structure of this domain. [Courtesy of Dr. Barbara Amann and Dr. Wesley McDermott.]

**FIGURE 3.47 Structures calculated on the basis of NMR constraints.** (A) NOESY observations show that protons (connected by dotted red lines) are close to one another in space. (B) A three-dimensional structure calculated with these proton pairs constrained to be close together.

**FIGURE 3.48 A family of structures.** A set of 25 structures for a 28 amino acid domain from a zinc-finger-DNA-binding protein. The red line traces the average course of the protein backbone. Each of these structures is consistent with hundreds of constraints derived from NMR experiments. The differences between the individual structures are due to a combination of imperfections in the experimental data and the dynamic nature of proteins in solution. [Courtesy of Dr. Barbara Amann.]

reconstructed with the use of such proximity relations. Structures are calculated such that protons that must be separated by less than 5 Å on the basis of NOESY spectra are close to one another in the three-dimensional structure (Figure 3.47). If a sufficient number of distance constraints are applied, the three-dimensional structure can nearly be determined uniquely.

In practice, a family of related structures is generated by NMR spectroscopy for three reasons (Figure 3.48). First, not enough constraints may be experimentally accessible to fully specify the structure. Second, the distances obtained from analysis of the NOESY spectrum are only approximate. Finally, the experimental observations are made not on single molecules but on a large number of molecules in solution that may have slightly different structures at any given moment. Thus, the family of structures generated from NMR structure analysis indicates the range of conformations for the protein in solution. At present, structural determination by NMR spectroscopy is generally limited to proteins less than 50 kDa, but its resolving power is certain to increase. The power of NMR has been greatly enhanced by the ability of recombinant DNA technology to produce proteins labeled uniformly or at specific sites with  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^2\text{H}$  (Chapter 5).

The structures of nearly 97,000 proteins had been elucidated by x-ray crystallography and NMR spectroscopy by the end of 2013 and several new structures are now determined each day. The coordinates are collected at the Protein Data Bank ([www.pdb.org](http://www.pdb.org)), and the structures can be accessed for visualization and analysis. Knowledge of the detailed molecular architecture of proteins has been a source of insight into how proteins recognize and bind other molecules, how they function as enzymes, how they fold, and how they evolved. This extraordinarily rich harvest is continuing at a rapid pace and is greatly influencing the entire field of biochemistry as well as other biological and physical sciences.

## SUMMARY

The rapid progress in gene sequencing has advanced another goal of biochemistry—elucidation of the proteome. The proteome is the complete set of proteins expressed and includes information about how they are modified, how they function, and how they interact with other molecules.

### 3.1 The Purification of Proteins Is an Essential First Step in Understanding Their Function

Proteins can be separated from one another and from other molecules on the basis of such characteristics as solubility, size, charge, and binding affinity. SDS–polyacrylamide gel electrophoresis separates the polypeptide chains of proteins under denaturing conditions largely according to mass. Proteins can also be separated electrophoretically on the basis of net

charge by isoelectric focusing in a pH gradient. Ultracentrifugation and gel-filtration chromatography resolve proteins according to size, whereas ion-exchange chromatography separates them mainly on the basis of net charge. The high affinity of many proteins for specific chemical groups is exploited in affinity chromatography, in which proteins bind to columns containing beads bearing covalently linked substrates, inhibitors, or other specifically recognized groups. The mass of a protein can be determined by sedimentation-equilibrium measurements.

### 3.2 Immunology Provides Important Techniques with Which to Investigate Proteins

Proteins can be detected and quantitated by highly specific antibodies; monoclonal antibodies are especially useful because they are homogeneous. Enzyme-linked immunosorbent assays and western blots of SDS-polyacrylamide gels are used extensively. Proteins can also be localized within cells by immunofluorescence microscopy and immunoelectron microscopy.

### 3.3 Mass Spectrometry Is a Powerful Technique for the Identification of Peptides and Proteins

Techniques such as matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization (ESI) allow the generation of ions of proteins and peptides in the gas phase. The mass of such protein ions can be determined with great accuracy and precision. Masses determined by these techniques act as protein name tags because the mass of a protein or peptide is precisely determined by its amino acid composition and, hence, by its sequence. In addition to chemical methods, such as the Edman degradation, tandem mass spectrometry enables the rapid and highly accurate sequencing of peptides. These sequences are rich in information concerning the kinship of proteins, their evolutionary relationships, and diseases produced by mutations. Knowledge of a sequence provides valuable clues to conformation and function. Mass spectrometric techniques are central to proteomics because they make it possible to analyze the constituents of large macromolecular assemblies or other collections of proteins.

### 3.4 Peptides Can Be Synthesized by Automated Solid-Phase Methods

Polypeptide chains can be synthesized by automated solid-phase methods in which the carboxyl end of the growing chain is linked to an insoluble support. The carboxyl group of the incoming amino acid is activated by dicyclohexylcarbodiimide and joined to the amino group of the growing chain. Synthetic peptides can serve as drugs and as antigens to stimulate the formation of specific antibodies. They can also be sources of insight into the relation between amino acid sequence and conformation.

### 3.5 Three-Dimensional Protein Structure Can Be Determined by X-ray Crystallography and NMR Spectroscopy

X-ray crystallography and nuclear magnetic resonance spectroscopy have greatly enriched our understanding of how proteins fold, recognize other molecules, and catalyze chemical reactions. X-ray crystallography is possible because electrons scatter x-rays. The diffraction pattern produced can be analyzed to reveal the arrangement of atoms in a protein. The three-dimensional structures of tens of thousands of proteins are now known in atomic detail. Nuclear magnetic resonance spectroscopy reveals the structure and dynamics of proteins in solution. The chemical shift of nuclei depends on their local environment. Furthermore, the spins of neighboring nuclei interact with each other in ways that provide definitive structural information. This information can be used to determine complete three-dimensional structures of proteins.

## PROBLEMS

1. *Valuable reagents.* The following reagents are often used in protein chemistry:

CNBr	Trypsin
Urea	Performic acid
Mercaptoethanol	6 N HCl
Chymotrypsin	Phenyl isothiocyanate

Which one is the best suited for accomplishing each of the following tasks?

- Determination of the amino acid sequence of a small peptide.
- Reversible denaturation of a protein devoid of disulfide bonds. Which additional reagent would you need if disulfide bonds were present?
- Hydrolysis of peptide bonds on the carboxyl side of aromatic residues.
- Cleavage of peptide bonds on the carboxyl side of methionines.
- Hydrolysis of peptide bonds on the carboxyl side of lysine and arginine residues.

2. *The only constant is change.* Explain how two different cell types from the same organism will have identical genomes but may have vastly divergent proteomes.

3. *Crafting a new breakpoint.* Ethyleneimine reacts with cysteine side chains in proteins to form S-aminoethyl derivatives. The peptide bonds on the carboxyl side of these modified cysteine residues are susceptible to hydrolysis by trypsin. Why?

4. *Spectrometry.* The absorbance  $A$  of a solution is defined as

$$A = \log_{10}(I_0/I)$$

in which  $I_0$  is the incident-light intensity and  $I$  is the transmitted-light intensity. The absorbance is related to the molar

absorption coefficient (extinction coefficient)  $\epsilon$  (in  $\text{M}^{-1} \text{cm}^{-1}$ ), concentration  $c$  (in M), and path length  $l$  (in cm) by

$$A = \epsilon lc$$

The absorption coefficient of myoglobin at 580 nm is  $15,000 \text{ M}^{-1} \text{cm}^{-1}$ . What is the absorbance of a  $1 \text{ mg ml}^{-1}$  solution across a 1-cm path? What percentage of the incident light is transmitted by this solution?

5. *It's in the bag.* Suppose that you precipitate a protein with  $1 \text{ M } (\text{NH}_4)_2\text{SO}_4$  and that you wish to reduce the concentration of the  $(\text{NH}_4)_2\text{SO}_4$ . You take 1 ml of your sample and dialyze it in 1000 ml of buffer. At the end of dialysis, what is the concentration of  $(\text{NH}_4)_2\text{SO}_4$  in your sample? How could you further lower the  $(\text{NH}_4)_2\text{SO}_4$  concentration?

6. *Too much or not enough.* Why do proteins precipitate at high salt concentrations? Although many proteins precipitate at high salt concentrations, some proteins require salt to dissolve in water. Explain why some proteins require salt to dissolve.

7. *A slow mover.* Tropomyosin, a 70-kDa muscle protein, sediments more slowly than does hemoglobin (65 kDa). Their sedimentation coefficients are 2.6S and 4.31S, respectively. Which structural feature of tropomyosin accounts for its slow sedimentation?

8. *Sedimenting spheres.* What is the dependence of the sedimentation coefficient  $s$  of a spherical protein on its mass? How much more rapidly does an 80-kDa protein sediment than does a 40-kDa protein?

9. *Frequently used in shampoos.* The detergent sodium dodecyl sulfate (SDS) denatures proteins. Suggest how SDS destroys protein structure.

10. *Size estimate.* The relative electrophoretic mobilities of a 30-kDa protein and a 92-kDa protein used as standards

on an SDS–polyacrylamide gel are 0.80 and 0.41, respectively. What is the apparent mass of a protein having a mobility of 0.62 on this gel?

11. *Unexpected migration.* Some proteins migrate anomalously in SDS-PAGE gels. For instance, the molecular weight determined from an SDS-PAGE gel is sometimes very different from the molecular weight determined from the amino acid sequence. Suggest an explanation for this discrepancy.

12. *Sorting cells.* Fluorescence-activated cell sorting (FACS) is a powerful technique for separating cells according to their content of particular molecules. For example, a fluorescence-labeled antibody specific for a cell-surface protein can be used to detect cells containing such a molecule. Suppose that you want to isolate cells that possess a receptor enabling them to detect bacterial degradation products. However, you do not yet have an antibody directed against this receptor. Which fluorescence-labeled molecule would you prepare to identify such cells?

13. *Column choice.* (a) The octapeptide AVGWRVKS was digested with the enzyme trypsin. Which method would be most appropriate for separating the products: ion-exchange or gel-filtration chromatography? Explain. (b) Suppose that the peptide was digested with chymotrypsin. What would be the optimal separation technique? Explain.

14. *Power(ful) tools.* Monoclonal antibodies can be conjugated to an insoluble support by chemical methods. Explain how these antibody-bound beads can be exploited for protein purification.

15. *Assay development.* You wish to isolate an enzyme from its native source and need a method for measuring its activity throughout the purification. However, neither the substrate nor the product of the enzyme-catalyzed reaction can be detected by spectroscopy. You discover that the product of the reaction is highly antigenic when injected into mice. Propose a strategy to develop a suitable assay for this enzyme.

16. *Making more enzyme?* In the course of purifying an enzyme, a researcher performs a purification step that results in an *increase* in the total activity to a value greater than that present in the original crude extract. Explain how the amount of total activity might increase.

17. *Divide and conquer.* The determination of the mass of a protein by mass spectrometry often does not allow its unique identification among possible proteins within a complete proteome, but determination of the masses of all fragments produced by digestion with trypsin almost always allows unique identification. Explain.

18. *Know your limits.* Which two amino acids are indistinguishable in peptide sequencing by the tandem mass spectrometry method described in this chapter and why?

19. *Protein purification problem.* Complete the following table.

Purification Procedure	Total protein (mg)	Total activity (units)	Specific activity (units mg <sup>-1</sup> )	Purification level	Yield (%)
Crude extract	20,000	4,000,000		1	100
(NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> precipitation	5,000	3,000,000			
DEAE-cellulose chromatography	1,500	1,000,000			
Gel-filtration chromatography	500	750,000			
Affinity chromatography	45	675,000			

20. *Part of the mix.* Your frustrated colleague hands you a mixture of four proteins with the following properties:

	Isoelectric point (pI)	Molecular weight (in kDa)
Protein A	4.1	80
Protein B	9.0	81
Protein C	8.8	37
Protein D	3.9	172

(a) Propose a method for the isolation of Protein B from the other proteins. (b) If Protein B also carried a His tag at its N-terminus, how could you revise your method?

21. *The challenge of flexibility.* Structures of proteins comprising domains separated by flexible linker regions can be quite difficult to solve by x-ray crystallographic methods. Why might this be the case? What are possible experimental approaches to circumvent this barrier?

### Chapter Integration Problems

22. *Quaternary structure.* A protein was purified to homogeneity. Determination of the mass by gel-filtration chromatography yields 60 kDa. Chromatography in the presence of 6 M urea yields a 30-kDa species. When the chromatography is repeated in the presence of 6 M urea and 10 mM β-mercaptoethanol, a single molecular species of 15 kDa results. Describe the structure of the molecule.

23. *Helix–coil transitions.* (a) NMR measurements have shown that poly-L-lysine is a random coil at pH 7 but becomes a helix as the pH is raised above 10. Account for this pH-dependent conformational transition. (b) Predict the pH dependence of the helix–coil transition of poly-L-glutamate.

24. *Peptide mass determination.* You have isolated a protein from the bacterium *E. coli* and seek to confirm its identity by trypsin digestion and mass spectrometry. Determination of the masses of several peptide fragments has enabled you to deduce the identity of the protein. However, there is a discrepancy with one of the peptide fragments, which you believe should have the sequence MLNSFK and an (M+H)<sup>+</sup> value of 739.38. In your experiments, you repeatedly obtain an (M+H)<sup>+</sup> value of 767.38. What is the cause

of this discrepancy and what does it tell you about the region of the protein from which this peptide is derived?

25. *Peptides on a chip*. Large numbers of different peptides can be synthesized in a small area on a solid support. This high-density array can then be probed with a fluorescence-labeled protein to find out which peptides are recognized. The binding of an antibody to an array of 1024 different peptides occupying a total area the size of a thumbnail is shown in the adjoining illustration. How would you synthesize such a peptide array? (Hint: Use light instead of acid to deprotect the terminal amino group in each round of synthesis.)

**Fluorescence scan of an array of 1024 peptides in a 1.6-cm<sup>2</sup> area.** Each synthesis site is a 400- $\mu\text{m}$  square. A fluorescently labeled monoclonal antibody was added to the array to identify peptides that are recognized. The height and color of each square denote the fluorescence intensity. [Information from S. P. A. Fodor et al., *Science* 251(1991):767.]

26. *Exchange rate*. The amide hydrogen atoms of peptide bonds within proteins can exchange with protons in the solvent. In general, amide hydrogen atoms in buried regions of proteins and protein complexes exchange more slowly than those on the solvent-accessible surface do. Determination of these rates can be used to explore the protein-folding reaction, probe the tertiary structure of proteins, and identify the regions of protein-protein interfaces. These exchange reactions can be followed by studying the behavior of the protein in solvent that has been labeled with deuterium (<sup>2</sup>H), a stable isotope of hydrogen. What two methods described in this chapter could be readily applied to the study of hydrogen-deuterium exchange rates in proteins?

### Data Interpretation Problems

27. *Protein sequencing 1*. Determine the sequence of hexapeptide on the basis of the following data. Note: When the sequence is not known, a comma separates the amino acids (Table 3.3).

Amino acid composition: (2R,A,S,V,Y)

N-terminal analysis of the hexapeptide: A

Trypsin digestion: (R,A,V) and (R,S,Y)

Carboxypeptidase digestion: No digestion.

Chymotrypsin digestion: (A,R,V,Y) and (R,S)

28. *Protein sequencing 2*. Determine the sequence of a peptide consisting of 14 amino acids on the basis of the following data.

Amino acid composition: (4S,2L,F,G,I,K,M,T,W,Y)

N-terminal analysis: S

Carboxypeptidase digestion: L

Trypsin digestion: (3S,2L,F,I,M,T,W) (G,K,S,Y)

Chymotrypsin digestion: (F,I,S) (G,K,L) (L,S) (M,T) (S,W) (S,Y)

N-terminal analysis of (F,I,S) peptide: S

Cyanogen bromide treatment: (2S,F,G,I,K,L,M\*,T,Y) (2S,L,W)

M\*, methionine detected as homoserine

29. *Applications of two-dimensional electrophoresis*. Performic acid cleaves the disulfide linkage of cystine and converts the sulfhydryl groups into cysteic acid residues, which are then no longer capable of disulfide-bond formation.

Consider the following experiment: You suspect that a protein containing three cysteine residues has a single disulfide bond. You digest the protein with trypsin and subject the mixture to electrophoresis along one end of a sheet of paper. After treating the paper with performic acid, you subject the sheet to electrophoresis in the perpendicular direction and stain it with a reagent that detects proteins. How would the paper appear if the protein did not contain any disulfide bonds? If the protein contained a single disulfide bond? Propose an experiment to identify which cysteine residues form the disulfide bond.

# DNA, RNA, and the Flow of Genetic Information

Family resemblance, very evident in this photograph of four sisters, results from having genes in common. Genes must be expressed to exert an effect, and proteins regulate such expression. One such regulatory protein, a zinc-finger protein (zinc ion is blue, protein is red), is shown bound to a control region of DNA (black). [(Left) © Nicholas Nixon, courtesy Fraenkel Gallery, San Francisco. (Right) Drawn from 1AAY.pdb.]

**D**NA and RNA are long linear polymers, called nucleic acids, that carry information in a form that can be passed from one generation to the next. These macromolecules consist of a large number of linked nucleotides, each composed of a sugar, a phosphate, and a base. Sugars linked by phosphates form a common backbone that plays a structural role, whereas the sequence of bases along a nucleic acid strand carries genetic information. The DNA molecule has the form of a *double helix*, a helical structure consisting of two complementary nucleic acid strands. Each strand serves as the template for the other in DNA replication. The genes of all cells and many viruses are made of DNA.

Genes specify the kinds of proteins that are made by cells, but DNA is not the direct template for protein synthesis. Rather, a DNA strand is copied into a class of RNA molecules called messenger RNA (mRNA), the information-carrying intermediates in protein synthesis. This process of transcription is followed by translation, the synthesis of proteins according to instructions given by mRNA templates. Information processing in all cells is quite complex. The scheme that underlies information processing at the level of gene expression was first proposed by Francis Crick in 1958.

Crick called this scheme the *central dogma*. The basic tenets of this dogma are true, but, as we will see later, this scheme is not as simple as depicted.

## OUTLINE

- 4.1 A Nucleic Acid Consists of Four Kinds of Bases Linked to a Sugar-Phosphate Backbone
- 4.2 A Pair of Nucleic Acid Strands with Complementary Sequences Can Form a Double-Helical Structure
- 4.3 The Double Helix Facilitates the Accurate Transmission of Hereditary Information

- 4.7 Most Eukaryotic Genes Are Mosaics of Introns and Exons

This flow of information depends on the genetic code, which defines the relation between the sequence of bases in DNA (or its mRNA transcript) and the sequence of amino acids in a protein. The code is nearly the same in all organisms: a sequence of three bases, called a *codon*, specifies an amino acid. There is another step in the expression of most eukaryotic genes, which are mosaics of nucleic acid sequences called *introns* and *exons*. Both are transcribed, but before translation takes place, introns are cut out of newly synthesized RNA molecules, leaving mature RNA molecules with continuous exons. The existence of introns and exons has crucial implications for the evolution of proteins.

## 4.1 A Nucleic Acid Consists of Four Kinds of Bases Linked to a Sugar–Phosphate Backbone

The nucleic acids DNA and RNA are well suited to function as the carriers of genetic information by virtue of their covalent structures. These macromolecules are *linear polymers* built up from similar units connected end to end (Figure 4.1). Each monomer unit within the polymer is a *nucleotide*. A single nucleotide unit consists of three components: a sugar, a phosphate, and one of four bases. *The sequence of bases in the polymer uniquely characterizes a nucleic acid and constitutes a form of linear information*—information analogous to the letters that spell a person’s name.

FIGURE 4.1 Polymeric structure of nucleic acids.

### RNA and DNA differ in the sugar component and one of the bases

The sugar in *deoxyribonucleic acid* (DNA) is *deoxyribose*. The prefix *deoxy* indicates that the 2'-carbon atom of the sugar lacks the oxygen atom that is linked to the 2'-carbon atom of *ribose*, as shown in Figure 4.2. Note that sugar carbons are numbered with primes to differentiate them from atoms in the bases. The sugars in both nucleic acids are linked to one another by phosphodiester bridges. Specifically, the 3'-hydroxyl (3'-OH) group of the sugar moiety of one nucleotide is esterified to a phosphate group, which is, in turn, joined to the 5'-hydroxyl group of the adjacent sugar. The chain of sugars linked by phosphodiester bridges is referred to as the *backbone* of the nucleic acid (Figure 4.3). Whereas the backbone is constant in a nucleic

FIGURE 4.2 Ribose and deoxyribose. Atoms in sugar units are numbered with primes to distinguish them from atoms in bases (see Figure 4.4).

FIGURE 4.3 Backbones of DNA and RNA. The backbones of these nucleic acids are formed by 3'-to-5' phosphodiester linkages. A sugar unit is highlighted in red and a phosphate group in blue.

**FIGURE 4.4 Purines and pyrimidines.** Atoms within bases are numbered without primes. Uracil is present in RNA instead of thymine.

acid, the bases vary from one monomer to the next. Two of the bases of DNA are derivatives of *purine*—adenine (A) and guanine (G)—and two of *pyrimidine*—cytosine (C) and thymine (T), as shown in Figure 4.4.

*Ribonucleic acid* (RNA), like DNA, is a long unbranched polymer consisting of nucleotides joined by 3'-to-5' phosphodiester linkages (Figure 4.3). The covalent structure of RNA differs from that of DNA in two respects. First, the sugar units in RNA are riboses rather than deoxyriboses. Ribose contains a 2'-hydroxyl group not present in deoxyribose. Second, one of the four major bases in RNA is uracil (U) instead of thymine (T).

Note that each phosphodiester bridge has a negative charge. This negative charge repels nucleophilic species such as hydroxide ions, which are capable of hydrolytic attack on the phosphate backbone. This resistance is crucial for maintaining the integrity of information stored in nucleic acids. The absence of the 2'-hydroxyl group in DNA further increases its resistance to hydrolysis. The greater stability of DNA probably accounts for its use rather than RNA as the hereditary material in all modern cells and in many viruses.

### Nucleotides are the monomeric units of nucleic acids

The building blocks of nucleic acids and the precursors of these building blocks play many other roles throughout the cell—for instance, as energy currency and as molecular signals. Consequently, it is important to be familiar with the nomenclature of nucleotides and their precursors. A unit consisting of a base bonded to a sugar is referred to as a *nucleoside*. The four nucleoside units in RNA are called *adenosine*, *guanosine*, *cytidine*, and *uridine*, whereas those in DNA are called *deoxyadenosine*, *deoxyguanosine*, *deoxycytidine*, and *thymidine*. In each case, N-9 of a purine or N-1 of a pyrimidine is attached to C-1' of the sugar by an *N*-glycosidic linkage (Figure 4.5). The base lies above the plane of the sugar when the structure is written in the standard orientation; that is, the configuration of the *N*-glycosidic linkage is  $\beta$  (Section 11.1). Note that thymidine contains deoxyribose; by convention, the prefix deoxy is not added because thymine-containing nucleosides are only rarely found in RNA.

A *nucleotide* is a nucleoside joined to one or more phosphoryl groups by an ester linkage. *Nucleotide triphosphates*, nucleosides joined to three phosphoryl groups, are the monomers—the building blocks—that are linked to form RNA and DNA. The four nucleotide units that link to form DNA are nucleotide monophosphates called *deoxyadenylate*, *deoxyguanylate*, *deoxycytidylate*, and *thymidylate*. Similarly, the most common nucleotides

**FIGURE 4.5  $\beta$ -Glycosidic linkage in a nucleoside.**

that link to form RNA are nucleotide monophosphates adenylate, guanylate, cytidylate and uridylate.

This nomenclature does not describe the number of phosphoryl groups or the site of attachment to carbon of the ribose. A more precise nomenclature is also commonly used. A compound formed by the attachment of a phosphoryl group to C-5' of a nucleoside sugar (the most common site of phosphate esterification) is called a *nucleoside 5'-phosphate* or a *5'-nucleotide*. In this naming system for nucleotides, the number of phosphoryl groups and the attachment site are designated. Look, for example, at *adenosine 5'-triphosphate* (ATP; Figure 4.6). This nucleotide is tremendously important because, in addition to being a building block for RNA, it is the most commonly used energy currency. The energy released from cleavage of the triphosphate group is used to power many cellular processes (Chapter 15). Another nucleotide is deoxyguanosine 3'-monophosphate (3'-dGMP; Figure 4.6). This nucleotide differs from ATP in that it contains guanine rather than adenine, deoxyribose rather than ribose (indicated by the prefix “d”), and one rather than three phosphoryl groups. In addition, the phosphoryl group is esterified to the hydroxyl group in the 3' rather than the 5' position.

FIGURE 4.6 Nucleotides adenosine 5'-triphosphate (5'-ATP) and deoxyguanosine 3'-monophosphate (3'-dGMP).

### DNA molecules are very long and have directionality

Scientific communication frequently requires the sequence of a nucleic acid—in some cases, a sequence thousands of nucleotides in length—to be written like that on page 17. Rather than writing the cumbersome chemical structures, scientists have adopted the use of abbreviations. The abbreviated notations pApCpG or ACG denote a trinucleotide of DNA consisting of the building blocks deoxyadenylate monophosphate, deoxycytidylate monophosphate, and deoxyguanylate monophosphate linked by a phosphodiester bridge, where “p” denotes a phosphoryl group (Figure 4.7). The 5' end will often have a phosphoryl group attached to the 5'-OH group. Note that, like a polypeptide (Section 2.2), a *DNA chain has directionality*, commonly called *polarity*. One end of the chain has a free 5'-OH group (or a 5'-OH group attached to a phosphoryl group) and the other end has a free 3'-OH group, neither of which is linked to another nucleotide. By convention, *the base sequence is written in the 5'-to-3' direction*. Thus, ACG indicates that the unlinked 5'-OH group is on deoxyadenylate, whereas the unlinked 3'-OH group is on deoxyguanylate. Because of this polarity, ACG and GCA correspond to different compounds.

FIGURE 4.7 Structure of a DNA strand. The strand has a 5' end, which is usually attached to a phosphoryl group, and a 3' end, which is usually a free hydroxyl group.

A striking characteristic of naturally occurring DNA molecules is their length. A DNA molecule must comprise many nucleotides to carry the genetic information necessary for even the simplest organisms. For example, the DNA of a virus such as polyoma, which can cause cancer in certain organisms, consists of two paired strands of DNA, each 5100 nucleotides in length. The *E. coli* genome is a single DNA molecule consisting of two strands of 4.6 million nucleotides each (Figure 4.8).

The DNA molecules of higher organisms can be much larger. The human genome comprises approximately 3 billion nucleotides in each strand of DNA, divided among 24 distinct molecules of DNA called chromosomes (22 autosomal chromosomes plus the X and Y sex chromosomes) of different sizes. One of the largest known DNA molecules is found in the Indian muntjac, an Asiatic deer; its genome is nearly as large as the human genome but is distributed on only 3 chromosomes (Figure 4.9). The largest of these chromosomes has two strands of more than 1 billion nucleotides each. If such a DNA molecule could be fully extended, it would stretch more than 1 foot in length. Some plants contain even larger DNA molecules.

## 4.2 A Pair of Nucleic Acid Strands with Complementary Sequences Can Form a Double-Helical Structure

As discussed in Chapter 1, the covalent structure of nucleic acids accounts for their ability to carry information in the form of a sequence of bases along a nucleic acid strand. The bases on the two separate nucleic acid strands form *specific base pairs* in such a way that a helical structure is formed. The double-helical structure of DNA facilitates the *replication* of the genetic material—that is, the generation of two copies of a nucleic acid from one.

### The double helix is stabilized by hydrogen bonds and van der Waals interactions

The ability of nucleic acids to form specific base pairs was discovered in the course of studies directed at determining the three-dimensional structure of DNA. Maurice Wilkins and Rosalind Franklin obtained x-ray diffraction photographs of fibers of DNA (Figure 4.10). The characteristics of these diffraction patterns indicated that DNA is formed of two strands that wind in a regular helical structure. From these data and others, James Watson and Francis Crick deduced a structural model for DNA that accounted for the diffraction pattern

**FIGURE 4.10** X-ray diffraction photograph of a hydrated DNA fiber. When crystals of a biomolecule are irradiated with x-rays, the x-rays are diffracted and these diffracted x-rays are seen as a series of spots, called reflections, on a screen behind the crystal. The structure of the molecule can be determined by the pattern of the reflections (Section 3.5). In regard to DNA crystals, the central cross is diagnostic of a helical structure. The strong arcs on the meridian arise from the stack of nucleotide bases, which are 3.4 Å apart. [Science Photo Library.]

**FIGURE 4.11 Watson-Crick model of double-helical DNA.** (A) Side view. Adjacent bases are separated by 3.4 Å. The structure repeats along the helical axis (vertical) at intervals of 34 Å, which corresponds to approximately 10 nucleotides on each chain. (B) Axial view, looking down the helix axis, reveals a rotation of 36° per base and shows that the bases are stacked on top of one another [Source: J. L. Tymoczko, J. Berg, and L. Stryer, *Biochemistry: A Short Course*, 2nd ed. (W. H. Freeman and Company, 2013), Fig. 33.11.].

and was the source of some remarkable insights into the functional properties of nucleic acids (Figure 4.11).

The features of the Watson-Crick model of DNA deduced from the diffraction patterns are:

1. Two helical polynucleotide strands are coiled around a common axis with a right-handed screw sense (pp. 40-41). The strands are antiparallel, meaning that they have opposite directionality.
2. The sugar-phosphate backbones are on the outside and the purine and pyrimidine bases lie on the inside of the helix.
3. The bases are nearly perpendicular to the helix axis, and adjacent bases are separated by approximately 3.4 Å. The helical structure repeats on the order of every 34 Å, with about 10.4 bases per turn of helix. There is a rotation of nearly 36 degrees per base (360 degrees per full turn/10.4 bases per turn).
4. The diameter of the helix is about 20 Å.

How is such a regular structure able to accommodate an arbitrary sequence of bases, given the different sizes and shapes of the purines and pyrimidines? In attempting to answer this question, Watson and Crick discovered that guanine can be paired with cytosine and adenine with thymine to form base pairs that have essentially the same shape (Figure 4.12). These base pairs are held together by specific hydrogen bonds, which, although weak ( $4-21 \text{ kJ mol}^{-1}$ , or  $1-5 \text{ kcal mol}^{-1}$ ), stabilize the helix because of their large numbers in a DNA molecule. These *base-pairing rules* account for the observation, originally made by Erwin Chargaff in 1950, that the ratios of adenine to thymine and of guanine to cytosine are nearly the same in all species studied, whereas the adenine-to-guanine ratio varies considerably (Table 4.1).

Inside the helix, the bases are essentially stacked one on top of another (Figure 4.11B). The stacking of base pairs contributes to the stability of the double helix in two ways. First, the formation of the double helix is facilitated by the hydrophobic effect (p. 9). The hydrophobic bases cluster in the interior of the helix away

**FIGURE 4.12 Structures of the base pairs proposed by Watson and Crick.**

**TABLE 4.1** Base compositions experimentally determined for a variety of organisms

Organism	A : T	G : C	A : G
Human being	1.00	1.00	1.56
Salmon	1.02	1.02	1.43
Wheat	1.00	0.97	1.22
Yeast	1.03	1.02	1.67
<i>Escherichia coli</i>	1.09	0.99	1.05
<i>Serratia marcescens</i>	0.95	0.86	0.70

from the surrounding water, whereas the more polar surfaces are exposed to water. This arrangement is reminiscent of protein folding, where hydrophobic amino acids are in the protein's interior and the hydrophilic amino acids are on the exterior (Section 2.4). Second, the stacked base pairs attract one another through van der Waals forces (p. 8), appropriately referred to as *stacking forces*, further contributing to stabilization of the helix (Figure 4.13). The energy associated with a single van der Waals interaction is quite small, typically from 2 to 4 kJ mol<sup>-1</sup> (0.5–1.0 kcal mol<sup>-1</sup>). In the double helix, however, a large number of atoms are in van der Waals contact, and the net effect, summed over these atom pairs, is substantial. In addition, base stacking in DNA is favored by the conformations of the somewhat rigid five-membered rings of the backbone sugars.

### DNA can assume a variety of structural forms

Watson and Crick based their model (known as the *B-DNA helix*) on x-ray diffraction patterns of highly hydrated DNA fibers, which provided information about properties of the double helix that are averaged over its constituent residues. Under physiological conditions, most DNA is in the B form. X-ray diffraction studies of less-hydrated DNA fibers revealed a different form called *A-DNA*. Like B-DNA, A-DNA is a right-handed double helix made up of anti-parallel strands held together by Watson–Crick base-pairing. The A-form helix is wider and shorter than the B-form helix, and its base pairs are tilted rather than perpendicular to the helix axis (Figure 4.14).

If the A-form helix were simply a property of dehydrated DNA, it would be of little significance. However, double-stranded regions of RNA and at least some RNA–DNA hybrids adopt a double-helical form very similar to that of A-DNA. What is the biochemical basis for differences between the two forms of DNA? Many of the structural differences between B-DNA and A-DNA arise from different puckerings of their ribose units (Figure 4.15). In A-DNA, C-3' lies out of the plane (a conformation referred to as C-3' endo) formed by the other four atoms of the ring; in B-DNA, C-2' lies out of the plane (a conformation called C-2' endo). The C-3'-endo pucker in A-DNA leads to an 11-degree tilting of

Base stacking  
(van der Waal interactions)

**FIGURE 4.13** A side view of DNA. Base pairs are stacked nearly one on top of another in the double helix. The stacked bases interact with van der Waals forces. Such stacking forces help stabilize the double helix. [Source: J. L. Tymoczko, J. Berg, and L. Stryer, *Biochemistry: A Short Course*, 2nd ed. (W. H. Freeman and Company, 2013), Fig. 33.13.]

**FIGURE 4.14** B-form and A-form DNA. Space-filling models of 10 base pairs of B-form and A-form DNA depict their right-handed helical structures. Notice that the B-form helix is longer and narrower than the A-form helix. The carbon atoms of the backbone are shown in white. [Drawn from 1BNA.pdb and 1DNZ.pdb.]

**FIGURE 4.15 Sugar pucker.** In A-form DNA, the C-3' carbon atom lies above the approximate plane defined by the four other sugar nonhydrogen atoms (called C-3' endo). In B-form DNA, each deoxyribose is in a C-2'-endo conformation, in which C-2' lies out of the plane.

the base pairs away from perpendicular to the helix. RNA helices are further induced to take the A-DNA form because of steric hindrance from the 2'-hydroxyl group: the 2'-oxygen atom would be too close to three atoms of the adjoining phosphoryl group and to one atom in the next base. In an A-form helix, in contrast, the 2'-oxygen atom projects outward, away from other atoms. The phosphoryl and other groups in the A-form helix bind fewer H<sub>2</sub>O molecules than do those in B-DNA. Hence, dehydration favors the A form.

### Z-DNA is a left-handed double helix in which backbone phosphates zigzag

A third type of double helix is *left-handed*, in contrast with the *right-handed* screw sense of the A and B helices. Furthermore, the phosphoryl groups in the backbone are *zigzagged*; hence, this form of DNA is called *Z-DNA* (Figure 4.16).

Although the biological role of Z-DNA is still under investigation, Z-DNA-binding proteins have been isolated, one of which is required for viral pathogenesis of poxviruses, including variola, the agent of smallpox. The existence of Z-DNA shows that DNA is a flexible, dynamic molecule whose parameters are not as fixed as depictions suggest. The properties of A-, B-, and Z-DNA are compared in Table 4.2.

**FIGURE 4.16 Z-DNA.** DNA oligomers such as CGCGCG adopt an alternative conformation under some conditions. This conformation is called Z-DNA because the phosphoryl groups zigzag along the backbone. [Drawn from 131D.pdb.]

**TABLE 4.2** Comparison of A-, B-, and Z-DNA

	A	B	Z
Shape	Broadest	Intermediate	Narrowest
Rise per base pair	2.3 Å	3.4 Å	3.8 Å
Helix diameter	~26 Å	~20 Å	~18 Å
Screw sense	Right-handed	Right-handed	Left-handed
Glycosidic bond*	<i>anti</i>	<i>anti</i>	Alternating <i>anti</i> and <i>syn</i>
Base pairs per turn of helix	11	10.4	12
Pitch per turn of helix	25.3 Å	35.4 Å	45.6 Å
Tilt of base pairs from perpendicular to helix axis	19 degrees	1 degree	9 degrees

\**Syn* and *anti* refer to the orientation of the N-glycosidic bond between the base and deoxyribose. In the *anti* orientation, the base extends away from the deoxyribose. In the *syn* orientation, the base is above the deoxyribose. Pyrimidines can be in *anti* orientations only, whereas purines can be *anti* or *syn*.

**FIGURE 4.17** Electron micrographs of circular DNA from mitochondria. (A) Relaxed form. (B) Supercoiled form [Courtesy of Dr. David Clayton.]

### Some DNA molecules are circular and supercoiled

The DNA molecules in human chromosomes are linear. However, electron microscopic and other studies have shown that intact DNA molecules from bacteria and archaea are circular (Figure 4.17A). The term *circular* refers to the continuity of the DNA strands, not to their geometric form. DNA molecules inside cells necessarily have a very compact shape. Note that the *E. coli* chromosome, fully extended, would be about 1000 times as long as the greatest diameter of the bacterium.

A closed DNA molecule has a property unique to circular DNA. The axis of the double helix can itself be twisted or supercoiled into a *superhelix* (Figure 4.17B). A circular DNA molecule without any superhelical turns is known as a *relaxed molecule*. Supercoiling is biologically important for two reasons. First, a *supercoiled DNA molecule is more compact than its relaxed counterpart*. Second, *supercoiling may hinder or favor the capacity of the double helix to unwind and thereby affect the interactions between DNA and other molecules*. These topological features of DNA will be considered further in Chapter 28.

### Single-stranded nucleic acids can adopt elaborate structures

Single-stranded nucleic acids often fold back on themselves to form well-defined structures. Such structures are especially prominent in RNA and RNA-containing complexes such as the ribosome—a large complex of RNAs and proteins on which proteins are synthesized.

The simplest and most-common structural motif formed is a *stem-loop*, created when two complementary sequences within a single strand come together to form double-helical structures (Figure 4.18). In many cases, these double helices are made up entirely of Watson–Crick base pairs. In other cases, however, the structures include mismatched base pairs or unmatched bases that bulge out from the helix. Such mismatches destabilize

**FIGURE 4.18** Stem-loop structures. Stem-loop structures can be formed from single-stranded DNA and RNA molecules.

### Differences in DNA density established the validity of the semiconservative replication hypothesis

Matthew Meselson and Franklin Stahl carried out a critical test of this hypothesis in 1958. They labeled the parent DNA with  $^{15}\text{N}$ , a heavy isotope of nitrogen, to make it denser than ordinary DNA. The labeled DNA was generated by growing *E. coli* for many generations in a medium that contained  $^{15}\text{NH}_4\text{Cl}$  as the sole nitrogen source. After the incorporation of heavy nitrogen was complete, the bacteria were abruptly transferred to a medium that contained  $^{14}\text{N}$ , the ordinary isotope of nitrogen. The question asked was: What is the distribution of  $^{14}\text{N}$  and  $^{15}\text{N}$  in the DNA molecules after successive rounds of replication?

The distribution of  $^{14}\text{N}$  and  $^{15}\text{N}$  was revealed by the technique of *density-gradient equilibrium sedimentation*. A small amount of DNA was dissolved in a concentrated solution of cesium chloride having a density close to that of the DNA ( $1.7 \text{ g cm}^{-3}$ ). This solution was centrifuged until it was nearly at equilibrium. At that point, the opposing processes of sedimentation and diffusion created a gradient in the concentration of cesium chloride across the centrifuge cell. The result was a stable density gradient ranging from  $1.66$  to  $1.76 \text{ g cm}^{-3}$ . The DNA molecules in this density gradient were driven by centrifugal force into the region where the solution's density was equal to their own. The DNA yielded a narrow band that was detected by its absorption of ultraviolet light. A mixture of  $^{14}\text{N}$  DNA and  $^{15}\text{N}$  DNA molecules gave clearly separate bands because they differ in density by about 1% (Figure 4.20).

DNA was extracted from the bacteria at various times after they were transferred from a  $^{15}\text{N}$  to a  $^{14}\text{N}$  medium. Analysis of these samples by the density-gradient technique showed that there was a single band of DNA after one generation. The density of this band was precisely halfway between the densities of the  $^{14}\text{N}$  DNA and  $^{15}\text{N}$  DNA bands (Figure 4.21).

**FIGURE 4.20** Resolution of  $^{14}\text{N}$  DNA and  $^{15}\text{N}$  DNA by density-gradient centrifugation. (A) Ultraviolet-absorption photograph of a centrifuged cell showing the two distinct bands of DNA. (B) Densitometric tracing of the absorption photograph. [Data from M. Meselson and F. W. Stahl. *Proc. Natl. Acad. Sci. U. S. A.* 44:671–682, 1958.]

**FIGURE 4.21** Detection of semiconservative replication of *E. coli* DNA by density-gradient centrifugation. The position of a band of DNA depends on its content of  $^{14}\text{N}$  and  $^{15}\text{N}$ . After 1.0 generation, all of the DNA molecules were hybrids containing equal amounts of  $^{14}\text{N}$  and  $^{15}\text{N}$ . [Data from M. Meselson and F. W. Stahl. *Proc. Natl. Acad. Sci. U. S. A.* 44:671–682, 1958.]

**FIGURE 4.22 Diagram of semiconservative replication.** Parental DNA is shown in blue and newly synthesized DNA in red. [Information from M. Meselson and F. W. Stahl. *Proc. Natl. Acad. Sci. U. S. A.* 44:671–682, 1958.]

The absence of  $^{15}\text{N}$  DNA indicated that parental DNA was not preserved as an intact unit after replication. The absence of  $^{14}\text{N}$  DNA indicated that all the daughter DNA derived some of their atoms from the parent DNA. This proportion had to be half because the density of the hybrid DNA band was halfway between the densities of the  $^{14}\text{N}$  DNA and  $^{15}\text{N}$  DNA bands.

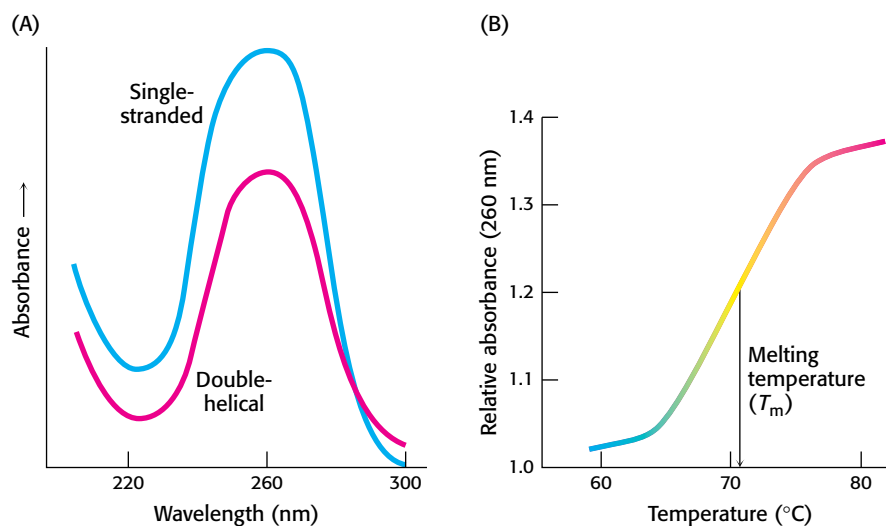

After two generations, there were equal amounts of two bands of DNA. One was hybrid DNA, and the other was  $^{14}\text{N}$  DNA. Meselson and Stahl concluded from these incisive experiments that replication was semiconservative, and so each new double helix contains a parent strand and a newly synthesized strand. Their results agreed perfectly with the Watson–Crick model for DNA replication (Figure 4.22).

### The double helix can be reversibly melted

During DNA replication and transcription, the two strands of the double helix must be separated from each other, at least in a local region. The two strands of a DNA helix readily come apart when the hydrogen bonds between base pairs are disrupted. In the laboratory, the double helix can be disrupted by heating a solution of DNA or by adding acid or alkali to ionize its bases. The dissociation of the double helix is called *melting* because it occurs abruptly at a certain temperature. The *melting temperature* ( $T_m$ ) of DNA is defined as the temperature at which half the helical structure is lost. Inside cells, however, the double helix is not melted by the addition of heat. Instead, proteins called *helicases* use chemical energy (from ATP) to disrupt the helix (Chapter 28).

Stacked bases in nucleic acids absorb less ultraviolet light than do unstacked bases, an effect called *hypochromism*. Thus, the melting of nucleic acids is readily monitored by measuring their absorption of light, which is maximal at a wavelength of 260 nm (Figure 4.23).

Separated complementary strands of nucleic acids spontaneously reassociate to form a double helix when the temperature is lowered below  $T_m$ . This renaturation process is sometimes called *annealing*. The facility with which double helices can be melted and then reassociated is crucial for the biological functions of nucleic acids.

**FIGURE 4.23 Hypochromism.** (A) Single-stranded DNA absorbs light more effectively than does double-helical DNA. (B) The absorbance of a DNA solution at a wavelength of 260 nm increases when the double helix is melted into single strands.

The ability to melt and reanneal DNA reversibly in the laboratory provides a powerful tool for investigating sequence similarity. For instance, DNA molecules from two different organisms can be melted and allowed to reanneal, or *hybridize*, in the presence of each other. If the sequences are similar, hybrid DNA duplexes, with DNA from each organism contributing a strand of the double helix, can form. The degree of hybridization is an indication of the relatedness of the genomes and hence the organisms. Similar hybridization experiments with RNA and DNA can locate genes in a cell's DNA that correspond to a particular RNA. We will return to this important technique in Chapter 5.

## 4.4 DNA Is Replicated by Polymerases That Take Instructions from Templates

We now turn to the molecular mechanism of DNA replication. The full replication machinery in a cell comprises more than 20 proteins engaged in intricate and coordinated interplay. In 1958, Arthur Kornberg and his colleagues isolated from *E. coli* the first known of the enzymes, called *DNA polymerases*, that promote the formation of the bonds joining units of the DNA backbone. *E. coli* has a number of DNA polymerases, designated by roman numerals, that participate in DNA replication and repair (Chapter 28).

### DNA polymerase catalyzes phosphodiester-bridge formation

*DNA polymerases catalyze the step-by-step addition of deoxyribonucleotide units to a DNA strand* (Figure 4.24). The reaction catalyzed, in its simplest form, is

where dNTP stands for any deoxyribonucleotide and  $\text{PP}_i$  is a pyrophosphate ion.

DNA synthesis has the following characteristics:

1. The reaction requires all four activated precursors—that is, *the deoxynucleoside 5'-triphosphates dATP, dGTP, dCTP, and TTP*—as well as  $\text{Mg}^{2+}$  ion.
2. *The new DNA strand is assembled directly on a preexisting DNA template.* DNA polymerases catalyze the formation of a phosphodiester linkage efficiently only if the base on the incoming nucleoside triphosphate is complementary to the base on the template strand. Thus, DNA polymerase is a *template-directed enzyme* that synthesizes a product with a base sequence complementary to that of the template.

FIGURE 4.24 Polymerization reaction catalyzed by DNA polymerases.

**FIGURE 4.25 Strand-elongation reaction.** DNA polymerases catalyze the formation of a phosphodiester bridge. [Source: J. L. Tymoczko, J. Berg, and L. Stryer, *Biochemistry: A Short Course*, 2nd ed. (W. H. Freeman and Company, 2013), Fig. 34.2.]

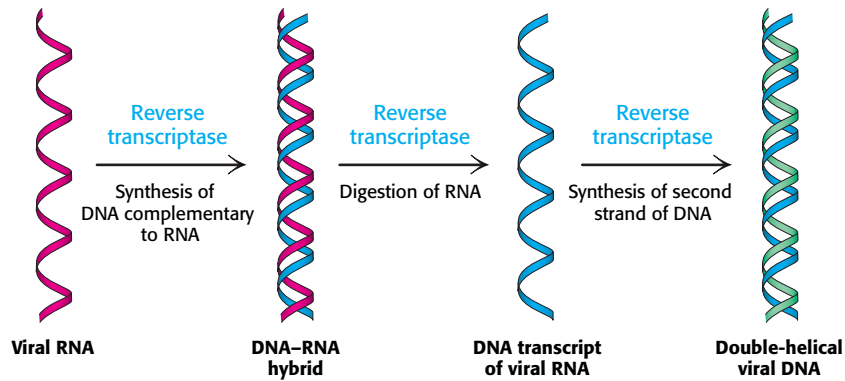

3. *DNA polymerases require a primer to begin synthesis.* A primer strand having a free 3'-OH group must be already bound to the template strand. The chain-elongation reaction catalyzed by DNA polymerases is a nucleophilic attack by the 3'-OH terminus of the growing strand on the innermost phosphorus atom of the deoxynucleoside triphosphate (Figure 4.25). A phosphodiester bridge is formed and pyrophosphate is released. The subsequent hydrolysis of pyrophosphate to yield two ions of orthophosphate ( $P_i$ ) by *pyrophosphatase* helps drive the polymerization forward. *Elongation of the DNA chain proceeds in the 5'-to-3' direction.*

4. *Many DNA polymerases are able to correct mistakes in DNA by removing mismatched nucleotides.* These polymerases have a distinct nuclease activity that allows them to excise incorrect bases by a separate reaction. This nuclease activity contributes to the remarkably high fidelity of DNA replication, which has an error rate of less than  $10^{-8}$  per base pair.

### The genes of some viruses are made of RNA

Genes in all cellular organisms are made of DNA. The same is true for some viruses but, for others, the genetic material is RNA. Viruses are genetic elements enclosed in protein coats that can move from one cell to another but are not capable of independent growth. A well-studied example of an RNA virus is the tobacco mosaic virus, which infects the leaves of tobacco plants. This virus consists of a single strand of RNA (6390 nucleotides) surrounded by a protein coat of 2130 identical subunits. An RNA polymerase that takes direction from an RNA template, called an *RNA-directed RNA polymerase*, copies the viral RNA. The infected cells die because of virus-instigated programmed cell death; in essence, the virus instructs the cell to commit suicide. Cell death results in discoloration in the tobacco leaf in a variegated pattern, hence the name mosaic virus.

Another important class of RNA virus comprises the *retroviruses*, so called because the genetic information flows from RNA to DNA rather than from DNA to RNA. This class includes human immunodeficiency virus 1 (HIV-1), the cause of acquired immunodeficiency syndrome (AIDS), as well as a number of RNA viruses that produce tumors in

**FIGURE 4.26 Flow of information from RNA to DNA in retroviruses.** The RNA genome of a retrovirus is converted into DNA by reverse transcriptase, an enzyme brought into the cell by the infecting virus particle. Reverse transcriptase possesses several activities and catalyzes the synthesis of a complementary DNA strand, the digestion of the RNA, and the subsequent synthesis of the DNA strand.

susceptible animals. Retrovirus particles contain two copies of a single-stranded RNA molecule. On entering the cell, the RNA is copied into DNA through the action of a viral enzyme called *reverse transcriptase*, which acts as both a polymerase and an RNase (Figure 4.26). The resulting double-helical DNA version of the viral genome can become incorporated into the chromosomal DNA of the host and is replicated along with the normal cellular DNA. At a later time, the integrated viral genome is expressed to form viral RNA and viral proteins, which assemble into new virus particles.

## 4.5 Gene Expression Is the Transformation of DNA Information into Functional Molecules

The information stored as DNA becomes useful when it is expressed in the production of RNA and proteins. This rich and complex topic is the subject of several chapters later in this book, but here we introduce the basics of gene expression. DNA can be thought of as archival information, stored and manipulated judiciously to minimize damage (mutations). It is expressed in two steps. First, an RNA copy is made that encodes directions for protein synthesis. This messenger RNA can be thought of as a photocopy of the original information: it can be made in multiple copies, used, and then disposed of. Second, the information in messenger RNA is translated to synthesize functional proteins. Other types of RNA molecules exist to facilitate this translation.

### Several kinds of RNA play key roles in gene expression

Scientists used to believe that RNA played a passive role in gene expression, as a mere conveyor of information. However, recent investigations have shown that RNA plays a variety of roles, from catalysis to regulation. Cells contain several kinds of RNA (Table 4.3):

**TABLE 4.3** RNA molecules in *E. coli*

Type	Relative amount (%)	Sedimentation coefficient (S)	Mass (kDa)	Number of nucleotides
Ribosomal RNA (rRNA)	80	23	$1.2 \times 10^3$	3700
		16	$0.55 \times 10^3$	1700
		5	$3.6 \times 10^1$	120
Transfer RNA (tRNA)	15	4	$2.5 \times 10^1$	75
Messenger RNA (mRNA)	5		Heterogeneous	

1. *Messenger RNA* (mRNA) is the template for protein synthesis, or *translation*. An mRNA molecule may be produced for each gene or group of genes that is to be expressed in *E. coli*, whereas a distinct mRNA is produced for each gene in eukaryotes. Consequently, mRNA is a heterogeneous class of molecules. In prokaryotes, the average length of an mRNA molecule is about 1.2 kilobases (kb). In eukaryotes, mRNA has structural features, such as stem-loop structures, that regulate the efficiency of translation and the lifetime of the mRNA.

2. *Transfer RNA* (tRNA) carries amino acids in an activated form to the ribosome for peptide-bond formation, in a sequence dictated by the mRNA template. There is at least one kind of tRNA for each of the 20 amino acids. Transfer RNA consists of about 75 nucleotides (having a mass of about 25 kDa).

3. *Ribosomal RNA* (rRNA) is the major component of ribosomes (Chapter 30). In prokaryotes, there are three kinds of rRNA, called 23S, 16S, and 5S RNA because of their sedimentation behavior (p. 74). One molecule of each of these species of rRNA is present in each ribosome. Ribosomal RNA was once believed to play only a structural role in ribosomes. We now know that rRNA is the actual catalyst for protein synthesis.

Ribosomal RNA is the most abundant of these three types of RNA. Transfer RNA comes next, followed by messenger RNA, which constitutes only 5% of the total RNA. Eukaryotic cells contain additional small RNA molecules that play a variety of roles including the regulation of gene expression, processing of RNA and the synthesis of proteins. We will examine these small RNAs in later chapters. In this chapter, we will consider rRNA, mRNA, and tRNA.

### All cellular RNA is synthesized by RNA polymerases

The synthesis of RNA from a DNA template is called *transcription* and is catalyzed by the enzyme *RNA polymerase* (Figure 4.27). RNA polymerase

#### Kilobase (kb)

A unit of length equal to 1000 base pairs of a double-stranded nucleic acid molecule (or 1000 bases of a single-stranded molecule).

One kilobase of double-stranded DNA has a length of 0.34  $\mu\text{m}$  at its maximal extension (called the contour length) and a mass of about 660 kDa.

**FIGURE 4.27 RNA Polymerase.** This large enzyme comprises many subunits, including  $\beta$  (red) and  $\beta'$  (yellow), which form a “claw” that holds the DNA to be transcribed. Notice that the active site includes a  $\text{Mg}^{2+}$  ion (green) at the center of the structure. The curved tubes making up the protein in the image represent the backbone of the polypeptide chain. [Drawn from 1L9Z, pdb.]

**FIGURE 4.28** Transcription mechanism of the chain-elongation reaction catalyzed by RNA polymerase. [Source: J. L. Tymoczko, J. Berg, and L. Stryer, *Biochemistry: A Short Course*, 2nd ed. (W. H. Freeman and Company, 2013), Fig. 36.3.]

catalyzes the initiation and elongation of RNA chains. The reaction catalyzed by this enzyme is

RNA polymerase requires the following components:

1. *A template.* The preferred template is *double-stranded DNA*. Single-stranded DNA also can serve as a template. RNA, whether single or double stranded, is not an effective template; nor are RNA–DNA hybrids.
2. *Activated precursors.* All four *ribonucleoside triphosphates*—ATP, GTP, UTP, and CTP—are required.
3. *A divalent metal ion.* Either  $\text{Mg}^{2+}$  or  $\text{Mn}^{2+}$  is effective.

The synthesis of RNA is like that of DNA in several respects (Figure 4.28). First, the direction of synthesis is  $5' \rightarrow 3'$ . Second, the mechanism of elongation is similar: the  $3'$ -OH group at the terminus of the growing chain makes a nucleophilic attack on the innermost phosphoryl group of the incoming nucleoside triphosphate. Third, the synthesis is driven forward by the hydrolysis of pyrophosphate. In contrast with DNA polymerase, however, RNA polymerase does not require a primer. In addition, the ability of RNA polymerase to correct mistakes is not as extensive as that of DNA polymerase.

All three types of cellular RNA—mRNA, tRNA, and rRNA—are synthesized in *E. coli* by the same RNA polymerase according to instructions given by a DNA template. In mammalian cells, there is a division of labor among several different kinds of RNA polymerases. We shall return to these RNA polymerases in Chapter 29.

### RNA polymerases take instructions from DNA templates

RNA polymerase, like the DNA polymerases described earlier, takes instructions from a DNA template. The earliest evidence was the finding that the *base composition* of newly synthesized RNA is the complement of that of the DNA template strand, as exemplified by the RNA synthesized from a template of single-stranded DNA from the  $\phi\text{X174}$  virus (Table 4.4). The strongest evidence for the fidelity of transcription came from

**Table 4.4** Base composition (percentage) of RNA synthesized from a viral DNA template

DNA template (plus, or coding, strand of $\phi\text{X174}$ )	RNA product
A 25	U 25
T 33	A 32
G 24	C 23
C 18	G 20

base-sequence studies. For instance, the nucleotide sequence of a segment of the gene encoding the enzymes required for tryptophan synthesis was determined with the use of DNA-sequencing techniques (Section 5.1). Likewise, the sequence of the mRNA for the corresponding gene was determined. The results showed that the RNA sequence is the precise complement of the DNA template sequence (Figure 4.29).

**FIGURE 4.29 Complementarity between mRNA and DNA.** The base sequence of mRNA (red) is the complement of that of the DNA template strand (blue). The sequence shown here is from the tryptophan operon, a segment of DNA containing the genes for five enzymes that catalyze the synthesis of tryptophan. The other strand of DNA (black) is called the coding strand because it has the same sequence as the RNA transcript except for thymine (T) in place of uracil (U).

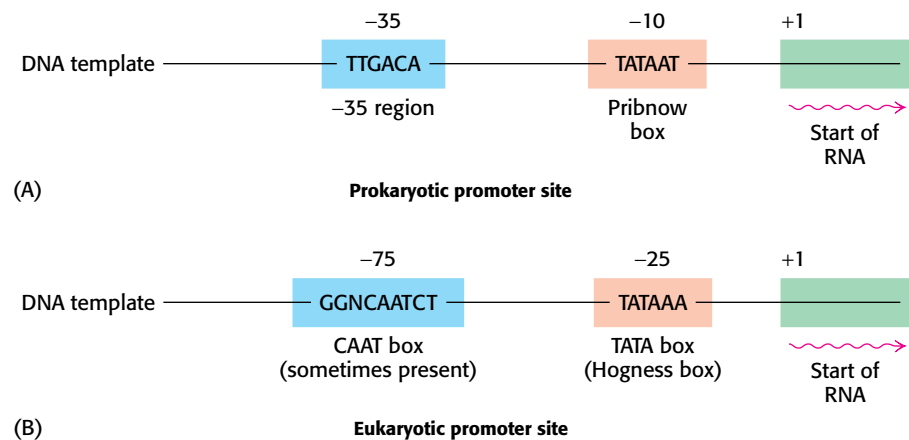

#### Consensus sequence

Not all base sequences of promoter sites are identical. However, they do possess common features, which can be represented by an idealized consensus sequence. Each base in the consensus sequence TATAAT is found in most prokaryotic promoters. Nearly all promoter sequences differ from this consensus sequence at only one or two bases.

#### Transcription begins near promoter sites and ends at terminator sites

RNA polymerase must detect and transcribe discrete genes from within large stretches of DNA. What marks the beginning of the unit to be transcribed? DNA templates contain regions called *promoter sites* that specifically bind RNA polymerase and determine where transcription begins. In bacteria, two sequences on the 5' (upstream) side of the first nucleotide to be transcribed function as promoter sites (Figure 4.30A). One of them, called the *Pribnow box*, has the consensus sequence TATAAT and is centered at  $-10$  (10 nucleotides on the 5' side of the first nucleotide transcribed, which is denoted by  $+1$ ). The other, called the  $-35$  region, has the consensus sequence TTGACA. The first nucleotide transcribed is usually a purine.

Eukaryotic genes encoding proteins have promoter sites with a TATAAA consensus sequence, called a *TATA box* or a *Hogness box*, centered at about  $-25$  (Figure 4.30B). Many eukaryotic promoters also have a *CAAT box* with a GGNCAATCT consensus sequence centered at about  $-75$ . The transcription of eukaryotic genes is further stimulated by *enhancer sequences*, which can be quite distant (as many as several kilobases) from the start site, on either its 5' or its 3' side.

**FIGURE 4.30 Promoter sites for transcription in (A) prokaryotes and (B) eukaryotes.** Consensus sequences are shown. The first nucleotide to be transcribed is numbered  $+1$ . The adjacent nucleotide on the 5' side is numbered  $-1$ . The sequences shown are those of the coding strand of DNA.

In *E. coli*, RNA polymerase proceeds along the DNA template, transcribing one of its strands until it synthesizes a terminator sequence. This sequence encodes a termination signal, which is a *base-paired hairpin* on the newly synthesized RNA molecule (Figure 4.31). This hairpin is formed by base-pairing of self-complementary sequences that are rich in G and C. Nascent RNA spontaneously dissociates from RNA polymerase when this hairpin is followed by a string of U residues. Alternatively, RNA synthesis can be terminated by the action of *rho*, a protein. Less is known about the termination of transcription in eukaryotes. A more detailed discussion of the initiation and termination of transcription will be given in Chapter 29. The important point now is that *discrete start and stop signals for transcription are encoded in the DNA template*.

In eukaryotes, the messenger RNA is modified after transcription (Figure 4.32). A “cap” structure, a guanosine nucleotide attached to the mRNA with an unusual 5'-5' triphosphate linkage, is attached to the 5' end, and a sequence of adenylates, the poly(A) tail, is added to the 3' end. These modifications will be presented in detail in Chapter 29.

**FIGURE 4.32 Modification of mRNA.** Messenger RNA in eukaryotes is modified after transcription. A nucleotide “cap” structure is added to the 5' end, and a poly(A) tail is added at the 3' end.

### Transfer RNAs are the adaptor molecules in protein synthesis

We have seen that mRNA is the template for protein synthesis. How then does it direct amino acids to become joined in the correct sequence to form a protein? In 1958, Francis Crick wrote:

RNA presents mainly a sequence of sites where hydrogen bonding could occur. One would expect, therefore, that whatever went onto the template in a *specific* way did so by forming hydrogen bonds. It is therefore a natural hypothesis that the amino acid is carried to the template by an adaptor molecule, and that the adaptor is the part that actually fits onto the RNA. In its simplest form, one would require twenty adaptors, one for each amino acid.

This highly innovative hypothesis soon became established as fact. *The adaptors in protein synthesis are transfer RNAs*. The structure and reactions of these remarkable molecules will be considered in detail in Chapter 30. For the moment, it suffices to note that tRNAs contain an *amino acid-attachment site* and a *template-recognition site*. A tRNA molecule carries a specific amino acid in an activated form to the ribosome. The carboxyl group of this amino acid is esterified to the 3'- or 2'-hydroxyl group of the ribose unit of an adenylate at the 3' end of the tRNA molecule. The adenylate is always preceded by two cytidylates to form the CCA arm of the tRNA (Figure 4.33). The joining of an amino acid to a tRNA molecule to form an *aminoacyl-tRNA* is catalyzed by a specific enzyme called an *aminoacyl-tRNA synthetase*. This esterification reaction is driven by ATP cleavage. There is at least one specific synthetase for each of the 20 amino acids. The template-recognition site on tRNA is a sequence of three bases called an *anticodon* (Figure 4.34). The anticodon on tRNA recognizes a complementary sequence of three bases, called a *codon*, on mRNA.

**FIGURE 4.31 Base sequence of the 3' end of an mRNA transcript in *E. coli*.**

A stable hairpin structure is followed by a sequence of uridine (U) residues.

**FIGURE 4.33 Attachment of an amino acid to a tRNA molecule.** The amino acid (shown in blue) is esterified to the 3'-hydroxyl group of the terminal adenylate of tRNA. [Source: J. L. Tymoczko, J. Berg, and L. Stryer, *Biochemistry: A Short Course*, 2nd ed. (W. H. Freeman and Company, 2013), Fig. 39.3.]

**FIGURE 4.34** General structure of an aminoacyl-tRNA. The amino acid is attached at the 3' end of the RNA. The anticodon is the template-recognition site. Notice that the tRNA has a cloverleaf structure with many hydrogen bonds (green dots) between bases.

## 4.6 Amino Acids Are Encoded by Groups of Three Bases Starting from a Fixed Point

The *genetic code* is the relation between the sequence of bases in DNA (or its RNA transcripts) and the sequence of amino acids in proteins. Experiments by Marshall Nirenberg, Har Gobind Khorana, Francis Crick, Sydney Brenner, and others established the following features of the genetic code by 1961:

1. *Three nucleotides encode an amino acid.* Proteins are built from a basic set of 20 amino acids, but there are only four bases. Simple calculations show that a minimum of three bases is required to encode at least 20 amino acids. Genetic experiments showed that *an amino acid is in fact encoded by a group of three bases, or codon.*
2. *The code is nonoverlapping.* Consider a base sequence ABCDEF. In an overlapping code, ABC specifies the first amino acid, BCD the next, CDE the next, and so on. In a nonoverlapping code, ABC designates the first amino acid, DEF the second, and so forth. Genetic experiments again established the code to be nonoverlapping.
3. *The code has no punctuation.* In principle, one base (denoted as Q) might serve as a “comma” between groups of three bases.

... QABCQDEFQGHIQJKLQ ...

However, it is not the case. Rather, *the sequence of bases is read sequentially from a fixed starting point, without punctuation.*

4. *The code has directionality.* The code is read from the 5' end of the messenger RNA to its 3' end.

5. *The genetic code is degenerate.* Most amino acids are encoded by more than one codon. There are 64 possible base triplets and only 20 amino acids, and in fact 61 of the 64 possible triplets specify particular amino acids. Three triplets (called *stop codons*) designate the termination of translation. Thus, *for most amino acids, there is more than one code word.*

### Major features of the genetic code

All 64 codons have been deciphered (Table 4.5). Because the code is highly degenerate, only tryptophan and methionine are encoded by just one triplet each. Each of the other 18 amino acids is encoded by two or more. Indeed, leucine, arginine, and serine are specified by six codons each.

Codons that specify the same amino acid are called *synonyms*. For example, CAU and CAC are synonyms for histidine. Note that synonyms are not distributed haphazardly throughout the genetic code. In Table 4.5, an amino acid specified by two or more synonyms occupies a single box (unless it is specified by more than four synonyms). The amino acids in a box are specified by codons that have the same first two bases but differ in the third base, as exemplified by GUU, GUC, GUA, and GUG. Thus, *most synonyms differ only in the last base of the triplet*. Inspection of the code shows that XYC and XYU always encode the same amino acid, and XYG and XYA usually encode the same amino acid as well. The structural basis for these equivalences of codons becomes evident when we consider the nature of the anticodons of tRNA molecules (Section 30.3).

What is the biological significance of the extensive degeneracy of the genetic code? If the code were not degenerate, 20 codons would designate amino acids and 44 would lead to chain termination. The probability of mutating to chain termination would therefore be much higher with a non-degenerate code. Chain-termination mutations usually lead to inactive proteins, whereas substitutions of one amino acid for another are usually rather harmless. Moreover, the code is constructed such that a change in any single nucleotide base of a codon results in a synonym or an amino acid with similar chemical properties. Thus, *degeneracy minimizes the deleterious effects of mutations.*

**TABLE 4.5** The genetic code

First Position (5' end)	Second Position				Third Position (3' end)
	U	C	A	G	
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	Stop	Stop	A
	Leu	Ser	Stop	Trp	G
C	Leu	Pro	His	Arg	U
	Leu	Pro	His	Arg	C
	Leu	Pro	Gln	Arg	A
	Leu	Pro	Gln	Arg	G
A	Ile	Thr	Asn	Ser	U
	Ile	Thr	Asn	Ser	C
	Ile	Thr	Lys	Arg	A
	Met	Thr	Lys	Arg	G
G	Val	Ala	Asp	Gly	U
	Val	Ala	Asp	Gly	C
	Val	Ala	Glu	Gly	A
	Val	Ala	Glu	Gly	G

Note: This table identifies the amino acid encoded by each triplet. For example, the codon 5'-AUG-3' on mRNA specifies methionine, whereas CAU specifies histidine. UAA, UAG, and UGA are termination signals. AUG is part of the initiation signal, in addition to coding for internal methionine residues.

### Messenger RNA contains start and stop signals for protein synthesis

Messenger RNA is translated into proteins on *ribosomes*—large molecular complexes assembled from proteins and ribosomal RNA. How is mRNA interpreted by the translation apparatus? The start signal for protein synthesis is complex in bacteria. Polypeptide chains in bacteria start with a modified amino acid—namely, formylmethionine (fMet). A specific tRNA, the initiator tRNA, carries fMet. This fMet-tRNA recognizes the codon AUG. However, AUG is also the codon for an internal methionine residue. Hence, the signal for the first amino acid in a prokaryotic polypeptide chain must be more complex than that for all subsequent ones. *AUG is only part of the initiation signal* (Figure 4.35). In bacteria, the initiating AUG codon is preceded several nucleotides away by a purine-rich sequence, called the *Shine–Dalgarno sequence*, that base-pairs with a complementary sequence in a ribosomal RNA molecule (Section 30.3). In eukaryotes, the AUG closest to the 5' end of an mRNA molecule is usually the start signal for protein synthesis. This particular AUG is read by an initiator tRNA conjugated to methionine. After the initiator AUG has been located, the *reading frame* is established—groups of three nonoverlapping nucleotides are defined, beginning with the initiator AUG codon.

As already mentioned, *UAA*, *UAG*, and *UGA* designate *chain termination*. These codons are read not by tRNA molecules but rather by specific proteins called *release factors* (Section 30.3). Binding of a release factor to the ribosome releases the newly synthesized protein.

**FIGURE 4.35** Initiation of protein synthesis. Start signals are required for the initiation of protein synthesis in (A) prokaryotes and (B) eukaryotes.

### The genetic code is nearly universal

Most organisms use the same genetic code. This universality accounts for the fact that human proteins, such as insulin, can be synthesized in the bacterium *E. coli* and harvested from it for the treatment of diabetes. However, genome-sequencing studies have shown that not all genomes are translated by the same code. Ciliated protozoa, for example, differ from most organisms in that *UAA* and *UAG* are read as codons for amino acids rather than as stop signals; *UGA* is their sole termination signal. The first variations in the genetic code were found in mitochondria from a number of species, including human beings (Table 4.6). The genetic code of mitochondria can differ from that of the rest of the cell because mitochondrial DNA encodes a distinct set of transfer RNAs, adaptor molecules that recognize the alternative codons. Thus, the genetic code is nearly but not absolutely universal.

Why has the code remained nearly invariant through billions of years of evolution, from bacteria to human beings? A mutation that altered the reading of mRNA would change the amino acid sequence of most, if not all,

**TABLE 4.6** Distinctive codons of human mitochondria

Codon	Standard code	Mitochondrial code
UGA	Stop	Trp
UGG	Trp	Trp
AUA	Ile	Met
AUG	Met	Met
AGA	Arg	Stop
AGG	Arg	Stop

proteins synthesized by that particular organism. Many of these changes would undoubtedly be deleterious, and so there would be strong selection against a mutation with such pervasive consequences.

## 4.7 Most Eukaryotic Genes Are Mosaics of Introns and Exons

In bacteria, polypeptide chains are encoded by a continuous array of triplet codons in DNA. For many years, genes in higher organisms were assumed to be organized in the same manner. This view was unexpectedly shattered in 1977, when investigators discovered that most eukaryotic genes are *discontinuous*. The mosaic nature of eukaryotic genes was revealed by electron microscopic studies of hybrids formed between mRNA and a segment of DNA containing the corresponding gene (Figure 4.36). For example, the

**FIGURE 4.36 Detection of introns by electron microscopy.** An mRNA molecule (shown in red) is hybridized to genomic DNA containing the corresponding gene. (A) A single loop of single-stranded DNA (shown in blue) is seen if the gene is continuous. (B) Two loops of single-stranded DNA (blue) and a loop of double-stranded DNA (blue and green) are seen if the gene contains an intron. Additional loops are evident if more than one intron is present.

gene for the  $\beta$  chain of hemoglobin is interrupted within its amino acid-coding sequence by a long stretch of of 550 non-coding base pairs and a short one of 120 base pairs. Thus, the  $\beta$ -globin gene is split into three coding sequences (Figure 4.37). Non-coding regions are called *introns* (for *intervening sequences*), whereas coding regions are called *exons* (for *expressed sequences*). The average human gene has 8 introns, and some have more than 100. The size ranges from 50 to 10,000 nucleotides.

**FIGURE 4.37 Structure of the  $\beta$ -globin gene.**

### RNA processing generates mature RNA

At what stage in gene expression are introns removed? Newly synthesized RNA molecules (pre-mRNA or primary transcript) isolated from nuclei are much larger than the mRNA molecules derived from them; in regard to  $\beta$ -globin RNA, the former consists of approximately 1600 nucleotides and the latter approximately 900 nucleotides. In fact, the primary transcript of the  $\beta$ -globin gene contains two regions that are not present in the mRNA. *These regions in primary transcript are excised, and the coding sequences are simultaneously linked by a precise splicing complex to form the mature mRNA*

**FIGURE 4.38 Transcription and processing of the  $\beta$ -globin gene.** The gene is transcribed to yield the primary transcript, which is modified by cap and poly(A) addition. The introns in the primary RNA transcript are removed to form the mRNA.

(Figure 4.38). A common feature in the expression of discontinuous, or split, genes is that their exons are ordered in the same sequence in mRNA as in DNA. Thus, the codons in split genes, like continuous genes, are in the same linear order as the amino acids in the polypeptide products.

*Splicing* is a complex operation that is carried out by *spliceosomes*, which are assemblies of proteins and small RNA molecules (snRNA). RNA plays the catalytic role (Section 29.3). Spliceosomes recognize signals in the nascent RNA that specify the splice sites. *Introns nearly always begin with GU and end with an AG that is preceded by a pyrimidine-rich tract* (Figure 4.39). *This consensus sequence is part of the signal for splicing.*

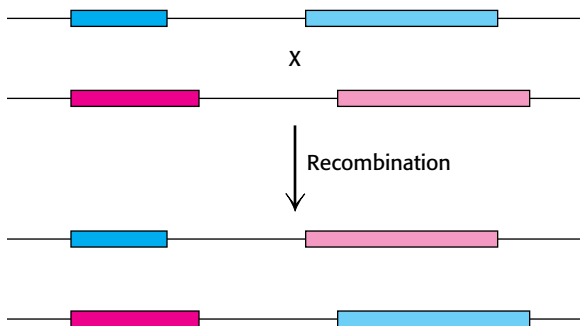

**FIGURE 4.39 Consensus sequence for the splicing of mRNA precursors.**

### Many exons encode protein domains

Most genes of higher eukaryotes, such as birds and mammals, are split. Lower eukaryotes, such as yeast, have a much higher proportion of continuous genes. In prokaryotes, split genes are extremely rare. Have introns been inserted into genes in the evolution of higher organisms? Or have introns been removed from genes to form the streamlined genomes of prokaryotes and simple eukaryotes? Comparisons of the DNA sequences of genes encoding evolutionarily conserved proteins suggest that *introns were present in ancestral genes and were lost in the evolution of organisms that have become optimized for very rapid growth, such as prokaryotes*. The positions of introns in some genes are at least 1 billion years old. Furthermore, a common mechanism of splicing developed before the divergence of fungi, plants, and vertebrates, as shown by the finding that mammalian cell extracts can splice yeast RNA.

What advantages might split genes confer? *Many exons encode discrete structural and functional domains of proteins*. An attractive hypothesis is that *new proteins arose in evolution by the rearrangement of exons encoding discrete structural elements, binding sites, and catalytic sites*, a process called *exon shuffling*. Because it preserves functional units but allows them to interact in new ways, exon shuffling is a rapid and efficient means of generating novel genes (Figure 4.40). Figure 4.41 shows the composition of a gene that was formed in part by exon shuffling. DNA can break and recombine in introns with no deleterious effect on encoded proteins. In contrast, the exchange of sequences within different exons usually leads to loss of function.

*Another advantage of split genes is the potential for generating a series of related proteins by alternative splicing of the primary transcript*. For example, a precursor of an antibody-producing cell forms an antibody that is anchored in the cell's plasma membrane (Figure 4.42). The attached antibody recognizes a specific foreign antigen, an event that leads to cell differentiation and proliferation. The activated antibody-producing cells then splice their primary transcript in an alternative manner to form soluble antibody molecules that are secreted rather than retained on the cell surface. *Alternative splicing is a facile means of forming a set of proteins that are variations of a basic motif without requiring a gene for each protein*. Because of alternative splicing, the proteome is more diverse than the genome in eukaryotes.

**FIGURE 4.40 Exon shuffling.** Exons can be readily shuffled by recombination of DNA to expand the genetic repertoire.

**FIGURE 4.41 The tissue plasminogen activator (TPA) gene was generated by exon shuffling.** The gene for TPA encodes an enzyme that functions in hemostasis (Section 10.4). This gene consists of 4 exons, one (F) derived from the fibronectin gene which encodes an extracellular matrix protein, one from the epidermal growth factor gene (EGF), and two from the plasminogen gene (K, Section 10.4), the substrate of the TPA protein. The K domain appears to have arrived by exon shuffling and then been duplicated to generate the TPA gene that exists today. [Information from: [www.ehu.es/ehusfera/genetica/2012/10/02/demostracion-molecular-de-microevolucion/](http://www.ehu.es/ehusfera/genetica/2012/10/02/demostracion-molecular-de-microevolucion/)]

**FIGURE 4.42 Alternative splicing.** Alternative splicing generates mRNAs that are templates for different forms of a protein: (A) a membrane-bound antibody on the surface of a lymphocyte and (B) its soluble counterpart, exported from the cell. The membrane-bound antibody is anchored to the plasma membrane by a helical segment (highlighted in yellow) that is encoded by its own exon.

## SUMMARY

### 4.1 A Nucleic Acid Consists of Four Kinds of Bases Linked to a Sugar-Phosphate Backbone

DNA and RNA are linear polymers of a limited number of monomers. In DNA, the repeating units are nucleotides, with the sugar being a deoxyribose and the bases being adenine (A), thymine (T), guanine (G), and cytosine (C). In RNA, the sugar is a ribose and the base uracil (U) is used in place of thymine. DNA is the molecule of heredity in all prokaryotic and eukaryotic organisms. In viruses, the genetic material is either DNA or RNA.

### 4.2 A Pair of Nucleic Acid Strands with Complementary Sequences Can Form a Double-Helical Structure

All cellular DNA consists of two very long, helical polynucleotide strands coiled around a common axis. The sugar-phosphate backbone of each strand is on the outside of the double helix, whereas the purine and pyrimidine bases are on the inside stabilized by stacking forces. The two strands are held together by hydrogen bonds between pairs of bases: adenine is always paired with thymine, and guanine is always paired with cytosine. Hence, one strand of a double helix is the complement of the other. The two strands of the double helix run in opposite directions. Genetic information is encoded in the precise sequence of bases along a strand.

DNA is a structurally dynamic molecule that can exist in a variety of helical forms: A-DNA, B-DNA (the classic Watson–Crick helix), and Z-DNA. In A-, B-, and Z-DNA, two antiparallel chains are held together by Watson–Crick base pairs and stacking interactions between bases in the same strand. A- and B-DNA are right-handed helices. In B-DNA, the base pairs are nearly perpendicular to the helix axis. Z-DNA is a left-handed helix. Most of the DNA in a cell is in the B-form.

Double-stranded DNA can also wrap around itself to form a supercoiled structure. The supercoiling of DNA has two important consequences. Supercoiling compacts the DNA and, because supercoiled DNA is partly unwound, it is more accessible for interactions with other biomolecules.

Single-stranded nucleic acids, most notably RNA, can form complicated three-dimensional structures that may contain extensive double-helical regions that arise from the folding of the chain into hairpins.

#### 4.3 The Double Helix Facilitates the Accurate Transmission of Hereditary Information

The structural nature of the double helix readily accounts for the accurate replication of genetic material because the sequence of bases in one strand determines the sequence of bases in the other strand. In replication, the strands of the helix separate and a new strand complementary to each of the original strands is synthesized. Thus, two new double helices are generated, each composed of one strand from the original molecule and one newly synthesized strand. This mode of replication is called semiconservative replication because each new helix retains one of the original strands.

In order for replication to take place, the strands of the double helix must be separated. *In vitro*, heating a solution of double-helical DNA separates the strands, a process called melting. On cooling, the strands reanneal and re-form the double helix. In the cell, special proteins temporarily separate the strands in replication.

#### 4.4 DNA Is Replicated by Polymerases That Take Instructions from Templates

In the replication of DNA, the two strands of a double helix unwind and separate as new strands are synthesized. Each parent strand, with the help of a primer, acts as a template for the formation of a new complementary strand. The replication of DNA is a complex process carried out by many proteins, including several DNA polymerases. The activated precursors in the synthesis of DNA are the four deoxyribonucleoside 5'-triphosphates. The new strand is synthesized in the 5' → 3' direction by a nucleophilic attack by the 3'-hydroxyl terminus of the primer strand on the innermost phosphorus atom of the incoming deoxyribonucleoside triphosphate. Most important, DNA polymerases catalyze the formation of a phosphodiester linkage only if the base on the incoming nucleotide is complementary to the base on the template strand. In other words, DNA polymerases are template-directed enzymes. The genes of some viruses, such as tobacco mosaic virus, are made of single-stranded RNA. An RNA-directed RNA polymerase mediates the replication of this viral RNA. Retroviruses, exemplified by HIV-1, have a single-stranded RNA genome that undergoes reverse transcription into double-stranded DNA by reverse transcriptase, an RNA-directed DNA polymerase.

#### 4.5 Gene Expression Is the Transformation of DNA Information into Functional Molecules

The flow of genetic information in normal cells is from DNA to RNA to protein. The synthesis of RNA from a DNA template is called

transcription, whereas the synthesis of a protein from an RNA template is termed translation. Cells contain several kinds of RNA, among which are messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA), which vary in size from 75 to more than 5000 nucleotides. All cellular RNA is synthesized by RNA polymerases according to instructions given by DNA templates. The activated intermediates are ribonucleoside triphosphates and the direction of synthesis, like that of DNA, is 5' → 3'. RNA polymerase differs from DNA polymerase in not requiring a primer.

#### 4.6 Amino Acids Are Encoded by Groups of Three Bases Starting from a Fixed Point

The genetic code is the relation between the sequence of bases in DNA (or its RNA transcript) and the sequence of amino acids in proteins. Amino acids are encoded by groups of three bases (called codons) starting from a fixed point. Sixty-one of the 64 codons specify particular amino acids, whereas the other 3 codons (UAA, UAG, and UGA) are signals for chain termination. Thus, for most amino acids, there is more than one code word. In other words, the code is degenerate. The genetic code is nearly the same in all organisms. Natural mRNAs contain start and stop signals for translation, just as genes do for directing where transcription begins and ends.

#### 4.7 Most Eukaryotic Genes Are Mosaics of Introns and Exons

Most genes in higher eukaryotes are discontinuous. Coding sequences in these split genes, called exons, are separated by noncoding sequences, called introns, which are removed in the conversion of the primary transcript into mRNA and other functional mature RNA molecules. Split genes, like continuous genes, are colinear with their polypeptide products. A striking feature of many exons is that they encode functional domains in proteins. New proteins probably arose in the course of evolution by the shuffling of exons. Introns may have been present in primordial genes but were lost in the evolution of such fast-growing organisms as bacteria and yeast.

### KEY TERMS

double helix (p. 105)	semiconservative replication (p. 114)	anticodon (p. 123)
deoxyribonucleic acid (DNA) (p. 106)	DNA polymerase (p. 117)	codon (p. 123)
deoxyribose (p. 106)	template (p. 117)	genetic code (p. 124)
ribose (p. 106)	primer (p. 118)	ribosome (p. 126)
purine (p. 107)	reverse transcriptase (p. 119)	Shine–Dalgarno sequence (p. 126)
pyrimidine (p. 107)	messenger RNA (mRNA) (p. 120)	intron (p. 127)
ribonucleic acid (RNA) (p. 107)	translation (p. 120)	exon (p. 127)
nucleoside (p. 107)	transfer RNA (tRNA) (p. 120)	splicing (p. 128)
nucleotide (p. 107)	ribosomal RNA (rRNA) (p. 120)	spliceosomes (p. 128)
B-DNA (p. 111)	transcription (p. 120)	exon shuffling (p. 128)
A-DNA (p. 111)	RNA polymerase (p. 120)	alternative splicing (p. 128)
Z-DNA (p. 112)	promoter site (p. 122)	

### PROBLEMS

1. *A t instead of an s?* Differentiate between a nucleoside and a nucleotide.
2. *A lovely pair.* What is a Watson–Crick base pair?
3. *Chargaff rules!* Biochemist Erwin Chargaff was the first to note that, in DNA,  $[A] = [T]$  and  $[G] = [C]$ , equalities now called Chargaff's rule. Using this rule, determine the percentages of all the bases in DNA that is 20% thymine.

4. *But not always.* A single strand of RNA is 20% U. What can you predict about the percentages of the remaining bases?
5. *Complements.* Write the complementary sequence (in the standard 5' → 3' notation) for (a) GATCAA, (b) TCGAAC, (c) ACGCGT, and (d) TACCAT.
6. *Compositional constraint.* The composition (in mole-fraction units) of one of the strands of a double-helical DNA molecule is [A] = 0.30 and [G] = 0.24. (a) What can you say about [T] and [C] for the same strand? (b) What can you say about [A], [G], [T], and [C] of the complementary strand?
7. *Size matters.* Why are GC and AT the only base pairs permissible in the double helix?
8. *Strong, but not strong enough.* Why does heat denature, or melt, DNA in solution?
9. *Uniqueness.* The human genome contains 3 billion nucleotides arranged in a vast array of sequences. What is the minimum length of a DNA sequence that will, in all probability, appear only once in the human genome? You need consider only one strand and may assume that all four nucleotides have the same probability of appearance.
10. *Coming and going.* What does it mean to say that the DNA strands in a double helix have opposite directionality or polarity?
11. *All for one.* If the forces—hydrogen bonds and stacking forces—holding a helix together are weak, why is it difficult to disrupt a double helix?
12. *Overcharged.* DNA in the form of a double helix must be associated with cations, usually  $Mg^{2+}$ . Why is this requirement the case?
13. *Not quite from A to Z.* Describe the three forms that a double helix can assume.
14. *Lost DNA.* The DNA of a deletion mutant of  $\lambda$  bacteriophage has a length of 15  $\mu m$  instead of 17  $\mu m$ . How many base pairs are missing from this mutant?
15. *Axial ratio.* What is the axial ratio (length:diameter) of a DNA molecule 20  $\mu m$  long?
16. *Guide and starting point.* Define template and primer as they relate to DNA synthesis.
17. *An unseen pattern.* What result would Meselson and Stahl have obtained if the replication of DNA were conservative (i.e., the parental double helix stayed together)? Give the expected distribution of DNA molecules after 1.0 and 2.0 generations for conservative replication.
18. *Which way?* Explain, on the basis of nucleotide structure, why DNA synthesis proceeds in the 5'-to-3' direction.
19. *Tagging DNA.*
- (a) Suppose that you want to radioactively label DNA but not RNA in dividing and growing bacterial cells. Which radioactive molecule would you add to the culture medium?
- (b) Suppose that you want to prepare DNA in which the backbone phosphorus atoms are uniformly labeled with  $^{32}P$ . Which precursors should be added to a solution containing DNA polymerase and primed template DNA? Specify the position of radioactive atoms in these precursors.
20. *Finding a template.* A solution contains DNA polymerase and the  $Mg^{2+}$  salts of dATP, dGTP, dCTP, and TTP. The following DNA molecules are added to aliquots of this solution. Which of them would lead to DNA synthesis?
- (a) A single-stranded closed circle containing 1000 nucleotide units.
- (b) A double-stranded closed circle containing 1000 nucleotide pairs.
- (c) A single-stranded closed circle of 1000 nucleotides base-paired to a linear strand of 500 nucleotides with a free 3'-OH terminus.
- (d) A double-stranded linear molecule of 1000 nucleotide pairs with a free 3'-OH group at each end.
21. *Retrograde.* What is a retrovirus and how does information flow for a retrovirus differ from that for the infected cell?
22. *The right start.* Suppose that you want to assay reverse transcriptase activity. If polyriboadenylate is the template in the assay, what should you use as the primer? Which radioactive nucleotide should you use to follow chain elongation?
23. *Essential degradation.* Reverse transcriptase has ribonuclease activity as well as polymerase activity. What is the role of its ribonuclease activity?
24. *Virus hunting.* You have purified a virus that infects turnip leaves. Treatment of a sample with phenol removes viral proteins. Application of the residual material to scraped leaves results in the formation of progeny virus particles. You infer that the infectious substance is a nucleic acid. Propose a simple and highly sensitive means of determining whether the infectious nucleic acid is DNA or RNA.
25. *Mutagenic consequences.* Spontaneous deamination of cytosine bases in DNA takes place at low but measurable frequency. Cytosine is converted into uracil by loss of its amino group. After this conversion, which base pair occupies this position in each of the daughter strands resulting from one round of replication? Two rounds of replication?
26. *Information content.*
- (a) How many different 8-mer sequences of DNA are there? (Hint: There are 16 possible dinucleotides and 64 possible trinucleotides.) We can quantify the information-carrying capacity of nucleic acids in the following way. Each position can be one of four bases, corresponding to two bits of

information ( $2^2 = 4$ ). Thus, a chain of 5100 nucleotides corresponds to  $2 \times 5100 = 10,200$  bits, or 1275 bytes (1 byte = 8 bits).

(b) How many bits of information are stored in an 8-mer DNA sequence? In the *E. coli* genome? In the human genome?

(c) Compare each of these values with the amount of information that can be stored on a computer compact disc, or CD (about 700 megabytes).

27. *Key polymerases.* Compare DNA polymerase and RNA polymerase from *E. coli* in regard to each of the following features: (a) activated precursors, (b) direction of chain elongation, (c) conservation of the template, and (d) need for a primer.

28. *Different strands.* Explain the difference between the coding strand and the template strand in DNA.

29. *Family resemblance.* Differentiate among mRNA, rRNA and tRNA.

30. *A code you can live by.* What are the key characteristics of the genetic code?

31. *Encoded sequences.*

(a) Write the sequence of the mRNA molecule synthesized from a DNA template strand having the following sequence:

(b) What amino acid sequence is encoded by the following base sequence of an mRNA molecule? Assume that the reading frame starts at the 5' end.

(c) What is the sequence of the polypeptide formed on addition of poly(UUAC) to a cell-free protein-synthesizing system?

32. *A tougher chain.* RNA is readily hydrolyzed by alkali, whereas DNA is not. Why?

33. *A picture is worth a thousand words.* Write a reaction sequence showing why RNA is more susceptible to nucleophilic attack than DNA.

34. *Flowing information.* What is meant by the phrase gene expression?

35. *We can all agree on that.* What is a consensus sequence?

36. *A potent blocker.* Cordycepin (3'-deoxyadenosine) is an adenosine analog. When converted into cordycepin 5'-triphosphate, it inhibits RNA synthesis. How does cordycepin 5'-triphosphate block the synthesis of RNA?

37. *Silent RNA.* The code word GGG cannot be deciphered in the same way as can UUU, CCC, and AAA, because poly(G) does not act as a template. Poly(G) forms a triple-stranded helical structure. Why is it an ineffective template?

38. *Sometimes it is not so bad.* What is meant by the degeneracy of the genetic code?

39. *In fact, it can be good.* What is the biological benefit of a degenerate genetic code?

40. *To bring together as associates.* Match the components in the right-hand column with the appropriate process in the left-hand column.

- |                         |                   |

42. *Two from one.* Synthetic RNA molecules of defined sequence were instrumental in deciphering the genetic code. Their synthesis first required the synthesis of DNA molecules to serve as templates. Har Gobind Khorana synthesized, by organic-chemical methods, two complementary deoxyribonucleotides, each with nine residues: d(TAC)<sub>3</sub> and d(GTA)<sub>3</sub>. Partly overlapping duplexes that formed on mixing these oligonucleotides then served as templates for the synthesis by DNA polymerase of long, repeating double-helical DNA strands. The next step was to obtain long polyribonucleotide chains with a sequence complementary to only one of the two DNA strands. How did Khorana obtain only poly(UAC)? Only poly(GUA)?

43. *Triple entendre.* The RNA transcript of a region of T4 phage DNA contains the sequence 5'-AAAUGAGGA-3'. This sequence encodes three different polypeptides. What are they?

44. *A new translation.* A transfer RNA with a UGU anticodon is enzymatically conjugated to <sup>14</sup>C-labeled cysteine. The cysteine unit is then chemically modified to alanine (with the use of Raney nickel, which removes the sulfur atom of

cysteine). The altered aminoacyl-tRNA is added to a protein-synthesizing system containing normal components except for this tRNA. The mRNA added to this mixture contains the following sequence:

What is the sequence of the corresponding radiolabeled peptide?

45. *A tricky exchange.* Define exon shuffling and explain why its occurrence might be an evolutionary advantage.

46. *From one, many.* Explain why alternative splicing increases the coding capacity of the genome.

47. *The unity of life.* What is the significance of the fact that human mRNA can be accurately translated in *E. coli*?

### Chapter Integration Problems

48. *Back to the bench.* A protein chemist told a molecular geneticist that he had found a new mutant hemoglobin in which aspartate replaced lysine. The molecular geneticist expressed surprise and sent his friend scurrying back to the laboratory. (a) Why did the molecular geneticist doubt the reported amino acid substitution? (b) Which amino acid substitutions would have been more palatable to the molecular geneticist?

49. *Eons apart.* The amino acid sequences of a yeast protein and a human protein having the same function are found to be 60% identical. However, the corresponding DNA sequences are only 45% identical. Account for this differing degree of identity.

### Data Interpretation Problems

50. *3 is greater than 2.* The adjoining illustration graphs the relation between the percentage of GC base pairs in DNA and the melting temperature. Suggest a plausible explanation for these results.

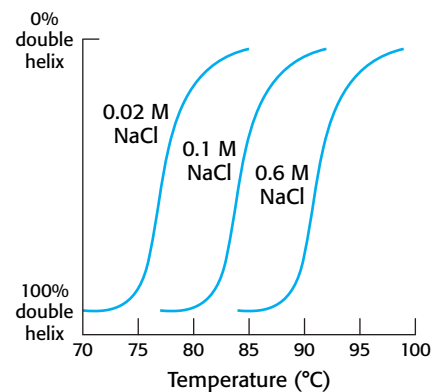

[Data from R. J. Britten and D. E. Kohne, *Science* 161:529–540, 1968.]

51. *Blast from the past.* The illustration below is a graph called a  $C_0t$  curve (pronounced “cot”). The y-axis shows the percentage of DNA that is double stranded. The x-axis is the product of the concentration of DNA and the time required for the double-stranded molecules to form. Explain why the mixture of poly(A) and poly(U) and the three DNAs shown vary in the  $C_0t$  value required to completely anneal. MS2 and T4 are bacterial viruses (bacteriophages) with genome sizes of 3569 and 168,903 bp, respectively. The *E. coli* genome is  $4.6 \times 10^6$  bp.

[Data from J. Marmur and P. Doty, *J. Mol. Biol.* 5:120, 1962.]

52. *Salt to taste.* The graph below shows the effect of salt concentration on melting temperature of bacterial DNA. How does salt concentration affect the melting temperature of DNA? Account for this effect.

## Exploring Genes and Genomes

Processes such as the development from a caterpillar into a butterfly entail dramatic changes in patterns of gene expression. The expression levels of thousands of genes can be monitored through the use of DNA arrays. At the right, a DNA microarray reveals the expression levels of more than 12,000 human genes; the brightness and color of each spot indicates a change in the expression level of the corresponding gene. [(Left) Cathy Keifer/istockphoto.com. (Right) Agilent Technologies.]

Since its emergence in the 1970s, recombinant DNA technology has revolutionized biochemistry. The genetic endowment of organisms can now be precisely changed in designed ways. Recombinant DNA technology is the fruit of several decades of basic research on DNA, RNA, and viruses. It depends, first, on having enzymes that can cut, join, and replicate DNA and those that can reverse transcribe RNA. Restriction enzymes cut very long DNA molecules into specific fragments that can be manipulated; DNA ligases join the fragments together. Many kinds of restriction enzymes are available. By applying this assortment cleverly, researchers can treat DNA sequences as modules that can be moved at will from one DNA molecule to another. Thus, recombinant DNA technology is based on the use of enzymes that act on nucleic acids as substrates.

A second foundation is the base-pairing language that allows complementary sequences to recognize and bind to each other. Hybridization with complementary DNA (cDNA) or RNA probes is a sensitive means of detecting specific nucleotide sequences. In recombinant DNA technology, base-pairing is used to construct new combinations of DNA as well as to detect and amplify particular sequences.

Third, powerful methods have been developed for determining the sequence of nucleotides in DNA. These methods have been harnessed to sequence complete genomes: first, small genomes from viruses; then, larger

## OUTLINE

- 5.1 The Exploration of Genes Relies on Key Tools
- 5.2 Recombinant DNA Technology Has Revolutionized All Aspects of Biology
- 5.3 Complete Genomes Have Been Sequenced and Analyzed
- 5.4 Eukaryotic Genes Can Be Quantitated and Manipulated with Considerable Precision

genomes from bacteria; and, finally, eukaryotic genomes, including the 3-billion-base-pair human genome. Scientists are just beginning to exploit the enormous information content of these genome sequences.

Finally, recombinant DNA technology critically depends on our ability to deliver foreign DNA into host organisms. For example, DNA fragments can be inserted into plasmids, where they can be replicated within a short period of time in their bacterial hosts. In addition, viruses efficiently deliver their own DNA (or RNA) into hosts, subverting them either to replicate the viral genome and produce viral proteins or to incorporate viral DNA into the host genome.

These new methods have wide-ranging benefits across a broad spectrum of disciplines, including biotechnology, agriculture, and medicine. Among these benefits is the dramatic expansion of our understanding of human disease. Throughout this chapter, a specific disorder, amyotrophic lateral sclerosis (ALS), will be used to illustrate the effect that recombinant DNA technology has had on our knowledge of disease mechanisms. ALS was first described clinically in 1869 by the French neurologist Jean-Martin Charcot as a fatal neurodegenerative disease of progressive weakening and atrophy of voluntary muscles. ALS is commonly referred to as Lou Gehrig's Disease, for the baseball legend whose career and life were prematurely cut short as a result of this devastating disease. For many years, little progress had been made in the study of the mechanisms underlying ALS. As we shall see, significant advances have been made with the use of research tools facilitated by recombinant DNA technology.

---

## 5.1 The Exploration of Genes Relies on Key Tools

The rapid progress in biotechnology—indeed its very existence—is a result of a few key techniques.

1. *Restriction-enzyme analysis.* Restriction enzymes are precise molecular scalpels that allow an investigator to manipulate DNA segments.
2. *Blotting techniques.* Southern and northern blots are used to separate and identify DNA and RNA sequences, respectively. The western blot, which uses antibodies to characterize proteins, was described in Chapter 3.
3. *DNA sequencing.* The precise nucleotide sequence of a molecule of DNA can be determined. Sequencing has yielded a wealth of information concerning gene architecture, the control of gene expression, and protein structure.
4. *Solid-phase synthesis of nucleic acids.* Precise sequences of nucleic acids can be synthesized de novo and used to identify or amplify other nucleic acids.
5. *The polymerase chain reaction (PCR).* The polymerase chain reaction leads to a billionfold amplification of a segment of DNA. One molecule of DNA can be amplified to quantities that permit characterization and manipulation. This powerful technique can be used to detect pathogens and genetic diseases, determine the source of a hair left at the scene of a crime, and resurrect genes from the fossils of extinct organisms.

A final set of techniques relies on the computer, without which, it would be impossible to catalog, access, and characterize the abundant information generated by the methods outlined above. Such uses of the computer will be presented in Chapter 6.

## Restriction enzymes split DNA into specific fragments

*Restriction enzymes*, also called *restriction endonucleases*, recognize specific base sequences in double-helical DNA and cleave both strands of that duplex at specific places. To biochemists, these exquisitely precise scalpels are marvelous gifts of nature. They are indispensable for analyzing chromosome structure, sequencing very long DNA molecules, isolating genes, and creating new DNA molecules that can be cloned.

Restriction enzymes are found in a wide variety of prokaryotes. Their biological role is to cleave foreign DNA molecules, providing the host organism with a primitive immune system. Many restriction enzymes recognize specific sequences of four to eight base pairs and hydrolyze a phosphodiester bond in each strand in this region. A striking characteristic of these cleavage sites is that they almost always possess *twofold rotational symmetry*. In other words, the recognized sequence is *palindromic*, or an inverted repeat, and the cleavage sites are symmetrically positioned. For example, the sequence recognized by a restriction enzyme from *Streptomyces achromogenes* is

In each strand, the enzyme cleaves the C—G phosphodiester bond on the 3' side of the symmetry axis. As we shall see in Chapter 9, this symmetry corresponds to that of the structures of the restriction enzymes themselves.

Several hundred restriction enzymes have been purified and characterized. Their names consist of a three-letter abbreviation for the host organism (e.g., *Eco* for *Escherichia coli*, *Hin* for *Haemophilus influenzae*, *Hae* for *Haemophilus aegyptius*) followed by a strain designation (if needed) and a roman numeral (to distinguish multiple enzymes from the same strain). The specificities of several of these enzymes are shown in Figure 5.1.

Restriction enzymes are used to cleave DNA molecules into specific fragments that are more readily analyzed and manipulated than the entire parent molecule. For example, the 5.1-kb circular duplex DNA of the tumor-producing SV40 virus is cleaved at one site by *EcoRI*, at four sites by *HpaI*, and at 11 sites by *HindIII*. A piece of DNA, called a restriction fragment, produced by the action of one restriction enzyme can be specifically cleaved into smaller fragments by another restriction enzyme. The pattern of such fragments can serve as a *fingerprint* of a DNA molecule, as will be considered shortly. Indeed, complex chromosomes containing hundreds of millions of base pairs can be mapped by using a series of restriction enzymes.

## Restriction fragments can be separated by gel electrophoresis and visualized

In Chapter 3, we considered the use of gel electrophoresis to separate protein molecules (Section 3.1). Because the phosphodiester backbone of DNA is highly negatively charged, this technique is also suitable for the separation of nucleic acid fragments. Among the many applications of DNA electrophoresis are the detection of mutations that affect restriction fragment size (such as insertions and deletions) and the isolation, purification, and quantitation of a specific DNA fragment.

For most gels, the shorter the DNA fragment, the farther the migration. Polyacrylamide gels are used to separate, by size, fragments containing as

### Palindrome

A word, sentence, or verse that reads the same from right to left as it does from left to right.

Radar

Senile felines

Do geese see God?

Roma tibi subito motibus ibit amor

Derived from the Greek *palindromos*, "running back again."

**FIGURE 5.1 Specificities of some restriction endonucleases.** The sequences that are recognized by these enzymes contain a twofold axis of symmetry. The two strands in these regions are related by a 180-degree rotation about the axis marked by the green symbol. The cleavage sites are denoted by red arrows. The abbreviated name of each restriction enzyme is given at the right of the sequence that it recognizes. Note that the cuts may be staggered or even.

**FIGURE 5.2 Gel-electrophoresis pattern of a restriction digest.** This gel shows the fragments produced by cleaving DNA from two viral strains (odd- vs. even-numbered lanes) with each of four restriction enzymes. These fragments were made fluorescent by staining the gel with ethidium bromide. [Data from Carr et al., *Emerging Infectious Diseases*, www.cdc.gov/eid, 17(8), August 2011.]

many as 1000 base pairs, whereas more-porous agarose gels are used to resolve mixtures of larger fragments (as large as 20 kb). An important feature of these gels is their high resolving power. In certain kinds of gels, fragments differing in length by just one nucleotide out of several hundred can be distinguished. Bands or spots of radioactive DNA in gels can be visualized by autoradiography. Alternatively, a gel can be stained with a dye such as ethidium bromide, which fluoresces an intense orange under irradiation with ultraviolet light when bound to a double-helical DNA molecule (Figure 5.2). A band containing only 10 ng of DNA can be readily seen.

It is often necessary to determine if a particular base sequence is represented in a given DNA sample. For example, one may wish to confirm the presence of a specific mutation in genomic DNA isolated from patients known to be at risk for a particular disease. This specific sequence can be identified by hybridizing it with a labeled complementary DNA strand (Figure 5.3). A mixture of restriction fragments is separated by electrophoresis through an agarose gel, denatured to form single-stranded DNA, and transferred to a nitrocellulose sheet. The positions of the DNA fragments in the gel are preserved during the transfer. The nitrocellulose is then exposed to a  $^{32}\text{P}$ -labeled or fluorescently tagged DNA probe, a short stretch of single-stranded DNA which contains a known base sequence. The probe hybridizes with a restriction fragment having a complementary sequence, and autoradiography or fluorescence imaging then reveals the position of the restriction-fragment-probe duplex. A particular fragment amid a million others can be readily identified in this way. This powerful technique is named *Southern blotting*, for its inventor Edwin Southern.

In a similar manner, RNA molecules of a specific sequence can also be readily identified. After separation by gel electrophoresis and transfer to nitrocellulose, specific sequences can be detected by DNA probes. This analogous technique for the analysis of RNA has been whimsically termed *northern blotting*. A further play on words accounts for the term *western blotting*, which refers to a technique for detecting a particular protein by staining with specific antibody (Section 3.3).

### DNA can be sequenced by controlled termination of replication

The analysis of DNA structure and its role in gene expression have been markedly facilitated by the development of powerful techniques for the *sequencing* of DNA molecules. One of the first and most widely-used techniques for DNA sequencing is *controlled termination of replication*, also referred to as the Sanger dideoxy method for its pioneer, Frederick Sanger. The key to this approach is

**FIGURE 5.3 Southern blotting.** A DNA fragment containing a specific sequence can be identified by separating a mixture of fragments by electrophoresis, transferring them to nitrocellulose, and hybridizing with a  $^{32}\text{P}$ -labeled probe complementary to the sequence. The fragment containing the sequence is then visualized by autoradiography.

the generation of DNA fragments whose length is determined by the last base in the sequence (Figure 5.4). In the current application of this method, a DNA polymerase is used to make the complement of a particular sequence within a single-stranded DNA molecule. The synthesis is primed by a chemically synthesized fragment that is complementary to a part of the sequence known from other studies. In addition to the four deoxyribonucleoside triphosphates, the reaction mixture contains a small amount of the 2',3'-dideoxy analog of each nucleotide, each carrying a different fluorescent label attached to the base (e.g., a green emitter for termination at A and a red one for termination at T).

The incorporation of this analog blocks further growth of the new chain because it lacks the 3'-hydroxyl terminus needed to form the next phosphodiester bond. The concentration of the dideoxy analog is low enough that chain termination will take place only occasionally. The polymerase will insert the correct nucleotide sometimes and the dideoxy analog other times, stopping the reaction. For instance, if the dideoxy analog of dATP is present, fragments of various lengths are produced, but all will be terminated by the dideoxy analog. Importantly, this dideoxy analog of dATP will be inserted only where a T was located in the DNA being sequenced. Thus, the fragments of different length will correspond to the positions of T.

The resulting fragments are separated by a technique known as *capillary electrophoresis*, in which the mixture is passed through a very narrow tube containing a gel matrix at high voltage to achieve efficient separation within a short time. As the DNA fragments emerge from the capillary, they are detected by their fluorescence; the sequence of their colors directly gives the base sequence. Sequences of as many as 1000 bases can be determined in this way. Indeed, automated Sanger sequencing machines can read more than 1 million bases per day.

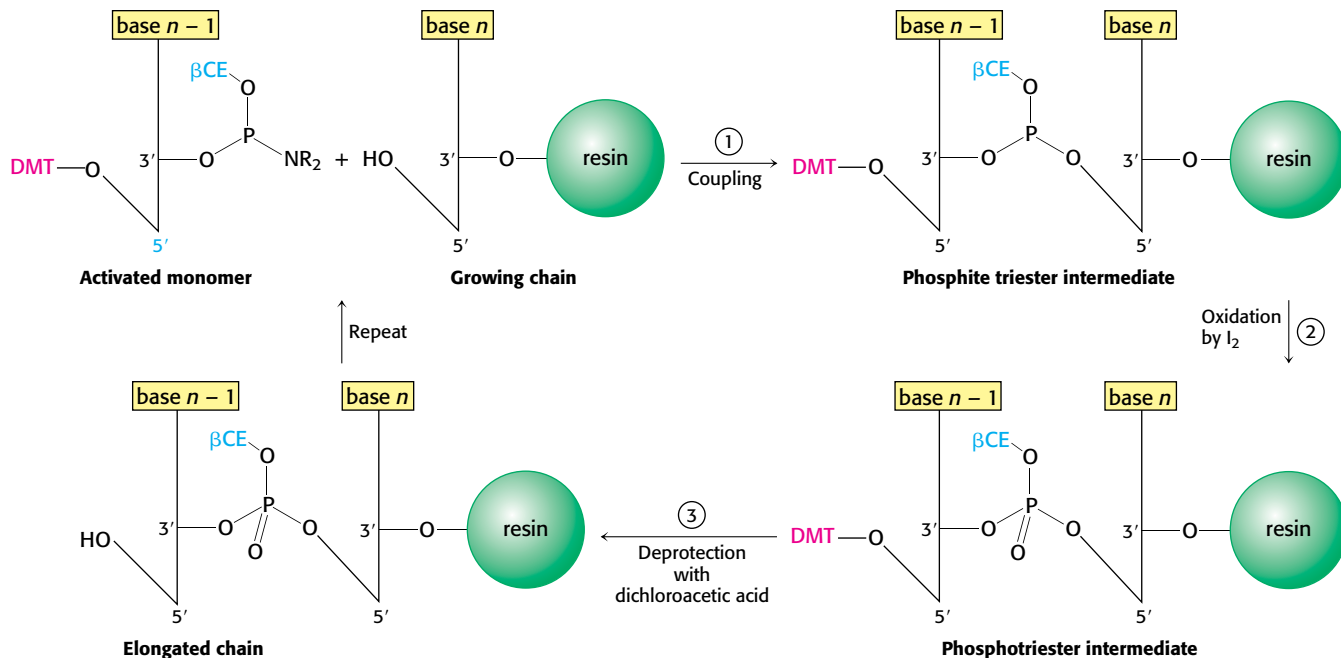

### DNA probes and genes can be synthesized by automated solid-phase methods

DNA strands, like polypeptides (Section 3.4), can be synthesized by the sequential addition of activated monomers to a growing chain that is linked to a solid support. The activated monomers are protected *deoxyribonucleoside 3'-phosphoramidites*. In step 1, the 3'-phosphorus atom of this incoming unit becomes joined to the 5'-oxygen atom of the growing chain to form a *phosphite triester* (Figure 5.5). The 5'-OH group of the activated monomer is unreactive because it is blocked by a dimethoxytrityl (DMT) protecting group, and the 3'-phosphoryl oxygen atom is rendered unreactive by attachment of the  $\beta$ -cyanoethyl ( $\beta$ CCE) group. Likewise, amino groups on the purine and pyrimidine bases are blocked.

Coupling is carried out under anhydrous conditions because water reacts with phosphoramidites. In step 2, the phosphite triester (in which P is trivalent) is oxidized by iodine to form a *phosphotriester* (in which P is pentavalent). In step 3, the DMT protecting group on the 5'-OH group of the growing chain is removed by the addition of dichloroacetic acid, which

**FIGURE 5.4** Fluorescence detection of oligonucleotide fragments produced by the dideoxy method. A sequencing reaction is performed with four chain-terminating dideoxy nucleotides, each labeled with a tag that fluoresces at a different wavelength. The color of each fragment indicates the identity of the last base in the chain. The fragments are separated by size using capillary electrophoresis and the fluorescence at each of the four wavelengths indicates the sequence of the complement of the original DNA template.

**FIGURE 5.5 Solid-phase synthesis of a DNA chain by the phosphite triester method.** The activated monomer added to the growing chain is a deoxyribonucleoside 3'-phosphoramidite containing a dimethoxytrityl (DMT) protecting group on its 5'-oxygen atom, a  $\beta$ -cyanoethyl ( $\beta$ CE) protecting group on its 3'-phosphoryl oxygen atom, and a protecting group on the base.

leaves other protecting groups intact. The DNA chain is now elongated by one unit and ready for another cycle of addition. Each cycle takes only about 10 minutes and usually elongates more than 99% of the chains.

This solid-phase approach is ideal for the synthesis of DNA, as it is for polypeptides, because the desired product stays on the insoluble support until the final release step. All the reactions take place in a single vessel, and excess soluble reagents can be added to drive reactions to completion. At the end of each step, soluble reagents and by-products are washed away from the resin that bears the growing chains. At the end of the synthesis,  $\text{NH}_3$  is added to remove all protecting groups and release the oligonucleotide from the solid support. Because elongation is never 100% complete, the new DNA chains are of diverse lengths—the desired chain is the longest one. The sample can be purified by high-performance liquid chromatography or by electrophoresis on polyacrylamide gels. DNA chains of as many as 100 nucleotides can be readily synthesized by this automated method.

The ability to rapidly synthesize DNA chains of any selected sequence opens many experimental avenues. For example, a synthesized oligonucleotide labeled at one end with  $^{32}\text{P}$  or a fluorescent tag can be used to search for a complementary sequence in a very long DNA molecule or even in a genome consisting of many chromosomes. The use of labeled oligonucleotides as DNA probes is powerful and general. For example, a DNA probe that can base-pair to a known complementary sequence in a chromosome can serve as the starting point of an exploration of adjacent uncharted DNA. Such a probe can be used as a *primer* to initiate the replication of neighboring DNA by DNA polymerase. An exciting application of the solid-phase approach is the synthesis of new tailor-made genes. New proteins with novel

properties can now be produced in abundance by the expression of synthetic genes. Finally, the synthetic scheme heretofore described can be slightly modified for the solid-phase synthesis of RNA oligonucleotides, which can be very powerful reagents for the degradation of specific mRNA molecules in living cells by a technique known as RNA interference (Section 5.4).

### Selected DNA sequences can be greatly amplified by the polymerase chain reaction

In 1984, Kary Mullis devised an ingenious method called the *polymerase chain reaction* (PCR) for amplifying specific DNA sequences. Consider a DNA duplex consisting of a target sequence surrounded by nontarget DNA. Millions of copies of the target sequences can be readily obtained by PCR if the sequences flanking the target are known. PCR is carried out by adding the following components to a solution containing the target sequence: (1) a pair of primers that hybridize with the flanking sequences of the target, (2) all four deoxyribonucleoside triphosphates (dNTPs), and (3) a heat-stable DNA polymerase. A PCR cycle consists of three steps (Figure 5.6).

1. *Strand separation.* The two strands of the parent DNA molecule are separated by heating the solution to 95°C for 15 s.
2. *Hybridization of primers.* The solution is then abruptly cooled to 54°C to allow each primer to hybridize to a DNA strand. One primer hybridizes to the 3' end of the target on one strand, and the other primer hybridizes to the 3' end on the complementary target strand. Parent DNA duplexes do not form, because the primers are present in large excess. Primers are typically from 20 to 30 nucleotides long.
3. *DNA synthesis.* The solution is then heated to 72°C, the optimal temperature for heat-stable polymerases. One such enzyme is *Taq* DNA polymerase, which is derived from *Thermus aquaticus*, a thermophilic bacterium that lives in hot springs. The polymerase elongates both primers in the direction of the target sequence because DNA synthesis is in the 5'-to-3' direction. DNA synthesis takes place on both strands but extends beyond the target sequence.

These three steps—strand separation, hybridization of primers, and DNA synthesis—constitute one cycle of the PCR amplification and can be carried out repetitively just by changing the temperature of the reaction mixture. The thermostability of the polymerase makes it feasible to carry out PCR in a closed container; no reagents are added after the first cycle. At the completion of the second cycle, four duplexes containing the target sequence have been generated (Figure 5.7). Of the eight DNA strands comprising these duplexes, two short strands constitute only the target sequence—the sequence including and bounded by the primers. Subsequent cycles will amplify the target sequence exponentially. Ideally, after  $n$  cycles, the desired sequence is amplified  $2^n$ -fold. The amplification is a millionfold after 20 cycles and a billionfold after 30 cycles, which can be carried out in less than an hour.

Several features of this remarkable method for amplifying DNA are noteworthy. First, the sequence of the target need not be known. All that is required is knowledge of the flanking sequences so that complementary primers can be synthesized. Second, the target can be much larger than the primers. Targets larger than 10 kb have been amplified by PCR. Third, primers do not have to be perfectly matched to flanking sequences to amplify targets. With the use of primers derived from a gene of known sequence, it is possible to search for variations on the theme. In this way, families of genes are being discovered by PCR. Fourth, PCR is highly specific because of the

**FIGURE 5.6** The first cycle in the polymerase chain reaction (PCR). A cycle consists of three steps: DNA double strand separation, the hybridization of primers, and the extension of primers by DNA synthesis.

stringency of hybridization at relatively high temperature. *Stringency* is the required closeness of the match between primer and target, which can be controlled by temperature and salt. At high temperatures, only the DNA between hybridized primers is amplified. A gene constituting less than a millionth of the total DNA of a higher organism is accessible by PCR. Fifth, PCR is exquisitely sensitive. A single DNA molecule can be amplified and detected.

### PCR is a powerful technique in medical diagnostics, forensics, and studies of molecular evolution

PCR can provide valuable diagnostic information in medicine. Bacteria and viruses can be readily detected with the use of specific primers. For example, PCR can reveal the presence of small amounts of DNA from the human immunodeficiency virus (HIV) in persons who have not yet mounted an immune response to this pathogen. In these patients, assays designed to detect antibodies against the virus would yield a false negative test result. Finding *Mycobacterium tuberculosis* bacilli in tissue specimens is slow and laborious. With PCR, as few as 10 tubercle bacilli per million human cells can be readily detected. PCR is a promising method for the early detection of certain cancers. This technique can identify mutations of certain growth-control genes, such as the *ras* genes (Chapter 14). The capacity to greatly amplify selected regions of DNA can also be highly informative in monitoring cancer chemotherapy. Tests using PCR can detect when cancerous cells have been eliminated and treatment can be stopped; they can also detect a relapse and the need to immediately resume treatment. PCR is ideal for detecting leukemias caused by chromosomal rearrangements.

In addition, PCR has made an impact on forensics and legal medicine. An individual DNA profile is highly distinctive because many genetic loci are highly variable within a population. For example, variations at one specific location determine a person's HLA type (human leukocyte antigen type; Section 34.5); organ transplants are rejected when the HLA types of the donor and recipient are not sufficiently matched. PCR amplification of multiple genes is being used to establish biological parentage in disputed paternity and immigration cases. Analyses of blood stains and semen samples by PCR have implicated guilt or innocence in numerous assault and rape cases (Figure 5.8). The root of a single shed hair found at a crime scene contains enough DNA for typing by PCR.

DNA is a remarkably stable molecule, particularly when shielded from air, light, and water. Under such circumstances, large fragments of DNA can remain intact for thousands of years or longer. PCR provides an ideal method for amplifying such ancient DNA molecules so that they can be detected and characterized (Section 6.5). PCR can also be used to amplify DNA from microorganisms that have not yet been isolated and cultured. As will be discussed in Chapter 6, sequences from these PCR products

**FIGURE 5.7 Multiple cycles of the polymerase chain reaction.** The two short strands produced at the end of the third cycle (along with longer stands not shown) represent the target sequence. Subsequent cycles will amplify the target sequence exponentially and the parent sequence arithmetically.

can be sources of considerable insight into evolutionary relationships between organisms.

### The tools for recombinant DNA technology have been used to identify disease-causing mutations

Let us consider how the techniques just described have been utilized in concert to study ALS, introduced at the beginning of this chapter. Five percent of all patients suffering from ALS have family members who also have been diagnosed with the disease. A heritable disease pattern is indicative of a strong genetic component of disease causation. To identify these disease-causing genetic alterations, researchers identify *polymorphisms* (instances of genetic variation) within an affected family that correlate with the emergence of disease. These polymorphisms may themselves cause disease or be closely linked to the responsible genetic alteration. *Restriction-fragment-length polymorphisms* (RFLPs) are polymorphisms within restriction sites that change the sizes of DNA fragments produced by the appropriate restriction enzyme. Using restriction digests and Southern blots of the DNA from members of ALS-affected families, researchers identified RFLPs that were found preferentially in those family members diagnosed with the disease. For some of these families, strong evidence was obtained for the disease-causing mutation within a specific region of chromosome 21.

After the probable location of one disease-causing gene had been identified, this same research group compared the locations of the ALS-associated RFLPs with the known sequence of chromosome 21. They noted that this chromosomal locus contains the *SOD1* gene, which encodes the Cu/Zn superoxide dismutase protein SOD1, an enzyme important for the protection of cells against oxidative damage (Section 18.3). PCR amplification of regions of the *SOD1* gene from the DNA of affected family members, followed by Sanger dideoxy sequencing of the targeted fragment, enabled the identification of 11 disease-causing mutations from 13 different families. This work was pivotal for focusing further inquiry into the roles that superoxide dismutase and its corresponding mutant forms play in the pathology of some forms of ALS.

**FIGURE 5.8 DNA and forensics.** DNA isolated from sperm obtained during the examination of a rape victim was amplified by PCR, then compared with DNA from the victim and three potential suspects—the victim’s husband and two additional individuals—using gel electrophoresis and autoradiography. Sperm DNA matched the pattern of Suspect 1, but not that of Suspect 2 or the victim’s husband. Sizing marker and K562 lanes refer to control DNA samples. [Martin Shields/Science Source.]

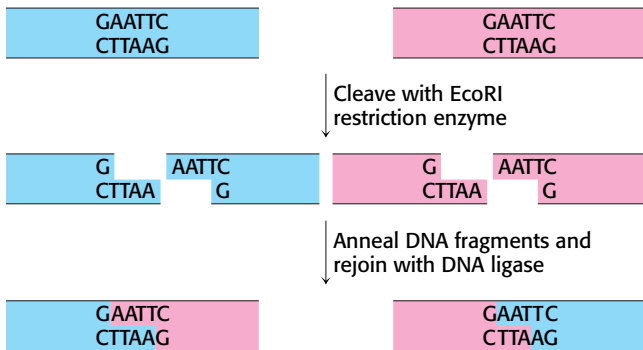

## 5.2 Recombinant DNA Technology Has Revolutionized All Aspects of Biology

The development of recombinant DNA technology has taken biology from an exclusively analytical science to a synthetic one. New combinations of unrelated genes can be constructed in the laboratory by applying recombinant DNA techniques. These novel combinations can be cloned—amplified many-fold—by introducing them into suitable cells, where they are replicated by the DNA-synthesizing machinery of the host. The inserted genes are often transcribed and translated in their new setting. What is most striking is that the genetic endowment of the host can be permanently altered in a designed way.

### Restriction enzymes and DNA ligase are key tools in forming recombinant DNA molecules

Let us begin by seeing how novel DNA molecules can be constructed in the laboratory. An essential tool for the manipulation of recombinant DNA is a *vector*, a DNA molecule that can replicate autonomously in an appropriate host organism. Vectors are designed to enable the rapid,

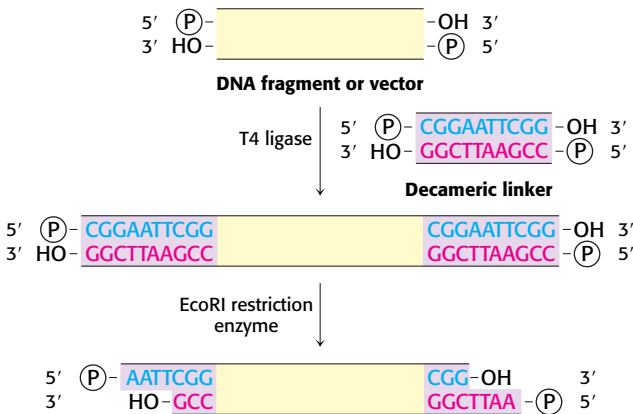

**FIGURE 5.9 Joining of DNA molecules by the cohesive-end method.** Two DNA molecules, cleaved with a common restriction enzyme such as EcoRI, can be ligated to form recombinant molecules.

covalent insertion of DNA fragments of interest. *Plasmids* (naturally occurring circles of DNA that act as accessory chromosomes in bacteria) and bacteriophage lambda ( $\lambda$  phage), a virus, are choice vectors for cloning in *E. coli*. The vector can be prepared for accepting a new DNA fragment by cleaving it at a single specific site with a restriction enzyme. For example, the plasmid pSC101, a 9.9-kb double-helical circular DNA molecule, is split at a unique site by the EcoRI restriction enzyme. The staggered cuts made by this enzyme produce *complementary single-stranded ends*, which have specific affinity for each other and hence are known as *cohesive* or *sticky ends*. Any DNA fragment can be inserted into this plasmid if it has the same cohesive ends. Such a fragment can be extracted from a larger piece of DNA by using the same restriction enzyme as was used to open the plasmid DNA (Figure 5.9).

The single-stranded ends of the fragment are then complementary to those of the cut plasmid. The DNA fragment and the cut plasmid can be annealed and then joined by *DNA ligase*, which catalyzes the formation of a phosphodiester bond at a break in a DNA chain. DNA ligase requires a free 3'-hydroxyl group and a 5'-phosphoryl group. Furthermore, the chains joined by ligase must be in a double helix. An energy source such as ATP or NAD<sup>+</sup> is required for the joining reaction, as will be discussed in Chapter 28.

What if the target DNA is not naturally flanked by the appropriate restriction sites? How is the fragment cut and annealed to the vector? The cohesive-end method for joining DNA molecules can still be used in these cases by adding a *short, chemically synthesized DNA linker* that can be cleaved by restriction enzymes. First, the linker is covalently joined to the ends of a DNA fragment. For example, the 5' ends of a decameric linker and a DNA molecule are phosphorylated by polynucleotide kinase and then joined by the ligase from T4 phage (Figure 5.10). This ligase can form a covalent bond between blunt-ended double-helical DNA molecules. Cohesive ends are produced when these terminal extensions are cut by an appropriate restriction enzyme. Thus, *cohesive ends corresponding to a particular restriction enzyme can be added to virtually any DNA molecule*. We see here the fruits of combining enzymatic and synthetic chemical approaches in crafting new DNA molecules.

**FIGURE 5.10 Formation of cohesive ends.** Cohesive ends can be formed by the addition and cleavage of a chemically synthesized linker.

### Plasmids and $\lambda$ phage are choice vectors for DNA cloning in bacteria

Many plasmids and bacteriophages have been ingeniously modified by researchers to enhance the delivery of recombinant DNA molecules into bacteria and to facilitate the genetic selection of bacteria harboring these vectors. As already mentioned, plasmids are circular double-stranded DNA molecules that occur naturally in some bacteria. They range in size from two to several hundred kilobases. Plasmids carry genes for the inactivation of antibiotics, the production of toxins, and the breakdown of natural products. These accessory chromosomes can replicate independently of the host chromosome. In contrast with the host genome, they are dispensable under certain conditions. A bacterial cell may have no plasmids at all or it may house as many as 20 copies of a naturally-occurring plasmid.

Many plasmids have been optimized for a particular experimental task. Some engineered plasmids, for example, can achieve nearly a thousand copies per bacterial cell. One class of plasmids, known as *cloning vectors*, is particularly suitable for the facile insertion and replication of a collection of DNA fragments. These vectors often feature a *polylinker* region that includes many unique restriction sites within its sequence. This polylinker can be cleaved with many different restriction enzymes or combinations of enzymes, providing great versatility in the DNA fragments that can be inserted. In addition, these plasmids contain *reporter genes*, which encode rapidly-detectable markers such as antibiotic-resistance enzymes or fluorescent proteins. Creative placement of these reporter genes within these plasmids enables the rapid identification of those vectors that harbor the desired DNA insert. For example, in the cloning vector pUC18, insertion of DNA in the polylinker region (Figure 5.11) disrupts the *lacZα* gene, an effect called *insertional inactivation*. This gene encodes an essential fragment of the protein *β-galactosidase*, an enzyme which naturally cleaves the milk sugar galactose (Section 11.2). *β-Galactosidase* also cleaves the synthetic substrate X-gal, releasing a blue dye. Bacterial cells containing a DNA insert at the polylinker will no longer produce the dye in the presence of X-gal, and are readily identified by their white color (Figure 5.12).

**FIGURE 5.11 A polylinker in the plasmid pUC18.** The plasmid pUC18 includes a polylinker within an essential fragment of the *β-galactosidase* gene (often called the *lacZ* gene). Insertion of a DNA fragment into one of the many restriction sites within this polylinker can be detected by the absence of *β-galactosidase* activity.

**FIGURE 5.12 Insertional inactivation.** Successful insertion of DNA fragments into the polylinker region of pUC18 will result in the disruption of the *β-galactosidase* gene. Bacterial colonies that harbor such plasmids will no longer convert X-gal into a colored product, and will appear white on the plate.

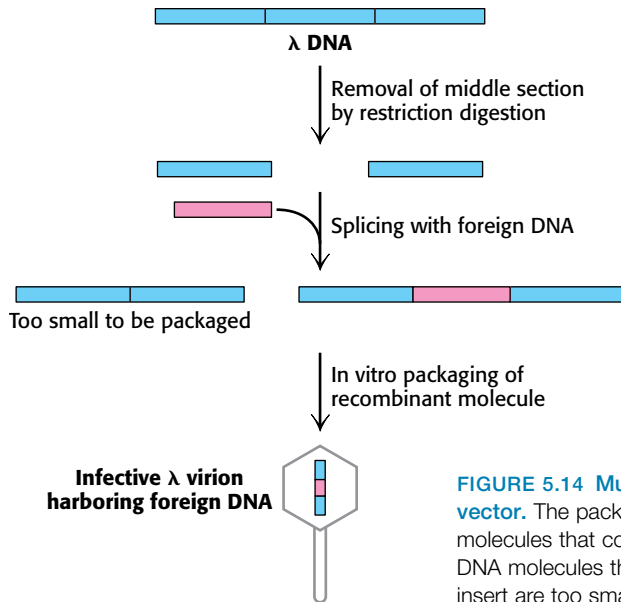

Another class of plasmids has been optimized for use as *expression vectors* for the production of large amounts of protein. In addition to antibiotic-resistance genes, they contain promoter sequences designed to drive the transcription of large amounts of a protein-coding DNA sequence. In addition to polylinkers, these vectors often contain sequences flanking the cloning site that simplify the addition of fusion tags to the protein of interest (Section 3.1), greatly facilitating the purification of the overexpressed protein.

Another widely used vector,  $\lambda$  *phage*, enjoys a choice of life styles: this bacteriophage can destroy its host or it can become part of its host (Figure 5.13). In the *lytic pathway*, viral functions are fully expressed: viral DNA and proteins are quickly produced and packaged into virus particles, leading to the lysis (destruction) of the host cell and the sudden appearance of about 100 progeny virus particles, or *virions*. In the *lysogenic pathway*, the phage DNA becomes inserted into the host-cell genome and can be replicated together with host-cell DNA for many generations, remaining inactive. Certain environmental changes can trigger the expression of this dormant viral DNA, which leads to the formation of progeny viruses and lysis of the host. Large segments of the 48-kb DNA of  $\lambda$  phage are not essential for productive infection and can be replaced by foreign DNA, thus making  $\lambda$  phage an ideal vector.

**FIGURE 5.13 Alternative infection modes for  $\lambda$  phage.** Lambda phage can multiply within a host and lyse it (lytic pathway) or its DNA can become integrated into the host genome (lysogenic pathway), where it is dormant until activated.

Mutant  $\lambda$  phages designed for cloning have been constructed. An especially useful one called  $\lambda$ gt- $\lambda$  $\beta$  contains only two EcoRI cleavage sites instead of the five normally present (Figure 5.14). After cleavage, the middle segment of this  $\lambda$  DNA molecule can be removed. The two remaining pieces of DNA (called arms) have a combined length equal to 72% of a normal genome length. This amount of DNA is too little to be packaged into a  $\lambda$  particle, which can take up only DNA measuring from 78% to 105% of a normal genome. However, a suitably long DNA insert (such as 10 kb) between the two ends of  $\lambda$  DNA enables such a recombinant DNA molecule (93% of normal length) to be packaged. Nearly all infectious  $\lambda$  particles formed in this way will contain an inserted piece of foreign DNA. Another advantage of using these modified viruses as vectors is that they enter bacteria much more easily than do plasmids. Among the variety of  $\lambda$  mutants that have been constructed for use as cloning vectors, one of them, called a *cosmid*, is essentially a hybrid of  $\lambda$  phage and a plasmid that can serve as a vector for large DNA inserts (as large as 45 kb).

**FIGURE 5.14** Mutant  $\lambda$  phage as a cloning vector. The packaging process selects DNA molecules that contain an insert (colored red). DNA molecules that have resealed without an insert are too small to be efficiently packaged.

### Bacterial and yeast artificial chromosomes

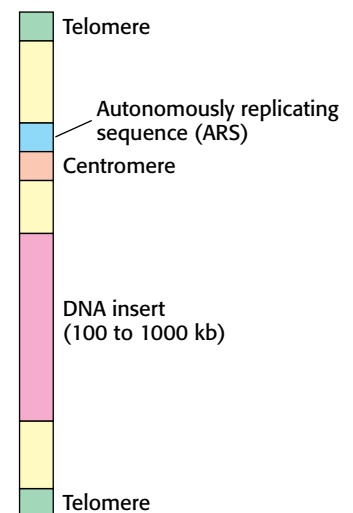

Much larger pieces of DNA can be propagated in *bacterial artificial chromosomes* (BACs) or *yeast artificial chromosomes* (YACs). BACs are highly engineered versions of the *E. coli* fertility (F) factor that can include inserts as large as 300 kb. YACs contain a centromere, an *autonomously replicating sequence* (ARS, where replication begins), a pair of telomeres (normal ends of eukaryotic chromosomes), selectable marker genes, and a cloning site (Figure 5.15). Inserts as large as 1000 kb can be cloned into YAC vectors.

### Specific genes can be cloned from digests of genomic DNA

Ingenious cloning and selection methods have made it possible to isolate small stretches of DNA in a genome containing more than  $3 \times 10^6$  kb. The approach is to prepare a large collection (*library*) of DNA fragments and then to identify those members of the collection that have the gene of interest. Hence, to clone a gene that is present just once in an entire genome, two critical components must be available: a specific oligonucleotide probe for the gene of interest and a DNA library that can be screened rapidly.

How is a specific probe obtained? In one approach, a probe for a gene can be prepared if a part of the amino acid sequence of the protein encoded by the gene is known. Peptide sequencing of a purified protein (Chapter 3) or knowledge of the sequence of a homologous protein from a related species (Chapter 6) are two potential sources of such information. However, a problem arises because a single peptide sequence can be encoded by a number of different oligonucleotides (Figure 5.16). Thus, for this purpose, peptide sequences containing tryptophan and methionine are preferred, because these amino acids are specified by a single codon, whereas other amino acid residues have between two and six codons (Table 4.5). All the possible DNA sequences (or their complements) that encode the targeted peptide sequence are synthesized by the solid-phase method and made radioactive by phosphorylating their 5' ends with  $^{32}\text{P}$ .

To prepare the DNA library, a sample containing many copies of total genomic DNA is first mechanically sheared or partly digested by restriction enzymes

**FIGURE 5.15** Diagram of a yeast artificial chromosome (YAC). These vectors include features necessary for replication and stability in yeast cells.

			T				T		

**FIGURE 5.16** Probes generated from a protein sequence. A probe can be generated by synthesizing all possible oligonucleotides encoding a particular sequence of amino acids. Because of the degeneracy of the genetic code, 256 distinct oligonucleotides must be synthesized to ensure that the probe matching the sequence of seven amino acids in this example is present.

**FIGURE 5.17 Creation of a genomic library.** A genomic library can be created from a digest of a whole complex genome. After fragmentation of the genomic DNA into overlapping segments, the DNA is inserted into the  $\lambda$  phage vector (shown in yellow). Packaging into virions and amplification by infection in *E. coli* yields a genomic library.

into large fragments (Figure 5.17). This process yields a nearly random population of overlapping DNA fragments. These fragments are then separated by gel electrophoresis to isolate the set of all fragments that are about 15 kb long. Synthetic linkers are attached to the ends of these fragments, cohesive ends are formed, and the fragments are then inserted into a vector, such as  $\lambda$  phage DNA, prepared with the same cohesive ends. *E. coli* bacteria are then infected with these recombinant phages. These phages replicate themselves and then lyse their bacterial hosts. The resulting lysate contains fragments of human DNA housed in a sufficiently large number of virus particles to ensure that nearly the entire genome is represented. These phages constitute a *genomic library*. Phages can be propagated indefinitely such that the library can be used repeatedly over long periods.

This genomic library is then screened to find the very small number of phages harboring the gene of interest. For the human genome, a calculation shows that a 99% probability of success requires screening about 500,000 clones; hence, a very rapid and efficient screening process is essential. Rapid screening can be accomplished by DNA hybridization.

A dilute suspension of the recombinant phages is first plated on a lawn of bacteria (Figure 5.18). Where each phage particle has landed and infected a bacterium, a *plaque* containing identical phages develops on the plate. A replica of this master plate is then made by applying a sheet of nitrocellulose. Infected bacteria and phage DNA released from lysed cells adhere to the sheet in a pattern of spots corresponding to the plaques. Intact bacteria on this sheet are lysed with NaOH, which also serves to denature the DNA so that it becomes accessible for hybridization with a  $^{32}\text{P}$ -labeled probe. The presence of a specific DNA sequence in a single spot on the replica can be detected by using a radioactive complementary DNA or RNA molecule as a probe. Autoradiography then reveals the positions of spots harboring recombinant DNA. The corresponding plaques are picked out of the intact master plate and grown. A single investigator can readily screen a million clones in a day. This method makes it possible to isolate virtually any gene, provided that a probe is available.

**FIGURE 5.18 Screening a genomic library for a specific gene.** Here, a plate is tested for plaques containing gene *a* of Figure 5.17.

## Complementary DNA prepared from mRNA can be expressed in host cells

The preparation of eukaryotic DNA libraries presents unique challenges, especially if the researcher is interested primarily in the protein-coding region of a particular gene. Recall that most mammalian genes are mosaics of introns and exons. These interrupted genes cannot be expressed by bacteria, which lack the machinery to splice introns out of the primary transcript. However, this difficulty can be circumvented by causing bacteria to take up recombinant DNA that is complementary to mRNA, where the intronic sequences have been removed.

The key to forming *complementary DNA* is the enzyme *reverse transcriptase*. As discussed in Section 4.3, a retrovirus uses this enzyme to form a DNA–RNA hybrid in replicating its genomic RNA. Reverse transcriptase synthesizes a DNA strand complementary to an RNA template if the transcriptase is provided with a DNA primer that is base-paired to the RNA and contains a free 3'-OH group. We can use a simple sequence of linked thymidine [oligo(T)] residues as the primer. This oligo(T) sequence pairs with the poly(A) sequence at the 3' end of most eukaryotic mRNA molecules (Section 4.4), as shown in Figure 5.19. The reverse transcriptase then synthesizes the rest of the cDNA strand in the presence of the four deoxyribonucleoside triphosphates (step 1). The RNA strand of this RNA–DNA hybrid is subsequently hydrolyzed by raising the pH (step 2). Unlike RNA, DNA is resistant to alkaline hydrolysis. The single-stranded DNA is converted into double-stranded DNA by creating another primer site. The enzyme *terminal transferase* adds nucleotides—for instance, several residues of dG—to the 3' end of DNA (step 3). Oligo(dC) can bind to dG residues and prime the synthesis of the second DNA strand (step 4). Synthetic linkers can be added to this double-helical DNA for ligation to a suitable vector. Complementary DNA for all mRNA that a cell contains can be made, inserted into vectors, and then inserted into bacteria. Such a collection is called a *cDNA library*.

**FIGURE 5.19 Formation of a cDNA duplex.** A complementary DNA (cDNA) duplex is created from mRNA by (1) use of reverse transcriptase to synthesize a cDNA strand, (2) digestion of the original RNA strand, (3) addition of several G bases to the DNA by terminal transferase, and (4) synthesis of a complementary DNA strand using the newly synthesized cDNA strand as a template.

Complementary DNA molecules can be inserted into expression vectors to enable the production of the corresponding protein of interest. Clones of cDNA can be screened on the basis of their capacity to direct the synthesis of a foreign protein in bacteria, a technique referred to as *expression cloning*. A labeled antibody specific for the protein of interest can be used to identify colonies of bacteria that express the corresponding protein product (Figure 5.20). As described earlier, spots of bacteria on a replica plate are lysed to release proteins, which bind to an applied nitrocellulose

**FIGURE 5.20 Screening of cDNA clones.** A method of screening for cDNA clones is to identify expressed products by staining with specific antibody.

**FIGURE 5.21 Synthesis of proinsulin by bacteria.** Proinsulin, a precursor of insulin, can be synthesized by transformed (genetically altered) clones of *E. coli*. The clones contain the mammalian proinsulin gene.

filter. With the addition of labeled antibody specific for the protein of interest, the location of the desired colonies on the master plate can be readily identified. This immunochemical screening approach can be used whenever a protein is expressed and corresponding antibody is available.

Complementary DNA has many applications beyond the generation of genetic libraries. The overproduction and purification of most eukaryotic proteins in prokaryotic cells necessitates the insertion of cDNA into plasmid vectors. For example, proinsulin, a precursor of insulin, is synthesized by bacteria-harboring plasmids that contain DNA complementary to mRNA for proinsulin (Figure 5.21). Indeed, bacteria produce much of the insulin used today by millions of diabetics.

### Proteins with new functions can be created through directed changes in DNA

Much has been learned about genes and proteins by analyzing the effects that mutations have on their structure and function. In the classic genetic approach, mutations are generated randomly throughout the genome of a host organism, and those individuals exhibiting a phenotype of interest are selected. Analysis of these mutants then reveals which genes are altered, and DNA sequencing identifies the precise nature of the changes. *Recombinant DNA technology makes the creation of specific mutations feasible in vitro*. We can construct new genes with designed properties by making three kinds of directed changes: *deletions*, *insertions*, and *substitutions*. A variety of methods can be used to introduce these types of mutations, including the following examples.

**Site-directed mutagenesis.** Mutant proteins with single amino acid substitutions can be readily produced by *site-directed mutagenesis* (Figure 5.22). Suppose that we want to replace a particular serine residue with cysteine. This mutation can be made if (1) we have a plasmid containing the gene or cDNA for the protein and (2) we know the base sequence around the site to be altered. If the serine of interest is encoded by TCT, mutation of the central base from C to G yields the TGT codon, which encodes cysteine. This type of mutation is called a *point mutation* because only one base is altered. To introduce this mutation into our plasmid, we prepare an oligonucleotide primer that is complementary to this region of the gene except that it contains TGT instead of TCT. The two strands of the plasmid are separated, and the primer is then annealed to the complementary strand. The mismatch of 1 of 15 base pairs is tolerable if the annealing is carried out at an appropriate temperature. After annealing to the complementary strand, the primer is elongated by DNA polymerase, and the double-stranded circle is closed by adding DNA ligase. Subsequent replication of this duplex yields two kinds of progeny plasmid, half with the original TCT sequence and half with the mutant TGT sequence. Expression of the plasmid containing the new TGT

**FIGURE 5.22 Oligonucleotide-directed mutagenesis.** A primer containing a mismatched nucleotide is used to produce a desired change in the DNA sequence.

sequence will produce a protein with the desired substitution of cysteine for serine at a unique site. We will encounter many examples of the use of site-directed mutagenesis to precisely alter regulatory regions of genes and to produce proteins with tailor-made features.

**Cassette mutagenesis.** In *cassette mutagenesis*, a variety of mutations, including insertions, deletions, and multiple point mutations, can be introduced into the gene of interest. A plasmid harboring the original gene is cut with a pair of restriction enzymes to remove a short segment (Figure 5.23). A synthetic double-stranded oligonucleotide—the *cassette*—carrying the genetic alterations of interest is prepared with cohesive ends that are complementary to the ends of the cut plasmid. Ligation of the cassette into the plasmid yields the desired mutated gene product.

**Mutagenesis by PCR.** In Section 5.1, we learned how PCR can be used to amplify a specific region of DNA using primers that flank the region of interest. In fact, the creative design of PCR primers enables the introduction of specific insertions, deletions, and substitutions into the amplified sequence. A number of methods have been developed for this purpose. Here, we shall consider one: *inverse PCR* to introduce deletions into plasmid DNA (Figure 5.24). In this approach, primers are designed to flank the sequence to be deleted. However, these primers are oriented in the opposite

**FIGURE 5.23 Cassette mutagenesis.** DNA is cleaved at a pair of unique restriction sites by two different restriction endonucleases. A synthetic oligonucleotide with ends that are complementary to these sites (the cassette) is then ligated to the cleaved DNA. The method is highly versatile because the inserted DNA can have any desired sequence.

**FIGURE 5.24 Deletion mutagenesis by inverse PCR.** A deletion can be introduced into a plasmid with primers that flank this region but are oriented away from the segment to be removed. PCR amplification yields a linear product that contains the entire plasmid minus the unwanted sequence. If the primers contained a 5' phosphate group, this product can be recircularized using DNA ligase, generating a plasmid with the desired mutation.

direction, such that they direct the amplification of the entire plasmid, minus the region to be deleted. If each of the primers contains a 5' phosphate group, the amplified product can be recircularized with DNA ligase, yielding the desired deletion mutation.

**Designer genes.** Novel proteins can also be created by splicing together gene segments that encode domains that are not associated in nature. For example, a gene for an antibody can be joined to a gene encoding a toxic protein, yielding a chimeric protein that kills those cells recognized by the antibody. These *immunotoxins* are being evaluated as anticancer agents. Furthermore, noninfectious coat proteins of viruses can be produced in large amounts by recombinant DNA methods. They can serve as *synthetic vaccines* that are safer than conventional vaccines prepared by inactivating pathogenic viruses. A subunit of the hepatitis B virus produced in yeast is proving to be an effective vaccine against this debilitating viral disease. Finally, entirely new genes can be synthesized de novo by the solid-phase method described above. These genes can encode proteins with no known counterparts in nature.

### Recombinant methods enable the exploration of the functional effects of disease-causing mutations

The application of recombinant DNA technology to the production of mutated proteins has had a significant effect in the study of ALS. Recall that genetic studies had identified a number of ALS-inducing mutations within the gene encoding Cu/Zn superoxide dismutase. As we shall learn in Section 18.3, SOD1 catalyzes the conversion of the superoxide radical anion into hydrogen peroxide, which, in turn, is converted into molecular oxygen and water by catalase. To study the potential effect of ALS-causing mutations on SOD1 structure and function, the *SOD1* gene was isolated from a human cDNA library by PCR amplification. The amplified fragments containing the gene were then digested by an appropriate restriction enzyme and inserted into a similarly digested plasmid vector. Mutations corresponding to those observed in ALS patients were introduced into these plasmids by oligonucleotide-directed mutagenesis and the protein products were expressed and assayed for their catalytic activity. Surprisingly, these mutations did not significantly alter the enzymatic activity of the corresponding recombinant proteins. These observations have led to the prevailing notion that these mutations impart toxic properties to SOD1. Although the nature of this toxicity is not yet completely understood, one hypothesis is that mutant SOD1 is prone to form toxic aggregates in the cytoplasm of neuronal cells.

---

## 5.3 Complete Genomes Have Been Sequenced and Analyzed

The methods just described are extremely effective for the isolation and characterization of fragments of DNA. However, the genomes of organisms ranging from viruses to human beings contain considerably longer sequences, arranged in very specific ways crucial for their integrated functions. Is it possible to sequence complete genomes and analyze them? For small genomes, this sequencing was accomplished soon after DNA-sequencing methods were developed. Sanger and his coworkers determined the complete sequence of the 5386 bases in the genome of the  $\phi$ X174 DNA virus in 1977, just a quarter century after Sanger's pioneering elucidation of the amino acid sequence of a protein. This tour de force was followed several years later by the determination of the sequence of human mitochondrial DNA, a double-stranded

circular DNA molecule containing 16,569 base pairs. It encodes 2 ribosomal RNAs, 22 transfer RNAs, and 13 proteins. Many other viral genomes were sequenced in subsequent years. However, the genomes of free-living organisms presented a great challenge because even the simplest comprises more than 1 million base pairs. Thus, sequencing projects require both rapid sequencing techniques and efficient methods for assembling many short stretches of 300 to 500 base pairs into a complete sequence.

### The genomes of organisms ranging from bacteria to multicellular eukaryotes have been sequenced

With the development of automatic DNA sequencers based on fluorescent dideoxynucleotide chain terminators, high-volume, rapid DNA sequencing became a reality. The genome sequence of the bacterium *Haemophilus influenzae* was determined in 1995 by using a “shotgun” approach. The genomic DNA was sheared randomly into fragments that were then sequenced. Computer programs assembled the complete sequence by matching up overlapping regions between fragments. The *H. influenzae* genome comprises 1,830,137 base pairs and encodes approximately 1740 proteins (Figure 5.25). Using similar approaches, as well as more advanced methods described below, investigators have determined the sequences of more than 10,000 bacterial and archaeal species, including key model organisms such as *E. coli*, *Salmonella typhimurium*, and *Archaeoglobus fulgidus*, as well as pathogenic organisms such as *Yersina pestis* (bubonic plague) and *Bacillus anthracis* (anthrax).

The first eukaryotic genome to be completely sequenced was that of baker’s yeast, *Saccharomyces cerevisiae*, in 1996. The yeast genome comprises approximately 12 million base pairs, distributed on 16 chromosomes, and encodes more than 6000 proteins. This achievement was followed in 1998 by the first complete sequencing of the genome of a multicellular organism, the nematode *Caenorhabditis elegans*, which contains 97 million base pairs. This genome includes more than 19,000 genes. The genomes of

**FIGURE 5.25 A complete genome.** The diagram depicts the genome of *Haemophilus influenzae*, the first complete genome of a free-living organism to be sequenced. The genome encodes more than 1700 proteins and 70 RNA molecules. The likely function of approximately one-half of the proteins was determined by comparisons with sequences of proteins already characterized in other species. [Data from R. D. Fleischmann et al., *Science* 269:496–512, 1995; scan courtesy of The Institute for Genomic Research.]

many additional organisms widely used in biological and biomedical research have now been sequenced, including those of the fruit fly *Drosophila melanogaster*, the model plant *Arabidopsis thaliana*, the mouse, the rat, and the dog. Note that even after a genome sequence has been considered complete, some sections, such as the repetitive sequences that make up heterochromatin, may be missing because these DNA sequences are very difficult to manipulate with the use of standard techniques.

### The sequence of the human genome has been completed

The ultimate goal of much of genomics research has been the sequencing and analysis of the human genome. Given that the human genome comprises approximately 3 billion base pairs of DNA distributed among 24 chromosomes, the challenge of producing a complete sequence was daunting. However, through an organized international effort of academic laboratories and private companies, the human genome has progressed from a draft sequence first reported in 2001 to a finished sequence reported in late 2004 (Figure 5.26).

**FIGURE 5.26 The human genome.** The human genome is arrayed on 46 chromosomes—22 pairs of autosomes and the X and Y sex chromosomes. The locations of several genes associated with important pathways in biochemistry are highlighted.

The human genome is a rich source of information about many aspects of humanity, including biochemistry and evolution. Analysis of the genome will continue for many years to come. Developing an inventory of protein-encoding genes is one of the first tasks. At the beginning of the genome-sequencing project, the number of such genes was estimated to be approximately 100,000. With the availability of the completed (but not finished) genome, this estimate was reduced to between 30,000 and 35,000. With the finished sequence, the estimate fell to between 20,000 to 25,000. We will use the estimate of 23,000 throughout this book. The reduction in this estimate is due, in part, to the realization that there are a large number of *pseudogenes*, formerly functional genes that have accumulated mutations such that they no longer produce proteins. For example, more than half of the genomic regions that correspond to olfactory receptors—key molecules responsible for our sense of smell—are pseudogenes (Section 33.1). The corresponding regions in the genomes of other primates and rodents encode functional olfactory receptors.

Nonetheless, the surprisingly small number of genes belies the complexity of the human proteome. *Many genes encode more than one protein through mechanisms such as alternative splicing of mRNA and posttranslational modifications of proteins.* The different proteins encoded by a single gene often display important variations in functional properties.

The human genome contains a large amount of DNA that does not encode proteins. A great challenge in modern biochemistry and genetics is to elucidate the roles of this noncoding DNA. Much of this DNA is present because of the existence of *mobile genetic elements*. These elements, related to retroviruses (Section 4.3), have inserted themselves throughout the genome over time. Most of these elements have accumulated mutations and are no longer functional. For example, more than 1 million *Alu sequences*, each approximately 300 bases in length, are present in the human genome. *Alu sequences* are examples of *SINES*, *short interspersed elements*. The human genome also includes nearly 1 million *LINES*, *long interspersed elements*, DNA sequences that can be as long as 10 kilobases (kb). The roles of these elements as neutral genetic parasites or instruments of genome evolution are under current investigation.

## Next-generation sequencing methods enable the rapid determination of a complete genome sequence

Since the introduction of Sanger dideoxy method in the mid-1970s, significant advances have been made in DNA-sequencing technologies, enabling the readout of progressively longer sequences with higher fidelity and shorter run times. The development of *next-generation sequencing* (NGS) platforms has extended this capability to formerly unforeseen levels. By combining technological breakthroughs in the handling of very small amounts of liquid, high-resolution optics, and computing power, these methods have already made a significant impact on the ability to obtain whole genome sequences rapidly and cheaply (Chapter 1).

Next-generation sequencing refers to a family of technologies, each of which utilizes a unique approach for the determination of a DNA sequence. All of these methods are *highly parallel*: from 1 million to 1 billion DNA fragment sequences are acquired in a single experiment. How are NGS methods capable of attaining such a high number of parallel runs? Individual DNA fragments are amplified by PCR on a solid support—a single bead or a small region of a glass slide—such that clusters of identical DNA fragments are distinguishable by high-resolution imaging. These fragments then serve as templates for DNA polymerase, where the addition of nucleotide triphosphates is converted to a signal that can be detected in a highly sensitive manner. The technique used to detect individual base incorporation varies among the variety of NGS methods. However, most of these can be understood simply by considering the overall reaction of chain elongation catalyzed by DNA polymerase (Figure 5.27). In the *reversible terminator method*, the four nucleotides are added to the template DNA, with each base tagged with a unique fluorescent label and a reversibly-blocked 3' end. The blocked end assures that only one phosphodiester linkage will form. Once the nucleotide is incorporated into the growing strand, it is identified by its fluorescent tag, the blocking agent is removed, and the process is repeated.

In *pyrosequencing*, nucleotides are added to the template DNA, one at a time in a defined order. One of the nucleotides will be incorporated into the growing strand, releasing a pyrophosphate which is detected by coupling

**FIGURE 5.27 Detection methods in next-generation sequencing.** Measurement of base incorporation in next-generation sequencing methods relies on the detection of the various products of the DNA polymerase reaction. Reversible terminator sequencing measures the nucleotide incorporation in a manner similar to Sanger sequencing, while pyrosequencing and ion semiconductor sequencing detect the release of pyrophosphate and protons, respectively.

the formation of pyrophosphate with the production of light by the sequential action of the enzymes ATP sulfurylase and luciferase:

The protocol for *ion semiconductor sequencing* is similar to pyrosequencing except that nucleotide incorporation is detected by sensitively measuring the very small changes in pH of the reaction mixture due to the release of proton upon nucleotide incorporation.

Regardless of the sequencing method, the technology exists to quantify the signal produced by millions of DNA fragment templates simultaneously. However, for many approaches, as few as 50 bases are read per fragment. Hence, significant computing power is required to both store the massive amounts of sequence data and perform the necessary alignments required to assemble a completed sequence. NGS methods are being used to answer an ever-growing number of questions in genomics, transcriptomics, and evolutionary biology, to name a few. Additionally, individual genome sequences will provide information about genetic variation within populations and may usher in an era of personalized medicine, when these data can be used to guide treatment decisions.

### Comparative genomics has become a powerful research tool

Comparisons with genomes from other organisms are sources of insight into the human genome. The sequencing of the genome of the chimpanzee, our closest living relative, as well as that of other mammals that are widely used in biological research, such as the mouse and the rat, have been completed. Comparisons reveal that an astonishing 99% of human genes have counterparts in these rodent genomes. However, these genes have been substantially reassorted among chromosomes in the estimated 75 million years of evolution since humans and rodents had a common ancestor (Figure 5.28).

**FIGURE 5.28 Genome comparison.** A schematic comparison of the human genome and the mouse genome shows reassortment of large chromosomal fragments. The small numbers to the right of the mouse chromosomes indicate the human chromosome to which each region is most closely related.

The genomes of other organisms also have been determined specifically for use in comparative genomics. For example, the genomes of two species of puffer fish, *Takifugu rubripes* and *Tetraodon nigroviridis*, have been determined. These genomes were selected because they are very small and lack much of the intergenic DNA present in such abundance in the human genome. The puffer fish genomes include fewer than 400 megabase pairs (Mbp), one-eighth of the number in the human genome, yet the puffer fish and human genomes contain essentially the same number of genes. Comparison of the genomes of these species with that of humans revealed more than 1000 formerly unrecognized human genes. Furthermore, comparison of the two species of puffer fish, which had a common ancestor approximately 25 million years ago, is a source of insight into more-recent events in evolution. Comparative genomics is a powerful tool, both for interpreting the human genome and for understanding major events in the origin of genera and species.

## 5.4 Eukaryotic Genes Can Be Quantitated and Manipulated with Considerable Precision

After a gene of interest has been identified, cloned, and sequenced, it is often desirable to understand how that gene and its corresponding protein product function in the context of a whole cell or organism. It is now possible to determine how the expression of a particular gene is regulated, how mutations in the gene affect the function of the corresponding protein product, and how the behavior of an entire cell or model organism is altered by the introduction of mutations within specific genes. Levels of transcription of large families of genes within cells and tissues can be readily quantitated and compared across a range of environmental conditions. Eukaryotic genes can be introduced into bacteria, and the bacteria can be used as factories to produce a desired protein product. DNA can also be introduced into the cells of higher organisms. Genes introduced into animals are valuable tools for examining gene action, and they are the basis of gene therapy. Genes introduced into plants can make the plants resistant to pests, able to grow in harsh conditions, or carry greater quantities of essential nutrients. The manipulation of eukaryotic genes holds much promise as a source of medical and agricultural benefits.

### Gene-expression levels can be comprehensively examined

Most genes are present in the same quantity in every cell—namely, one copy per haploid cell or two copies per diploid cell. However, the level at which a gene is expressed, as indicated by mRNA quantities, can vary widely, ranging from no expression to hundreds of mRNA copies per cell. Gene-expression patterns vary from cell type to cell type, distinguishing, for example, a muscle cell from a nerve cell. Even within the same cell, gene-expression levels may vary as the cell responds to changes in physiological circumstances. Note that mRNA levels sometimes correlate with the levels of proteins expressed, but this correlation does not always hold. Thus, care must be exercised when interpreting the results of mRNA levels alone.

The quantity of individual mRNA transcripts can be determined by *quantitative PCR* (qPCR), or real-time PCR. RNA is first isolated from the cell or tissue of interest. With the use of reverse transcriptase, cDNA is prepared from this RNA sample. In one qPCR approach, the transcript of interest is PCR amplified with the appropriate primers in the presence of the dye SYBR Green I, which fluoresces brightly when bound to

**FIGURE 5.29 Quantitative PCR.** (A) In qPCR, fluorescence is monitored in the course of PCR amplification to determine  $C_T$ , the cycle at which this signal exceeds a defined threshold. Each color represents a different starting quantity of DNA. (B)  $C_T$  values are inversely proportional to the number of copies of the original cDNA template. [Data from N. J. Walker, *Science* 296:557–559, 2002.]

double-stranded DNA. In the initial PCR cycles, not enough duplex is present to allow a detectable fluorescence signal. However, after repeated PCR cycles, the fluorescence intensity exceeds the detection threshold and continues to rise as the number of duplexes corresponding to the transcript of interest increases (Figure 5.29). Importantly, the cycle number at which the fluorescence becomes detectable over a defined threshold (or  $C_T$ ) is indirectly proportional to the number of copies of the original template. After the relation between the original copy number and the  $C_T$  has been established with the use of a known standard, subsequent qPCR experiments can be used to determine the number of copies of any desired transcript in the original sample, provided the appropriate primers are available.

Although qPCR is a powerful technique for quantitation of a small number of transcripts in any given experiment, we can now use our knowledge of complete genome sequences to investigate an entire *transcriptome*, the pattern and level of expression of all genes in a particular cell or tissue. One of the most powerful methods for this purpose is based on hybridization. Single-stranded oligonucleotides whose sequences correspond to coding regions of the genome are affixed to a solid support such as a microscope slide, creating a *DNA microarray*. Importantly, the position of each sequence within the array is known. mRNA is isolated from the cells of interest (a tumor, for example) as well as a control sample (Figure 5.30). From this mRNA, cDNA is prepared (Section 5.2) in the presence of fluorescent nucleotides using different labels, usually green and red, for the two samples. The samples are combined, separated into single strands, and hybridized to the slide. The relative levels of green and red fluorescence at each

**FIGURE 5.30 Using DNA microarrays to measure gene expression changes in a tumor.** mRNA is isolated from two samples, tumor cells and a control sample. From these transcripts, cDNA is prepared in the presence of a fluorescent nucleotide, with a red label for the tumor sample and a green label for the control sample. The cDNA strands are separated, hybridized to the microarray, and the unbound DNA is washed away. Spots that are red indicate genes which are expressed more highly in the tumor, while the green spots indicate reduced expression relative to control. Spots that are black or yellow indicate comparable expression at either low or high levels, respectively. [Information from D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry* 6th ed. (W. H. Freeman and Company, 2013)]

spot indicate the differences in expression for each gene. DNA chips have been prepared such that thousands of transcript levels can be assessed in a single experiment. Hence, over several arrays, the differences in expression of many genes across a number of different cell types or conditions can be measured (Figure 5.31).

Microarray analyses can be quite informative in the study of gene-expression changes in diseased mammals compared with their healthy counterparts. As noted earlier, although ALS-causing mutations within the *SOD1* gene had been identified, the mechanism by which the mutant SOD1 protein ultimately leads to motor-neuron loss remains a mystery. Many research groups have used microarray analysis of neuronal cells isolated from humans and mice carrying *SOD1* gene mutations to search for clues into the pathways of disease progression and to suggest potential avenues for treatment. These studies have implicated a variety of biochemical pathways, including immunological activation, handling of oxidative stress, and protein degradation, in the cellular response to the mutant, toxic forms of SOD1.

### New genes inserted into eukaryotic cells can be efficiently expressed

Bacteria are ideal hosts for the amplification of DNA molecules. They can also serve as factories for the production of a wide range of prokaryotic and eukaryotic proteins. However, bacteria lack the necessary enzymes to carry out posttranslational modifications such as the specific cleavage of polypeptides and the attachment of carbohydrate units. Thus, many eukaryotic genes can be expressed correctly only in eukaryotic host cells. The introduction of recombinant DNA molecules into cells of higher organisms can also be a source of insight into how their genes are organized and expressed. How are genes turned on and off in embryological development? How does a fertilized egg give rise to an organism with highly differentiated cells that are organized in space and time? These central questions of biology can now be fruitfully approached by expressing foreign genes in mammalian cells.

Recombinant DNA molecules can be introduced into animal cells in several ways. In one method, foreign DNA molecules precipitated by calcium phosphate are taken up by animal cells. A small fraction of the imported DNA becomes stably integrated into the chromosomal DNA. The efficiency of incorporation is low, but the method is useful because it is easy to apply. In another method, DNA is *microinjected* into cells. A fine-tipped glass micropipette containing a solution of foreign DNA is inserted into a nucleus (Figure 5.32). A skilled investigator can inject hundreds of cells per hour. About 2% of injected mouse cells are viable and contain the new gene. In a third method, *viruses* are used to introduce new genes into animal cells. The most effective vectors are *retroviruses*, whose genomes are encoded by RNA and replicate through DNA intermediates. A striking feature of the life cycle of a retrovirus is that the double-helical DNA form of its genome, produced by the action of reverse transcriptase, becomes randomly incorporated into host chromosomal DNA. This DNA version of the viral genome, called *proviral DNA*, can be efficiently expressed by the host cell and replicated along with normal cellular DNA. Retroviruses do not usually kill their hosts. Foreign genes have been efficiently introduced into mammalian cells by infecting them with vectors derived from the *Moloney murine leukemia virus*, a retrovirus which can accept inserts as long as 6 kb. Some genes introduced by this vector into the genome of a transformed host cell are efficiently expressed.

**FIGURE 5.31 Gene-expression analysis with the use of microarrays.** The expression levels of thousands of genes can be simultaneously analyzed with DNA microarrays. Here, an analysis of 1733 genes in 84 breast tumor samples reveals that the tumors can be divided into distinct classes based on their gene-expression patterns. In this “heat map” representation, each row represents a different gene and each column represents a different breast tumor sample (i.e., a separate microarray experiment). Red corresponds to gene induction and green corresponds to gene repression. [Data from C. M. Perou et al., *Nature* 406:747–752, 2000.]

**FIGURE 5.32 Microinjection of DNA.** Cloned plasmid DNA is being microinjected into the male pronucleus of a fertilized mouse egg.

Two other viral vectors are extensively used. *Vaccinia virus*, a large DNA-containing virus, replicates in the cytoplasm of mammalian cells, where it shuts down host-cell protein synthesis. *Baculovirus* infects insect cells, which can be conveniently cultured. Insect larvae infected with this virus can serve as efficient protein factories. Vectors based on these large-genome viruses have been engineered to express DNA inserts efficiently.

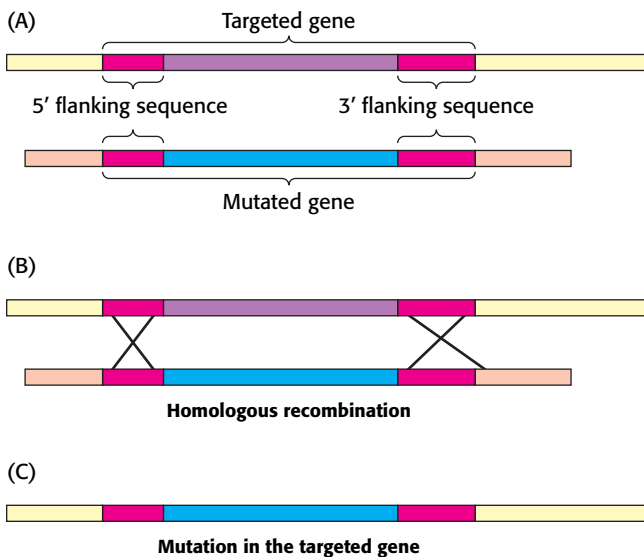

### Transgenic animals harbor and express genes introduced into their germ lines

As shown in Figure 5.32, plasmids harboring foreign genes can be microinjected into the male pronucleus of fertilized mouse eggs, which are then inserted into the uterus of a foster-mother mouse. A subset of the resulting embryos in this host will then harbor the foreign gene; these embryos may develop into mature animals. Southern blotting or PCR analysis of DNA isolated from the progeny can be used to determine which offspring carry the introduced gene. These *transgenic mice* are a powerful means of exploring the role of a specific gene in the development, growth, and behavior of an entire organism. Transgenic animals often serve as useful models for a particular disease process, enabling researchers to test the efficacy and safety of a newly developed therapy.

Let us return to our example of ALS. Research groups have generated transgenic mouse lines that express forms of human superoxide dismutase that harbor mutations matching those identified in earlier genetic analyses. Many of these strains exhibit a clinical picture similar to that observed in ALS patients: progressive weakness of voluntary muscles and eventual paralysis, motor-neuron loss, and rapid progression to death. Since their first characterization in 1994, these strains continue to serve as valuable sources of information for the exploration of the mechanism, and potential treatment, of ALS.

**FIGURE 5.33 Gene disruption by homologous recombination.** (A) A mutated version of the gene to be disrupted is constructed, maintaining some regions of homology with the normal gene (red).

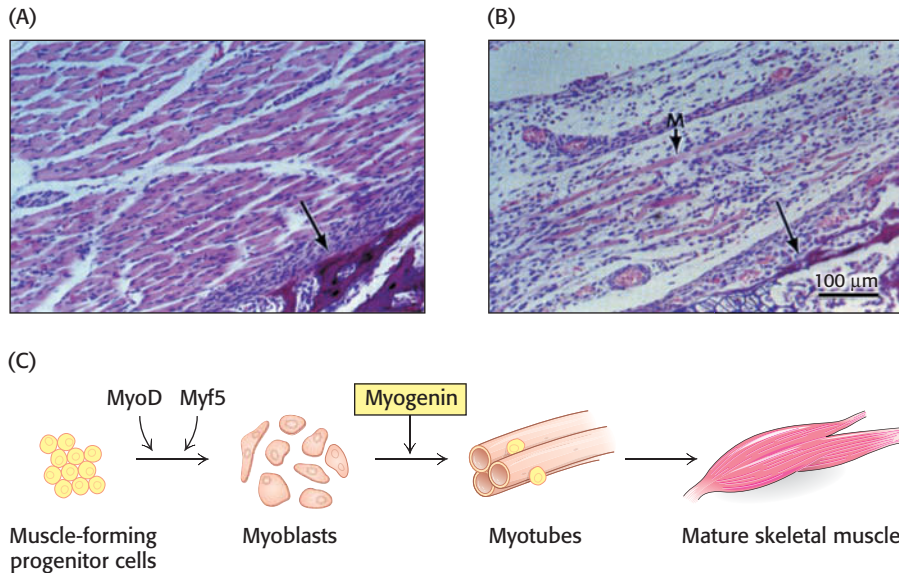

When the foreign mutated gene is introduced into an embryonic stem cell, (B) recombination takes place at regions of homology and (C) the normal (targeted) gene is replaced, or “knocked out,” by the foreign gene. The cell is inserted into embryos, and mice lacking the gene (knockout mice) are produced.

### Gene disruption and genome editing provide clues to gene function and opportunities for new therapies

The function of a gene can also be probed by inactivating it and looking for resulting abnormalities. Powerful methods have been developed for accomplishing *gene disruption* (also called *gene knockout*) in organisms such as yeast and mice. These methods rely on the process of *homologous recombination* (Section 28.5), in which two DNA molecules with strong sequence similarity exchange segments. If a region of foreign DNA is flanked by sequences that have high homology to a particular region of genomic DNA, two recombination events will yield the transfer of the foreign DNA into the genome (Figure 5.33). In this manner, specific genes can be targeted if their flanking nucleotide sequences are known.

For example, the gene-knockout approach has been applied to the genes encoding gene-regulatory proteins (also called *transcription factors*) that control the differentiation of muscle cells. When both copies of the gene for the regulatory protein *myogenin* are disrupted, an animal dies at birth because it lacks functional skeletal muscle. Microscopic inspection reveals that the tissues from which muscle normally forms contain precursor cells that have failed to differentiate fully (Figure 5.34A and B). Heterozygous mice containing one normal *myogenin* gene and one disrupted gene appear normal, suggesting that a reduced level of gene expression is still sufficient for normal muscle development. The generation and characterization of this knockout strain provided strong evidence that functional *myogenin* is essential for proper development of skeletal muscle tissue.

**FIGURE 5.34 Consequences of gene disruption.** Sections of muscle from normal (A) and myogenin-knockout (B) mice, as viewed under the light microscope. The unlabeled arrows in both panels identify comparable sections of the pelvic bone, indicating that similar anatomical regions are depicted. Muscles do not develop properly in mice having both myogenin genes disrupted. A poorly formed muscle fiber in the knockout strain is indicated by the M arrow. (C) The development of mature skeletal muscle from progenitor cells is a highly regulated process involving a number of intermediate cell types and multiple transcription factors. Through the gene-disruption studies in (A) and (B), myogenin was identified as an essential component of this pathway. [(A) and (B) From P. Hasty, et al., *Nature* 364:501–506, 1993; (C) Information from S. Hettmer and A. J. Wagers, *Nat. Med.* 16:171–173, 2010, Fig. 1]

(Figure 5.34C). Analogous studies have probed the function of many other genes to generate animal models for known human genetic diseases.

Manipulation of genomic DNA using homologous recombination, while a powerful tool, has limitations. Introduction of point mutations into genes, rather than knocking out the entire gene, can be difficult and time-consuming. In addition, these methods are generally limited to specific model organisms, such as yeast, mice, and fruit flies. Over the past 10 years, new methods for the highly specific modification of genomic DNA, or *genome editing*, have emerged. These approaches rely on engineered site-specific nucleases that introduce double-strand breaks at precisely-determined sequences within genomic DNA. In one approach, the nonspecific nuclease domain of the restriction enzyme FokI is fused to a DNA-binding domain designed to bind to a particular DNA sequence. In *zinc-finger nucleases* (ZFNs), the DNA-binding domain contains a series of zinc finger domains (Section 32.2), small zinc-binding motifs that each recognize a sequence of three base pairs. The preferred DNA binding sequence can be altered by changing the identity of only four contact residues within each finger. In *transcription activator-like effector nucleases* (TALENs), the DNA-binding domain is comprised of an array of TALE repeats. Each repeat contains 34 amino acids and two  $\alpha$ -helices, yet only two of these residues (at positions 12 and 13) are responsible for the unique recognition of a single nucleotide within the double helix (Figure 5.35). Mutation of these residues within an array of repeats enables the recognition of a vast number of possible DNA target sequences with a high degree of specificity.

How do these engineered nucleases effect a change in the genomic DNA sequence? Upon binding of the ZFN or

**FIGURE 5.35 TALE repeats recognize individual bases in DNA.** Each TALE repeat contains 34 amino acids, two of which specify its nucleotide binding partner. In this figure, the identity of these residues is indicated by the color of the repeat. TALE proteins can be designed to uniquely recognize extended oligonucleotide sequences. In this example, a 22 base-pair sequence is bound by a single TALE protein, the bacterial effector PthXo1. [Drawn from 3UGM.pdb]

**FIGURE 5.36 Genome editing by site-specific nucleases.** A pair of ZFNs or TALENs cleave opposite strands of a targeted gene (blue) within the genome. The DNA repair machinery of the cell will use a homologous donor template DNA fragment to fix the double-strand break, incorporating the desired modifications (green) into the targeted gene.

**FIGURE 5.37 RNA interference mechanism.** A double-stranded RNA molecule is cleaved into 21-bp fragments by the enzyme Dicer to produce siRNAs. These siRNAs are incorporated into the RNA-induced silencing complex (RISC), where the single-stranded RNAs guide the cleavage of mRNAs that contain complementary sequences.

TALEN to DNA, the nuclease domain cleaves the phosphate backbone of one of the DNA strands. A second nuclease, designed to recognize the opposite strand, introduces a second cleavage site, yielding a complete double-strand break. The resulting cleavage site is repaired by the DNA repair machinery of the host cell (Section 28.5). If a DNA fragment containing the desired sequence change is simultaneously introduced with the nucleases, the repair machinery will use this donor template to introduce these changes directly into the genomic sequence, in a manner similar to the homologous recombination process described above (Figure 5.36).

Site-specific nuclease-based genome editing methods have now been applied to a variety of species, including model organisms used in the laboratory (rat, zebrafish, and fruit fly), various forms of livestock (pig, cow), and a number of plants. In addition, their use as therapeutic tools in humans is currently under investigation. For example, a ZFN which inactivates the human CCR5 gene, a coreceptor for cellular invasion of human immunodeficiency virus (HIV), is currently in clinical trials for the treatment of patients infected with HIV.

### RNA interference provides an additional tool for disrupting gene expression

An extremely powerful tool for disrupting gene expression was serendipitously discovered in the course of studies that required the introduction of RNA into a cell. The introduction of a specific double-stranded RNA molecule into a cell was found to suppress the transcription of genes that contained sequences present in the double-stranded RNA molecule. Thus, the introduction of a specific RNA molecule can interfere with the expression of a specific gene.

The mechanism of *RNA interference* has been largely established (Figure 5.37). When a double-stranded RNA molecule is introduced into an appropriate cell, the RNA is cleaved by the enzyme Dicer into fragments approximately 21 nucleotides in length. Each fragment, termed a small interfering RNA (siRNA), consists of 19 bp of double-stranded RNA and 2 bases of unpaired RNA on each 5' end. The siRNA is loaded into an assembly of several proteins referred to as the *RNA-induced silencing complex* (RISC), which unwinds the RNA duplex and cleaves one of the strands, the so-called *passenger strand*. The uncleaved single-stranded RNA segment, the *guide strand*, remains

incorporated into the enzyme. The fully assembled RISC cleaves mRNA molecules that contain exact complements of the guide-strand sequence. Thus, levels of such mRNA molecules are dramatically reduced. The technique of RNA interference is called *gene knockdown*, because the expression of the gene is reduced but not eliminated, as is the case with gene knockouts.

The machinery necessary for RNA interference is found in many cells. In some organisms such as *C. elegans*, RNA interference is quite efficient. Indeed, RNA interference can be induced simply by feeding *C. elegans* strains of *E. coli* that have been engineered to produce appropriate double-stranded RNA molecules. Although not as efficient in mammalian cells, RNA interference has emerged as a powerful research tool for reducing the expression of specific genes. Moreover, initial clinical trials of therapies based on RNA interference are underway.

### Tumor-inducing plasmids can be used to introduce new genes into plant cells

The common soil bacterium *Agrobacterium tumefaciens* infects plants and introduces foreign genes into plant cells (Figure 5.38). A lump of tumor tissue called a *crown gall* grows at the site of infection. Crown galls synthesize opines, a group of amino acid derivatives that are metabolized by the infecting bacteria. In essence, the metabolism of the plant cell is diverted to satisfy the highly distinctive appetite of the intruder. *Tumor-inducing plasmids* (Ti plasmids) that are carried by *A. tumefaciens* carry instructions for the switch to the tumor state and the synthesis of opines. A small part of the Ti plasmid becomes integrated into the genome of infected plant cells; this 20-kb segment is called *T-DNA* (transferred DNA; Figure 5.39).

Ti-plasmid derivatives can be used as vectors to deliver foreign genes into plant cells. First, a segment of foreign DNA is inserted into the T-DNA region of a small plasmid through the use of restriction enzymes and ligases. This synthetic plasmid is added to *A. tumefaciens* colonies harboring naturally occurring Ti plasmids. By recombination, Ti plasmids containing the foreign gene are formed. These Ti vectors hold great promise as tools for exploring the genomes of plant cells and modifying plants to improve their agricultural value and crop yield. However, they are not suitable for transforming all types of plants. Ti-plasmid transfer is effective with dicots (broad-leaved plants such as grapes) and a few kinds of monocots but not as effective with economically important cereal monocots.

Foreign DNA can be introduced into cereal monocots as well as dicots by applying intense electric fields, a technique called *electroporation* (Figure 5.40). First, the cellulose wall surrounding plant cells is removed by adding cellulase; this treatment produces *protoplasts*, plant cells with exposed plasma membranes. Electric pulses are then applied to a suspension of protoplasts and plasmid DNA. Because high electric fields make membranes transiently permeable to large molecules, plasmid DNA molecules enter the cells. The cell wall is then allowed to reform, and the plant cells are again viable. Maize cells and carrot cells have been stably transformed in this way with the use of plasmid DNA that includes genes for resistance to herbicides. Moreover, the transformed cells efficiently express the plasmid DNA. Electroporation is also an effective means of delivering foreign DNA into animal cells and bacterial cells.

The most effective means of transforming plant cells is through the use of “gene guns,” or *bombardment-mediated transformation*. DNA is coated onto 1- $\mu\text{m}$ -diameter tungsten pellets, and these microprojectiles are fired at the target cells with a velocity greater than 400  $\text{m s}^{-1}$ . Despite its apparent crudeness, this technique is proving to be the most effective way of transforming

**FIGURE 5.38 Tumors in plants.** Crown gall, a plant tumor, is caused by a bacterium (*Agrobacterium tumefaciens*) that carries a tumor-inducing plasmid (Ti plasmid). [From M. Escobar et al., *Proc. Natl. Acad. Sci. U. S. A.* 98:13437–13442, 2001. Copyright © 2001 National Academy of Sciences, U. S. A.]

**FIGURE 5.39 Ti plasmids.** *Agrobacteria* containing Ti plasmids can deliver foreign genes into some plant cells. [Information from M. Chilton. A vector for introducing new genes into plants. Copyright © 1983 by Scientific American, Inc. All rights reserved.]

**FIGURE 5.40 Electroporation.** Foreign DNA can be introduced into plant cells by electroporation, the application of intense electric fields to make their plasma membranes transiently permeable.

plants, especially important crop species such as soybean, corn, wheat, and rice. The gene-gun technique affords an opportunity to develop genetically modified organisms (GMOs) with beneficial characteristics, such as the ability to grow in poor soils, resistance to natural climatic variation, resistance to pests, and the ability to fortify nutritional content. These crops might be most useful in developing countries. However, the use of GMOs is highly controversial, as some fear that their safety risks have not been adequately addressed.

The first GMO to come to market was a tomato characterized by delayed ripening, rendering it ideal for shipment. Pectin is a polysaccharide that gives tomatoes their firmness and is naturally destroyed by the enzyme *polygalacturonase*. As pectin is destroyed, the tomatoes soften, making shipment difficult. DNA was introduced that disrupts the polygalacturonase gene. Less of the enzyme was produced, and the tomatoes stayed fresh longer. However, the tomato's poor taste hindered its commercial success. An especially successful result of the use of Ti plasmid to modify crops is golden rice. Golden rice is a variety of genetically modified rice that contains the genes for  $\beta$ -carotene synthesis, a required precursor for vitamin A synthesis in humans. Consumption of this rice will benefit children and pregnant woman in parts of the world where rice is a dietary staple and vitamin A deficiency is common.

### Human gene therapy holds great promise for medicine

 The field of *gene therapy* attempts to express specific genes within the human body in such a way that beneficial results are obtained. The gene targeted for expression may be already present or specially introduced. Alternatively, gene therapy may attempt to modify genes containing sequence variations that have harmful consequences. A tremendous amount of research remains to be done before gene therapy becomes practical. Nonetheless, considerable progress has been made. For example, some people lack functional genes for *adenosine deaminase* and succumb to infections if exposed to a normal environment, a condition called *severe combined immunodeficiency* (SCID). Functional genes for this enzyme have been introduced by using gene-therapy vectors based on retroviruses. Although these vectors have produced functional enzymes and reduced the clinical symptoms, challenges remain. These challenges include increasing the longevity of the effects and eliminating unwanted side effects. Future research promises to transform gene therapy into an important tool for clinical medicine.

## SUMMARY

### 5.1 The Exploration of Genes Relies on Key Tools

The recombinant DNA revolution in biology is rooted in the repertoire of enzymes that act on nucleic acids. Restriction enzymes are a key group among them. These endonucleases recognize specific base sequences in double-helical DNA and cleave both strands of the duplex, forming specific fragments of DNA. These restriction fragments can be separated and displayed by gel electrophoresis. The pattern of these fragments on the gel is a fingerprint of a DNA molecule. A DNA fragment containing a particular sequence can be identified by hybridizing it with a labeled single-stranded DNA probe (Southern blotting).

Rapid sequencing techniques have been developed to further the analysis of DNA molecules. DNA can be sequenced by controlled

interruption of replication. The fragments produced are separated by gel electrophoresis and visualized by autoradiography of a  $^{32}\text{P}$  label at the 5' end or by fluorescent tags.

DNA probes for hybridization reactions, as well as new genes, can be synthesized by the automated solid-phase method. DNA chains as long as 100 nucleotides can be readily synthesized. The polymerase chain reaction makes it possible to greatly amplify specific segments of DNA in vitro. The region amplified is determined by the placement of a pair of primers that are added to the target DNA along with a thermostable DNA polymerase and deoxyribonucleoside triphosphates. The exquisite sensitivity of PCR makes it a choice technique in detecting pathogens and cancer markers, in genotyping, and in amplifying DNA from fossils that are many thousands of years old.

### 5.2 Recombinant DNA Technology Has Revolutionized All Aspects of Biology

New genes can be constructed in the laboratory, introduced into host cells, and expressed. Novel DNA molecules are made by joining fragments that have complementary cohesive ends produced by the action of a restriction enzyme. DNA ligase seals breaks in DNA chains. Vectors for propagating the DNA include plasmids,  $\lambda$  phage, and bacterial and yeast artificial chromosomes. Specific genes can be cloned from a genomic library with the use of a DNA or RNA probe. Foreign DNA can be expressed after insertion into prokaryotic and eukaryotic cells by the appropriate vector. Specific mutations can be generated in vitro to engineer novel proteins. A mutant protein with a single amino acid substitution can be produced by priming DNA replication with an oligonucleotide encoding the new amino acid. Plasmids can be engineered to permit the facile insertion of a DNA cassette containing any desired mutation. The techniques of protein and nucleic acid chemistry are highly synergistic. Investigators now move back and forth between gene and protein with great facility.

### 5.3 Complete Genomes Have Been Sequenced and Analyzed

The sequences of many important genomes are known in their entirety. More than 10,000 bacterial and archaeal genomes have been sequenced, including those from key model organisms and important pathogens. The sequence of the human genome has now been completed with nearly full coverage and high precision. Only from 20,000 to 25,000 protein-encoding genes appear to be present in the human genome, a substantially smaller number than earlier estimates. Comparative genomics has become a powerful tool for analyzing individual genomes and for exploring evolution. Genomewide gene-expression patterns can be examined through the use of DNA microarrays.

### 5.4 Eukaryotic Genes Can Be Quantitated and Manipulated with Considerable Precision

Changes in gene expression can be readily determined by such techniques as quantitative PCR and hybridization to microarrays. The production of transgenic mice carrying mutations known to cause ALS in humans has been a source of considerable insight into the disease mechanism and its possible treatment. The functions of particular genes can be investigated by disruption. One method of disrupting the expression of a particular gene is through RNA interference, which depends on the introduction of specific double-stranded RNA molecules into eukaryotic cells. New DNA can be brought into plant cells by the soil bacterium *Agrobacterium tumefaciens*, which harbors Ti

plasmids. DNA can also be introduced into plant cells by applying intense electric fields, which render them transiently permeable to very large molecules, or by bombarding them with DNA-coated microparticles. Gene therapy holds great promise for clinical medicine, but many challenges remain.

## PROBLEMS

1. *It's not the heat . . .* Why is *Taq* polymerase especially useful for PCR?
2. *The right template.* Ovalbumin is the major protein of egg white. The chicken ovalbumin gene contains eight exons separated by seven introns. Should ovalbumin cDNA or ovalbumin genomic DNA be used to form the protein in *E. coli*? Why?
3. *Handle with care.* Ethidium bromide is a commonly used stain for DNA molecules after separation by gel electrophoresis. The chemical structure of ethidium bromide is shown here. Based on this structure, suggest how this stain binds to DNA.

4. *Cleavage frequency.* The restriction enzyme *AluI* cleaves at the sequence 5'-AGCT-3', and *NotI* cleaves at 5'-GCGGCCGC-3'. What would be the average distance between cleavage sites for each enzyme on digestion of double-stranded DNA? Assume that the DNA contains equal proportions of A, G, C, and T.
5. *The right cuts.* Suppose that a human genomic library is prepared by exhaustive digestion of human DNA with the *EcoRI* restriction enzyme. Fragments averaging about 4 kb in length would be generated. Is this procedure suitable for cloning large genes? Why or why not?
6. *A revealing cleavage.* Sickle-cell anemia arises from a mutation in the gene for the  $\beta$  chain of human hemoglobin. The change from GAG to GTG in the mutant eliminates a cleavage site for the restriction enzyme *MstII*, which recognizes the target sequence CCTGAGG. These findings form the basis of a diagnostic test for the sickle-cell gene. Propose a rapid procedure for distinguishing between the normal and the mutant gene. Would a positive result prove that the mutant contains GTG in place of GAG?
7. *Sticky ends?* The restriction enzymes *KpnI* and *Acc65I* recognize and cleave the same 6-bp sequence. However, the sticky end formed from *KpnI* cleavage cannot

be ligated directly to the sticky end formed from Acc65I cleavage. Explain why.

8. *Many melodies from one cassette.* Suppose that you have isolated an enzyme that digests paper pulp and have obtained its cDNA. The goal is to produce a mutant that is effective at high temperature. You have engineered a pair of unique restriction sites in the cDNA that flank a 30-bp coding region. Propose a rapid technique for generating many different mutations in this region.

9. *A blessing and a curse.* The power of PCR can also create problems. Suppose someone claims to have isolated dinosaur DNA by using PCR. What questions might you ask to determine if it is indeed dinosaur DNA?

10. *Rich or poor?* DNA sequences that are highly enriched in G–C base pairs typically have high melting temperatures. Moreover, once separated, single strands containing these regions can form rigid secondary structures. How might the presence of G–C-rich regions in a DNA template affect PCR amplification?

11. *Questions of accuracy.* The stringency of PCR amplification can be controlled by altering the temperature at which the primers and the target DNA undergo hybridization. How would altering the temperature of hybridization affect the amplification? Suppose that you have a particular yeast gene *A* and that you wish to see if it has a counterpart in humans. How would controlling the stringency of the hybridization help you?

12. *Terra incognita.* PCR is typically used to amplify DNA that lies between two known sequences. Suppose that you want to explore DNA on both sides of a single known sequence. Devise a variation of the usual PCR protocol that would enable you to amplify entirely new genomic terrain.

13. *A puzzling ladder.* A gel pattern displaying PCR products shows four strong bands. The four pieces of DNA have lengths that are approximately in the ratio of 1 : 2 : 3 : 4. The largest band is cut out of the gel, and PCR is repeated with the same primers. Again, a ladder of four bands is evident in the gel. What does this result reveal about the structure of the encoded protein?

14. *Chromosome walking.* Propose a method for isolating a DNA fragment that is adjacent in the genome to a previously isolated DNA fragment. Assume that you have access to a complete library of DNA fragments in a BAC vector

but that the sequence of the genome under study has not yet been determined.

15. *Probe design.* Which of the following amino acid sequences would yield the most optimal oligonucleotide probe?

Ala–Met–Ser–Leu–Pro–Trp  
 Gly–Trp–Asp–Met–His–Lys  
 Cys–Val–Trp–Asn–Lys–Ile  
 Arg–Ser–Met–Leu–Gln–Asn

16. *Man's best friend.* Why might the genomic analysis of dogs be particularly useful for investigating the genes responsible for body size and other physical characteristics?

17. *Of mice and men.* You have identified a gene that is located on human chromosome 20 and wish to identify its location within the mouse genome. On which chromosome would you be most likely to find the mouse counterpart of this gene?

### Chapter Integration Problems

18. *Designing primers I.* A successful PCR experiment often depends on designing the correct primers. In particular, the  $T_m$  for each primer should be approximately the same. What is the basis of this requirement?

19. *Designing primers II.* You wish to amplify a segment of DNA from a plasmid template by PCR with the use of the following primers: 5'-GGATCGATGCTCGCGA-3' and 5'-AGGATCGGGTTCGCGAG-3'. Despite repeated attempts, you fail to observe a PCR product of the expected length after electrophoresis on an agarose gel. Instead, you observe a bright smear on the gel with an approximate length of 25 to 30 base pairs. Explain these results.

### Chapter Integration and Data Interpretation Problem

20. *Any direction but east.* A series of people are found to have difficulty eliminating certain types of drugs from their bloodstreams. The problem has been linked to a gene *X*, which encodes an enzyme *Y*. Six people were tested with the use of various techniques of molecular biology. Person *A* is a normal control, person *B* is asymptomatic but some of his children have the metabolic problem, and persons *C* through *F* display the trait. Tissue samples from each person were obtained. Southern analysis was performed on the DNA after digestion with the restriction enzyme *Hind*III. Northern analysis of mRNA also was done. In both types of analysis, the gels were probed with labeled *X* cDNA. Finally, a western blot with an enzyme-linked monoclonal antibody was used to test for the presence of protein *Y*. The results are shown here. Why is person *B* without symptoms? Suggest possible defects in the other people.

Data Interpretation Problems

21. *DNA diagnostics.* Representations of sequencing chromatograms for variants of the  $\alpha$  chain of human hemoglobin are shown here. What is the nature of the amino acid change in each of the variants? The first triplet encodes valine.

Colors: ddATP, ddCTP, ddGTP, ddTTP

22. *Two peaks.* In the course of studying a gene and its possible mutation in humans, you obtain genomic DNA samples from a collection of persons and PCR amplify a region of interest within this gene. For one of the samples, you obtain the sequencing chromatogram shown here. Provide an explanation for the appearance of these data at position 49 (indicated by the arrow):

## Exploring Evolution and Bioinformatics

Evolutionary relationships are manifest in protein sequences. The close kinship between human beings and chimpanzees, hinted at by the mutual interest shown by Jane Goodall and a chimpanzee in the photograph, is revealed in the amino acid sequences of myoglobin. The human sequence (red) differs from the chimpanzee sequence (blue) in only one amino acid in a protein chain of 153 residues. [(Left) Kennan Ward/Corbis.]

Like members of a human family, members of molecular families often have features in common. Such family resemblance is most easily detected by comparing three-dimensional structure, the aspect of a molecule most closely linked to function. Consider as an example ribonuclease from cows, which was introduced in our consideration of protein folding (Section 2.6). Comparing structures reveals that the three-dimensional structure of this protein and that of a human ribonuclease are quite similar (Figure 6.1). Although the degree of overlap between these two structures is not unexpected, given their nearly identical biological functions, similarities revealed by other such comparisons are sometimes surprising. For example, angiogenin, a protein that stimulates the growth of new blood vessels, is also structurally similar to ribonuclease—so similar that both angiogenin and ribonuclease are clearly members of the same protein family (Figure 6.2). Angiogenin and ribonuclease must have had a common ancestor at some earlier stage of evolution.

Three-dimensional structures have been determined for only a small proportion of the total number of proteins. In contrast, gene sequences and the corresponding amino acid sequences are available for a great number of proteins, largely owing to the tremendous power of DNA cloning and sequencing techniques, including applications to complete-genome sequencing (Chapter 5). Evolutionary relationships also are manifest in amino acid sequences. For example, 35% of the amino acids in corresponding positions are identical in the sequences of bovine ribonuclease and angiogenin. Is this level sufficiently

## OUTLINE

high to ensure an evolutionary relationship? If not, what level is required? In this chapter, we shall examine the methods that are used to compare amino acid sequences and to deduce such evolutionary relationships.

*Sequence-comparison methods are powerful tools in modern biochemistry.* Sequence databases can be probed for matches to a newly elucidated sequence to identify related molecules. This information can often be a source of considerable insight into the function and mechanism of the newly sequenced molecule. When three-dimensional structures are available, they can be compared to confirm relationships suggested by sequence comparisons and to reveal others that are not readily detected at the level of sequence alone.

By examining the footprints present in modern protein sequences, the biochemist can learn about events in the evolutionary past. Sequence comparisons can often reveal pathways of evolutionary descent and estimated dates of specific evolutionary landmarks. This information can be used to construct evolutionary trees that trace the evolution of a particular protein or nucleic acid, in many cases from Archaea and Bacteria through Eukarya, including human beings. Molecular evolution can also be studied experimentally. In some cases, DNA from fossils can be amplified by PCR methods and sequenced, giving a direct view into the past. In addition, investigators can observe molecular evolution taking place in the laboratory, through experiments based on nucleic acid replication. The results of such studies are revealing more about how evolution proceeds.

## 6.1 Homologs Are Descended from a Common Ancestor

The exploration of biochemical evolution consists largely of an attempt to determine how proteins, other molecules, and biochemical pathways have been transformed through time. The most fundamental relationship between two entities is *homology*; two molecules are said to be *homologous* if they have been derived from a common ancestor. Homologous molecules, or *homologs*, can be divided into two classes (Figure 6.3). *Paralogs* are homologs that are present within one species. Paralogs often differ in their detailed biochemical functions. *Orthologs* are homologs that are present within different species and have very similar or identical functions. Understanding the homology between molecules can reveal the evolutionary history of the molecules as well as information about their function; if a newly sequenced protein is homologous to an already characterized protein, we have a strong indication of the new protein's biochemical function.

How can we tell whether two human proteins are paralogs or whether a yeast protein is the ortholog of a human protein? As will be discussed in Section 6.2, *homology is often detectable by significant similarity in nucleotide or amino acid sequence and almost always manifested in three-dimensional structure.*

## 6.2 Statistical Analysis of Sequence Alignments Can Detect Homology

A significant sequence similarity between two molecules implies that they are likely to have the same evolutionary origin and, therefore, similar three-dimensional structures, functions, and mechanisms. Both nucleic acid and protein sequences can be compared to detect homology. However, the possibility exists that the observed agreement between any two sequences is solely a product of chance. Because nucleic acids are composed of fewer building blocks than proteins (4 bases versus 20 amino acids), the likelihood of random agreement between two DNA or RNA sequences is significantly greater than that for protein sequences. For this reason, detection of homology between protein sequences is typically far more effective.

To illustrate sequence-comparison methods, let us consider a class of proteins called the *globins*. Myoglobin is a protein that binds oxygen in muscle, whereas hemoglobin is the oxygen-carrying protein in blood (Chapter 7). Both proteins cradle a heme group, an iron-containing organic molecule that binds the oxygen. Each human hemoglobin molecule is composed of four heme-containing polypeptide chains, two identical  $\alpha$  chains and two identical  $\beta$  chains. Here, we shall consider only the  $\alpha$  chain. To examine the similarity between the amino acid sequence of the human  $\alpha$  chain and that of human myoglobin (Figure 6.4), we apply a method, referred to as a *sequence alignment*, in which the two sequences are systematically aligned with respect to each other to identify regions of significant overlap.

**FIGURE 6.4 Amino acid sequences of human hemoglobin ( $\alpha$  chain) and human myoglobin.**  $\alpha$ -Hemoglobin is composed of 141 amino acids; myoglobin consists of 153 amino acids. (One-letter abbreviations designating amino acids are used; see Table 2.2.)

**FIGURE 6.5 Comparing the amino acid sequences of  $\alpha$ -hemoglobin and myoglobin.** (A) A comparison is made by sliding the sequences of the two proteins past each other, one amino acid at a time, and counting the number of amino acid identities between the proteins. (B) The two alignments with the largest number of matches are shown above the graph, which plots the matches as a function of alignment.

How can we tell where to align the two sequences? In the course of evolution, the sequences of two proteins that have an ancestor in common will have diverged in a variety of ways. Insertions and deletions may have occurred at the ends of the proteins or within the functional domains themselves. Individual amino acids may have been mutated to other residues of varying degrees of similarity. To understand how the methods of sequence alignment take these potential sequence variations into account, let us first consider the simplest approach, where we slide one sequence past the other, one amino acid at a time, and count the number of matched residues, or *sequence identities* (Figure 6.5). For  $\alpha$ -hemoglobin and myoglobin, the best alignment reveals 23 sequence identities, spread throughout the central parts of the sequences.

However, careful examination of all the possible alignments and their scores suggests that important information regarding the relationship between myoglobin and hemoglobin  $\alpha$  has been lost with this method. In particular, we see that another alignment, featuring 22 identities, is nearly as good. This alignment is shifted by six residues relative to the preceding alignment and yields identities that are concentrated toward the amino-terminal end of the sequences. By introducing a *gap* into one of the sequences, the identities found in *both* alignments will be represented (Figure 6.6). Insertion of gaps allows the alignment method to compensate for the insertions or deletions of nucleotides that may have taken place in the gene for one molecule but not the other in the course of evolution.

$$\begin{array}{r}
 38 \text{ identities: } 38 \times (+10) = 380 \\
 1 \text{ gap: } 1 \times (-25) = -25 \\
 \hline
 355
 \end{array}$$

**FIGURE 6.6 Alignment with gap insertion.**

The alignment of  $\alpha$ -hemoglobin and myoglobin after a gap has been inserted into the hemoglobin  $\alpha$  sequence.

The use of gaps substantially increases the complexity of sequence alignment because a vast number of possible gaps, varying in both position and length, must be considered throughout each sequence. Moreover, the introduction of an excessive number of gaps can yield an artificially high number of identities. Nevertheless, methods have been developed for the insertion of gaps in the automatic alignment of sequences. These methods use scoring systems to compare different alignments, including penalties for gaps to prevent the insertion of an unreasonable number of them. For example, in one scoring system, each identity between aligned sequences is counted as +10 points, whereas each gap introduced, regardless of size, counts for -25 points. For the alignment shown in Figure 6.6, there are 38 identities ( $38 \times 10 = 380$ ) and 1 gap ( $1 \times -25 = -25$ ), producing a score of ( $380 + -25 = 355$ ). Overall, there are 38 matched amino acids in an average length of 147 residues; thus, the sequences are 25.9% identical. Next, we must determine the significance of this score and level of identity.

### The statistical significance of alignments can be estimated by shuffling

The similarities in sequence in Figure 6.5 appear striking, yet there remains the possibility that a grouping of sequence identities has occurred by chance alone. Because proteins are composed of the same set of 20 amino acid monomers, the alignment of any two unrelated proteins will yield some identities, particularly if we allow the introduction of gaps. Even if two proteins have identical amino acid composition, they may not be linked by evolution. It is the order of the residues within their sequences that implies a relationship between them. Hence, we can assess the significance of our alignment by “shuffling,” or randomly rearranging, one of the sequences (Figure 6.7), repeating the sequence alignment, and determining a new alignment score. This process is repeated many times to yield a histogram showing, for each possible score, the number of shuffled sequences that received that score (Figure 6.8). If the original score is not appreciably different from the scores from the shuffled alignments, then we cannot exclude the possibility that the original alignment is merely a consequence of chance.

When this procedure is applied to the sequences of myoglobin and  $\alpha$ -hemoglobin, the authentic alignment (indicated by the red bar in Figure 6.8) clearly stands out. Its score is far above the mean for the alignment scores

**FIGURE 6.7 The generation of a shuffled sequence.**

**FIGURE 6.8 Statistical comparison of alignment scores.** Alignment scores are calculated for many shuffled sequences, and the number of sequences generating a particular score is plotted against the score. The resulting plot is a distribution of alignment scores occurring by chance. The alignment score for unshuffled  $\alpha$ -hemoglobin and myoglobin (shown in red) is substantially greater than any of these scores, strongly suggesting that the sequence similarity is significant.

based on shuffled sequences. The probability that such a deviation occurred by chance alone is approximately 1 in  $10^{20}$ . Thus, we can comfortably conclude that the two sequences are genuinely similar; the simplest explanation for this similarity is that these sequences are homologous—that is, the two molecules have descended from a common ancestor.

### Distant evolutionary relationships can be detected through the use of substitution matrices

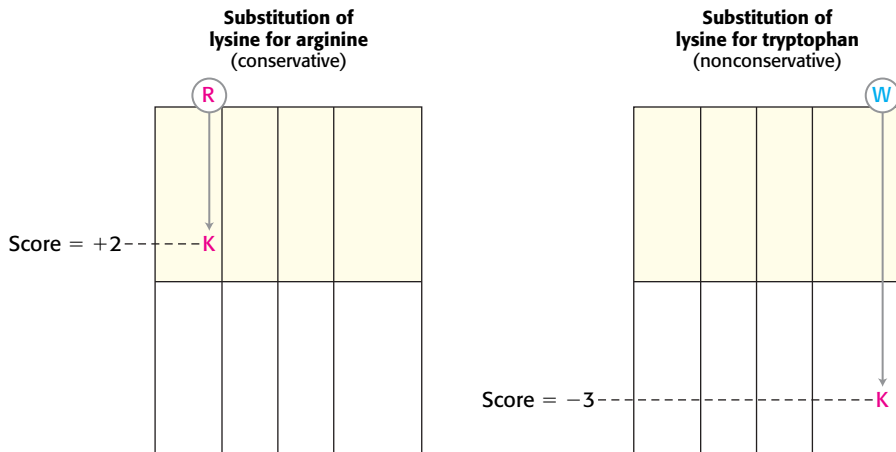

The scoring scheme heretofore described assigns points only to positions occupied by identical amino acids in the two sequences being compared. No credit is given for any pairing that is not an identity. However, as already discussed, two proteins related by evolution undergo amino acid substitutions as they diverge. A scoring system based solely on amino acid identity cannot account for these changes. To add greater sensitivity to the detection of evolutionary relationships, methods have been developed to compare two amino acids and assess their degree of *similarity*.

Not all substitutions are equivalent. For example, amino acid changes can be classified as structurally conservative or nonconservative. A *conservative substitution* replaces one amino acid with another that is similar in size and chemical properties. Conservative substitutions may have only minor effects on protein structure and often can be tolerated without compromising protein function. In contrast, in a *nonconservative substitution*, an amino acid is replaced by one that is structurally dissimilar. Amino acid changes can also be classified by the fewest number of nucleotide changes necessary to achieve the corresponding amino acid change. Some substitutions arise from the replacement of only a single nucleotide in the gene sequence; whereas others require two or three replacements. Conservative and single-nucleotide substitutions are likely to be more common than are substitutions with more radical effects.

How can we account for the type of substitution when comparing sequences? We can approach this problem by first examining the substitutions that have been observed in proteins known to be evolutionarily related. From an examination of appropriately aligned sequences, substitution matrices have been deduced. A *substitution matrix* describes a scoring system for the replacement of any amino acid with each of the other 19 amino acids. In these matrices, a large positive score corresponds to a substitution that occurs relatively frequently, whereas a large negative score corresponds to a substitution that occurs only rarely. A commonly used substitution matrix, the Blosum-62 (for *Blocks of amino acid substitution matrix*), is illustrated in Figure 6.9. In this depiction, each column in this matrix represents one of the 20 amino acids, whereas the position of the single-letter codes within each column specifies the score for the corresponding substitution. Notice that scores corresponding to identity (the boxed codes at the top of each column) are not the same for each residue, owing to the fact that less frequently occurring amino acids such as cysteine (C) and tryptophan (W) will align by chance less often than the more common residues. Furthermore, structurally conservative substitutions such as lysine (K) for arginine (R) and isoleucine (I) for valine (V) have relatively high scores, whereas nonconservative substitutions such as lysine for tryptophan result in negative scores (Figure 6.10). When two sequences are compared, each pair of aligned residues is assigned a score based on the matrix. In addition, gap penalties are often assessed. For example, the introduction of a single-residue gap lowers the alignment score by 12 points and the extension of an existing gap costs 2 points per residue. With the use of this scoring system, the alignment shown in Figure 6.6 receives a score of 115. In many regions, most substitutions are

**FIGURE 6.9 A graphic view of the Blosum-62.** This substitution matrix was derived by examining substitutions within aligned sequence blocks in related proteins. Amino acids are classified into four groups (charged, red; polar, green; large and hydrophobic, blue; other, black). Substitutions that require the change of only a single nucleotide are shaded. Identities are boxed. To find the score for a substitution of, for instance, a Y for an H, you find the Y in the column having H at the top and check the number at the left. In this case, the resulting score is 2.

**FIGURE 6.10 Scoring of conservative and nonconservative substitutions.** The Blosum-62 indicates that a conservative substitution (lysine for arginine) receives a positive score, whereas a nonconservative substitution (lysine for tryptophan) is scored negatively. The matrix is depicted as an abbreviated form of Figure 6.9.

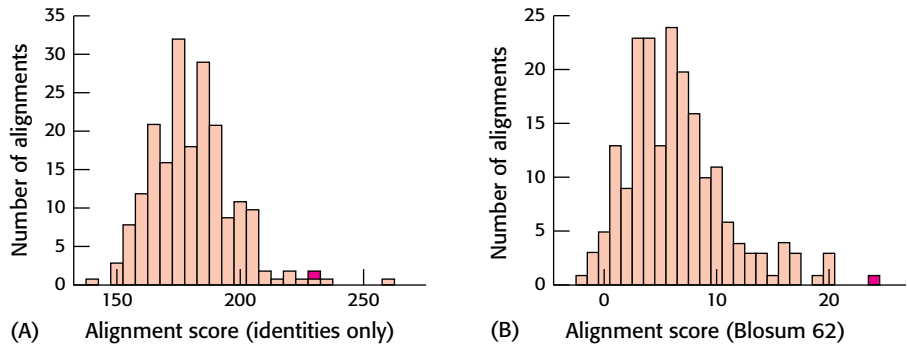

**FIGURE 6.11 Alignment with conservative substitutions noted.** The alignment of  $\alpha$ -hemoglobin and myoglobin with conservative substitutions indicated by yellow shading and identities by orange.

conservative (defined as those substitutions with scores greater than 0) and relatively few are strongly disfavored (Figure 6.11).

This scoring system detects homology between less obviously related sequences with greater sensitivity than would a comparison of identities only. Consider, for example, the protein leghemoglobin, an oxygen-binding protein found in the roots of some plants. The amino acid sequence of leghemoglobin from the herb lupine can be aligned with that of human myoglobin and scored by using either the simple scoring scheme based on identities only or the Blosum-62 (Figure 6.9). Repeated shuffling and scoring provides a distribution of alignment scores (Figure 6.12). Scoring based solely

**FIGURE 6.12 Alignment of identities only versus the Blosum-62.** Repeated shuffling and scoring reveal the significance of sequence alignment for human myoglobin versus lupine leghemoglobin with the use of either (A) the simple, identity-based scoring system or (B) the Blosum-62. The scores for the alignment of the authentic sequences are shown in red. Accounting for amino acid similarity in addition to identity reveals a greater separation between the authentic alignment and the population of shuffled alignments.

on identities indicates that the probability of the alignment between myoglobin and leghemoglobin occurring by chance alone is 1 in 20. Thus, although the level of similarity suggests a relationship, there is a 5% chance that the similarity is accidental on the basis of this analysis. In contrast, users of the substitution matrix are able to incorporate the effects of conservative substitutions. From such an analysis, the odds of the alignment occurring by chance are calculated to be approximately 1 in 300. Thus, an analysis performed with the substitution matrix reaches a much firmer conclusion about the evolutionary relationship between these proteins (Figure 6.13).

**FIGURE 6.13 Alignment of human myoglobin and lupine leghemoglobin.** The use of Blosum-62 yields the alignment shown between human myoglobin and lupine leghemoglobin, illustrating identities (orange boxes) and conservative substitutions (yellow). These sequences are 23% identical.

Experience with sequence analysis has led to the development of simpler rules of thumb. For sequences longer than 100 amino acids, sequence identities greater than 25% are almost certainly not the result of chance alone; such sequences are probably homologous. In contrast, if two sequences are less than 15% identical, their alignment alone is unlikely to indicate statistically significant similarity. For sequences that are between 15 and 25% identical, further analysis is necessary to determine the statistical significance of the alignment. It must be emphasized that *the lack of a statistically significant degree of sequence similarity does not rule out homology*. The sequences of many proteins that have descended from common ancestors have diverged to such an extent that the relationship between the proteins can no longer be detected from their sequences alone. As we will see, such homologous proteins can often be detected by examining three-dimensional structures.

### Databases can be searched to identify homologous sequences

When the sequence of a protein is first determined, comparing it with all previously characterized sequences can be a source of tremendous insight into its evolutionary relatives and, hence, its structure and function. Indeed, an extensive sequence comparison is almost always the first analysis performed on a newly elucidated sequence. The sequence-alignment methods just described are used to compare an individual sequence with all members of a database of known sequences.

Database searches for homologous sequences are most often accomplished by using resources available on the Internet at the National Center for Biotechnology Information ([www.ncbi.nih.gov](http://www.ncbi.nih.gov)). The procedure used is referred to as a *BLAST* (Basic Local Alignment Search Tool) *search*. An amino acid sequence is typed or pasted into the Web browser, and a search is performed, most often against a nonredundant database of all known sequences. At the end of 2013, this database included more than 35 million sequences. A BLAST search yields a list of sequence alignments, each accompanied by an estimate giving the likelihood that the alignment occurred by chance (Figure 6.14).

In 1995, investigators reported the first complete sequence of the genome of a free-living organism, the bacterium *Haemophilus influenzae*. With the sequences available, they performed a BLAST search with each deduced protein sequence. Of 1743 identified protein-coding regions, also called *open reading frames* (ORFs), 1007 (58%) could be linked to some protein of known function that had been previously characterized in another organism. An additional 347 ORFs could be linked to sequences in the database for which no function had yet been assigned (“hypothetical proteins”). The remaining 389 sequences did not match any sequence present in the database at that time. Thus, investigators were able to identify likely functions for more than half the proteins within this organism solely by sequence comparisons.

---

## 6.3 Examination of Three-Dimensional Structure Enhances Our Understanding of Evolutionary Relationships

Sequence comparison is a powerful tool for extending our knowledge of protein function and kinship. However, biomolecules generally function as intricate three-dimensional structures rather than as linear polymers. Mutations occur at the level of sequence, but the effects of the mutations are

**FIGURE 6.14** BLAST search results. Part of the results from a BLAST search of the nonredundant (nr) protein sequence database using the sequence of ribose 5-phosphate isomerase (also called phosphopentose isomerase, Chapter 20) from *E. coli* as a query. Among the thousands of sequences found is the orthologous sequence from humans, and the alignment between these sequences is shown (highlighted in yellow). The number of sequences with this level of similarity expected to be in the database by chance is  $2 \times 10^{-27}$  as shown by the E value (highlighted in red). Because this value is much less than 1, the observed sequence alignment is highly significant.

at the level of function, and function is directly related to tertiary structure. Consequently, to gain a deeper understanding of evolutionary relationships between proteins, we must examine three-dimensional structures, especially in conjunction with sequence information. The techniques of structural determination were presented in Section 3.5.

### Tertiary structure is more conserved than primary structure

Because three-dimensional structure is much more closely associated with function than is sequence, tertiary structure is more evolutionarily conserved than is primary structure. This conservation is apparent in the tertiary structures of the globins (Figure 6.15), which are extremely similar even though the similarity between human myoglobin and lupine leghemoglobin is just barely detectable at the sequence level (Figure 6.12) and that between human  $\alpha$ -hemoglobin and lupine leghemoglobin is not statistically significant (15% identity). This structural similarity firmly establishes that the framework that binds the heme group and

facilitates the reversible binding of oxygen has been conserved over a long evolutionary period.

Anyone aware of the similar biochemical functions of hemoglobin, myoglobin, and leghemoglobin could expect the structural similarities. In a growing number of other cases, however, a comparison of three-dimensional structures has revealed striking similarities between proteins that were *not* expected to be related, on the basis of their diverse functions. A case in point

is the protein actin, a major component of the cytoskeleton (Section 35.2), and heat shock protein 70 (Hsp70), which assists protein folding inside cells. These two proteins were found to be noticeably similar in structure despite only 16% sequence identity (Figure 6.16). On the basis of their three-dimensional structures, actin and Hsp70 are paralogs. The level of structural similarity strongly suggests that, despite their different biological roles in modern organisms, these proteins descended from a common ancestor. As the three-dimensional structures of more proteins are determined, such unexpected kinships are being discovered with increasing frequency. The search for such kinships relies ever more frequently on computer-based searches that are able to compare the three-dimensional structure of any protein with all other known structures.

#### Knowledge of three-dimensional structures can aid in the evaluation of sequence alignments

The sequence-comparison methods described thus far treat all positions within a sequence equally. However, we know from examining families

**FIGURE 6.15 Conservation of three-dimensional structure.** The tertiary structures of human hemoglobin ( $\alpha$  chain), human myoglobin, and lupine leghemoglobin are conserved. Each heme group contains an iron atom to which oxygen binds. [Drawn from 1HBB.pdb, 1MBD.pdb, and 1GDJ.pdb.]

**FIGURE 6.16 Structures of actin and a large fragment of heat shock protein 70 (Hsp70).** A comparison of the identically colored elements of secondary structure reveals the overall similarity in structure despite the difference in biochemical activities. [Drawn from 1ATN.pdb and 1ATR.pdb.]

of homologous proteins for which at least one three-dimensional structure is known that regions and residues critical to protein function are more strongly conserved than are other residues. For example, each type of globin contains a bound heme group with an iron atom at its center. A histidine residue that interacts directly with this iron atom (residue 64 in human myoglobin) is conserved in all globins. After we have identified key residues or highly conserved sequences within a family of proteins, we can sometimes identify other family members even when the overall level of sequence similarity is below statistical significance. Thus it may be useful to generate a *sequence template*—a map of conserved residues that are structurally and functionally important and are characteristic of particular families of proteins, which makes it possible to recognize new family members that might be undetectable by other means. A variety of other methods for sequence classification that take advantage of known three-dimensional structures also are being developed. Still other methods are able to identify conserved residues within a family of homologous proteins, even without a known three-dimensional structure. These methods often use substitution matrices that differ at each position within a family of aligned sequences. Such methods can often detect quite distant evolutionary relationships.

### Repeated motifs can be detected by aligning sequences with themselves

More than 10% of all proteins contain sets of two or more domains that are similar to one another. Sequence search methods can often detect internally repeated sequences that have been characterized in other proteins. Often, however, repeated units do not correspond to previously identified domains. In these cases, their presence can be detected by attempting to align a given sequence with itself. The statistical significance of such repeats can be tested by aligning the regions in question as if these regions were sequences from separate proteins. For the TATA-box-binding protein (Figure 6.17A), a key protein in controlling gene transcription (Section 29.2), such an alignment is highly significant: 30% of the amino acids are identical over 90 residues (Figure 6.17B). The

estimated probability of such an alignment occurring by chance is 1 in  $10^{13}$ . The determination of the three-dimensional structure of the TATA-box-binding protein confirmed the presence of repeated structures; the protein is formed of two nearly identical domains (Figure 6.17C). The evidence is convincing that the gene encoding this protein evolved by duplication of a gene encoding a single domain.

### Convergent evolution illustrates common solutions to biochemical challenges

Thus far, we have been exploring proteins derived from common ancestors—that is, through *divergent evolution*. Other cases have been found of proteins that are structurally similar in important ways but are not descended from a common ancestor. How might two unrelated proteins come to resemble each other structurally? Two proteins evolving independently may have converged on similar structural features to perform a similar biochemical activity. Perhaps that structure was an especially effective solution to a biochemical problem that organisms face. The process by which very different evolutionary pathways lead to the same solution is called *convergent evolution*.

An example of convergent evolution is found among the serine proteases. These enzymes, to be considered in more detail in Chapter 9, cleave peptide bonds by hydrolysis. Figure 6.18 shows the structure of the active sites—that is, the sites on the proteins at which the hydrolysis reaction takes place—for two such enzymes, chymotrypsin and subtilisin. These active-site structures are remarkably similar. In each case, a serine residue, a histidine residue, and an aspartic acid residue are positioned in space in nearly identical arrangements. As we will see, this conserved spatial arrangement is critical for the activity of these enzymes and affords the same mechanistic solution to the problem of peptide hydrolysis. At first glance, this similarity might suggest that these proteins are homologous. However, striking differences in the overall structures of these proteins make an evolutionary relationship extremely unlikely (Figure 6.19). Whereas chymotrypsin consists almost entirely of  $\beta$  sheets, subtilisin contains extensive  $\alpha$ -helical

**FIGURE 6.18** Convergent evolution of protease active sites. The relative positions of the three key residues shown are nearly identical in the active sites of the serine proteases chymotrypsin and subtilisin.

**FIGURE 6.19 Structures of mammalian chymotrypsin and bacterial subtilisin.** The overall structures are quite dissimilar, in stark contrast with the active sites, shown at the top of each structure. The  $\beta$  strands are shown in yellow and the  $\alpha$  helices in blue. [Drawn from 1GCT.pdb. and 1SUP.pdb.]

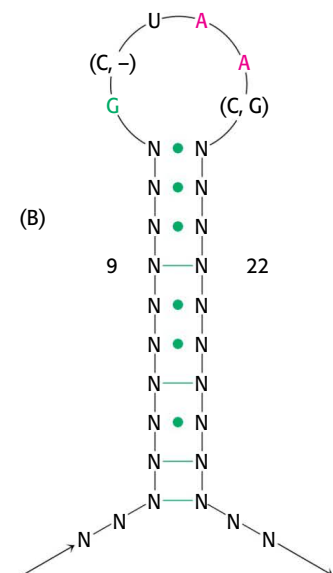

structure. Moreover, the key serine, histidine, and aspartic acid residues do not occupy similar positions or even appear in the same order within the two sequences. It is extremely unlikely that two proteins evolving from a common ancestor could have retained similar active-site structures while other aspects of the structure changed so dramatically.

### Comparison of RNA sequences can be a source of insight into RNA secondary structures

Homologous RNA sequences can be compared in a manner similar to that already described for protein sequences. Such comparisons can be a source of important insights into evolutionary relationships; in addition, they provide clues to the three-dimensional structure of the RNA itself. As noted in Chapter 4, single-stranded nucleic acid molecules fold back on themselves to form elaborate structures held together by Watson–Crick base-pairing and other interactions. In a family of sequences that form similar base-paired structures, base sequences may vary, but base-pairing ability is conserved. Consider, for example, a region from a large RNA molecule present in the ribosomes of all organisms (Figure 6.20). In the region shown, the *E. coli* sequence has a guanine (G) residue in position 9 and a cytosine (C) residue in position 22, whereas the human sequence has uracil (U) in position 9 and adenine (A) in position 22. Examination of the six sequences shown in Figure 6.20 reveals that the

**FIGURE 6.20 Comparison of RNA sequences.** (A) A comparison of sequences in a part of ribosomal RNA taken from a variety of species. (B) The implied secondary structure. Green lines indicate positions at which Watson–Crick base-pairing is completely conserved in the sequences shown, whereas dots indicate positions at which Watson–Crick base-pairing is conserved in most cases.

bases in positions 9 and 22, as well as several of the neighboring positions, retain the ability to form Watson–Crick base pairs even though the identities of the bases in these positions vary. We can deduce that two segments with paired mutations that maintain base-pairing ability are likely to form a double helix. Where sequences are known for several homologous RNA molecules, this type of sequence analysis can often suggest complete secondary structures as well as some additional interactions. For this particular ribosomal RNA, the subsequent determination of its three-dimensional structure (Section 30.3) confirmed the predicted secondary structure.

## 6.4 Evolutionary Trees Can Be Constructed on the Basis of Sequence Information

The observation that homology is often manifested as sequence similarity suggests that the evolutionary pathway relating the members of a family of proteins may be deduced by examination of sequence similarity. This approach is based on the notion that sequences that are more similar to one another have had less evolutionary time to diverge than have sequences that are less similar. This method can be illustrated by using the three globin sequences in Figures 6.11 and 6.13, as well as the sequence for the human hemoglobin  $\beta$  chain. These sequences can be aligned with the additional constraint that gaps, if present, should be at the same positions in all of the proteins. These aligned sequences can be used to construct an *evolutionary tree* in which the length of the branch connecting each pair of proteins is proportional to the number of amino acid differences between the sequences (Figure 6.21).

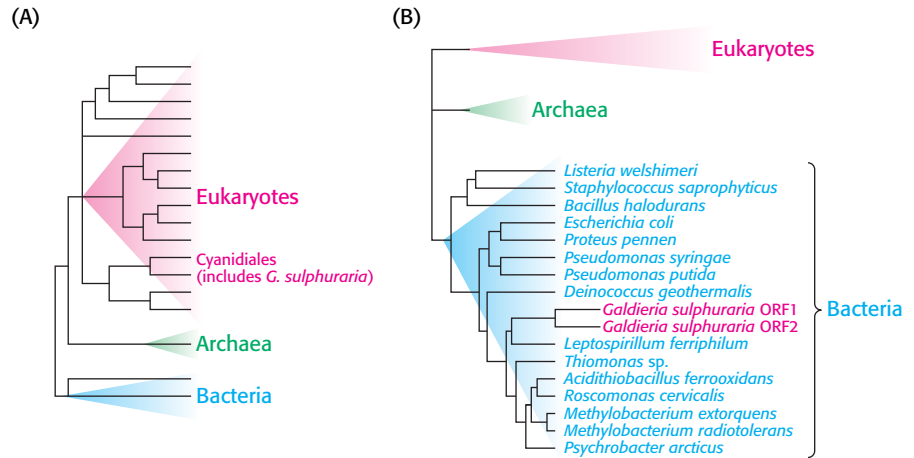

Such comparisons reveal only the relative divergence times—for example, that myoglobin diverged from hemoglobin twice as long ago as the  $\alpha$  chain diverged from the  $\beta$  chain. How can we estimate the approximate dates of gene duplications and other evolutionary events? Evolutionary trees can be calibrated by comparing the deduced branch points with divergence times determined from the fossil record. For example, the duplication leading to the two chains of hemoglobin appears to have occurred 350 million years ago. This estimate is supported by the observation that jawless fish such as the lamprey, which diverged from bony fish approximately 400 million years ago, contain hemoglobin built from a single type of subunit (Figure 6.22). These methods can be applied to both relatively modern and very ancient

**FIGURE 6.22 The lamprey.** A jawless fish whose ancestors diverged from bony fish approximately 400 million years ago, the lamprey has hemoglobin molecules that contain only a single type of polypeptide chain. [Brent P. Kent.]

**FIGURE 6.23 Evidence of horizontal gene transfer.** (A) The unicellular red alga *Galdieria sulphuraria* belongs to the order Cyanidiales, clearly within the eukaryotic branch of the evolutionary tree. (B) Within the completely sequenced *G. sulphuraria* genome, two ORFs encode proteins involved in transport of arsenate ions across membranes. Alignment of these ORFs against orthologs from a variety of species reveals that these pumps are most closely related to their bacterial counterparts, suggesting that a horizontal gene transfer event occurred during the evolution of this species. [(A) Information from Dr. Gerald Schönknecht; (B) Information from G. Schönknecht et al. *Science* 339:1207–1210, 2013, Fig. 3.]

molecules, such as the ribosomal RNAs that are found in all organisms. Indeed, such an RNA sequence analysis led to the realization that Archaea are a distinct group of organisms that diverged from Bacteria very early in evolutionary history.

### Horizontal gene transfer events may explain unexpected branches of the evolutionary tree

Evolutionary trees that encompass orthologs of a particular protein across a range of species can lead to unexpected findings. For example, let us consider the unicellular red alga *Galdieria sulphuraria*, a remarkable eukaryote that can thrive in extreme environments, including at temperatures up to 56°C, at pH values between 0 and 4, and in the presence of high concentrations of toxic metals. *G. sulphuraria* belongs to the order Cyanidiales, clearly within the eukaryotic branch of the evolutionary tree (Figure 6.23A). However, the complete genome sequence of this organism revealed that nearly 5% of the *G. sulphuraria* ORFs encode proteins that are more closely related to bacterial or archaeal, not eukaryotic, orthologs. Furthermore, the proteins that exhibited these unexpected evolutionary relationships possess functions that are likely to confer a survival advantage in extreme environments, such as the removal of metal ions from inside the cell (Figure 6.23B). One likely explanation for these observations is *horizontal gene transfer*, or *the exchange of DNA between species* that provides a selective advantage to the recipient. Amongst prokaryotes, horizontal gene transfer is a well-characterized and important evolutionary mechanism. For example, as we shall discuss in Chapter 9, exchange of plasmid DNA between bacterial species likely facilitated the acquisition of restriction endonuclease activities. However, recent studies such as those on *G. sulphuraria*, made possible by the expansive growth of complete genome sequence information, suggest that horizontal gene transfer from prokaryotes to eukaryotes, between different domains of life, may also represent evolutionarily significant events.

## 6.5 Modern Techniques Make the Experimental Exploration of Evolution Possible

Two techniques of biochemistry have made it possible to examine the course of evolution more directly and not simply by inference. The polymerase chain reaction (Section 5.1) allows the direct examination of ancient DNA sequences, releasing us, at least in some cases, from the constraints of being able to examine existing genomes from living organisms only. Molecular evolution may be investigated through the use of *combinatorial chemistry*, the process of producing large populations of molecules en masse and selecting for a biochemical property. This exciting process provides a glimpse into the types of molecules that may have existed very early in evolution.

### Ancient DNA can sometimes be amplified and sequenced

The tremendous chemical stability of DNA makes the molecule well suited to its role as the storage site of genetic information. So stable is the molecule that samples of DNA have survived for many thousands of years under appropriate conditions. With the development of PCR and advanced DNA-sequencing methods, such ancient DNA can be amplified and sequenced. This approach was first applied to mitochondrial DNA isolated from a Neanderthal fossil estimated at 38,000 years of age. Comparison of the complete Neanderthal mitochondrial sequence with those from *Homo sapiens* individuals revealed between 201 and 234 substitutions, considerably fewer than the approximately 1500 differences between human beings and chimpanzees over the same region.

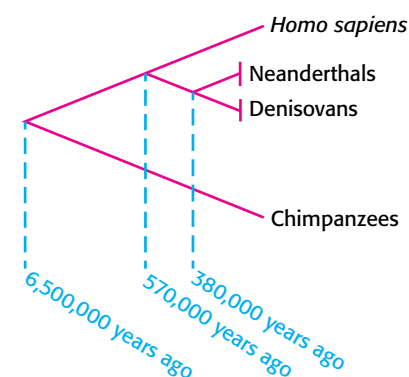

Remarkably, the complete genome sequences of a Neanderthal and a closely related hominin known as a Denisovan have been obtained using DNA isolated from nearly 50,000-year-old fossils. Comparison of these sequences suggests that the common ancestor of modern human beings and Neanderthals lived approximately 570,000 years ago, while the common ancestor between Neanderthals and Denisovans lived nearly 380,000 years ago. An evolutionary tree constructed from these data revealed that the Neanderthal was not an intermediate between chimpanzees and human beings but, instead, was an evolutionary “dead end” that became extinct (Figure 6.24). Further analysis of these sequences has enabled researchers to determine the extent of interbreeding between these groups, elucidate the geographic history of these populations, and make assertions about additional ancestors whose DNA has not yet been sequenced.

A few earlier studies claimed to determine the sequences of far more ancient DNA such as that found in insects trapped in amber, but these studies appear to have been flawed. The source of these sequences turned out to be contaminating modern DNA. Successful sequencing of ancient DNA requires sufficient DNA for reliable amplification and the rigorous exclusion of all sources of contamination.

### Molecular evolution can be examined experimentally

Evolution requires three processes: (1) the generation of a diverse population, (2) the selection of members based on some criterion of fitness, and (3) reproduction to enrich the population in these more-fit members. Nucleic acid molecules are capable of undergoing all three processes in vitro under appropriate conditions. The results of such studies enable us to glimpse how evolutionary processes might have generated catalytic activities and specific binding abilities—important biochemical functions in all living systems.

A diverse population of nucleic acid molecules can be synthesized in the laboratory by the process of combinatorial chemistry, which rapidly

**FIGURE 6.24** Placing Neanderthals and Denisovans on an evolutionary tree.

Comparison of DNA sequences revealed that neither Neanderthals nor the Denisovans are on the line of direct descent leading to *Homo sapiens* but, instead, branched off earlier and then became extinct.

produces large populations of a particular type of molecule such as a nucleic acid. A population of molecules of a given size can be generated randomly so that many or all possible sequences are present in the mixture. When an initial population has been generated, it is subjected to a selection process that isolates specific molecules with desired binding or reactivity properties. Finally, molecules that have survived the selection process are replicated through the use of PCR; primers are directed toward specific sequences included at the ends of each member of the population. Errors that occur naturally in the course of the replication process introduce additional variation into the population in each “generation.” Let us consider an application of this approach. Early in evolution, before the emergence of proteins, RNA molecules may have played all major roles in biological catalysis. To understand the properties of potential RNA catalysts, researchers have used the methods heretofore described to create an RNA molecule capable of binding adenosine triphosphate and related nucleotides. An initial population of RNA molecules 169 nucleotides long was created; 120 of the positions differed randomly, with equimolar mixtures of adenine, cytosine, guanine, and uracil. The initial synthetic pool that was used contained approximately  $10^{14}$  RNA molecules. Note that this number is a very small fraction of the total possible pool of random 120-base sequences. From this pool, those molecules that bound to ATP, which had been immobilized on a column, were selected (Figure 6.25).

The collection of molecules that were bound well by the ATP affinity column was replicated by reverse transcription into DNA, amplification by PCR, and transcription back into RNA. The somewhat error-prone reverse transcriptase may have introduced additional mutations into the population

**FIGURE 6.25 Evolution in the laboratory.** A collection of RNA molecules of random sequences is synthesized by combinatorial chemistry. This collection is selected for the ability to bind ATP by passing the RNA through an ATP affinity column (Section 3.1). The ATP-binding RNA molecules are released from the column by washing with excess ATP and then replicated. The process of selection and replication is then repeated several times. The final RNA products with significant ATP-binding ability are isolated and characterized.

in each cycle. The new population was subjected to additional rounds of selection for ATP-binding activity. After eight generations, members of the selected population were characterized by sequencing. Seventeen different sequences were obtained, 16 of which could form the structure shown in Figure 6.26. Each of these molecules bound ATP with dissociation constants less than  $50 \mu\text{M}$ .

The folded structure of the ATP-binding region from one of these RNAs was determined by nuclear magnetic resonance (NMR) methods (Section 3.6). As expected, this 40-nucleotide molecule is composed of two Watson–Crick base-paired helical regions separated by an 11-nucleotide loop (Figure 6.27A). This loop folds back on itself in an intricate way (Figure 6.27B) to form a deep pocket into which the adenine ring can fit (Figure 6.27C). Thus, a structure had evolved in vitro that was capable of a specific interaction.

 Synthetic oligonucleotides that can specifically bind ligands, such as the ATP-binding RNA molecules described above, are referred to as *aptamers*. In addition to their role in understanding molecular evolution, aptamers have shown promise as versatile tools for biotechnology and medicine. They have been developed for diagnostic applications, serving as sensors for ligands ranging from small organic molecules, such as cocaine, to larger proteins, such as thrombin. Several aptamers are also in clinical trials as therapies for diseases ranging from leukemia to diabetes. Macugen (pegaptanib sodium), an aptamer which binds to and inhibits the protein vascular endothelial growth factor (VEGF), has been approved for the treatment of age-related macular degeneration.

## SUMMARY

### 6.1 Homologs Are Descended from a Common Ancestor

Exploring evolution biochemically often means searching for homology between molecules, because homologous molecules, or homologs, evolved from a common ancestor. Paralogs are homologous molecules that are found in one species and have acquired different functions through evolutionary time. Orthologs are homologous molecules that are found in different species and have similar or identical functions.

### 6.2 Statistical Analysis of Sequence Alignments Can Detect Homology

Protein and nucleic acid sequences are two of the primary languages of biochemistry. Sequence-alignment methods are the most powerful tools of the evolutionary detective. Sequences can be aligned to maximize their similarity, and the significance of these alignments can be judged by statistical tests. The detection of a statistically significant alignment

between two sequences strongly suggests that two sequences are related by divergent evolution from a common ancestor. The use of substitution matrices makes the detection of more-distant evolutionary relationships possible. Any sequence can be used to probe sequence databases to identify related sequences present in the same organism or in other organisms.

### 6.3 Examination of Three-Dimensional Structure Enhances Our Understanding of Evolutionary Relationships

The evolutionary kinship between proteins may be even more strikingly evident in the conserved three-dimensional structures. The analysis of three-dimensional structure in combination with the analysis of especially conserved sequences has made it possible to determine evolutionary relationships that cannot be detected by other means. Sequence-comparison methods can also be used to detect imperfectly repeated sequences within a protein, indicative of linked similar domains.

### 6.4 Evolutionary Trees Can Be Constructed on the Basis of Sequence Information

Evolutionary trees can be constructed with the assumption that the number of sequence differences corresponds to the time since the two sequences diverged. Construction of an evolutionary tree based on sequence comparisons revealed approximate times for the gene-duplication events separating myoglobin and hemoglobin as well as the  $\alpha$  and  $\beta$  subunits of hemoglobin. Evolutionary trees based on sequences can be compared with those based on fossil records. Horizontal gene transfer events can manifest as unexpected branches on the evolutionary tree.

### 6.5 Modern Techniques Make the Experimental Exploration of Evolution Possible

The exploration of evolution can also be a laboratory science. In favorable cases, PCR amplification of well-preserved samples allows the determination of nucleotide sequences from extinct organisms. Sequences so determined can help authenticate parts of an evolutionary tree constructed by other means. Molecular evolutionary experiments performed in the test tube can examine how molecules such as ligand-binding RNA molecules might have been generated.

## KEY TERMS

homolog (p. 170)

paralog (p. 170)

ortholog (p. 170)

sequence alignment (p. 171)

nonconservative substitution (p. 174)

substitution matrix (p. 174)

BLAST search (p. 177)

sequence template (p. 180)

divergent evolution (p. 181)

convergent evolution (p. 181)

evolutionary tree (p. 183)

horizontal gene transfer (p. 184)

combinatorial chemistry (p. 185)

aptamers (p. 187)

## PROBLEMS

1. *What's the score?* Using the identity-based scoring system (Section 6.2), calculate the score for the following alignment. Do you think the score is statistically significant?

(1) WYLGK ITRMDAEVLLKKPTVRDGHFLVTQCESSPGEF-

(2) WYFGK ITRRESERLLLLNPNPRGTFVRESEETTKGAY-

SISVRFGDSVQ-----HFKVLRDQNGKYLLWAVK-FN-  
CLSVSDFDNAKGLNVKHYKIRKLDGGFYITSRITQFS-

SLNELVAYHRTASVSRTHITILLSDMNV  
SSLQQLVAYYSKHADGLCHRLTNV

2. *Sequence and structure.* A comparison of the aligned amino acid sequences of two proteins each consisting of 150 amino acids reveals them to be only 8% identical. However, their three-dimensional structures are very similar. Are these two proteins related evolutionarily? Explain.

3. *It depends on how you count.* Consider the following two sequence alignments:

(1) A-SNLFDIRLIG  
GSNDFYEVKIMD

(2) ASNLFDIRLI-G  
GSNDFYEVKIMD

Which alignment has a higher score if the identity-based scoring system (Section 6.2) is used? Which alignment has a higher score if the Blosum-62 substitution matrix (Figure 6.9) is used?

4. *Discovering a new base pair.* Examine the ribosomal RNA sequences in Figure 6.20. In sequences that do not contain Watson–Crick base pairs, what base tends to be paired with G? Propose a structure for your new base pair.

5. *Overwhelmed by numbers.* Suppose that you wish to synthesize a pool of RNA molecules that contain all four bases at each of 40 positions. How much RNA must you have in grams if the pool is to have at least a single molecule of each sequence? The average molecular weight of a nucleotide is  $330 \text{ g mol}^{-1}$ .

6. *Form follows function.* The three-dimensional structure of biomolecules is more conserved evolutionarily than is sequence. Why?

7. *Shuffling.* Using the identity-based scoring system (Section 6.2), calculate the alignment score for the alignment of the following two short sequences:

- (1) **ASNFLDKAGK**
- (2) **ATDYLEKAGK**

Generate a shuffled version of sequence 2 by randomly reordering these 10 amino acids. Align your shuffled sequence with sequence 1 without allowing gaps, and calculate the alignment score between sequence 1 and your shuffled sequence.

8. *Interpreting the score.* Suppose that the sequences of two proteins each consisting of 200 amino acids are aligned and that the percentage of identical residues has been calculated. How would you interpret each of the following results in regard to the possible divergence of the two proteins from a common ancestor?

- (a) 80%
- (b) 50%
- (c) 20%
- (d) 10%.

9. *Particularly unique.* Consider the Blosum-62 matrix in Figure 6.9. Replacement of which three amino acids never yields a positive score? What features of these residues might contribute to this observation?

10. *A set of three.* The sequences of three proteins (A, B, and C) are compared with one another, yielding the following levels of identity:

	A	B	C
A	100%	65%	15%
B	65%	100%	55%
C	15%	55%	100%

Assume that the sequence matches are distributed uniformly along each aligned sequence pair. Would you expect protein A and protein C to have similar three-dimensional structures? Explain.

11. *RNA alignment.* Sequences of an RNA fragment from five species have been determined and aligned. Propose a likely secondary structure for these fragments.

- (1) UUGGAGAUUCGGUAGAAUCUCCC
- (2) GCCGGGAAUCGACAGAUUCCCCG
- (3) CCCAAGUCCCAGGACAGGACUUA
- (4) CUCACCUGCCGAUAGGCAGGUCA
- (5) AAUACCACCCGGUAGGGUGGUUC

12. *The more the merrier.* When RNA alignments are used to determine secondary structure, it is advantageous to have many sequences representing a wide variety of species. Why?

13. *To err is human.* You have discovered a mutant form of a thermostable DNA polymerase with significantly reduced fidelity in adding the appropriate nucleotide to the growing DNA strand, compared with wild-type DNA polymerase. How might this mutant be useful in the molecular-evolution experiments described in Section 6.5?

14. *Generation to generation.* When performing a molecular-evolution experiment, such as that described in Section 6.5, why is it important to repeat the selection and replication steps for several generations?

15. *BLAST away.* Using the National Center for Biotechnology Information Web site ([www.ncbi.nlm.nih.gov](http://www.ncbi.nlm.nih.gov)), find the sequence of the enzyme triose phosphate isomerase from *E. coli* strain K-12. Use this sequence as the query for a protein–protein BLAST search. In the output, find the alignment with the sequence of triose phosphate isomerase from human beings (*Homo sapiens*). How many identities are observed in the alignment?

# Hemoglobin: Portrait of a Protein in Action

Beta chain of hemoglobin

In the bloodstream, red cells carry oxygen from the lungs to the tissues, where demand is high. Hemoglobin, the protein that gives blood its red color, is responsible for the transport of oxygen via its four heme-bound subunits. Hemoglobin was one of the first proteins to have its structure determined; the folding of a single subunit is shown in this hand-drawn view. [Left, Andrew Syred/Stone/Getty Images.]

The transition from anaerobic to aerobic life was a major step in evolution because it uncovered a rich reservoir of energy. Fifteen times as much energy is extracted from glucose in the presence of oxygen than in its absence. For single-celled and other small organisms, oxygen can be absorbed into actively metabolizing cells directly from the air or surrounding water. Vertebrates evolved two principal mechanisms for supplying their cells with an adequate supply of oxygen. The first is a circulatory system that actively delivers oxygen to cells throughout the body. The second is the use of the oxygen-transport and oxygen-storage proteins, hemoglobin and myoglobin. Hemoglobin, which is contained in red blood cells, is a fascinating protein, efficiently carrying oxygen from the lungs to the tissues while also contributing to the transport of carbon dioxide and hydrogen ions back to the lungs. Myoglobin, located in muscle, facilitates the diffusion of oxygen through the cell for the generation of cellular energy and provides a reserve supply of oxygen available in time of need.

A comparison of myoglobin and hemoglobin illuminates some key aspects of protein structure and function. These two evolutionarily related proteins employ nearly identical structures for oxygen binding (Chapter 6). However, hemoglobin is a remarkably efficient oxygen carrier, able to use as much as 90% of its potential oxygen-carrying capacity effectively. Under similar conditions, myoglobin would be able to use only 7% of its potential capacity. What accounts

## OUTLINE

- 7.1 Myoglobin and Hemoglobin Bind Oxygen at Iron Atoms in Heme

Myoglobin

**FIGURE 7.1 Structure of myoglobin.** Notice that myoglobin consists of a single polypeptide chain, formed of  $\alpha$  helices connected by turns, with one oxygen-binding site. [Drawn from 1MBD.pdb.]

for this dramatic difference? Myoglobin exists as a single polypeptide, whereas hemoglobin comprises four polypeptide chains. The four chains in hemoglobin bind oxygen *cooperatively*, meaning that the binding of oxygen to a site in one chain increases the likelihood that the remaining chains will bind oxygen. Furthermore, the oxygen-binding properties of hemoglobin are modulated by the binding of hydrogen ions and carbon dioxide in a manner that enhances oxygen-carrying capacity. Both cooperativity and the response to modulators are made possible by variations in the quaternary structure of hemoglobin when different combinations of molecules are bound.

Hemoglobin and myoglobin have played important roles in the history of biochemistry. They were the first proteins for which three-dimensional structures were determined by x-ray crystallography. Furthermore, the possibility that variations in protein sequence could lead to disease was first proposed and demonstrated for sickle-cell anemia, a blood disease caused by mutation of a single amino acid in one hemoglobin chain. Hemoglobin has been and continues to be a valuable source of knowledge and insight, both in itself and as a prototype for many other proteins that we will encounter throughout our study of biochemistry.

## 7.1 Myoglobin and Hemoglobin Bind Oxygen at Iron Atoms in Heme

Sperm whale myoglobin was the first protein for which the three-dimensional structure was determined. X-ray crystallographic studies pioneered by John Kendrew revealed the structure of this protein in the 1950s (Figure 7.1). Myoglobin consists largely of  $\alpha$  helices that are linked to one another by turns to form a globular structure.

Myoglobin can exist in an oxygen-free form called *deoxymyoglobin* or in a form with an oxygen molecule bound called *oxymyoglobin*. The ability of myoglobin and hemoglobin to bind oxygen depends on the presence of a *heme* molecule. As we shall discuss in Chapter 9, heme is one example of a prosthetic group, a molecule that binds tightly to a protein and is essential for its function.

The heme group gives muscle and blood their distinctive red color. It consists of an organic component and a central iron atom. The organic component, called *protoporphyrin*, is made up of four pyrrole rings linked by methine bridges to form a tetrapyrrole ring. Four methyl groups, two vinyl groups, and two propionate side chains are attached to the central tetrapyrrole.

**FIGURE 7.2** Oxygen binding changes the position of the iron ion. The iron ion lies slightly outside the plane of the porphyrin in deoxymyoglobin heme (left), but moves into the plane of the heme on oxygenation (right).

The iron atom lies in the center of the protoporphyrin, bonded to the four pyrrole nitrogen atoms. Although the heme-bound iron can be in either the ferrous ( $\text{Fe}^{2+}$ ) or ferric ( $\text{Fe}^{3+}$ ) oxidation state, only the  $\text{Fe}^{2+}$  state is capable of binding oxygen. The iron ion can form two additional bonds, one on each side of the heme plane. These binding sites are called the fifth and sixth coordination sites. In myoglobin, the fifth coordination site is occupied by the imidazole ring of a histidine residue from the protein. This histidine is referred to as the *proximal histidine*.

Oxygen binding occurs at the sixth coordination site. In deoxymyoglobin, this site remains unoccupied. The iron ion is slightly too large to fit into the well-defined hole within the porphyrin ring; it lies approximately 0.4 Å outside the porphyrin plane (Figure 7.2, left). Binding of the oxygen molecule at the sixth coordination site substantially rearranges the electrons within the iron so that the ion becomes effectively smaller, allowing it to move within the plane of the porphyrin (Figure 7.2, right). Remarkably, the structural changes that take place on oxygen binding were predicted by Linus Pauling, on the basis of magnetic measurements in 1936, nearly 25 years before the three-dimensional structures of myoglobin and hemoglobin were elucidated.

### Changes in heme electronic structure upon oxygen binding are the basis for functional imaging studies

 The change in electronic structure that occurs when the iron ion moves into the plane of the porphyrin is paralleled by alterations in the magnetic properties of hemoglobin; these changes are the basis for *functional magnetic resonance imaging* (fMRI), one of the most powerful methods for examining brain function. Nuclear magnetic resonance techniques detect signals that originate primarily from the protons in water molecules and are altered by the magnetic properties of hemoglobin. With the use of appropriate techniques, images can be generated that reveal differences in the relative amounts of deoxy- and oxyhemoglobin and thus the relative activity of various parts of the brain. When a specific part of the brain is active, blood vessels relax to allow more blood flow to that region. Thus, a more-active region of the brain will be richer in oxyhemoglobin.

These noninvasive methods identify areas of the brain that process sensory information. For example, subjects have been imaged while breathing air that either does or does not contain odorants. When odorants are present, fMRI detects an increase in the level of hemoglobin oxygenation (and, hence,

**FIGURE 7.3 Functional magnetic resonance imaging of the brain.** A functional magnetic resonance image reveals brain response to odorants. The light spots indicate regions of the brain activated by odorants. [From Osterbauer, R. et al., “Color of Scents: Chromatic Stimuli Modulate Odor Responses in the Human Brain.” *Journal of Neurophysiology* 93 (2005) 3434–3441.]

of activity) in several regions of the brain (Figure 7.3). These regions are in the primary olfactory cortex, as well as in areas in which secondary processing of olfactory signals presumably takes place. Further analysis reveals the time course of activation of particular regions. Functional MRI shows tremendous potential for mapping regions and pathways engaged in processing sensory information obtained from all the senses. A seemingly incidental aspect of the biochemistry of hemoglobin has enabled observation of the brain in action.

### The structure of myoglobin prevents the release of reactive oxygen species

Oxygen binding to iron in heme is accompanied by the partial transfer of an electron from the ferrous ion to oxygen. In many ways, the structure is best described as a complex between ferric ion ( $\text{Fe}^{3+}$ ) and *superoxide anion* ( $\text{O}_2^-$ ), as illustrated in Figure 7.4. It is crucial that oxygen, when it is released, leaves as dioxygen rather than superoxide, for two important reasons. First, superoxide and other species generated from it are *reactive oxygen species* that can be damaging to many biological materials. Second, release of superoxide would leave the iron ion in the ferric state. This species, termed *metmyoglobin*, does not bind oxygen. Thus, potential oxygen-storage capacity is lost. Features of myoglobin stabilize the oxygen complex such that superoxide is less likely to be released. In particular, the binding pocket of myoglobin includes an additional histidine residue (termed the *distal histidine*) that donates a hydrogen bond to the bound oxygen molecule (Figure 7.5). The superoxide character of the bound oxygen species strengthens this interaction. Thus, *the protein component of myoglobin controls the intrinsic reactivity*

**FIGURE 7.4 Iron–oxygen bonding.** The interaction between iron and oxygen in myoglobin can be described as a combination of resonance structures, one with  $\text{Fe}^{2+}$  and dioxygen and another with  $\text{Fe}^{3+}$  and superoxide ion.

**FIGURE 7.5 Stabilizing bound oxygen.** A hydrogen bond (dotted green line) donated by the distal histidine residue to the bound oxygen molecule helps stabilize oxymyoglobin.

of heme, making it more suitable for reversible oxygen binding. The distal histidine may also impair access of carbon monoxide to the heme, which binds tightly to the heme iron with dire consequences (p. 201).

### Human hemoglobin is an assembly of four myoglobin-like subunits

The three-dimensional structure of hemoglobin from horse heart was solved by Max Perutz shortly after the determination of the myoglobin structure. Since then, the structures of hemoglobins from other species including humans have been determined. Hemoglobin consists of four polypeptide chains, two identical  $\alpha$  chains and two identical  $\beta$  chains (Figure 7.6). Each of the subunits consists of a set of  $\alpha$  helices in the same arrangement as the  $\alpha$  helices in myoglobin (see Figure 6.15 for a comparison of the structures). The recurring structure is called a *globin fold*. Consistent with this structural similarity, alignment of the amino acid sequences of the  $\alpha$  and  $\beta$  chains of human hemoglobin with those of sperm whale myoglobin yields 25% and 24% identity, respectively, and good conservation of key residues such as the proximal and distal histidines. Thus, the  $\alpha$  and  $\beta$  chains are related to each other and to myoglobin by divergent evolution (Section 6.2).

**FIGURE 7.6 Quaternary structure of deoxyhemoglobin.** Hemoglobin, which is composed of two  $\alpha$  chains and two  $\beta$  chains, functions as a pair of  $\alpha\beta$  dimers. (A) A ribbon diagram. (B) A space-filling model. [Drawn from 1A3N.pdb.]

The hemoglobin tetramer, referred to as *hemoglobin A* (HbA), is best described as a pair of identical  $\alpha\beta$  dimers ( $\alpha_1\beta_1$  and  $\alpha_2\beta_2$ ) that associate to form the tetramer. In deoxyhemoglobin, these  $\alpha\beta$  dimers are linked by an extensive interface, which includes the carboxyl terminus of each chain. The heme groups are well separated in the tetramer by iron–iron distances ranging from 24 to 40 Å.

## 7.2 Hemoglobin Binds Oxygen Cooperatively

We can determine the oxygen-binding properties of each of these proteins by observing its *oxygen-binding curve*, a plot of the *fractional saturation* versus the concentration of oxygen. The fractional saturation,  $Y$ , is defined as the fraction of possible binding sites that contain bound oxygen. The value of  $Y$  can range from 0 (all sites empty) to 1 (all sites filled). The concentration of oxygen is most conveniently measured by its *partial pressure*,  $pO_2$ .

**Torr**

A unit of pressure equal to that exerted by a column of mercury 1 mm high at 0°C and standard gravity (1 mm Hg). Named after Evangelista Torricelli (1608–1647), inventor of the mercury barometer.

**FIGURE 7.8 Oxygen binding by hemoglobin.** This curve, obtained for hemoglobin in red blood cells, is shaped somewhat like an “S,” indicating that distinct, but interacting, oxygen-binding sites are present in each hemoglobin molecule. Half-saturation for hemoglobin is 26 torr. For comparison, the binding curve for myoglobin is shown as a dashed black curve.

**FIGURE 7.7 Oxygen binding by myoglobin.** Half the myoglobin molecules have bound oxygen when the oxygen partial pressure is 2 torr.

For myoglobin, a binding curve indicating a simple chemical equilibrium is observed (Figure 7.7). Notice that the curve rises sharply as  $pO_2$  increases and then levels off. Half-saturation of the binding sites, referred to as  $P_{50}$  (for 50% saturated), is at the relatively low value of 2 torr (mm Hg), indicating that oxygen binds with high affinity to myoglobin.

In contrast, the oxygen-binding curve for hemoglobin in red blood cells shows some remarkable features (Figure 7.8). It does not look like a simple binding curve such as that for myoglobin; instead, it resembles an “S.” Such curves are referred to as *sigmoid* because of their S-like shape. In addition, oxygen binding for hemoglobin ( $P_{50} = 26$  torr) is significantly weaker than that for myoglobin. Note that this binding curve is derived from hemoglobin in red blood cells.

A sigmoid binding curve indicates that a protein exhibits a special binding behavior. For hemoglobin, this shape suggests that the binding of oxygen at one site within the hemoglobin tetramer increases the likelihood that oxygen binds at the remaining unoccupied sites. Conversely, the unloading of oxygen at one heme facilitates the unloading of oxygen at the others. This sort of binding behavior is referred to as *cooperative*, because the binding reactions at individual sites in each hemoglobin molecule are not independent of one another. We will return to the mechanism of this cooperativity shortly.

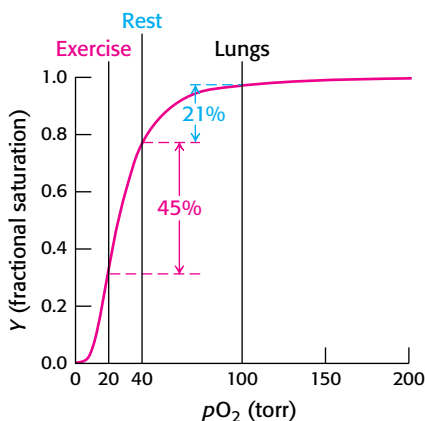

What is the physiological significance of the cooperative binding of oxygen by hemoglobin? Oxygen must be transported in the blood from the lungs, where the partial pressure of oxygen is relatively high (approximately 100 torr), to the actively metabolizing tissues, where the partial pressure of oxygen is much lower (typically, 20 torr). Let us consider how the cooperative behavior indicated by the sigmoid curve leads to efficient oxygen transport (Figure 7.9). In the lungs, hemoglobin becomes nearly

**FIGURE 7.9 Cooperativity enhances oxygen delivery by hemoglobin.** Because of cooperativity between  $O_2$  binding sites, hemoglobin delivers more  $O_2$  to actively metabolizing tissues than would myoglobin or any noncooperative protein, even one with optimal  $O_2$  affinity.

saturated with oxygen such that 98% of the oxygen-binding sites are occupied. When hemoglobin moves to the tissues and releases  $O_2$ , the saturation level drops to 32%. Thus, a total of  $98 - 32 = 66\%$  of the potential oxygen-binding sites contribute to oxygen transport. The cooperative release of oxygen favors a more-complete unloading of oxygen in the tissues. If myoglobin were employed for oxygen transport, it would be 98% saturated in the lungs, but would remain 91% saturated in the tissues, and so only  $98 - 91 = 7\%$  of the sites would contribute to oxygen transport; myoglobin binds oxygen too tightly to be useful in oxygen transport. Nature might have solved this problem by weakening the affinity of myoglobin for oxygen to maximize the difference in saturation between 20 and 100 torr. However, for such a protein, the most oxygen that could be transported from a region in which  $pO_2$  is 100 torr to one in which it is 20 torr is  $63 - 25 = 38\%$ , as indicated by the blue curve in Figure 7.9. Thus, the cooperative binding and release of oxygen by hemoglobin enables it to deliver nearly 10 times as much oxygen as could be delivered by myoglobin and more than 1.7 times as much as could be delivered by any noncooperative protein.

Closer examination of oxygen concentrations in tissues at rest and during exercise underscores the effectiveness of hemoglobin as an oxygen carrier (Figure 7.10). Under resting conditions, the oxygen concentration in muscle is approximately 40 torr, but during exercise the concentration is reduced to 20 torr. In the decrease from 100 torr in the lungs to 40 torr in resting muscle, the oxygen saturation of hemoglobin is reduced from 98% to 77%, and so  $98 - 77 = 21\%$  of the oxygen is released over a drop of 60 torr. In a decrease from 40 torr to 20 torr, the oxygen saturation is reduced from 77% to 32%, corresponding to an oxygen release of 45% over a drop of 20 torr. Thus, because the change in oxygen concentration from rest to exercise corresponds to the steepest part of the oxygen-binding curve, oxygen is effectively delivered to tissues where it is most needed. In Section 7.3, we shall examine other properties of hemoglobin that enhance its physiological responsiveness.

**FIGURE 7.10 Responding to exercise.** The drop in oxygen concentration from 40 torr in resting tissues to 20 torr in exercising tissues corresponds to the steepest part of the observed oxygen-binding curve. As shown here, hemoglobin is very effective in providing oxygen to exercising tissues.

### Oxygen binding markedly changes the quaternary structure of hemoglobin

The cooperative binding of oxygen by hemoglobin requires that the binding of oxygen at one site in the hemoglobin tetramer influence the oxygen-binding properties at the other sites. Given the large separation between the iron sites, direct interactions are not possible. Thus, indirect mechanisms

for coupling the sites must be at work. These mechanisms are intimately related to the quaternary structure of hemoglobin.

Hemoglobin undergoes substantial changes in quaternary structure on oxygen binding: the  $\alpha_1\beta_1$  and  $\alpha_2\beta_2$  dimers rotate approximately 15 degrees with respect to one another (Figure 7.11). The dimers themselves are relatively unchanged, although there are localized conformational shifts. Thus, the interface between the  $\alpha_1\beta_1$  and  $\alpha_2\beta_2$  dimers is most affected by this structural transition. In particular, the  $\alpha_1\beta_1$  and  $\alpha_2\beta_2$  dimers are freer to move with respect to one another in the oxygenated state than they are in the deoxygenated state.

**FIGURE 7.11** Quaternary structural changes on oxygen binding by hemoglobin.

Notice that, on oxygenation, one  $\alpha\beta$  dimer shifts with respect to the other by a rotation of 15 degrees. [Drawn from 1A3N.pdb and 1LFQ.pdb.]

The quaternary structure observed in the deoxy form of hemoglobin, *deoxyhemoglobin*, is often referred to as the *T* (for tense) state because it is quite constrained by subunit–subunit interactions. The quaternary structure of the fully oxygenated form, *oxyhemoglobin*, is referred to as the *R* (for relaxed) state. In light of the observation that the *R* form of hemoglobin is less constrained, the tense and relaxed designations seem particularly apt. Importantly, in the *R* state, the oxygen-binding sites are free of strain and are capable of binding oxygen with higher affinity than are the sites in the *T* state. *By triggering the shift of the hemoglobin tetramer from the T state to the R state, the binding of oxygen to one site increases the binding affinity of other sites.*

### Hemoglobin cooperativity can be potentially explained by several models

Two limiting models have been developed to explain the cooperative binding of ligands to a multisubunit assembly such as hemoglobin. In the *concerted model*, also known as the *MWC model* after Jacques Monod, Jeffries Wyman, and Jean-Pierre Changeux, who first proposed it, the overall assembly can exist only in two forms: the *T* state and the *R* state. The binding of ligands simply shifts the equilibrium between these two states (Figure 7.12).

**FIGURE 7.12 Concerted model.** All molecules exist either in the T state or in the R state. At each level of oxygen loading, an equilibrium exists between the T and R states. The equilibrium shifts from strongly favoring the T state with no oxygen bound to strongly favoring the R state when the molecule is fully loaded with oxygen. The R state has a greater affinity for oxygen than does the T state.

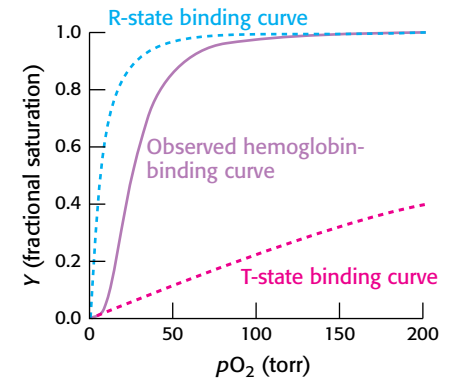

Thus, as a hemoglobin tetramer binds each oxygen molecule, the probability that the tetramer is in the R state increases. Deoxyhemoglobin tetramers are almost exclusively in the T state. However, the binding of oxygen to one site in the molecule shifts the equilibrium toward the R state. If a molecule assumes the R quaternary structure, the oxygen affinity of its sites increases. Additional oxygen molecules are now more likely to bind to the three unoccupied sites. Thus, the binding curve for hemoglobin can be seen as a combination of the binding curves that would be observed if all molecules remained in the T state or if all of the molecules were in the R state. As oxygen molecules bind, the hemoglobin tetramers convert from the T state into the R state, yielding the sigmoid binding curve so important for efficient oxygen transport (Figure 7.13).

In the concerted model, each tetramer can exist in only two states, the T state and the R state. In an alternative model, the *sequential model*, the binding of a ligand to one site in an assembly increases the binding affinity of neighboring sites without inducing a full conversion from the T into the R state (Figure 7.14).

**FIGURE 7.14 Sequential model.** The binding of a ligand changes the conformation of the subunit to which it binds. This conformational change induces changes in neighboring subunits that increase their affinity for the ligand.

Is the cooperative binding of oxygen by hemoglobin better described by the concerted or the sequential model? Neither model in its pure form fully accounts for the behavior of hemoglobin. Instead, a combined model is required. Hemoglobin behavior is concerted in that the tetramer with three sites occupied by oxygen is almost always in the quaternary structure associated with the R state. The remaining open binding site has an affinity for oxygen more than 20-fold greater than that of fully deoxygenated hemoglobin binding its first oxygen. However, the behavior is not fully concerted, because hemoglobin with oxygen bound to only one of four sites remains primarily in the T-state quaternary structure. Yet, this molecule binds oxygen three times as strongly as does fully deoxygenated hemoglobin, an observation consistent only with a sequential model. These results highlight the fact that the concerted and sequential models represent idealized limiting cases, which real systems may approach but rarely attain.

**FIGURE 7.13 T-to-R transition.** The binding curve for hemoglobin can be seen as a combination of the binding curves that would be observed if all molecules remained in the T state or if all of the molecules were in the R state. The sigmoidal curve is observed because molecules convert from the T state into the R state as oxygen molecules bind.

**FIGURE 7.15** Conformational changes in hemoglobin. The movement of the iron ion on oxygenation brings the iron-associated histidine residue toward the porphyrin ring. The associated movement of the histidine-containing  $\alpha$  helix alters the interface between the  $\alpha\beta$  dimers, instigating other structural changes. For comparison, the deoxyhemoglobin structure is shown in gray behind the oxyhemoglobin structure in red.

### Structural changes at the heme groups are transmitted to the $\alpha_1\beta_1-\alpha_2\beta_2$ interface

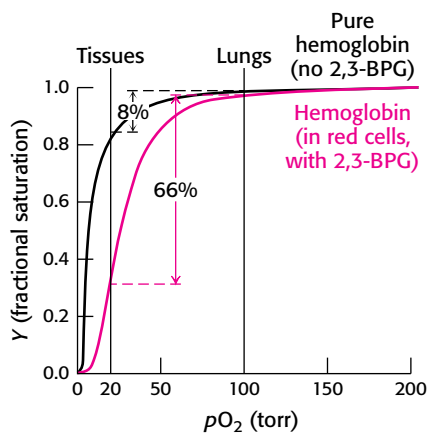

We now examine how oxygen binding at one site is able to shift the equilibrium between the T and R states of the entire hemoglobin tetramer. As in myoglobin, oxygen binding causes each iron atom in hemoglobin to move from outside the plane of the porphyrin into the plane. When the iron atom moves, the proximal histidine residue moves with it. This histidine residue is part of an  $\alpha$  helix, which also moves (Figure 7.15). The carboxyl terminal end of this  $\alpha$  helix lies in the interface between the two  $\alpha\beta$  dimers. The change in position of the carboxyl terminal end of the helix favors the T-to-R transition. Consequently, *the structural transition at the iron ion in one subunit is directly transmitted to the other subunits*. The rearrangement of the dimer interface provides a pathway for communication between subunits, enabling the cooperative binding of oxygen.

### 2,3-Bisphosphoglycerate in red cells is crucial in determining the oxygen affinity of hemoglobin

For hemoglobin to function efficiently, the T state must remain stable until the binding of sufficient oxygen has converted it into the R state. In fact, however, the T state of hemoglobin is highly unstable, pushing the equilibrium so far toward the R state that little oxygen would be released in physiological conditions. Thus, an additional mechanism is needed to properly stabilize the T state. This mechanism was discovered by comparing the oxygen-binding properties of hemoglobin in red blood cells with fully purified hemoglobin (Figure 7.16). Pure hemoglobin binds oxygen much more tightly than does hemoglobin in red blood cells. This dramatic difference is due to the presence within these cells of *2,3-bisphosphoglycerate* (2,3-BPG; also known as 2,3-diphosphoglycerate or 2,3-DPG).

**2,3-Bisphosphoglycerate (2,3-BPG)**

**FIGURE 7.16** Oxygen binding by pure hemoglobin compared with hemoglobin in red blood cells. Pure hemoglobin binds oxygen more tightly than does hemoglobin in red blood cells. This difference is due to the presence of 2,3-bisphosphoglycerate (2,3-BPG) in red blood cells.

This highly anionic compound is present in red blood cells at approximately the same concentration as that of hemoglobin ( $\sim 2$  mM). Without 2,3-BPG, hemoglobin would be an extremely inefficient oxygen transporter, releasing only 8% of its cargo in the tissues.

How does 2,3-BPG lower the oxygen affinity of hemoglobin so significantly? Examination of the crystal structure of deoxyhemoglobin in the presence of 2,3-BPG reveals that a single molecule of 2,3-BPG binds in the center of the tetramer, in a pocket present only in the T form (Figure 7.17). On T-to-R transition, this pocket collapses and 2,3-BPG is released. Thus, in order for the structural transition from T to R to take place, the bonds between hemoglobin and 2,3-BPG must be broken. In the presence of 2,3-BPG, more oxygen-binding sites within the hemoglobin tetramer must be occupied in order to induce the T-to-R transition, and so hemoglobin remains in the lower-affinity T state until higher oxygen concentrations are reached. This mechanism of regulation is remarkable because 2,3-BPG does not in any way resemble oxygen, the molecule on which hemoglobin carries out its primary function. 2,3-BPG is referred to as an *allosteric effector* (from

**FIGURE 7.17** Mode of binding of 2,3-BPG to human deoxyhemoglobin. 2,3-Bisphosphoglycerate binds to the central cavity of deoxyhemoglobin (left). There, it interacts with three positively charged groups on each  $\beta$  chain (right). [Drawn from 1B86.pdb.]

the Greek *allos*, “other,” and *stereos*, “structure”). Regulation by a molecule structurally unrelated to oxygen is possible because the allosteric effector binds to a site that is completely distinct from that for oxygen. We will encounter allosteric effects again when we consider enzyme regulation in Chapter 10.

The binding of 2,3-BPG to hemoglobin has other crucial physiological consequences. The globin gene expressed by human fetuses differs from that expressed by adults; *fetal hemoglobin* tetramers include two  $\alpha$  chains and two  $\gamma$  chains. The  $\gamma$  chain, a result of gene duplication, is 72% identical in amino acid sequence with the  $\beta$  chain. One noteworthy change is the substitution of a serine residue for His 143 in the  $\beta$  chain, part of the 2,3-BPG-binding site. This change removes two positive charges from the 2,3-BPG-binding site (one from each chain) and reduces the affinity of 2,3-BPG for fetal hemoglobin. Consequently, the oxygen-binding affinity of fetal hemoglobin is higher than that of maternal (adult) hemoglobin (Figure 7.18). This difference in oxygen affinity allows oxygen to be effectively transferred from maternal to fetal red blood cells. We have here an example in which gene duplication and specialization produced a ready solution to a biological challenge—in this case, the transport of oxygen from mother to fetus.

**FIGURE 7.18** Oxygen affinity of fetal red blood cells. Fetal red blood cells have a higher oxygen affinity than do maternal red blood cells because fetal hemoglobin does not bind 2,3-BPG as well as maternal hemoglobin does.

### Carbon monoxide can disrupt oxygen transport by hemoglobin

*Carbon monoxide* (CO) is a colorless, odorless gas that binds to hemoglobin at the same site as oxygen, forming a complex termed *carboxyhemoglobin*. Formation of carboxyhemoglobin exerts devastating effects on normal oxygen transport in two ways. First, carbon monoxide binds to hemoglobin about 200-fold more tightly than does oxygen. Even at low partial pressures in the blood, carbon monoxide will displace oxygen from hemoglobin, preventing its delivery. Second, carbon monoxide bound to one site in hemoglobin will shift the oxygen saturation curve of the remaining sites to the left, forcing the tetramer into the R state. This results in an increased affinity for oxygen, preventing its dissociation at tissues.

Exposure to carbon monoxide—from gas appliances and running automobiles, for example—can cause carbon monoxide poisoning, in which patients exhibit nausea, vomiting, lethargy, weakness, and disorientation.

One treatment for carbon monoxide poisoning is administration of 100% oxygen, often at pressures greater than atmospheric pressure (this treatment is referred to as *hyperbaric oxygen therapy*). With this therapy, the partial pressure of oxygen in the blood becomes sufficiently high to increase substantially the displacement of carbon monoxide from hemoglobin. Exposure to high concentrations of carbon monoxide, however, can be rapidly fatal: in the United States, about 2,500 people die each year from carbon monoxide poisoning, about 500 of them from accidental exposures and nearly 2,000 by suicide.

### 7.3 Hydrogen Ions and Carbon Dioxide Promote the Release of Oxygen: The Bohr Effect

We have seen how cooperative release of oxygen from hemoglobin helps deliver oxygen to where it is most needed: tissues exhibiting low oxygen partial pressures. This ability is enhanced by the facility of hemoglobin to respond to other cues in its physiological environment that signal the need for oxygen. Rapidly metabolizing tissues, such as contracting muscle, generate large amounts of hydrogen ions and carbon dioxide (Chapter 16). To release oxygen where the need is greatest, hemoglobin has evolved to respond to higher levels of these substances. Like 2,3-BPG, hydrogen ions and carbon dioxide are allosteric effectors of hemoglobin that bind to sites on the molecule that are distinct from the oxygen-binding sites. The regulation of oxygen binding by hydrogen ions and carbon dioxide is called the *Bohr effect* after Christian Bohr, who described this phenomenon in 1904.

The oxygen affinity of hemoglobin decreases as pH decreases from a value of 7.4 (Figure 7.19). Consequently, as hemoglobin moves into a region of lower pH, its tendency to release oxygen increases. For example, transport from the lungs, with pH 7.4 and an oxygen partial pressure of 100 torr, to active muscle, with a pH of 7.2 and an oxygen partial pressure of 20 torr, results in a release of oxygen amounting to 77% of total carrying capacity. Only 66% of the oxygen would be released in the absence of any change in pH. Structural and chemical studies have revealed much about the chemical basis of the Bohr effect. Several chemical groups within the hemoglobin tetramer are important for sensing changes in pH; all of these have  $pK_a$  values near pH 7. Consider histidine  $\beta 146$ , the residue at the C terminus of the  $\beta$  chain. In deoxyhemoglobin, the terminal carboxylate group of  $\beta 146$  forms a ionic bond, also called a salt bridge, with a lysine residue in the  $\alpha$  subunit of the other  $\alpha\beta$  dimer. This interaction locks the side chain of histidine  $\beta 146$  in a position from which it can participate in a salt bridge with

**FIGURE 7.19** Effect of pH on the oxygen affinity of hemoglobin. Lowering the pH from 7.4 (red curve) to 7.2 (blue curve) results in the release of  $O_2$  from oxyhemoglobin.

**FIGURE 7.20 Chemical basis of the Bohr effect.** In deoxyhemoglobin, three amino acid residues form two salt bridges that stabilize the T quaternary structure. The formation of one of the salt bridges depends on the presence of an added proton on histidine  $\beta 146$ . The proximity of the negative charge on aspartate  $\beta 94$  in deoxyhemoglobin favors protonation of this histidine. Notice that the salt bridge between histidine  $\beta 146$  and aspartate  $\beta 94$  is stabilized by a hydrogen bond (green dashed line).

negatively charged aspartate  $\beta 94$  in the same chain, provided that the imidazole group of the histidine residue is protonated (Figure 7.20).

In addition to His  $\beta 146$ , the  $\alpha$ -amino groups at the amino termini of the  $\alpha$  chain and the side chain of histidine  $\alpha 122$  also participate in salt bridges in the T state. *The formation of these salt bridges stabilizes the T state, leading to a greater tendency for oxygen to be released.* For example, at high pH, the side chain of histidine  $\beta 146$  is not protonated and the salt bridge does not form. As the pH drops, however, the side chain of histidine  $\beta 146$  becomes protonated, the salt bridge with aspartate  $\beta 94$  forms, and the T state is stabilized.

Carbon dioxide, a neutral species, passes through the red-blood-cell membrane into the cell. This transport is also facilitated by membrane transporters, including proteins associated with Rh blood types. Carbon dioxide stimulates oxygen release by two mechanisms. First, the presence of high concentrations of carbon dioxide leads to a drop in pH within the red blood cell (Figure 7.21). Carbon dioxide reacts with water to form carbonic acid,  $\text{H}_2\text{CO}_3$ . This reaction is accelerated by *carbonic anhydrase*, an enzyme abundant in red blood cells that will be considered extensively in Chapter 9.  $\text{H}_2\text{CO}_3$  is a moderately strong acid with a  $\text{p}K_a$  of 3.5. Thus, once formed, carbonic acid dissociates to form bicarbonate ion,  $\text{HCO}_3^-$ , and  $\text{H}^+$ , resulting in a drop in pH that stabilizes the T state by the mechanism discussed previously.

**FIGURE 7.21 Carbon dioxide and pH.** Carbon dioxide in the tissues diffuses into red blood cells. Inside a red blood cell, carbon dioxide reacts with water to form carbonic acid, in a reaction catalyzed by the enzyme carbonic anhydrase. Carbonic acid dissociates to form  $\text{HCO}_3^-$  and  $\text{H}^+$ , resulting in a drop in pH inside the red cell.

**FIGURE 7.22 Carbon dioxide effects.** The presence of carbon dioxide decreases the affinity of hemoglobin for oxygen even beyond the effect due to a decrease in pH, resulting in even more efficient oxygen transport from the tissues to the lungs.

In the second mechanism, a direct chemical interaction between carbon dioxide and hemoglobin stimulates oxygen release. The effect of carbon dioxide on oxygen affinity can be seen by comparing oxygen-binding curves in the absence and in the presence of carbon dioxide *at a constant pH* (Figure 7.22). In the presence of carbon dioxide at a partial pressure of 40 torr at pH 7.2, the amount of oxygen released approaches 90% of the maximum carrying capacity. Carbon dioxide stabilizes deoxyhemoglobin by reacting with the terminal amino groups to form *carbamate* groups, which are negatively charged, in contrast with the neutral or positive charges on the free amino groups.

The amino termini lie at the interface between the  $\alpha\beta$  dimers, and these negatively charged carbamate groups participate in salt-bridge interactions that stabilize the T state, favoring the release of oxygen.

Carbamate formation also provides a mechanism for carbon dioxide transport from tissues to the lungs, but it accounts for only about 14% of the total carbon dioxide transport. Most carbon dioxide released from red blood cells is transported to the lungs in the form of  $\text{HCO}_3^-$  produced from the hydration of carbon dioxide inside the cell (Figure 7.23). Much of the  $\text{HCO}_3^-$  that is formed leaves the cell through a specific membrane-transport protein that exchanges  $\text{HCO}_3^-$  from one side of the membrane for  $\text{Cl}^-$  from the other side. Thus, the serum concentration of  $\text{HCO}_3^-$  increases. By this means, a large concentration of carbon dioxide is transported from tissues to the lungs in the form of  $\text{HCO}_3^-$ . In the lungs, this process is reversed:  $\text{HCO}_3^-$  is converted back into carbon dioxide and exhaled. Thus, carbon dioxide generated by active tissues contributes to a decrease in red-blood-cell pH and, hence, to oxygen release and is converted into a form that can be transported in the serum and released in the lungs.

**FIGURE 7.23 Transport of  $\text{CO}_2$  from tissues to lungs.** Most carbon dioxide is transported to the lungs in the form of  $\text{HCO}_3^-$  produced in red blood cells and then released into the blood plasma. A lesser amount is transported by hemoglobin in the form of an attached carbamate.

## 7.4 Mutations in Genes Encoding Hemoglobin Subunits Can Result in Disease

In modern times, particularly after the sequencing of the human genome, it is routine to think of genetically encoded variations in protein sequence as a factor in specific diseases. The notion that diseases might be caused by molecular defects was proposed by Linus Pauling in 1949 (four years before

Watson and Crick's proposal of the DNA double helix) to explain the blood disease *sickle-cell anemia*. The name of the disorder comes from the abnormal sickle shape of red blood cells deprived of oxygen in people suffering from this disease (Figure 7.24). Pauling proposed that sickle-cell anemia might be caused by a specific variation in the amino acid sequence of one hemoglobin chain. Today, we know that this bold hypothesis is correct. In fact, approximately 7% of the world's population are carriers of some disorder of hemoglobin caused by a variation in its amino acid sequence. In concluding this chapter, we will focus on the two most important of these disorders, sickle-cell anemia and thalassemia.

### Sickle-cell anemia results from the aggregation of mutated deoxyhemoglobin molecules

 People with sickled red blood cells experience a number of dangerous symptoms. Examination of the contents of these red cells reveals that the hemoglobin molecules have formed large fibrous aggregates (Figure 7.25). These fibers extend across the red blood cells, distorting them so that they clog small capillaries and impair blood flow. In addition, red cells from sickle cell patients are more adherent to the walls of blood vessels than those from normal individuals, prolonging the opportunity for capillary occlusion. The results may be painful swelling of the extremities and a higher risk of stroke or bacterial infection (due to poor circulation). The sickled red cells also do not remain in circulation as long as normal cells do, leading to anemia.

What is the molecular defect associated with sickle-cell anemia? Vernon Ingram demonstrated in 1956 that a single amino acid substitution in the  $\beta$  chain of hemoglobin is responsible—namely, the replacement of a glutamate residue with valine in position 6. The mutated form is referred to as *hemoglobin S* (HbS). In people with sickle-cell anemia, both alleles of the hemoglobin  $\beta$ -chain gene (HbB) are mutated. The HbS substitution substantially decreases the solubility of deoxyhemoglobin, although it does not markedly alter the properties of oxyhemoglobin.

Examination of the structure of hemoglobin S reveals that the new valine residue lies on the surface of the T-state molecule (Figure 7.26). This new hydrophobic patch interacts with another hydrophobic patch formed by Phe 85 and Leu 88 of the  $\beta$  chain of a neighboring molecule to initiate the aggregation process. More-detailed analysis reveals that a single hemoglobin S fiber is formed from 14 chains of multiple interlinked hemoglobin molecules. Why do these aggregates not form when hemoglobin S is oxygenated? Oxyhemoglobin S is in the R state, and residues Phe 85 and Leu 88 on the  $\beta$  chain are largely buried inside the hemoglobin assembly. In the

**FIGURE 7.26 Deoxygenated hemoglobin S.** The interaction between Val 6 (blue) on a  $\beta$  chain of one hemoglobin molecule and a hydrophobic patch formed by Phe 85 and Leu 88 (gray) on a  $\beta$  chain of another deoxygenated hemoglobin molecule leads to hemoglobin aggregation. The exposed Val 6 residues of other  $\beta$  chains participate in other such interactions in hemoglobin S fibers. [Drawn from 2HBS.pdb.]

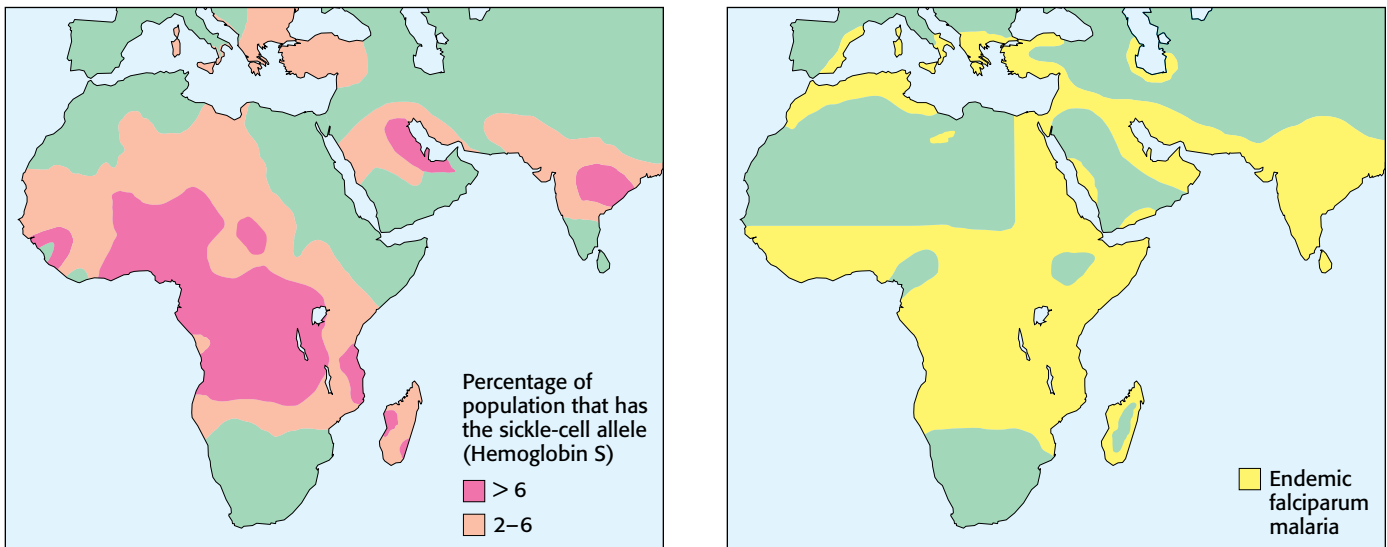

**FIGURE 7.27 The formation of HbS aggregates.** The mutation to Val 6 in hemoglobin S is represented by the red triangles, while the hydrophobic patch formed by Phe 85 and Leu 88 in deoxyhemoglobin is represented by the blue indentations. When HbS is in its deoxy form, it exhibits the complementary features necessary for aggregation.

absence of a partner with which to interact, the surface Val residue in position 6 is benign (Figure 7.27).

 Approximately 1 in 100 West Africans suffer from sickle-cell anemia. Given the often devastating consequences of the disease, why is the HbS mutation so prevalent in Africa and in some other regions? Recall that both copies of the HbB gene are mutated in people with sickle-cell anemia. Individuals with one copy of the HbB gene and one copy of the HbS gene are said to have *sickle-cell trait* because they can pass the HbS gene to their offspring. While sickle-cell trait is considered a benign condition, rare complications have been identified, including an increased risk of exercise-related death in high-performance athletes. However, people with sickle-cell trait exhibit enhanced resistance to *malaria*, a disease carried by a parasite, *Plasmodium falciparum*, that lives within red blood cells at one stage in its life cycle. The dire effect of malaria on health and reproductive likelihood in historically endemic regions has favored people with sickle-cell trait, increasing the prevalence of the HbS allele (Figure 7.28).

**FIGURE 7.28 Sickle-cell trait and malaria.** A significant correlation is observed between regions with a high frequency of the HbS allele and regions with a high prevalence of malaria.

## Thalassemia is caused by an imbalanced production of hemoglobin chains

 Sickle-cell anemia is caused by the substitution of a single specific amino acid in one hemoglobin chain. *Thalassemia*, the other prevalent inherited disorder of hemoglobin, is caused by the loss or substantial reduction of a single hemoglobin *chain*. The result is low levels of functional hemoglobin and a decreased production of red blood cells, which may lead to anemia, fatigue, pale skin, and spleen and liver malfunction. Thalassemia is a set of related diseases. In  $\alpha$ -thalassemia, the  $\alpha$  chain of hemoglobin is not produced in sufficient quantity. Consequently, hemoglobin tetramers form that contain only the  $\beta$  chain. These tetramers, referred to as *hemoglobin H* (HbH), bind oxygen with high affinity and no cooperativity. Thus, oxygen release in the tissues is poor. In  $\beta$ -thalassemia, the  $\beta$  chain of hemoglobin is not produced in sufficient quantity. In the absence of  $\beta$  chains, the  $\alpha$  chains form insoluble aggregates that precipitate inside immature red blood cells. The loss of red blood cells results in anemia. The most severe form of  $\beta$ -thalassemia is called *thalassemia major* or *Cooley anemia*.

Both  $\alpha$ - and  $\beta$ -thalassemia are associated with many different genetic variations and display a wide range of clinical severity. The most severe forms of  $\alpha$ -thalassemia are usually fatal shortly before or just after birth. However, these forms are relatively rare. An examination of the repertoire of hemoglobin genes in the human genome provides one explanation. Normally, humans have not two but four alleles for the  $\alpha$  chain, arranged such that the two genes are located adjacent to each other on one end of each chromosome 16. Thus, the complete loss of  $\alpha$ -chain expression requires the disruption of four alleles.  $\beta$ -Thalassemia is more common because humans normally have only two alleles for the  $\beta$  chain, one on each copy of chromosome 11.

### The accumulation of free alpha-hemoglobin chains is prevented

The presence of four genes expressing the  $\alpha$  chain, compared with two for the  $\beta$  chain, suggests that the  $\alpha$  chain would be produced in excess (given the overly simple assumption that protein expression from each gene is comparable). If this is correct, why doesn't the excess  $\alpha$  chain precipitate? One mechanism for maintaining  $\alpha$  chains in solution was revealed by the discovery of an 11-kDa protein in red blood cells called  *$\alpha$ -hemoglobin stabilizing protein* (AHSP). This protein forms a soluble complex specifically with newly synthesized  $\alpha$ -chain monomers. The crystal structure of a complex between AHSP and  $\alpha$ -hemoglobin reveals that AHSP binds to the same face of  $\alpha$ -hemoglobin as does  $\beta$ -hemoglobin (Figure 7.29). AHSP

 **FIGURE 7.29 Stabilizing free  $\alpha$ -hemoglobin.** The structure of a complex between AHSP and  $\alpha$ -hemoglobin is shown. In this complex, the iron atom is bound to oxygen and to the distal histidine. Notice that AHSP binds to the same surface of  $\alpha$ -hemoglobin as does  $\beta$ -hemoglobin. [Drawn from 1Y01.pdb.]

binds the  $\alpha$  chain in both the deoxygenated and oxygenated forms. In the complex with oxygen bound, the distal histidine, rather than the proximal histidine, binds the iron atom.

AHSP serves to bind and ensure the proper folding of  $\alpha$ -hemoglobin as it is produced. As  $\beta$ -hemoglobin is expressed, it displaces AHSP because the  $\alpha$ -hemoglobin– $\beta$ -hemoglobin dimer is more stable than the  $\alpha$ -hemoglobin–AHSP complex. Thus, AHSP prevents the misfolding, accumulation, and precipitation of free  $\alpha$ -hemoglobin. Studies are under way to determine if mutations in the gene encoding AHSP play a role in modulating the severity of  $\beta$ -thalassemia.

### Additional globins are encoded in the human genome

 In addition to the gene for myoglobin, the two genes for  $\alpha$ -hemoglobin, and the one for  $\beta$ -hemoglobin, the human haploid genome contains other globin genes. We have already encountered fetal hemoglobin, which contains the  $\gamma$  chain in place of the  $\beta$  chain. Several other genes encode other hemoglobin subunits that are expressed during development, including the  $\delta$  chain, the  $\epsilon$  chain, and the  $\zeta$  chain.

Examination of the human genome sequence has revealed two additional globins. Both of these proteins are monomeric proteins, more similar to myoglobin than to hemoglobin. The first, *neuroglobin*, is expressed primarily in the brain and at especially high levels in the retina. Neuroglobin may play a role in protecting neural tissues from hypoxia (insufficient oxygen). The second, *cytoglobin*, is expressed more widely throughout the body. Structural and spectroscopic studies reveal that, in both neuroglobin and cytoglobin, the proximal and the distal histidines are coordinated to the iron atom in the deoxy form. Oxygen binding displaces the distal histidine. Future studies should more completely elucidate the functions of these members of the globin family.

## SUMMARY

### 7.1 Myoglobin and Hemoglobin Bind Oxygen at Iron Atoms in Heme

Myoglobin is a largely  $\alpha$ -helical protein that binds the prosthetic group heme. Heme consists of protoporphyrin, an organic component with four linked pyrrole rings, and a central iron ion in the  $\text{Fe}^{2+}$  state. The iron ion is coordinated to the side chain of a histidine residue in myoglobin, referred to as the proximal histidine. One of the oxygen atoms in  $\text{O}_2$  binds to an open coordination site on the iron. Because of partial electron transfer from the iron to the oxygen, the iron ion moves into the plane of the porphyrin on oxygen binding. Hemoglobin consists of four polypeptide chains, two  $\alpha$  chains and two  $\beta$  chains. Each of these chains is similar in amino acid sequence to myoglobin and folds into a very similar three-dimensional structure. The hemoglobin tetramer is best described as a pair of  $\alpha\beta$  dimers.

### 7.2 Hemoglobin Binds Oxygen Cooperatively

The oxygen-binding curve for myoglobin reveals a simple equilibrium binding process. Myoglobin is half-saturated with oxygen at an oxygen concentration of approximately 2 torr. The oxygen-binding curve for hemoglobin has an “S”-like (sigmoid) shape, indicating that the oxygen binding is cooperative. The binding of oxygen at one site within the hemoglobin tetramer affects the affinities of the other sites for oxygen. Cooperative oxygen binding and

release significantly increase the efficiency of oxygen transport. The amount of the potential oxygen-carrying capacity utilized in transporting oxygen from the lungs (with a partial pressure of oxygen of 100 torr) to tissues (with a partial pressure of oxygen of 20 torr) is 66% compared with 7% if myoglobin had been used as the oxygen carrier.

The quaternary structure of hemoglobin changes on oxygen binding. The structure of deoxyhemoglobin is referred to as the T state. The structure of oxyhemoglobin is referred to as the R state. The two  $\alpha\beta$  dimers rotate by approximately 15 degrees with respect to one another in the transition from the T to the R state. Cooperative binding can be potentially explained by concerted and sequential models. In the concerted model, each hemoglobin adopts either the T state or the R state; the equilibrium between these two states is determined by the number of occupied oxygen-binding sites. Sequential models allow intermediate structures. Structural changes at the iron sites in response to oxygen binding are transmitted to the interface between  $\alpha\beta$  dimers, influencing the T-to-R equilibrium.

Red blood cells contain 2,3-bisphosphoglycerate in concentrations approximately equal to that for hemoglobin. 2,3-BPG binds tightly to the T state but not to the R state, stabilizing the T state and lowering the oxygen affinity of hemoglobin. Fetal hemoglobin binds oxygen more tightly than does adult hemoglobin owing to weaker 2,3-BPG binding. This difference allows oxygen transfer from maternal to fetal blood.

### 7.3 Hydrogen Ions and Carbon Dioxide Promote the Release of Oxygen: The Bohr Effect

The oxygen-binding properties of hemoglobin are markedly affected by pH and by the presence of carbon dioxide, a phenomenon known as the Bohr effect. Increasing the concentration of hydrogen ions—that is, decreasing pH—decreases the oxygen affinity of hemoglobin, owing to the protonation of the amino termini and certain histidine residues. The protonated residues help stabilize the T state. Increasing concentrations of carbon dioxide decrease the oxygen affinity of hemoglobin by two mechanisms. First, carbon dioxide is converted into carbonic acid, which lowers the oxygen affinity of hemoglobin by decreasing the pH inside the red blood cell. Second, carbon dioxide adds to the amino termini of hemoglobin to form carbamates. These negatively charged groups stabilize deoxyhemoglobin through ionic interactions. Because hydrogen ions and carbon dioxide are produced in rapidly metabolizing tissues, the Bohr effect helps deliver oxygen to sites where it is most needed.

### 7.4 Mutations in Genes Encoding Hemoglobin Subunits Can Result in Disease

Sickle-cell disease is caused by a mutation in the  $\beta$  chain of hemoglobin that substitutes a valine residue for a glutamate residue. As a result, a hydrophobic patch forms on the surface of deoxy (T-state) hemoglobin that leads to the formation of fibrous polymers. These fibers distort red blood cells into sickle shapes. Sickle-cell disease was the first disease to be associated with a change in the amino acid sequence of a protein. Thalassemias are diseases caused by the reduced production of either the  $\alpha$  or the  $\beta$  chain, yielding hemoglobin tetramers that contain only one type of hemoglobin chain. Such hemoglobin molecules are characterized by poor oxygen release and low solubility, leading to the destruction of red blood cells in the course of their development.

Red-blood-cell precursors normally produce a slight excess of hemoglobin  $\alpha$  chains compared with  $\beta$  chains. To prevent the aggregation of the excess  $\alpha$  chains, they produce  $\alpha$ -hemoglobin stabilizing protein, which binds specifically to newly synthesized  $\alpha$ -chain monomers to form a soluble complex.

## APPENDIX: Binding Models Can Be Formulated in Quantitative Terms: The Hill Plot and the Concerted Model

### The Hill Plot

A useful way of quantitatively describing cooperative binding processes such as that for hemoglobin was developed by Archibald Hill in 1913. Consider the *hypothetical* equilibrium for a protein X binding a ligand S:

where  $n$  is a variable that can take on both integral and fractional values. The parameter  $n$  is a measure of the degree of cooperativity in ligand binding. For X = hemoglobin and S = O<sub>2</sub>, the maximum value of  $n$  is 4. The value of  $n = 4$  would apply if oxygen binding by hemoglobin were completely cooperative. If oxygen binding were completely noncooperative, then  $n$  would be 1.

Analysis of the equilibrium in equation 1 yields the following expression for the fractional saturation,  $Y$ :

$$Y = \frac{[S]^n}{[S]^n + [S_{50}]^n}$$

where  $[S_{50}]$  is the concentration at which X is half-saturated. For hemoglobin, this expression becomes

$$Y = \frac{pO_2^n}{pO_2^n + P_{50}^n}$$

where  $P_{50}$  is the partial pressure of oxygen at which hemoglobin is half-saturated. This expression can be rearranged to:

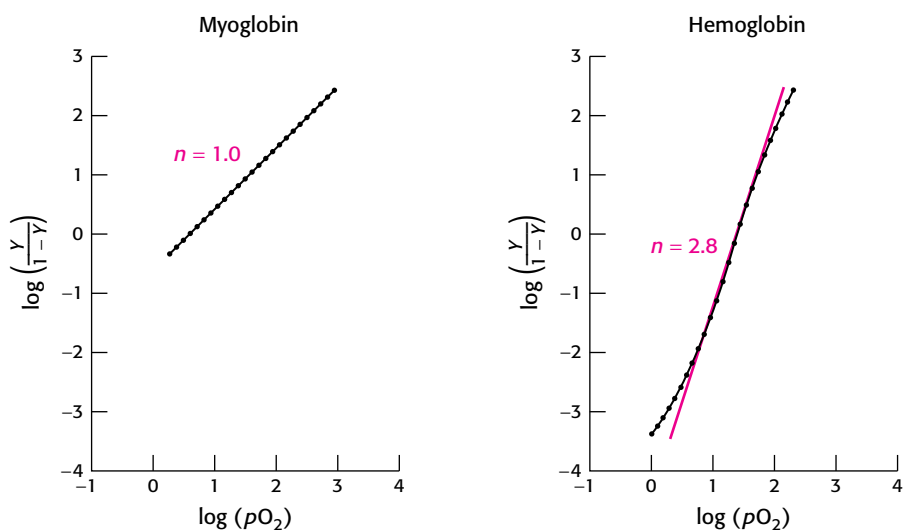

$$\frac{Y}{1 - Y} = \frac{pO_2^n}{P_{50}^n}$$

and so

$$\log\left(\frac{Y}{1 - Y}\right) = \log\left(\frac{pO_2^n}{P_{50}^n}\right) = n \log(pO_2) - n \log(P_{50})$$

This equation predicts that a plot of  $\log(Y/1 - Y)$  versus  $\log(P_{50})$ , called a *Hill plot*, should be linear with a slope of  $n$ .

Hill plots for myoglobin and hemoglobin are shown in Figure 7.30. For myoglobin, the Hill plot is linear with a slope of 1. For hemoglobin, the Hill plot is not completely linear, because the equilibrium on which the Hill plot is based is not entirely correct. However, the plot is approximately linear in the center with a slope of 2.8. The slope, often referred to as the *Hill coefficient*, is a measure of the cooperativity of oxygen binding. The utility of the Hill plot is that it provides a simply derived quantitative assessment of the degree of cooperativity in binding. With the use of the Hill equation and the derived Hill coefficient, a binding

APPENDIX FIGURE 7.30 Hill plots for myoglobin and hemoglobin.

curve that closely resembles that for hemoglobin is produced (Figure 7.31).

**APPENDIX FIGURE 7.31** Oxygen-binding curves for several Hill coefficients. The curve labeled  $n = 2.8$  closely resembles the curve for hemoglobin.

### The Concerted Model

The concerted model can be formulated in quantitative terms. Only four parameters are required: (1) the number of binding sites (assumed to be equivalent) in the protein, (2) the ratio of the concentrations of the T and R states in the absence of bound ligands, (3) the affinity of sites in proteins in the R state for ligand binding, and (4) a measure of how much more tightly subunits in proteins in the R state bind ligands compared with subunits in the T state. The number of binding sites,  $n$ , is usually known from other information. For hemoglobin,  $n = 4$ . The ratio of the concentrations of the T and R states with no ligands bound,  $L$ , is the allosteric constant:

$$L = [T_0]/[R_0]$$

where the subscript refers to the number of ligands bound (in this case, zero). The affinity of subunits in the R state is defined by the dissociation constant for a ligand binding to a single site in the R state,  $K_R$ . Similarly, the dissociation constant for a ligand binding to a single site in the T state is  $K_T$ . We can define the ratio of these two dissociation constants as

$$c = K_R/K_T$$

This is the measure of how much more tightly a subunit for a protein in the R state binds a ligand compared with a subunit for a protein in the T state. Note that  $c < 1$  because  $K_R$  and  $K_T$  are dissociation constants and tight binding corresponds to a small dissociation constant.

What is the ratio of the concentration of T-state proteins with one ligand bound to the concentration of R-state proteins with one ligand bound? The dissociation constant for a single site in the R state is  $K_R$ . For a protein with

$n$  sites, there are  $n$  possible sites for the first ligand to bind. This statistical factor favors ligand binding compared with a single-site protein. Thus,  $[R_1] = n[R_0][S]/K_R$ . Similarly,  $[T_1] = n[T_0][S]/K_T$ . Thus,

$$[T_1]/[R_1] = \frac{n[T_0][S]/K_T}{n[R_0][S]/K_R} = \frac{[T_0]}{[R_0](K_R/K_T)} = cL$$

Similar analysis reveals that, for states with  $i$  ligands bound,  $[T_i]/[R_i] = c^i L$ . In other words, the ratio of the concentrations of the T state to the R state is reduced by a factor of  $c$  for each ligand that binds.

Let us define a convenient scale for the concentration of S:

$$\alpha = [S]/K_R$$

This definition is useful because it is the ratio of the concentration of S to the dissociation constant that determines the extent of binding. Using this definition, we see that

$$[R_1] = \frac{n[R_0][S]}{K_R} = n[R_0]\alpha$$

Similarly,

$$[T_1] = \frac{n[T_0][S]}{K_T} = ncL[R_0]\alpha$$

What is the concentration of R-state molecules with two ligands bound? Again, we must consider the statistical factor—that is, the number of ways in which a second ligand can bind to a molecule with one site occupied. The number of ways is  $n - 1$ . However, because which ligand is the “first” and which is the “second” does not matter, we must divide by a factor of 2. Thus,

$$\begin{aligned} [R_2] &= \frac{\binom{n-1}{2}[R_1][S]}{K_R} \\ &= \binom{n-1}{2}[R_1]\alpha \\ &= \binom{n-1}{2}(n[R_0]\alpha)\alpha \\ &= n\binom{n-1}{2}[K_0]\alpha^2 \end{aligned}$$

We can derive similar equations for the case with  $i$  ligands bound and for T states.

We can now calculate the fractional saturation,  $Y$ . This is the total concentration of sites with ligands bound divided by the total concentration of potential binding sites. Thus,

$$Y = \frac{([R_1] + [T_1] + 2([R_2] + [T_2]) + \cdots + n([R_n] + [T_n]))}{n([R_0] + [T_0] + [R_1] + [T_1] + \cdots + [R_n] + [T_n])}$$

Substituting into this equation, we find

$$Y = \frac{n[R_0]\alpha + nc[T_0]\alpha + 2(n(n-1)/2)[R_0]\alpha^2 + 2(n(n-1)/2)c^2[T_0]\alpha^2 + \dots + n[R_0]\alpha^n + nc^n[T_0]\alpha^n}{n([R_0] + [T_0]) + n[R_0]\alpha + nc[T_0]\alpha + \dots + [R_0]\alpha^n + c^n[T_0]\alpha^n}$$

Substituting  $[T_0] = L[R_0]$  and summing these series yields

$$Y = \frac{\alpha(1 + \alpha)^{n-1} + Lc\alpha(1 + c\alpha)^{n-1}}{(1 + \alpha)^n + L(1 + c\alpha)^n}$$

We can now use this equation to fit the observed data for hemoglobin by varying the parameters  $L$ ,  $c$ , and  $K_R$  (with

**APPENDIX FIGURE 7.32 Modeling oxygen binding with the concerted model.** The fractional saturation ( $\gamma$ ) as a function  $pO_2$ :  $L = 9000$ ,  $c = 0.014$ , and  $K_R = 2.5$  torr. The fraction of molecules in the T state with zero, one, and two oxygen molecules bound ( $T_0$ ,  $T_1$ , and  $T_2$ ) and the fraction of molecules in the R state with two, three, and four oxygen molecules bound ( $R_2$ ,  $R_3$ , and  $R_4$ ) are shown. The fractions of molecules in other forms are too low to be shown.

## PROBLEMS

1. *Screening the biosphere.* The first protein structure to have its structure determined was myoglobin from sperm whale. Propose an explanation for the observation that sperm whale muscle is a rich source of this protein.

$n = 4$ ). An excellent fit is obtained with  $L = 9000$ ,  $c = 0.014$ , and  $K_R = 2.5$  torr (Figure 7.32).

In addition to the fractional saturation, the concentrations of the species  $T_0$ ,  $T_1$ ,  $T_2$ ,  $R_2$ ,  $R_3$ , and  $R_4$  are shown. The concentrations of all other species are very low. The addition of concentrations is a major difference between the analysis using the Hill equation and this analysis of the concerted model. The Hill equation gives only the fractional saturation, whereas the analysis of the concerted model yields concentrations for all species. In the present case, this analysis yields the expected ratio of T-state proteins to R-state proteins at each stage of binding. This ratio changes from 9000 to 126 to 1.76 to 0.025 to 0.00035 with zero, one, two, three, and four oxygen molecules bound. This ratio provides a quantitative measure of the switching of the population of hemoglobin molecules from the T state to the R state.

The sequential model can also be formulated in quantitative terms. However, the formulation entails many more parameters, and many different sets of parameters often yield similar fits to the experimental data.

2. *Hemoglobin content.* The average volume of a red blood cell is  $87 \mu\text{m}^3$ . The mean concentration of hemoglobin in red cells is  $0.34 \text{ g ml}^{-1}$ .

(a) What is the weight of the hemoglobin contained in an average red cell?

(b) How many hemoglobin molecules are there in an average red cell? Assume that the molecular weight of the human hemoglobin tetramer is 65 kDa.

(c) Could the hemoglobin concentration in red cells be much higher than the observed value? (Hint: Suppose that a red cell contained a crystalline array of hemoglobin molecules in a cubic lattice with 65 Å sides.)

3. *Iron content.* How much iron is there in the hemoglobin of a 70-kg adult? Assume that the blood volume is 70 ml kg<sup>-1</sup> of body weight and that the hemoglobin content of blood is 0.16 g ml<sup>-1</sup>.

4. *Oxygenating myoglobin.* The myoglobin content of some human muscles is about 8 g kg<sup>-1</sup>. In sperm whale, the myoglobin content of muscle is about 80 g kg<sup>-1</sup>.

(a) How much O<sub>2</sub> is bound to myoglobin in human muscle and in sperm whale muscle? Assume that the myoglobin is saturated with O<sub>2</sub>, and that the molecular weights of human and sperm whale myoglobin are the same.

(b) The amount of oxygen dissolved in tissue water (in equilibrium with venous blood) at 37°C is about 3.5 × 10<sup>-5</sup> M. What is the ratio of oxygen bound to myoglobin to that directly dissolved in the water of sperm whale muscle?

5. *Tuning proton affinity.* The pK<sub>a</sub> of an acid depends partly on its environment. Predict the effect of each of the following environmental changes on the pK<sub>a</sub> of a glutamic acid side chain.

(a) A lysine side chain is brought into proximity.

(b) The terminal carboxyl group of the protein is brought into proximity.

(c) The glutamic acid side chain is shifted from the outside of the protein to a nonpolar site inside.

6. *Saving grace.* Hemoglobin A inhibits the formation of the long fibers of hemoglobin S and the subsequent sickling of the red cell on deoxygenation. Why does hemoglobin A have this effect?

7. *Carrying a load.* Suppose that you are climbing a high mountain and the oxygen partial pressure in the air is reduced to 75 torr. Estimate the percentage of the oxygen-carrying capacity that will be utilized, assuming that the pH of both tissues and lungs is 7.4 and that the oxygen concentration in the tissues is 20 torr.

8. *Bohr for me, not for thee.* Does myoglobin exhibit a Bohr effect? Why or why not?

9. *High-altitude adaptation.* After spending a day or more at high altitude (with an oxygen partial pressure of 75 torr), the concentration of 2,3-bisphosphoglycerate (2,3-BPG) in red blood cells increases. What effect would an increased

concentration of 2,3-BPG have on the oxygen-binding curve for hemoglobin? Why would this adaptation be beneficial for functioning well at high altitude?

10. *Blood doping.* Endurance athletes sometimes try an illegal method of blood doping called autologous transfusion. Some blood from the athlete is removed well before competition, and then transfused back into the athlete just before competition.

(a) Why might blood transfusion benefit the athlete?

(b) With time, stored red blood cells become depleted in 2,3-BPG. What might be the consequences of using such blood for a blood transfusion?

11. *I'll take the lobster.* Arthropods such as lobsters have oxygen carriers quite different from hemoglobin. The oxygen-binding sites do not contain heme but, instead, are based on two copper(I) ions. The structural changes that accompany oxygen binding are shown below. How might these changes be used to facilitate cooperative oxygen binding?

12. *A disconnect.* With the use of site-directed mutagenesis, hemoglobin has been prepared in which the proximal histidine residues in both the α and the β subunits have been replaced by glycine. The imidazole ring from the histidine residue can be replaced by adding free imidazole in

solution. Would you expect this modified hemoglobin to show cooperativity in oxygen binding? Why or why not?

Imidazole

13. *Successful substitution.* Blood cells from some birds do not contain 2,3-bisphosphoglycerate but, instead, contain one of the compounds in parts *a* through *d*, which plays an analogous functional role. Which compound do you think is most likely to play this role? Explain briefly.

Choline

Spermine

Inositol pentaphosphate

Indole

14. *Theoretical curves.* (a) Using the Hill equation, plot an oxygen-binding curve for a hypothetical two-subunit hemoglobin with  $n = 1.8$  and  $P_{50} = 10$  torr. (b) Repeat, using the concerted model with  $n = 2$ ,  $L = 1000$ ,  $c = 0.01$ , and  $K_R = 1$  torr.

15. *Parasitic effect.* When *P. falciparum* lives inside red blood cells, the metabolism of the parasite tends to release acid. What effect is the presence of acid likely to have on the oxygen-carrying capacity of the red blood cells? On the likelihood that these cells sicken?

### Data Interpretation Problems

16. *Primitive oxygen binding.* Lampreys are primitive organisms whose ancestors diverged from the ancestors of fish and mammals approximately 400 million years ago. Lamprey blood contains a hemoglobin related to mammalian hemoglobin. However, lamprey hemoglobin is monomeric in the oxygenated state. Oxygen-binding data for lamprey hemoglobin are as follows:

$pO_2$	$Y$	$pO_2$	$Y$	$pO_2$	$Y$
0.1	.0060	2.0	.112	50.0	.889
0.2	.0124	3.0	.170	60.0	.905
0.3	.0190	4.0	.227	70.0	.917
0.4	.0245	5.0	.283	80.0	.927
0.5	.0307	7.5	.420	90.0	.935
0.6	.0380	10.0	.500	100	.941
0.7	.0430	15.0	.640	150	.960
0.8	.0481	20.0	.721	200	.970
0.9	.0530	30.0	.812		
1.0	.0591	40.0	.865		

(a) Plot these data to produce an oxygen-binding curve. At what oxygen partial pressure is this hemoglobin half-saturated? On the basis of the appearance of this curve, does oxygen binding seem to be cooperative?

(b) Construct a Hill plot using these data. Does the Hill plot show any evidence for cooperativity? What is the Hill coefficient?

(c) Further studies revealed that lamprey hemoglobin forms oligomers, primarily dimers, in the deoxygenated state. Propose a model to explain any observed cooperativity in oxygen binding by lamprey hemoglobin.

17. *Leaning to the left or to the right.* The illustration below shows several oxygen-dissociation curves. Assume that curve 3 corresponds to hemoglobin with physiological concentrations of  $CO_2$  and 2,3-BPG at pH 7. Which curves represent each of the following perturbations?

- Decrease in  $CO_2$
- Increase in 2,3-BPG
- Increase in pH
- Loss of quaternary structure

### Chapter Integration Problems

18. *Location is everything.* 2,3-Bisphosphoglycerate lies in a central cavity within the hemoglobin tetramer, stabilizing the T state. What would be the effect of mutations that placed the BPG-binding site on the surface of hemoglobin?

19. *A therapeutic option.* Hydroxyurea has been shown to increase the expression of fetal hemoglobin in adult red blood cells, by a mechanism that remains unclear. Explain why hydroxyurea can be a useful therapy for patients with sickle-cell anemia.

# Enzymes: Basic Concepts and Kinetics

The activity of an enzyme is responsible for the glow of the luminescent jellyfish at left. The enzyme aequorin catalyzes the oxidation of a compound by oxygen in the presence of calcium to release  $\text{CO}_2$  and light. [(Left) chain45154/Getty Images.]

Enzymes, the catalysts of biological systems, are remarkable molecular devices that determine the patterns of chemical transformations. They also mediate the transformation of one form of energy into another. About a quarter of the genes in the human genome encode enzymes, a testament to their importance to life. The most striking characteristics of enzymes are their *catalytic power* and *specificity*. Catalysis takes place at a particular site on the enzyme called the *active site*.

Nearly all known enzymes are proteins. However, proteins do not have an absolute monopoly on catalysis; the discovery of catalytically active RNA molecules provides compelling evidence that RNA was a biocatalyst early in evolution. Proteins as a class of macromolecules are highly effective catalysts for an enormous diversity of chemical reactions because of their capacity to specifically bind a very wide range of molecules. By utilizing the full repertoire of intermolecular forces, enzymes bring substrates together in an optimal orientation, the prelude to making and breaking chemical bonds. They catalyze reactions by stabilizing transition states, the highest-energy species in reaction pathways. By selectively stabilizing a transition state, an enzyme determines which one of several potential chemical reactions actually takes place.

## 8.1 Enzymes Are Powerful and Highly Specific Catalysts

Enzymes accelerate reactions by factors of as much as a million or more (Table 8.1). Indeed, most reactions in biological systems do not take place at perceptible rates in the absence of enzymes. Even a reaction as simple as the hydration of carbon dioxide is catalyzed by an enzyme—namely, carbonic anhydrase. The transfer of  $\text{CO}_2$  from the tissues to the blood and then to the air in the alveolae of the lungs would be less complete in the absence of this enzyme (p. 203). In fact, carbonic anhydrase is one of the fastest enzymes known. Each enzyme molecule can hydrate  $10^6$  molecules of  $\text{CO}_2$  *per second*. This catalyzed reaction is  $10^7$  times as fast as the uncatalyzed one. We will consider the mechanism of carbonic anhydrase catalysis in Chapter 9.

Enzymes are highly specific both in the reactions that they catalyze and in their choice of reactants, which are called *substrates*. An enzyme usually catalyzes a single chemical reaction or a set of closely related reactions. Let us consider *proteolytic enzymes* as an example. The biochemical function of these enzymes is to catalyze *proteolysis*, the hydrolysis of a peptide bond.

Most proteolytic enzymes also catalyze a different but related reaction *in vitro*—namely, the hydrolysis of an ester bond. Such reactions are more easily monitored than is proteolysis and are useful in experimental investigations of these enzymes.

Proteolytic enzymes differ markedly in their degree of substrate specificity. Papain, which is found in papaya plants, is quite indiscriminating: it will cleave any peptide bond with little regard to the identity of the adjacent side chains. This lack of specificity accounts for its use in meat-tenderizing

saucers. The digestive enzyme trypsin, on the other hand, is quite specific and catalyzes the splitting of peptide bonds only on the carboxyl side of lysine and arginine residues (Figure 8.1A). Thrombin, an enzyme that participates in blood clotting (Section 10.4), is even more specific than trypsin. It catalyzes the hydrolysis of Arg–Gly bonds in particular peptide sequences only (Figure 8.1B).

DNA polymerase I, a template-directed enzyme (Section 28.3), is another highly specific catalyst. DNA polymerase adds nucleotides to the strand being synthesized in a sequence determined by the sequence of nucleotides in another DNA strand that serves as a template. DNA polymerase I is remarkably precise in carrying out the instructions given by the template. It inserts the wrong nucleotide into a new DNA strand less than one in a thousand times. *The specificity of an enzyme is due to the precise interaction of the substrate with the enzyme. This precision is a result of the intricate three-dimensional structure of the enzyme protein.*

### Many enzymes require cofactors for activity

The catalytic activity of many enzymes depends on the presence of small molecules termed *cofactors*, although the precise role varies with the cofactor and the enzyme. Generally, these cofactors are able to execute chemical reactions that cannot be performed by the standard set of twenty amino acids. An enzyme without its cofactor is referred to as an *apoenzyme*; the complete, catalytically active enzyme is called a *holoenzyme*.

Cofactors can be subdivided into two groups: (1) metals and (2) small organic molecules called *coenzymes* (Table 8.2). Often derived from vitamins, coenzymes can be either tightly or loosely bound to the enzyme. Tightly bound coenzymes are called *prosthetic groups*. Loosely associated coenzymes are more like cosubstrates because, like substrates and products, they bind to the enzyme and are released from it. The use of the same coenzyme by a variety of enzymes sets coenzymes apart from normal substrates, however, as does their source in vitamins (Section 15.4). Enzymes that use the same coenzyme usually perform catalysis by similar mechanisms. In Chapter 9, we will examine the importance of metals to enzyme activity and, throughout the book, we will see how coenzymes and their enzyme partners operate in their biochemical context.

### Enzymes can transform energy from one form into another

A key activity in all living systems is the conversion of one form of energy into another. For example, in photosynthesis, light energy is converted into chemical-bond energy. In cellular respiration, which takes place in mitochondria, the free energy contained in small molecules derived from food is converted first into the free energy of an ion gradient and then into a different currency—the free energy of adenosine triphosphate. Given their centrality to life, it should come as no surprise that enzymes play vital roles in energy transformation. As we will see, enzymes perform fundamental roles in photosynthesis and cellular respiration. Other enzymes can then use the chemical-bond energy of ATP in diverse ways. For instance, the enzyme myosin converts the energy of ATP into the

**FIGURE 8.1 Enzyme specificity.** (A) Trypsin cleaves on the carboxyl side of arginine and lysine residues, whereas (B) thrombin cleaves Arg–Gly bonds in particular sequences only.

**TABLE 8.2 Enzyme cofactors**

mechanical energy of contracting muscles (Section 9.4 and Chapter 35). Pumps in the membranes of cells and organelles, which can be thought of as enzymes that move substrates rather than chemically alter them, use the energy of ATP to transport molecules and ions across the membrane (Chapter 13). The chemical and electrical gradients resulting from the unequal distribution of these molecules and ions are themselves forms of energy that can be used for a variety of purposes, such as sending nerve impulses.

The molecular mechanisms of these energy-transducing enzymes are being unraveled. We will see in subsequent chapters how unidirectional cycles of discrete steps—binding, chemical transformation, and release—lead to the conversion of one form of energy into another.

---

## 8.2 Gibbs Free Energy Is a Useful Thermodynamic Function for Understanding Enzymes

Enzymes speed up the rate of chemical reactions, but the properties of the reaction—whether it can take place at all and the degree to which the enzyme accelerates the reaction—depend on energy differences between reactants and products. *Gibbs free energy* ( $G$ ), which was touched on in Chapter 1, is a thermodynamic property that is a measure of useful energy, or the energy that is capable of doing work. To understand how enzymes operate, we need to consider only two thermodynamic properties of the reaction: (1) the free-energy difference ( $\Delta G$ ) between the products and reactants and (2) the energy required to initiate the conversion of reactants into products. The former determines whether the reaction will take place spontaneously, whereas the latter determines the rate of the reaction. Enzymes affect only the latter. Let us review some of the principles of thermodynamics as they apply to enzymes.

### The free-energy change provides information about the spontaneity but not the rate of a reaction

As discussed in Chapter 1, the free-energy change of a reaction ( $\Delta G$ ) tells us if the reaction can take place spontaneously:

1. A reaction can take place spontaneously only if  $\Delta G$  is negative. Such reactions are said to be *exergonic*.
2. A system is at equilibrium and no net change can take place if  $\Delta G$  is zero.
3. A reaction cannot take place spontaneously if  $\Delta G$  is positive. An input of free energy is required to drive such a reaction. These reactions are termed *endergonic*.
4. The  $\Delta G$  of a reaction depends only on the free energy of the products (the final state) minus the free energy of the reactants (the initial state). The  $\Delta G$  of a reaction is independent of the molecular mechanism of the transformation. For example, the  $\Delta G$  for the oxidation of glucose to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  is the same whether it takes place by combustion or by a series of enzyme-catalyzed steps in a cell.
5. The  $\Delta G$  provides no information about the rate of a reaction. A negative  $\Delta G$  indicates that a reaction *can* take place spontaneously, but it does not signify whether it will proceed at a perceptible rate. As will be discussed shortly (Section 8.3), the rate of a reaction depends on the *free energy of activation* ( $\Delta G^\ddagger$ ), which is largely unrelated to the  $\Delta G$  of the reaction.

## The standard free-energy change of a reaction is related to the equilibrium constant

As for any reaction, we need to be able to determine  $\Delta G$  for an enzyme-catalyzed reaction to know whether the reaction is spontaneous or requires an input of energy. To determine this important thermodynamic parameter, we need to take into account the nature of both the reactants and the products as well as their concentrations.

Consider the reaction

The  $\Delta G$  of this reaction is given by

$$\Delta G = \Delta G^\circ + RT \ln \frac{[C][D]}{[A][B]} \quad (1)$$

in which  $\Delta G^\circ$  is the *standard free-energy change*,  $R$  is the gas constant,  $T$  is the absolute temperature, and  $[A]$ ,  $[B]$ ,  $[C]$ , and  $[D]$  are the molar concentrations (more precisely, the activities) of the reactants.  $\Delta G^\circ$  is the free-energy change for this reaction under standard conditions—that is, when each of the reactants A, B, C, and D is present at a concentration of 1.0 M (for a gas, the standard state is usually chosen to be 1 atmosphere). Thus, the  $\Delta G$  of a reaction depends on the *nature* of the reactants (expressed in the  $\Delta G^\circ$  term of equation 1) and on their *concentrations* (expressed in the logarithmic term of equation 1).

A convention has been adopted to simplify free-energy calculations for biochemical reactions. The standard state is defined as having a pH of 7. Consequently, when  $H^+$  is a reactant, its activity has the value 1 (corresponding to a pH of 7) in equations 1 and 3 (below). The activity of water also is taken to be 1 in these equations. The *standard free-energy change at pH 7*, denoted by the symbol  $\Delta G^{\circ'}$ , will be used throughout this book. The *kilojoule* (abbreviated kJ) and the *kilocalorie* (kcal) will be used as the units of energy. One kilojoule is equivalent to 0.239 kilocalorie.

A simple way to determine  $\Delta G^{\circ'}$  is to measure the concentrations of reactants and products when the reaction has reached equilibrium. At equilibrium, there is no net change in reactants and products; in essence, the reaction has stopped and  $\Delta G = 0$ . At equilibrium, equation 1 then becomes

$$0 = \Delta G^{\circ'} + RT \ln \frac{[C][D]}{[A][B]} \quad (2)$$

and so

$$\Delta G^{\circ'} = -RT \ln \frac{[C][D]}{[A][B]} \quad (3)$$

The equilibrium constant under standard conditions,  $K'_{eq}$  is defined as

$$K'_{eq} = \frac{[C][D]}{[A][B]} \quad (4)$$

Substituting equation 4 into equation 3 gives

$$\Delta G^{\circ'} = -RT \ln K'_{eq} \quad (5)$$

which can be rearranged to give

$$K'_{eq} = e^{-\Delta G^{\circ'}/RT} \quad (6)$$

### Units of energy

A *kilojoule* (kJ) is equal to 1000 J.

A *joule* (J) is the amount of energy needed to apply a 1-newton force over a distance of 1 meter.

A *kilocalorie* (kcal) is equal to 1000 cal.

A *calorie* (cal) is equivalent to the amount of heat required to raise the temperature of 1 gram of water from 14.5°C to 15.5°C. 1 kJ = 0.239 kcal.

**TABLE 8.3** Relation between  $\Delta G^{\circ'}$  and  $K'_{\text{eq}}$  (at 25°C)

$K'_{\text{eq}}$	$\Delta G^{\circ'}$	
	$\text{kJ mol}^{-1}$	$\text{kcal mol}^{-1}$
$10^{-5}$	28.53	6.82
$10^{-4}$	22.84	5.46
$10^{-3}$	17.11	4.09
$10^{-2}$	11.42	2.73
$10^{-1}$	5.69	1.36
1	0.00	0.00
10	-5.69	-1.36
$10^2$	-11.42	-2.73
$10^3$	-17.11	-4.09
$10^4$	-22.84	-5.46
$10^5$	-28.53	-6.82

Substituting  $R = 8.315 \times 10^{-3} \text{ kJ mol}^{-1} \text{ deg}^{-1}$  and  $T = 298 \text{ K}$  (corresponding to 25°C) gives

$$K'_{\text{eq}} = e^{-\Delta G^{\circ'}/2.47} \quad (7)$$

where  $\Delta G^{\circ'}$  is here expressed in kilojoules per mole because of the choice of the units for  $R$  in equation 7. Thus, the standard free energy and the equilibrium constant of a reaction are related by a simple expression. For example, an equilibrium constant of 10 gives a standard free-energy change of  $-5.69 \text{ kJ mol}^{-1}$  ( $-1.36 \text{ kcal mol}^{-1}$ ) at 25°C (Table 8.3). Note that, for each 10-fold change in the equilibrium constant, the  $\Delta G^{\circ'}$  changes by  $5.69 \text{ kJ mol}^{-1}$  ( $1.36 \text{ kcal mol}^{-1}$ ).

As an example, let us calculate  $\Delta G^{\circ'}$  and  $\Delta G$  for the isomerization of dihydroxyacetone phosphate (DHAP) to glyceraldehyde 3-phosphate (GAP). This reaction takes place in glycolysis (Chapter 16). At equilibrium, the ratio of GAP to DHAP is 0.0475 at 25°C (298 K) and pH 7. Hence,  $K'_{\text{eq}} = 0.0475$ . The standard free-energy change for this reaction is then calculated from equation 5:

$$\begin{aligned} \Delta G^{\circ'} &= -RT \ln K'_{\text{eq}} \\ &= -8.315 \times 10^{-3} \times 298 \times \ln(0.0475) \\ &= +7.53 \text{ kJ mol}^{-1} (+1.80 \text{ kcal mol}^{-1}) \end{aligned}$$

Under these conditions, the reaction is endergonic. DHAP will not spontaneously convert into GAP.

Now let us calculate  $\Delta G$  for this reaction when the initial concentration of DHAP is  $2 \times 10^{-4} \text{ M}$  and the initial concentration of GAP is  $3 \times 10^{-6} \text{ M}$ . Substituting these values into equation 1 gives

$$\begin{aligned} \Delta G &= 7.53 \text{ kJ mol}^{-1} + RT \ln \frac{3 \times 10^{-6} \text{ M}}{2 \times 10^{-4} \text{ M}} \\ &= 7.53 \text{ kJ mol}^{-1} - 10.42 \text{ kJ mol}^{-1} \\ &= -2.89 \text{ kJ mol}^{-1} (-0.69 \text{ kcal mol}^{-1}) \end{aligned}$$

This negative value for the  $\Delta G$  indicates that the isomerization of DHAP to GAP is exergonic and can take place spontaneously when these species are present at the preceding concentrations. Note that  $\Delta G$  for this reaction is negative, although  $\Delta G^{\circ'}$  is positive. *It is important to stress that whether the  $\Delta G$  for a reaction is larger, smaller, or the same as  $\Delta G^{\circ'}$  depends on the concentrations of the reactants and products.* The criterion of spontaneity for a reaction is  $\Delta G$ , not  $\Delta G^{\circ'}$ . This point is important because reactions that are not spontaneous based on  $\Delta G^{\circ'}$  can be made spontaneous by adjusting the concentrations of reactants and products. This principle is the basis of the coupling of reactions to form metabolic pathways (Chapter 15).

### Enzymes alter only the reaction rate and not the reaction equilibrium

Because enzymes are such superb catalysts, it is tempting to ascribe to them powers that they do not have. An enzyme cannot alter the laws of thermodynamics and *consequently cannot alter the equilibrium of a chemical reaction.* Consider an enzyme-catalyzed reaction, the conversion of substrate, S, into product, P. Figure 8.2 shows the rate of product formation with time in the presence and absence of enzyme. Note that

**FIGURE 8.2** Enzymes accelerate the reaction rate. The same equilibrium point is reached but much more quickly in the presence of an enzyme.

the amount of product formed is the same whether or not the enzyme is present but, in the present example, the amount of product formed in seconds when the enzyme is present might take hours (or centuries, see Table 8.1) to form if the enzyme were absent.

Why does the rate of product formation level off with time? The reaction has reached equilibrium. Substrate S is still being converted into product P, but P is being converted into S at a rate such that the amount of P present stays the same.

Let us examine the equilibrium in a more quantitative way. Suppose that, in the absence of enzyme, the forward rate constant ( $k_F$ ) for the conversion of S into P is  $10^{-4} \text{ s}^{-1}$  and the reverse rate constant ( $k_R$ ) for the conversion of P into S is  $10^{-6} \text{ s}^{-1}$ . The equilibrium constant  $K$  is given by the ratio of these rate constants:

$$S \xrightleftharpoons[10^{-6} \text{ s}^{-1}]{10^{-4} \text{ s}^{-1}} P$$

$$K = \frac{[P]}{[S]} = \frac{k_F}{k_R} = \frac{10^{-4}}{10^{-6}} = 100$$

The equilibrium concentration of P is 100 times that of S, whether or not enzyme is present. However, it might take a very long time to approach this equilibrium without enzyme, whereas equilibrium would be attained rapidly in the presence of a suitable enzyme (Table 8.1). *Enzymes accelerate the attainment of equilibria but do not shift their positions. The equilibrium position is a function only of the free-energy difference between reactants and products.*

### 8.3 Enzymes Accelerate Reactions by Facilitating the Formation of the Transition State

The free-energy difference between reactants and products accounts for the equilibrium of the reaction, but enzymes accelerate how quickly this equilibrium is attained. How can we explain the rate enhancement in terms of thermodynamics? To do so, we have to consider not the end points of the reaction but the chemical pathway between the end points.

A chemical reaction of substrate S to form product P goes through a *transition state*  $X^\ddagger$  that has a higher free energy than does either S or P.

The double dagger denotes the transition state. The transition state is a transitory molecular structure that is no longer the substrate but is not yet the product. The transition state is the least-stable and most-seldom-occupied species along the reaction pathway because it is the one with the highest free energy. The difference in free energy between the transition state and the substrate is called the *Gibbs free energy of activation* or simply the *activation energy*, symbolized by  $\Delta G^\ddagger$  (Figure 8.3).

$$\Delta G^\ddagger = G_{X^\ddagger} - G_S$$

Note that the energy of activation, or  $\Delta G^\ddagger$ , does not enter into the final  $\Delta G$  calculation for the reaction, because the energy required to generate the transition state is released when the transition state forms the product. The activation-energy barrier immediately suggests how an enzyme enhances the reaction rate without altering  $\Delta G$  of the reaction: enzymes function to lower the activation energy, or, in other words, *enzymes facilitate the formation of the transition state.*

**FIGURE 8.3 Enzymes decrease the activation energy.** Enzymes accelerate reactions by decreasing  $\Delta G^\ddagger$ , the free energy of activation.

One approach to understanding the increase in reaction rates achieved by enzymes is to assume that the transition state ( $X^\ddagger$ ) and the substrate (S) are in equilibrium.

in which  $K^\ddagger$  is the equilibrium constant for the formation of  $X^\ddagger$  and  $v$  is the rate of formation of product from  $X^\ddagger$ . The rate of the reaction  $v$  is proportional to the concentration of  $X^\ddagger$ ,

$$v \propto [X^\ddagger],$$

because only  $X^\ddagger$  can be converted into product. The concentration of  $X^\ddagger$  at equilibrium is in turn related to the free-energy difference  $\Delta G^\ddagger$  between  $X^\ddagger$  and S; the greater the difference in free energy between these two states, the smaller the amount of  $X^\ddagger$ . Thus, the overall rate of reaction  $V$  depends on  $\Delta G^\ddagger$ . Specifically,

$$V = v[X^\ddagger] = \frac{kT}{h}[S]e^{-\Delta G^\ddagger/RT}$$

In this equation,  $k$  is Boltzmann's constant, and  $h$  is Planck's constant. The value of  $kT/h$  at 25°C is  $6.6 \times 10^{12} \text{ s}^{-1}$ . Suppose that the free energy of activation is  $28.53 \text{ kJ mol}^{-1}$  ( $6.82 \text{ kcal mol}^{-1}$ ). If we were to substitute this value of  $\Delta G$  in equation 7 (as shown in Table 8.3), this free-energy difference would result when the ratio  $[X^\ddagger]/[S]$  is  $10^{-5}$ . If we assume for simplicity's sake that  $[S] = 1 \text{ M}$ , then the reaction rate  $V$  is  $6.2 \times 10^7 \text{ s}^{-1}$ . If  $\Delta G^\ddagger$  were lowered by  $5.69 \text{ kJ mol}^{-1}$  ( $1.36 \text{ kcal mol}^{-1}$ ), the ratio  $[X^\ddagger]/[S]$  would then be  $10^{-4}$ , and the reaction rate would be  $6.2 \times 10^8 \text{ s}^{-1}$ . A decrease of  $5.69 \text{ kJ mol}^{-1}$  in  $\Delta G^\ddagger$  yields a 10-fold larger  $V$ . A relatively small decrease in  $\Delta G^\ddagger$  (20% in this particular reaction) results in a much greater increase in  $V$ .

Thus, we see the key to how enzymes operate: *enzymes accelerate reactions by decreasing  $\Delta G^\ddagger$ , the activation energy.* The combination of substrate and enzyme creates a reaction pathway whose transition-state energy is lower than that of the reaction in the absence of enzyme (Figure 8.3). Because the activation energy is lower, more molecules have the energy required to reach the transition state. Decreasing the activation barrier is analogous to lowering the height of a high-jump bar; more athletes will be able to clear the bar. *The essence of catalysis is facilitating the formation of the transition state.*

### The formation of an enzyme–substrate complex is the first step in enzymatic catalysis

Much of the catalytic power of enzymes comes from their binding to and then altering the structure of the substrate to promote the formation of the transition state. Thus, the first step in catalysis is the formation of an *enzyme–substrate* (ES) complex. Substrates bind to a specific region of the enzyme called the *active site*. Most enzymes are highly selective in the substrates that they bind. Indeed, the catalytic specificity of enzymes depends in part on the specificity of binding.

What is the evidence for the existence of an enzyme–substrate complex?

1. The first clue was the observation that, at a constant concentration of enzyme, the reaction rate increases with increasing substrate concentration until a maximal velocity is reached (Figure 8.4). In contrast, uncatalyzed reactions do not show this saturation effect. *The fact that an enzyme-catalyzed reaction has a maximal velocity suggests the formation of a discrete ES complex.* At a sufficiently high substrate concentration, all the catalytic sites are filled, or saturated, and so the reaction rate cannot increase. Although indirect, the

"I think that enzymes are molecules that are complementary in structure to the activated complexes of the reactions that they catalyze, that is, to the molecular configuration that is intermediate between the reacting substances and the products of reaction for these catalyzed processes. The attraction of the enzyme molecule for the activated complex would thus lead to a decrease in its energy and hence to a decrease in the energy of activation of the reaction and to an increase in the rate of reaction."

—Linus Pauling  
*Nature* 161:707, 1948

**FIGURE 8.4** Reaction velocity versus substrate concentration in an enzyme-catalyzed reaction. An enzyme-catalyzed reaction approaches a maximal velocity.

**FIGURE 8.5 Structure of an enzyme–substrate complex.** (Left) The enzyme cytochrome P450 is illustrated bound to its substrate camphor. (Right) Notice that, in the active site, the substrate is surrounded by residues from the enzyme. Note also the presence of a heme cofactor. [Drawn from 2CPP.pdb.]

ability to saturate an enzyme with substrate is the most general evidence for the existence of ES complexes.

2. The *spectroscopic characteristics* of many enzymes and substrates change on the formation of an ES complex. These changes are particularly striking if the enzyme contains a colored prosthetic group (Problem 39).
3. *X-ray crystallography* has provided high-resolution images of substrates and substrate analogs bound to the active sites of many enzymes (Figure 8.5). In Chapter 9, we will take a close look at several of these complexes.

### The active sites of enzymes have some common features

The active site of an enzyme is the region that binds the substrates (and the cofactor, if any). It also contains the amino acid residues that directly participate in the making and breaking of bonds. These residues are called the *catalytic groups*. In essence, *the interaction of the enzyme and substrate at the active site promotes the formation of the transition state*. The active site is the region of the enzyme that most directly lowers the  $\Delta G^\ddagger$  of the reaction, thus providing the rate-enhancement characteristic of enzyme action. Recall from Chapter 2 that proteins are not rigid structures, but are flexible and exist in an array of conformations. Thus, the interaction of the enzyme and substrate at the active site and the formation of the transition state is a dynamic process. Although enzymes differ widely in structure, specificity, and mode of catalysis, a number of generalizations concerning their active sites can be stated:

1. *The active site is a three-dimensional cleft, or crevice, formed by groups that come from different parts of the amino acid sequence*: indeed, residues far apart in the amino acid sequence may interact more strongly than adjacent residues in the sequence, which may be sterically constrained from interacting with one another. In lysozyme, an enzyme that degrades the cell walls of some bacteria, the important groups in the active site are contributed by residues numbered 35, 52, 62, 63, 101, and 108 in the sequence of 129 amino acids (Figure 8.6).

2. *The active site takes up a small part of the total volume of an enzyme*. Although most of the amino acid residues in an enzyme are not in contact with the substrate, the cooperative motions of the entire enzyme help to correctly position the catalytic residues at the active site. Experimental attempts to reduce the size of a catalytically active enzyme show that the minimum size requires about 100 amino acid

**FIGURE 8.6 Active sites may include distant residues.**

(A) Ribbon diagram of the enzyme lysozyme with several components of the active site shown in color. (B) A schematic representation of the primary structure of lysozyme shows that the active site is composed of residues that come from different parts of the polypeptide chain. [Drawn from 6LYZ.pdb.]

**FIGURE 8.7 Hydrogen bonds between an enzyme and substrate.** The enzyme ribonuclease forms hydrogen bonds with the uridine component of the substrate. [Information from F. M. Richards, H. W. Wyckoff, and N. Allewell. In *The Neurosciences: Second Study Program*, F. O. Schmidt, Ed. (Rockefeller University Press, 1970), p. 970.]

residues. In fact, nearly all enzymes are made up of more than 100 amino acid residues, which gives them a mass greater than 10 kDa and a diameter of more than 25 Å, suggesting that all amino acids in the protein, not just those at the active site, are ultimately required to form a functional enzyme.

3. *Active sites are unique microenvironments.* In all enzymes of known structure, active sites are shaped like a cleft, or crevice, to which the substrates bind. Water is usually excluded unless it is a reactant. The nonpolar microenvironment of the cleft enhances the binding of substrates as well as catalysis. Nevertheless, the cleft may also contain polar residues, some of which may acquire special properties essential for substrate binding or catalysis. The internal positions of these polar residues are biologically crucial exceptions to the general rule that polar residues are located on the surface of proteins, exposed to water.

4. *Substrates are bound to enzymes by multiple weak attractions.* The noncovalent interactions in ES complexes are much weaker than covalent bonds, which have energies between  $-210$  and  $-460$  kJ mol $^{-1}$  (between  $-50$  and  $-110$  kcal mol $^{-1}$ ). In contrast, ES complexes usually have equilibrium constants that range from  $10^{-2}$  to  $10^{-8}$  M, corresponding to free energies of interaction ranging from about  $-13$  to  $-50$  kJ mol $^{-1}$  (from  $-3$  to  $-12$  kcal mol $^{-1}$ ). As discussed in Section 1.3, these weak reversible contacts are mediated by electrostatic interactions, hydrogen bonds, and van der Waals forces. Van der Waals forces become significant in binding only when numerous substrate atoms simultaneously come close to many enzyme atoms through the hydrophobic effect. Hence, the enzyme and substrate should have complementary shapes. The directional character of hydrogen bonds between enzyme and substrate often enforces a high degree of specificity, as seen in the RNA-degrading enzyme ribonuclease (Figure 8.7).

5. *The specificity of binding depends on the precisely defined arrangement of atoms in an active site.* Because the enzyme and the substrate interact by means of short-range forces that require close contact, a substrate must have a matching shape to fit into the site. Emil Fischer proposed the lock-and-key analogy in 1890 (Figure 8.8), which was the model for enzyme–substrate interaction for several decades. We now know that enzymes are flexible and that the shapes of the active sites can be markedly modified by the binding of substrate, a process of dynamic recognition called *induced fit* (Figure 8.9). Moreover, the substrate may bind to only certain conformations of the enzyme, in what is called *conformation selection*. Thus, the mechanism of catalysis is dynamic, involving structural changes with multiple intermediates of both reactants and the enzyme.

**FIGURE 8.8 Lock-and-key model of enzyme–substrate binding.** In this model, the active site of the unbound enzyme is complementary in shape to the substrate.

**FIGURE 8.9 Induced-fit model of enzyme–substrate binding.** In this model, the enzyme changes shape on substrate binding. The active site forms a shape complementary to the substrate only after the substrate has been bound.

### The binding energy between enzyme and substrate is important for catalysis

Enzymes lower the activation energy, but where does the energy to lower the activation energy come from? Free energy is released by the formation of a large number of weak interactions between a complementary enzyme and its substrate. The free energy released on binding is called the *binding energy*. Only the correct substrate can participate in most or all of the interactions with the enzyme and thus maximize binding energy, accounting for the exquisite substrate specificity exhibited by many enzymes. Furthermore, *the full complement of such interactions is formed only when the substrate is converted into the transition state*. Thus, the maximal binding energy is released when the enzyme facilitates the formation of the transition state. The energy released by the interaction between the enzyme and the substrate can be thought of as lowering the activation energy. The interaction of the enzyme with the substrate and reaction intermediates is fleeting, with molecular movements resulting in the optimal alignment of functional groups at the active site so that maximum binding energy occurs only between the enzyme and the transition state, the least-stable reaction intermediate. However, the transition state is too unstable to exist for long. It collapses to either substrate or product, but which of the two accumulates is determined only by the energy difference between the substrate and the product—that is, by the  $\Delta G$  of the reaction.

## 8.4 The Michaelis–Menten Model Accounts for the Kinetic Properties of Many Enzymes

The study of the rates of chemical reactions is called *kinetics*, and the study of the rates of enzyme-catalyzed reactions is called *enzyme kinetics*. A kinetic description of enzyme activity will help us understand how enzymes function. We begin by briefly examining some of the basic principles of reaction kinetics.

### Kinetics is the study of reaction rates

What do we mean when we say the “rate” of a chemical reaction? Consider a simple reaction:

The rate  $V$  is the quantity of  $A$  that disappears in a specified unit of time. It is equal to the rate of the appearance of  $P$ , or the quantity of  $P$  that appears in a specified unit of time.

$$V = -\Delta A/\Delta T = \Delta P/\Delta T \quad (8)$$

If  $A$  is yellow and  $P$  is colorless, we can follow the decrease in the concentration of  $A$  by measuring the decrease in the intensity of yellow color with time. Consider only the change in the concentration of  $A$  for now. The rate of the reaction is directly related to the concentration of  $A$  by a proportionality constant,  $k$ , called the *rate constant*.

$$V = k[A] \quad (9)$$

Reactions that are directly proportional to the reactant concentration are called *first-order reactions*. First-order rate constants have the units of  $s^{-1}$ .

Many important biochemical reactions include two reactants. For example,

or

**FIGURE 8.10** Determining the relation between initial velocity and substrate concentration. (A) The amount of product formed at different substrate concentrations is plotted as a function of time. The initial velocity ( $V_0$ ) for each substrate concentration is determined from the slope of the curve at the beginning of a reaction, when the reverse reaction is insignificant. (B) The values for initial velocity determined in part A are then plotted, with error bars, against substrate concentration. (C) The data points are connected to clearly reveal the relationship of initial velocity to substrate concentration.

They are called *bimolecular reactions* and the corresponding rate equations often take the form

$$V = k[A]^2 \quad (10)$$

and

$$V = k[A][B] \quad (11)$$

The rate constants, called second-order rate constants, have the units  $M^{-1} s^{-1}$ .

Sometimes, second-order reactions can appear to be first-order reactions. For instance, in reaction 11, if B is present in excess and A is present at low concentrations, the reaction rate will be first order with respect to A and will not appear to depend on the concentration of B. These reactions are called *pseudo-first-order reactions*, and we will see them a number of times in our study of biochemistry.

Interestingly enough, under some conditions, a reaction can be zero order. In these cases, the rate is independent of reactant concentrations. Enzyme-catalyzed reactions can approximate zero-order reactions under some circumstances (p. 228).

### The steady-state assumption facilitates a description of enzyme kinetics

The simplest way to investigate the reaction rate is to follow the increase in reaction product as a function of time. First, the extent of product formation is determined as a function of time for a series of substrate concentrations (Figure 8.10A). As expected, in each case, the amount of product formed increases with time, although eventually a time is reached when there is *no net change* in the concentration of S or P. The enzyme is still actively converting substrate into product and vice versa, but the reaction equilibrium has been attained. However, enzyme kinetics is more readily comprehended if we consider only the forward reaction. We can define the rate of catalysis  $V_0$ , or the initial rate of catalysis, as the number of moles of product formed per second when the reaction is just beginning—that is, when  $t \approx 0$  (Figure 8.10A). These experiments are repeated three to five times with each substrate concentration to insure the accuracy of and assess the variability of the values attained. Next, we plot  $V_0$  versus the substrate concentration [S], assuming a constant amount of enzyme, showing the data points with error bars (Figure 8.10B). Finally, the data points are connected, yielding the results shown in Figure 8.10C. The rate of catalysis rises linearly as substrate concentration increases and then begins to level off and approach a maximum at higher substrate concentrations. For convenience, we will show idealized data without error bars, throughout the text, but it is important to keep in mind that in reality, all experiments are repeated multiple times.

In 1913, Leonor Michaelis and Maud Menten proposed a simple model to account for these kinetic characteristics. The critical feature in their treatment is that a specific ES complex is a necessary intermediate in catalysis. The model proposed is

An enzyme E combines with substrate S to form an ES complex, with a rate constant  $k_1$ . The ES complex has two possible fates. It can dissociate to E and S, with a rate constant  $k_{-1}$ , or it can proceed to form product P, with a rate constant  $k_2$ . The ES complex can also be reformed from E and P by the reverse reaction with a rate constant  $k_{-2}$ . However, as before, we can simplify these reactions by considering the rate of reaction at times close to zero

(hence,  $V_0$ ) when there is negligible product formation and thus no back reaction ( $k_{-2}[E][P] \approx 0$ ).

Thus, for the graph in Figure 8.11,  $V_0$  is determined for each substrate concentration by measuring the rate of product formation at early times before P accumulates (Figure 8.10A).

We want an expression that relates the rate of catalysis to the concentrations of substrate and enzyme and the rates of the individual steps. Our starting point is that the catalytic rate is equal to the product of the concentration of the ES complex and  $k_2$ .

$$V_0 = k_2[ES] \quad (13)$$

Now we need to express  $[ES]$  in terms of known quantities. The rates of formation and breakdown of ES are given by

$$\text{Rate of formation of ES} = k_1[E][S] \quad (14)$$

$$\text{Rate of breakdown of ES} = (k_{-1} + k_2)[ES] \quad (15)$$

We will use the *steady-state assumption* to simplify matters. In a steady state, the concentrations of intermediates—in this case,  $[ES]$ —stay the same even if the concentrations of starting materials and products are changing. This steady state is reached when the rates of formation and breakdown of the ES complex are equal. Setting the right-hand sides of equations 14 and 15 equal gives

$$k_1[E][S] = (k_{-1} + k_2)[ES] \quad (16)$$

By rearranging equation 16, we obtain

$$[E][S]/[ES] = (k_{-1} + k_2)/k_1 \quad (17)$$

Equation 17 can be simplified by defining a new constant,  $K_M$ , called the Michaelis constant:

$$K_M = \frac{k_{-1} + k_2}{k_1} \quad (18)$$

Note that  $K_M$  has the units of concentration and is independent of enzyme and substrate concentrations. As will be explained,  $K_M$  is an important characteristic of enzyme–substrate interactions.

Inserting equation 18 into equation 17 and solving for  $[ES]$  yields

$$[ES] = \frac{[E][S]}{K_M} \quad (19)$$

Now let us examine the numerator of equation 19. Because the substrate is usually present at a much higher concentration than that of the enzyme, the concentration of uncombined substrate  $[S]$  is very nearly equal to the total substrate concentration. The concentration of uncombined enzyme  $[E]$  is equal to the total enzyme concentration  $[E]_T$  minus the concentration of the ES complex:

$$[E] = [E]_T - [ES] \quad (20)$$

Substituting this expression for  $[E]$  in equation 19 gives

$$[ES] = \frac{([E]_T - [ES])[S]}{K_M} \quad (21)$$

Solving equation 21 for  $[ES]$  gives

$$[ES] = \frac{[E]_T[S]/K_M}{1 + [S]/K_M} \quad (22)$$

**FIGURE 8.11 Michaelis–Menten kinetics.** A plot of the reaction velocity ( $V_0$ ) as a function of the substrate concentration  $[S]$  for an enzyme that obeys Michaelis–Menten kinetics shows that the maximal velocity ( $V_{\max}$ ) is approached asymptotically. The Michaelis constant ( $K_M$ ) is the substrate concentration yielding a velocity of  $V_{\max}/2$ .

or

$$[\text{ES}] = [\text{E}]_{\text{T}} \frac{[\text{S}]}{[\text{S}] + K_{\text{M}}} \quad (23)$$

By substituting this expression for [ES] into equation 13, we obtain

$$V_0 = k_2[\text{E}]_{\text{T}} \frac{[\text{S}]}{[\text{S}] + K_{\text{M}}} \quad (24)$$

The *maximal rate*,  $V_{\text{max}}$ , is attained when the catalytic sites on the enzyme are saturated with substrate—that is, when  $[\text{ES}] = [\text{E}]_{\text{T}}$ . Thus,

$$V_{\text{max}} = k_2[\text{E}]_{\text{T}} \quad (25)$$

Substituting equation 25 into equation 24 yields the *Michaelis–Menten equation*:

$$V_0 = V_{\text{max}} \frac{[\text{S}]}{[\text{S}] + K_{\text{M}}} \quad (26)$$

This equation accounts for the kinetic data given in Figure 8.11. At very low substrate concentration, when [S] is much less than  $K_{\text{M}}$ ,  $V_0 = (V_{\text{max}}/K_{\text{M}})[\text{S}]$ ; that is, the reaction is first order with the rate directly proportional to the substrate concentration. At high substrate concentration, when [S] is much greater than  $K_{\text{M}}$ ,  $V_0 = V_{\text{max}}$ ; that is, the rate is maximal. The reaction is zero order, independent of substrate concentration.

The significance of  $K_{\text{M}}$  is clear when we set  $[\text{S}] = K_{\text{M}}$  in equation 26. When  $[\text{S}] = K_{\text{M}}$ , then  $V_0 = V_{\text{max}}/2$ . Thus,  $K_{\text{M}}$  is equal to the substrate concentration at which the reaction rate is half its maximal value. As we will see,  $K_{\text{M}}$  is an important characteristic of an enzyme-catalyzed reaction and is significant for its biological function.

### Variations in $K_{\text{M}}$ can have physiological consequences

The physiological consequence of  $K_{\text{M}}$  is illustrated by the sensitivity of some persons to ethanol. Such persons exhibit facial flushing and rapid heart rate (tachycardia) after ingesting even small amounts of alcohol. In the liver, alcohol dehydrogenase converts ethanol into acetaldehyde.

Normally, the acetaldehyde, which is the cause of the symptoms when present at high concentrations, is processed to acetate by aldehyde dehydrogenase.

Most people have two forms of the aldehyde dehydrogenase, a low  $K_{\text{M}}$  mitochondrial form and a high  $K_{\text{M}}$  cytoplasmic form. In susceptible persons, the mitochondrial enzyme is less active owing to the substitution of a single amino acid, and acetaldehyde is processed only by the cytoplasmic enzyme. Because this enzyme has a high  $K_{\text{M}}$ , it achieves a high rate of catalysis only at very high concentrations of acetaldehyde. Consequently, less acetaldehyde is converted into acetate; excess acetaldehyde escapes into the blood and accounts for the physiological effects.

### $K_{\text{M}}$ and $V_{\text{max}}$ values can be determined by several means

$K_{\text{M}}$  is equal to the substrate concentration that yields  $V_{\text{max}}/2$ ; however  $V_{\text{max}}$ , like perfection, is only approached but never attained. How, then, can we experimentally determine  $K_{\text{M}}$  and  $V_{\text{max}}$ , and how do these parameters enhance

our understanding of enzyme-catalyzed reactions? The Michaelis constant,  $K_M$ , and the maximal rate,  $V_{\max}$ , can be readily derived from rates of catalysis measured at a variety of substrate concentrations if an enzyme operates according to the simple scheme given in equation 26. The derivation of  $K_M$  and  $V_{\max}$  is most commonly achieved with the use of curve-fitting programs on a computer. However, an older method, although rarely used because the data points at high and low concentrations are weighted differently and thus sensitive to errors, is a source of further insight into the meaning of  $K_M$  and  $V_{\max}$ .

Before the availability of computers, the determination of  $K_M$  and  $V_{\max}$  values required algebraic manipulation of the Michaelis–Menten equation. The Michaelis–Menten equation is transformed into one that gives a straight-line plot that yields values for  $V_{\max}$  and  $K_M$ . Taking the reciprocal of both sides of equation 26 gives

$$\frac{1}{V_0} = \frac{K_M}{V_{\max}} \cdot \frac{1}{S} + \frac{1}{V_{\max}} \quad (27)$$

A plot of  $1/V_0$  versus  $1/[S]$ , called a *Lineweaver–Burk* or *double-reciprocal plot*, yields a straight line with a y-intercept of  $1/V_{\max}$  and a slope of  $K_M/V_{\max}$  (Figure 8.12). The intercept on the x-axis is  $-1/K_M$ .

### $K_M$ and $V_{\max}$ values are important enzyme characteristics

The  $K_M$  values of enzymes range widely (Table 8.4). For most enzymes,  $K_M$  lies between  $10^{-1}$  and  $10^{-7}$  M. The  $K_M$  value for an enzyme depends on the particular substrate and on environmental conditions such as pH, temperature, and ionic strength. The Michaelis constant,  $K_M$ , as already noted, is equal to the concentration of substrate at which half the active sites are filled. Thus,  $K_M$  provides a measure of the substrate concentration required for significant catalysis to take place. For many enzymes, experimental evidence suggests that the  $K_M$  value provides an approximation of the substrate concentration *in vivo*, which in turn suggests that most enzymes evolved to have a  $K_M$  approximately equal to the substrate concentration commonly available. Why might it be beneficial to have a  $K_M$  value approximately equal to the commonly available substrate concentration? If the normal concentration of substrate is near  $K_M$ , the enzyme will display significant activity and yet the activity will be sensitive to changes in environmental conditions—that is, changes in substrate concentration. At values below  $K_M$ , enzymes are very sensitive to changes in substrate concentration but display little activity. At substrate values well above  $K_M$ , enzymes have great catalytic activity but are insensitive to changes in substrate concentration. Thus, with the normal substrate concentration being approximately  $K_M$ , the enzymes have significant activity ( $1/2 V_{\max}$ ) but are still sensitive to changes in substrate concentration.

Under certain circumstances,  $K_M$  reflects the strength of the enzyme–substrate interaction. In equation 18,  $K_M$  is defined as  $(k_{-1} + k_2)/k_1$ . Consider a case in which  $k_{-1}$  is much greater than  $k_2$ . Under such circumstances, the ES complex dissociates to E and S much more rapidly than product is formed. Under these conditions ( $k_{-1} \gg k_2$ )

$$K_M \approx \frac{k_{-1}}{k_1} \quad (28)$$

Equation 28 describes the *dissociation constant* of the ES complex.

$$K_{ES} = \frac{[E][S]}{[ES]} = \frac{k_{-1}}{k_1} \quad (29)$$

**FIGURE 8.12** A double-reciprocal or Lineweaver–Burk plot. A double-reciprocal plot of enzyme kinetics is generated by plotting  $1/V_0$  as a function of  $1/[S]$ . The slope is  $K_M/V_{\max}$ , the intercept on the vertical axis is  $1/V_{\max}$ , and the intercept on the horizontal axis is  $-1/K_M$ .

**TABLE 8.4**  $K_M$  values of some enzymes

Enzyme	Substrate	$K_M$ ( $\mu\text{M}$ )
Chymotrypsin	Acetyl-L-tryptophanamide	5000
Lysozyme	Hexa- <i>N</i> -acetylglucosamine	6
$\beta$ -Galactosidase	Lactose	4000
Threonine deaminase	Threonine	5000
Carbonic anhydrase	$\text{CO}_2$	8000
Penicillinase	Benzylpenicillin	50
Pyruvate carboxylase	Pyruvate	400
	$\text{HCO}_3^-$	1000
	ATP	60
Arginine-tRNA synthetase	Arginine	3
	tRNA	0.4
	ATP	300

In other words,  $K_M$  is equal to the dissociation constant of the ES complex if  $k_2$  is much smaller than  $k_{-1}$ . When this condition is met,  $K_M$  is a measure of the strength of the ES complex: a high  $K_M$  indicates weak binding; a low  $K_M$  indicates strong binding. It must be stressed that  $K_M$  indicates the affinity of the ES complex only when  $k_{-1}$  is much greater than  $k_2$ .

The maximal rate,  $V_{\max}$ , reveals the *turnover number* of an enzyme, which is the number of substrate molecules converted into product by an enzyme molecule in a unit time when the enzyme is fully saturated with substrate. It is equal to the rate constant  $k_2$ , which is also called  $k_{\text{cat}}$ . The maximal rate,  $V_{\max}$ , reveals the turnover number of an enzyme if the concentration of active sites  $[E]_T$  is known, because

$$V_{\max} = k_{\text{cat}}[E]_T \quad (30)$$

and thus

$$k_{\text{cat}} = V_{\max}/[E]_T \quad (31)$$

For example, a  $10^{-6}$  M solution of carbonic anhydrase catalyzes the formation of 0.6 M  $\text{H}_2\text{CO}_3$  per second when the enzyme is fully saturated with substrate. Hence,  $k_{\text{cat}}$  is  $6 \times 10^5 \text{ s}^{-1}$ . This turnover number is one of the largest known. Each catalyzed reaction takes place in a time equal to, on average,  $1/k_{\text{cat}}$ , which is 1.7  $\mu\text{s}$  for carbonic anhydrase. The turnover numbers of most enzymes with their physiological substrates range from 1 to  $10^4$  per second (Table 8.5).

$K_M$  and  $V_{\max}$  also permit the determination of  $f_{\text{ES}}$ , the fraction of active sites filled. This relation of  $f_{\text{ES}}$  to  $K_M$  and  $V_{\max}$  is given by the following equation:

$$f_{\text{ES}} = \frac{V}{V_{\max}} = \frac{[S]}{[S] + K_M} \quad (32)$$

### $k_{\text{cat}}/K_M$ is a measure of catalytic efficiency

When the substrate concentration is much greater than  $K_M$ , the rate of catalysis is equal to  $V_{\max}$ , which is a function of  $k_{\text{cat}}$ , the turnover number, as already described. However, most enzymes are not normally saturated with substrate. Under physiological conditions, the  $[S]/K_M$  ratio is typically between 0.01 and 1.0. When  $[S] \ll K_M$ , the enzymatic rate is much less than  $k_{\text{cat}}$  because most of the active sites are unoccupied. Is there a number that characterizes the kinetics of an enzyme under these more typical cellular conditions? Indeed there is, as can be shown by combining equations 13 and 19 to give

$$V_0 = \frac{k_{\text{cat}}}{K_M}[E][S] \quad (33)$$

When  $[S] \ll K_M$ , the concentration of free enzyme  $[E]$ , is nearly equal to the total concentration of enzyme  $[E]_T$ ; so

$$V_0 = \frac{k_{\text{cat}}}{K_M}[S][E]_T \quad (34)$$

Thus, when  $[S] \ll K_M$ , the enzymatic velocity depends on the values of  $k_{\text{cat}}/K_M$ ,  $[S]$ , and  $[E]_T$ . Under these conditions,  $k_{\text{cat}}/K_M$  is the rate constant for the interaction of S and E. The rate constant  $k_{\text{cat}}/K_M$ , called the *specificity constant*, is a measure of catalytic efficiency because it takes into account both the rate of catalysis with a particular substrate ( $k_{\text{cat}}$ ) and the nature of the enzyme–substrate interaction ( $K_M$ ). For instance, by using  $k_{\text{cat}}/K_M$  values, we can compare an enzyme's preference for different substrates. Table 8.6 shows the  $k_{\text{cat}}/K_M$  values for several different substrates of chymotrypsin. Chymotrypsin clearly has a preference for cleaving next to bulky, hydrophobic side chains.

**TABLE 8.5** Turnover numbers of some enzymes

Enzyme	Turnover number (per second)
Carbonic anhydrase	600,000
3-Ketosteroid isomerase	280,000
Acetylcholinesterase	25,000
Penicillinase	2,000
Lactate dehydrogenase	1,000
Chymotrypsin	100
DNA polymerase I	15
Tryptophan synthetase	2
Lysozyme	0.5

**TABLE 8.6** Substrate preferences of chymotrypsin

Amino acid in ester	Amino acid side chain	$k_{\text{cat}}/K_{\text{M}}$ ( $\text{s}^{-1} \text{M}^{-1}$ )
Glycine	—H	$1.3 \times 10^{-1}$
Valine	$\begin{array}{c} \text{CH}_2 \\   \\ \text{—CH} \\   \\ \text{CH}_2 \end{array}$	2.0
Norvaline	—CH <sub>2</sub> CH <sub>2</sub> CH <sub>3</sub>	$3.6 \times 10^2$
Norleucine	—CH <sub>2</sub> CH <sub>2</sub> CH <sub>2</sub> CH <sub>3</sub>	$3.0 \times 10^3$
Phenylalanine	—CH <sub>2</sub> — 	$1.0 \times 10^5$

Source: Information from A. Fersht, *Structure and Mechanism in Protein Science: A Guide to Enzyme Catalysis and Protein Folding* (W. H. Freeman and Company, 1999), Table 7.3.

How efficient can an enzyme be? We can approach this question by determining whether there are any physical limits on the value of  $k_{\text{cat}}/K_{\text{M}}$ . Note that the  $k_{\text{cat}}/K_{\text{M}}$  ratio depends on  $k_1$ ,  $k_{-1}$ , and  $k_{\text{cat}}$ , as can be shown by substituting for  $K_{\text{M}}$ :

$$k_{\text{cat}}/K_{\text{M}} = \frac{k_{\text{cat}}k_1}{k_{-1} + k_{\text{cat}}} = \left( \frac{k_{\text{cat}}}{k_{-1} + k_{\text{cat}}} \right) k_1 < k_1 \quad (35)$$

Suppose that the rate of formation of product ( $k_{\text{cat}}$ ) is much faster than the rate of dissociation of the ES complex ( $k_{-1}$ ). The value of  $k_{\text{cat}}/K_{\text{M}}$  then approaches  $k_1$ . Thus, the ultimate limit on the value of  $k_{\text{cat}}/K_{\text{M}}$  is set by  $k_1$ , the rate of formation of the ES complex. *This rate cannot be faster than the diffusion-controlled encounter of an enzyme and its substrate.* Diffusion limits the value of  $k_1$  and so it cannot be higher than between  $10^8$  and  $10^9 \text{ s}^{-1} \text{ M}^{-1}$ . Hence, the upper limit on  $k_{\text{cat}}/K_{\text{M}}$  is between  $10^8$  and  $10^9 \text{ s}^{-1} \text{ M}^{-1}$ .

The  $k_{\text{cat}}/K_{\text{M}}$  ratios of the enzymes superoxide dismutase, acetylcholinesterase, and triose phosphate isomerase are between  $10^8$  and  $10^9 \text{ s}^{-1} \text{ M}^{-1}$ . Enzymes that have  $k_{\text{cat}}/K_{\text{M}}$  ratios at the upper limits have attained *kinetic perfection*. *Their catalytic velocity is restricted only by the rate at which they encounter substrate in the solution* (Table 8.7). Any further gain in catalytic rate can come only by decreasing the time for diffusion of the substrate into the enzyme's immediate environment. Remember that the active site is only a small part of the total enzyme structure. Yet, for catalytically perfect enzymes, every encounter between enzyme and substrate is productive. In these cases, there may be attractive electrostatic forces on the enzyme that entice the substrate to the active site. These forces are sometimes referred to poetically as *Circe effects*.

The diffusion of a substrate throughout a solution can also be partly overcome by confining substrates and products in the limited volume of a multienzyme complex. Indeed, some series of enzymes are organized into complexes so that the product of one enzyme is very rapidly found by the next enzyme. In effect, products are channeled from one enzyme to the next, much as in an assembly line.

### Most biochemical reactions include multiple substrates

Most reactions in biological systems start with two substrates and yield two products. They can be represented by the bisubstrate reaction:

Many such reactions transfer a functional group, such as a phosphoryl or an ammonium group, from one substrate to the other. Those that are

**TABLE 8.7** Enzymes for which  $k_{\text{cat}}/K_{\text{M}}$  is close to the diffusion-controlled rate of encounter

Enzyme	$k_{\text{cat}}/K_{\text{M}}$ ( $\text{s}^{-1} \text{M}^{-1}$ )
Acetylcholinesterase	$1.6 \times 10^8$
Carbonic anhydrase	$8.3 \times 10^7$
Catalase	$4 \times 10^7$
Crotonase	$2.8 \times 10^8$
Fumarase	$1.6 \times 10^8$
Triose phosphate isomerase	$2.4 \times 10^8$
$\beta$ -Lactamase	$1 \times 10^8$
Superoxide dismutase	$7 \times 10^9$

#### Circe effect

The utilization of attractive forces to lure a substrate into a site in which it undergoes a transformation of structure, as defined by William P. Jencks, an enzymologist, who coined the term.

A goddess of Greek mythology, Circe lured Odysseus's men to her house and then transformed them into pigs.

oxidation–reduction reactions transfer electrons between substrates. Multiple substrate reactions can be divided into two classes: *sequential* reactions and *double-displacement* reactions.

**Sequential reactions.** In *sequential reactions*, all substrates must bind to the enzyme before any product is released. Consequently, in a bisubstrate reaction, a *ternary complex* of the enzyme and both substrates forms. Sequential mechanisms are of two types: ordered, in which the substrates bind the enzyme in a defined sequence, and random.

Many enzymes that have  $\text{NAD}^+$  or  $\text{NADH}$  as a substrate exhibit the ordered sequential mechanism. Consider lactate dehydrogenase, an important enzyme in glucose metabolism (Section 16.1). This enzyme reduces pyruvate to lactate while oxidizing  $\text{NADH}$  to  $\text{NAD}^+$ .

In the ordered sequential mechanism, the coenzyme always binds first and the lactate is always released first. This sequence can be represented by using a notation developed by W. Wallace Cleland:

The enzyme exists as a ternary complex consisting of, first, the enzyme and substrates and, after catalysis, the enzyme and products.

In the random sequential mechanism, the order of the addition of substrates and the release of products is random. An example of a random sequential reaction is the formation of phosphocreatine and ADP from creatine and ATP which is catalyzed by creatine kinase (Section 15.2).

Either creatine or ATP may bind first, and either phosphocreatine or ADP may be released first. Phosphocreatine is an important energy source in muscle. Sequential random reactions also can be depicted in the Cleland notation.

Although the order of certain events is random, the reaction still passes through the ternary complexes including, first, substrates and, then, products.

**Double-displacement (ping-pong) reactions.** In *double-displacement*, or *ping-pong*, reactions, one or more products are released before all substrates bind the enzyme. The defining feature of double-displacement reactions is the existence of a *substituted enzyme intermediate*, in which the enzyme is temporarily modified. Reactions that shuttle amino groups between amino acids and  $\alpha$ -ketoacids are classic examples of double-displacement mechanisms. The enzyme aspartate aminotransferase catalyzes the transfer of an amino group from aspartate to  $\alpha$ -ketoglutarate.

The sequence of events can be portrayed as the following Cleland notation:

After aspartate binds to the enzyme, the enzyme accepts aspartate's amino group to form the substituted enzyme intermediate. The first product, oxaloacetate, subsequently departs. The second substrate,  $\alpha$ -ketoglutarate, binds to the enzyme, accepts the amino group from the modified enzyme, and is then released as the final product, glutamate. In the Cleland notation, the substrates appear to bounce on and off the enzyme much as a Ping-Pong ball bounces on a table.

### Allosteric enzymes do not obey Michaelis–Menten kinetics

The Michaelis–Menten model has greatly assisted the development of enzymology. Its virtues are simplicity and broad applicability. However, the Michaelis–Menten model cannot account for the kinetic properties of many enzymes. An important group of enzymes that do not obey Michaelis–Menten kinetics are the *allosteric enzymes*. These enzymes consist of multiple subunits and multiple active sites.

Allosteric enzymes often display sigmoidal plots of the reaction velocity  $V_0$  versus substrate concentration  $[S]$  (Figure 8.13), rather than the hyperbolic plots predicted by the Michaelis–Menten equation (Figure 8.11). In allosteric enzymes, the binding of substrate to one active site can alter the properties of other active sites in the same enzyme molecule. A possible outcome of this interaction between subunits is that the binding of substrate becomes *cooperative*; that is, the binding of substrate to one active site facilitates the binding of substrate to the other active sites. Such cooperativity results in a sigmoidal plot of  $V_0$  versus  $[S]$ . In addition, the activity of an allosteric enzyme may be altered by regulatory molecules that reversibly bind to specific sites other than the catalytic sites. The catalytic properties of allosteric enzymes can thus be adjusted to meet the immediate needs of a cell. For this reason, allosteric enzymes are key regulators of metabolic pathways (Chapter 10). Recall that we have already met an allosteric protein, hemoglobin, in Chapter 7.

**FIGURE 8.13 Kinetics for an allosteric enzyme.** Allosteric enzymes display a sigmoidal dependence of reaction velocity on substrate concentration.

**FIGURE 8.14 Distinction between reversible inhibitors.** (A) Enzyme–substrate complex; (B) a competitive inhibitor binds at the active site and thus prevents the substrate from binding; (C) an uncompetitive inhibitor binds only to the enzyme–substrate complex; (D) a noncompetitive inhibitor does not prevent the substrate from binding.

## 8.5 Enzymes Can Be Inhibited by Specific Molecules

The activity of many enzymes can be inhibited by the binding of specific small molecules and ions. This means of inhibiting enzyme activity serves as a major control mechanism in biological systems, typified by the regulation of allosteric enzymes. In addition, many drugs and toxic agents act by inhibiting enzymes (Chapter 36). This type of enzyme inhibition is not usually the result of evolutionary forces, as it is for allosteric enzymes, but rather due to design of inhibitors by scientists or simple chance discovery of inhibitory molecules. Examining inhibition can be a source of insight into the mechanism of enzyme action: specific inhibitors can often be used to identify residues critical for catalysis. Transition-state analogs are especially potent inhibitors.

Enzyme inhibition can be either irreversible or reversible. An *irreversible inhibitor* dissociates very slowly from its target enzyme because it has become tightly bound to the enzyme, either covalently or noncovalently. Some irreversible inhibitors are important drugs. Penicillin acts by covalently modifying the enzyme transpeptidase, thereby preventing the synthesis of bacterial cell walls and thus killing the bacteria (p. 239). Aspirin acts by covalently modifying the enzyme cyclooxygenase, reducing the synthesis of signaling molecules in inflammation.

*Reversible inhibition*, in contrast with irreversible inhibition, is characterized by a rapid dissociation of the enzyme–inhibitor complex. In the type of reversible inhibition called *competitive inhibition*, an enzyme can bind substrate (forming an ES complex) or inhibitor (EI) but not both (ESI, enzyme–substrate–inhibitor complex). The competitive inhibitor often resembles the substrate and binds to the active site of the enzyme (Figure 8.14). The substrate is thereby prevented from binding to the same active site. A *competitive inhibitor diminishes the rate of catalysis by reducing the proportion of enzyme molecules bound to a substrate*. At any given inhibitor concentration, competitive inhibition can be relieved by increasing the substrate concentration. Under these conditions, the substrate successfully competes with the inhibitor for the active site. Methotrexate is an especially potent competitive inhibitor of the enzyme dihydrofolate reductase, which plays a role in the biosynthesis of purines and pyrimidines. Methotrexate is a structural analog of dihydrofolate, a substrate for dihydrofolate reductase (Figure 8.15). What makes it such a potent competitive inhibitor is that it binds to the enzyme 1000 times as tightly as the natural substrate binds, and it inhibits nucleotide base synthesis. It is used to treat cancer (Section 25.3).

*Uncompetitive inhibition* is essentially substrate-dependent inhibition in that the inhibitor binds only to the enzyme–substrate complex. The binding site of an uncompetitive inhibitor is created only on interaction of the enzyme and substrate (Figure 8.14C). Uncompetitive inhibition cannot be overcome by the addition of more substrate.

In *noncompetitive inhibition*, the inhibitor and substrate can bind simultaneously to an enzyme molecule at different binding sites (Figure 8.14D). Unlike uncompetitive inhibition, a noncompetitive inhibitor can bind free enzyme or the enzyme–substrate complex. A noncompetitive inhibitor acts by decreasing the concentration of functional enzyme rather than by diminishing the proportion of enzyme molecules that are bound to substrate. The net effect is to decrease the turnover number. Noncompetitive inhibition, like uncompetitive inhibition, cannot be overcome by

increasing the substrate concentration. A more complex pattern, called *mixed inhibition*, is produced when a single inhibitor both hinders the binding of substrate and decreases the turnover number of the enzyme.

### The different types of reversible inhibitors are kinetically distinguishable

How can we determine whether a reversible inhibitor acts by competitive, uncompetitive, or noncompetitive inhibition? Let us consider only enzymes that exhibit Michaelis–Menten kinetics. Measurements of the rates of catalysis at different concentrations of substrate and inhibitor serve to distinguish the three types of inhibition. In *competitive inhibition*, the inhibitor competes with the substrate for the active site. The dissociation constant for the inhibitor is given by

$$K_i = [E][I]/[EI]$$

The smaller the  $K_i$ , the more potent the inhibition. The hallmark of competitive inhibition is that it can be overcome by a sufficiently high concentration substrate (Figure 8.16). The effect of a competitive inhibitor is to increase the apparent value of  $K_M$ , meaning that more substrate is needed to obtain the same reaction rate. This new value of  $K_M$ , called  $K_M^{\text{app}}$  is numerically equal to

$$K_M^{\text{app}} = K_M(1 + [I]/K_i)$$

where  $[I]$  is the concentration of inhibitor and  $K_i$  is the dissociation constant for the enzyme–inhibitor complex. In the presence of a competitive inhibitor, an enzyme will have the same  $V_{\text{max}}$  as in the absence of an inhibitor. At a sufficiently high concentration, virtually all the active sites are filled with substrate, and the enzyme is fully operative.

Competitive inhibitors are commonly used as drugs. Drugs such as ibuprofen are competitive inhibitors of enzymes that participate in signaling pathways in the inflammatory response. Statins are drugs that reduce high cholesterol levels by competitively inhibiting a key enzyme in cholesterol biosynthesis (Section 26.3).

In *uncompetitive inhibition*, the inhibitor binds only to the ES complex. This enzyme–substrate–inhibitor complex, ESI, does not go on to form any product. Because some unproductive ESI complex will always be present,  $V_{\text{max}}$  will be lower in the presence of inhibitor than in its absence (Figure 8.17). The uncompetitive inhibitor lowers the apparent value of  $K_M$  because the inhibitor binds to ES to form ESI, depleting ES. To maintain the equilibrium between E and ES, more S binds to E, increasing the apparent value of  $k_1$  and thereby reducing the apparent value of  $K_M$  (see equation 18). Thus, a lower concentration of S is required to form half of the maximal concentration of ES. The herbicide glyphosate, also known as Roundup, is an uncompetitive inhibitor of an enzyme in the biosynthetic pathway for aromatic amino acids.

In *noncompetitive inhibition* (Figure 8.18), substrate can bind either

**FIGURE 8.17 Kinetics of an uncompetitive inhibitor.** The reaction pathway shows that the inhibitor binds only to the enzyme–substrate complex. Consequently,  $V_{\text{max}}$  cannot be attained, even at high substrate concentrations. The apparent value for  $K_M$  is lowered, becoming smaller as more inhibitor is added.

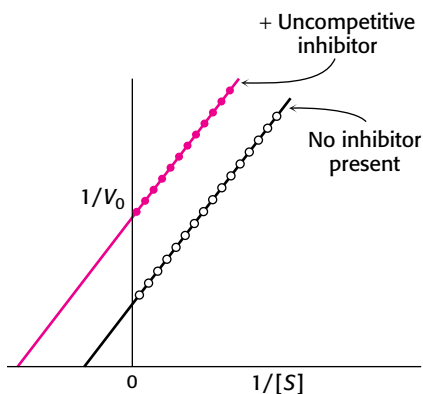

**FIGURE 8.16 Kinetics of a competitive inhibitor.** As the concentration of a competitive inhibitor increases, higher concentrations of substrate are required to attain a particular reaction velocity. The reaction pathway suggests how sufficiently high concentrations of substrate can completely relieve competitive inhibition.

**FIGURE 8.18 Kinetics of a noncompetitive inhibitor.** The reaction pathway shows that the inhibitor binds both to free enzyme and to an enzyme–substrate complex. Consequently, as with uncompetitive competition,  $V_{\text{max}}$  cannot be attained. In pure noncompetitive inhibition,  $K_M$  remains unchanged, and so the reaction rate increases more slowly at low substrate concentrations than is the case for uncompetitive competition.

**FIGURE 8.19 Competitive inhibition illustrated on a double-reciprocal plot.** A double-reciprocal plot of enzyme kinetics in the presence and absence of a competitive inhibitor illustrates that the inhibitor has no effect on  $V_{\max}$  but increases  $K_M$ .

**FIGURE 8.20 Uncompetitive inhibition illustrated by a double-reciprocal plot.** An uncompetitive inhibitor does not affect the slope of the double-reciprocal plot.  $V_{\max}$  and  $K_M$  are reduced by equivalent amounts.

**FIGURE 8.21 Noncompetitive inhibition illustrated on a double-reciprocal plot.** A double-reciprocal plot of enzyme kinetics in the presence and absence of a pure noncompetitive inhibitor shows that  $K_M$  is unaltered and  $V_{\max}$  is decreased.

to the enzyme or the enzyme–inhibitor complex. However, the enzyme–inhibitor–substrate complex *does not* proceed to form product. In pure noncompetitive inhibition, the  $K_i$  for the inhibitor binding to E is the same as for binding to ES complex. The value of  $V_{\max}$  is decreased to a new value called  $V_{\max}^{\text{app}}$ , whereas the value of  $K_M$  is unchanged. The maximal velocity in the presence of a pure noncompetitive inhibitor,  $V_{\max}^{\text{app}}$ , is given by

$$V_{\max}^{\text{app}} = \frac{V_{\max}}{1 + [I]/K_i} \quad (36)$$

Why is  $V_{\max}$  lowered though  $K_M$  remains unchanged? In essence, the inhibitor simply lowers the concentration of functional enzyme. The resulting solution behaves as a more dilute solution of enzyme does. *Noncompetitive inhibition cannot be overcome by increasing the substrate concentration.* Doxycycline, an antibiotic, functions at low concentrations as a noncompetitive inhibitor of a proteolytic enzyme (collagenase). It is used to treat periodontal disease. Some of the toxic effects of lead poisoning may be due to lead's ability to act as a noncompetitive inhibitor of a host of enzymes. Lead reacts with crucial sulfhydryl groups in these enzymes.

Double-reciprocal plots are especially useful for distinguishing between competitive, uncompetitive, and noncompetitive inhibitors. In competitive inhibition, the intercept on the y-axis of the plot of  $1/V_0$  versus  $1/[S]$  is the same in the presence and in the absence of inhibitor, although the slope is increased (Figure 8.19). The intercept is unchanged because a competitive inhibitor does not alter  $V_{\max}$ . The increase in the slope of the  $1/V_0$  versus  $1/[S]$  plot indicates the strength of binding of a competitive inhibitor. In the presence of a competitive inhibitor, equation 27 is replaced by

$$\frac{1}{V_0} = \frac{1}{V_{\max}} + \frac{K_M}{V_{\max}} \left( 1 + \frac{[I]}{K_i} \right) \left( \frac{1}{[S]} \right) \quad (37)$$

In other words, the slope of the plot is increased by the factor  $(1 + [I]/K_i)$  in the presence of a competitive inhibitor. Consider an enzyme with a  $K_M$  of  $10^{-4}$  M. In the absence of inhibitor, when  $V_0 = V_{\max}/2$  when  $[S] = 10^{-4}$  M. In the presence of a  $2 \times 10^{-3}$  M competitive inhibitor that is bound to the enzyme with a  $K_i$  of  $10^{-3}$  M, the apparent  $K_M$  ( $K_M^{\text{app}}$ ) will be equal to  $K_M(1 + [I]/K_i)$ , or  $3 \times 10^{-4}$  M. Substitution of these values into equation 37 gives when  $V_0 = V_{\max}/4$ , when  $[S] = 10^{-4}$  M. The presence of the competitive inhibitor thus cuts the reaction rate in half at this substrate concentration.

In uncompetitive inhibition (Figure 8.20), the inhibitor combines only with the enzyme–substrate complex. The equation that describes the double-reciprocal plot for an uncompetitive inhibitor is

$$\frac{1}{V_0} = \frac{K_M}{V_{\max}} \frac{1}{[S]} + \frac{1}{V_{\max}} \left( 1 + \frac{[I]}{K_i} \right) \quad (38)$$

The slope of the line,  $K_M/V_{\max}$ , is the same as that for the uninhibited enzyme, but the intercept on the y-axis will be increased by  $1 + [I]/K_i$ . Consequently, the lines in double-reciprocal plots will be parallel.

In pure noncompetitive inhibition (Figure 8.21), the inhibitor can combine with either the enzyme or the enzyme–substrate complex with the same dissociation constant. The value of  $V_{\max}$  is decreased to the new value  $V_{\max}^{\text{app}}$ , and so the intercept on the vertical axis is increased (equation 36). The new slope, which is equal to  $K_M/V_{\max}^{\text{app}}$ , is larger by the same factor. In contrast with  $V_{\max}$ ,  $K_M$  is not affected by pure noncompetitive inhibition.

## Irreversible inhibitors can be used to map the active site

In Chapter 9, we will examine the chemical details of how enzymes function. The first step in obtaining the chemical mechanism of an enzyme is to determine what functional groups are required for enzyme activity. How can we ascertain what these functional groups are? X-ray crystallography of the enzyme bound to its substrate or substrate analog provides one approach. Irreversible inhibitors that covalently bond to the enzyme provide an alternative and often complementary approach: the inhibitors modify the functional groups, which can then be identified. Irreversible inhibitors can be divided into three categories: group-specific reagents, reactive substrate analogs (also called affinity labels), and suicide inhibitors.

*Group-specific reagents* react with specific side chains of amino acids. An example of a group-specific reagent is diisopropylphosphofluoridate (DIPF). DIPF modifies only 1 of the 28 serine residues in the proteolytic enzyme chymotrypsin and yet inhibits the enzyme, implying that this serine residue is especially reactive. We will see in Chapter 9 that this serine residue is indeed located at the active site. DIPF also revealed a reactive serine residue in acetylcholinesterase, an enzyme important in the transmission of nerve impulses (Figure 8.22). Thus, DIPF and similar compounds that bind and inactivate acetylcholinesterase are potent nerve gases. Most group-specific reagents do not display the exquisite specificity shown by DIPF. Consequently, more specific means of modifying the active site are required.

*Affinity labels*, or *reactive substrate analogs*, are molecules that are structurally similar to the substrate for an enzyme and that covalently bind to active-site residues. They are thus more specific for the enzyme's active site than are group-specific reagents. Tosyl-L-phenylalanine chloromethyl ketone (TPCK) is a substrate analog for chymotrypsin (Figure 8.23). TPCK binds at the active

**FIGURE 8.22** Enzyme inhibition by diisopropylphosphofluoridate (DIPF), a group-specific reagent. DIPF can inhibit an enzyme by covalently modifying a crucial serine residue.

**FIGURE 8.23** Affinity labeling. (A) Tosyl-L-phenylalanine chloromethyl ketone (TPCK) is a reactive analog of the normal substrate for the enzyme chymotrypsin. (B) TPCK binds at the active site of chymotrypsin and modifies an essential histidine residue.

**FIGURE 8.24** Bromoacetol phosphate, an affinity label for triose phosphate isomerase (TPI). Bromoacetol phosphate, an analog of dihydroxyacetone phosphate, binds at the active site of the enzyme and covalently modifies a glutamic acid residue required for enzyme activity.

**FIGURE 8.25** Mechanism-based (suicide) inhibition. Monoamine oxidase, an enzyme important for neurotransmitter synthesis, requires the cofactor FAD (flavin adenine dinucleotide). *N,N*-Dimethylpropargylamine inhibits monoamine oxidase by covalently modifying the flavin prosthetic group only after the inhibitor has been oxidized. The N-5 flavin adduct is stabilized by the addition of a proton. R represents the remainder of the flavin prosthetic group.

site and then reacts irreversibly with a histidine residue at that site, inhibiting the enzyme. The compound 3-bromoacetol phosphate is an affinity label for the enzyme triose phosphate isomerase (TPI). It mimics the normal substrate, dihydroxyacetone phosphate, by binding at the active site; then it covalently modifies the enzyme such that the enzyme is irreversibly inhibited (Figure 8.24).

*Suicide inhibitors*, or *mechanism-based inhibitors*, are modified substrates that provide the most specific means for modifying an enzyme's active site. The inhibitor binds to the enzyme as a substrate and is initially processed by the normal catalytic mechanism. The mechanism of catalysis then generates a chemically reactive intermediate that inactivates the enzyme through covalent modification. The fact that the enzyme participates in its own irreversible inhibition strongly suggests that the covalently modified group on the enzyme is vital for catalysis. An example is *N,N*-dimethylpropargylamine, an inhibitor of the enzyme monoamine oxidase (MAO). A flavin prosthetic group of monoamine oxidase oxidizes the *N,N*-dimethylpropargylamine, which in turn inactivates the enzyme by binding to N-5 of the flavin prosthetic group (Figure 8.25). Monoamine oxidase deaminates neurotransmitters such as dopamine and serotonin, lowering their levels in the brain. Parkinson disease is associated with low levels of dopamine, and depression is associated with low levels of serotonin. *N,N*-Dimethylpropargylamine and (-)-deprenyl, another suicide inhibitor of monoamine oxidase, are used to treat Parkinson disease and depression.

## Penicillin irreversibly inactivates a key enzyme in bacterial cell-wall synthesis

 Penicillin, the first antibiotic discovered, provides us with another example of a clinically useful suicide inhibitor. Penicillin consists of a thiazolidine ring fused to a  $\beta$ -lactam ring to which a variable R group is attached by a peptide bond (Figure 8.26A). In benzylpenicillin, for example, R is a benzyl group (Figure 8.26B). This structure can undergo a variety of rearrangements, and, in particular, the  $\beta$ -lactam ring is very labile. Indeed, this instability is closely tied to the antibiotic action of penicillin, as will be evident shortly.

**FIGURE 8.26** The reactive site of penicillin is the peptide bond of its  $\beta$ -lactam ring.

(A) Structural formula of penicillin. (B) Representation of benzylpenicillin.

How does penicillin inhibit bacterial growth? Let us consider *Staphylococcus aureus*, the most common cause of staph infections. Penicillin interferes with the synthesis of the *S. aureus* cell wall. The *S. aureus* cell wall is made up of a macromolecule, called a *peptidoglycan* (Figure 8.27), which consists of linear polysaccharide chains that are cross-linked by short peptides (pentaglycines and tetrapeptides). The enormous peptidoglycan molecule confers mechanical support and prevents bacteria from bursting in response to their high internal osmotic pressure. *Glycopeptide transpeptidase* catalyzes the formation of the cross-links that make the peptidoglycan so stable (Figure 8.28). Bacterial cell walls are distinctive in containing D amino acids, which form cross-links by a mechanism different from that used to synthesize proteins.

Penicillin inhibits the cross-linking transpeptidase by the Trojan horse stratagem. The transpeptidase normally forms an *acyl intermediate* with the penultimate D-alanine residue of the D-Ala-D-Ala peptide (Figure 8.29). This covalent acyl-enzyme intermediate then reacts with the amino group of the terminal glycine in another peptide to form the cross-link. Penicillin is welcomed into the active site of the transpeptidase because it mimics the

**FIGURE 8.27** Schematic representation of the peptidoglycan in *Staphylococcus aureus*. The sugars are shown in yellow, the tetrapeptides in red, and the pentaglycine bridges in blue. The cell wall is a single, enormous, bag-shaped macromolecule because of extensive cross-linking.

**FIGURE 8.28** Formation of cross-links in *S. aureus* peptidoglycan. The terminal amino group of the pentaglycine bridge in the cell wall attacks the peptide bond between two D-alanine residues to form a cross-link.

**FIGURE 8.29 Transpeptidation reaction.**

An acyl-enzyme intermediate is formed in the transpeptidation reaction leading to cross-link formation.

D-Ala-D-Ala moiety of the normal substrate (Figure 8.30). Bound penicillin then forms a covalent bond with a serine residue at the active site of the enzyme. *This penicilloyl-enzyme does not react further. Hence, the transpeptidase is irreversibly inhibited and cell-wall synthesis cannot take place.*

**FIGURE 8.30 Conformations of penicillin and a normal substrate.** The conformation of penicillin in the vicinity of its reactive peptide bond (A) resembles the postulated conformation of the transition state of R-D-Ala-D-Ala (B) in the transpeptidation reaction. [Information from B. Lee, *J. Mol. Biol.* 61:463–469, 1971.]

Why is penicillin such an effective inhibitor of the transpeptidase? The highly strained, four-membered  $\beta$ -lactam ring of penicillin makes it especially reactive (Figure 8.26). On binding to the transpeptidase, the serine residue at the active site attacks the carbonyl carbon atom of the lactam ring to form the penicilloyl-serine derivative (Figure 8.31). Because the peptidase participates in its own inactivation, penicillin acts as a suicide inhibitor.

**FIGURE 8.31 Formation of a penicilloyl-enzyme derivative.** Penicillin reacts irreversibly with the transpeptidase to inactivate the enzyme.

### Transition-state analogs are potent inhibitors of enzymes

We turn now to compounds that provide the most intimate views of the catalytic process itself. Linus Pauling proposed in 1948 that compounds resembling the transition state of a catalyzed reaction should be very effective inhibitors of enzymes. These mimics are called *transition-state analogs*. The inhibition of proline racemase is an instructive example. The racemization

**FIGURE 8.32 Inhibition by transition-state analogs.** (A) The isomerization of L-proline to D-proline by proline racemase proceeds through a planar transition state in which the  $\alpha$ -carbon atom is trigonal rather than tetrahedral. (B) Pyrrole 2-carboxylic acid, a transition-state analog because of its trigonal geometry, is a potent inhibitor of proline racemase.

of proline proceeds through a transition state in which the tetrahedral  $\alpha$ -carbon atom has become trigonal (Figure 8.32). In the trigonal form, all three bonds are in the same plane;  $C_{\alpha}$  also carries a net negative charge. This symmetric carbanion can be reprotonated on one side to give the L isomer or on the other side to give the D isomer. This picture is supported by the finding that the inhibitor pyrrole 2-carboxylate binds to the racemase 160 times as tightly as does proline. *The  $\alpha$ -carbon atom of this inhibitor, like that of the transition state, is trigonal.* An analog that also carries a negative charge on  $C_{\alpha}$  would be expected to bind even more tightly. In general, highly potent and specific inhibitors of enzymes can be produced by synthesizing compounds that more closely resemble the transition state than the substrate itself. The inhibitory power of transition-state analogs underscores the essence of catalysis: *selective binding of the transition state.*

### Catalytic antibodies demonstrate the importance of selective binding of the transition state to enzymatic activity

Recall that antibodies bind precisely to their targets (antigens), and that specific antibodies can be generated against any antigen (Section 3.3). Antibodies that recognize transition states should function as catalysts, if our understanding of the importance of the transition state to catalysis is correct. The preparation of an antibody that catalyzes the insertion of a metal ion into a porphyrin nicely illustrates the validity of this approach. Ferrochelatase, the final enzyme in the biosynthetic pathway for the production of heme, catalyzes the insertion of  $Fe^{2+}$  into protoporphyrin IX (Section 24.4). The nearly planar porphyrin must be bent for iron to enter.

The challenge was to find a transition-state analog for this metallation reaction that could be used as an antigen (immunogen) to generate an antibody. The solution came from studies showing that an alkylated porphyrin, *N*-methylmesoporphyrin, is a potent inhibitor of ferrochelatase (Figure 8.33). This compound resembles the transition state because *N*-alkylation forces the porphyrin to be bent. Moreover, *N*-alkylporphyrins were known to chelate metal ions  $10^4$  times as fast as their unalkylated counterparts do. Bending increases the exposure of the pyrrole nitrogen lone pairs of electrons to solvent, which enables the binding of the iron ion.

An antibody catalyst was produced with the use of an *N*-alkylporphyrin as the antigen. The resulting antibody presumably distorts a planar porphyrin to facilitate the entry of a metal ion. On average, an antibody molecule metallated 80 porphyrin molecules per hour, a rate only 10-fold less than that of ferrochelatase, and 2500-fold faster than the uncatalyzed reaction. *Catalytic antibodies (abzymes) can indeed be produced by using transition-state analogs as antigens.* Antibodies catalyzing many other kinds of chemical reactions such as ester and amide hydrolysis have been produced by using similar strategies. Studies with transition-state analogs provide strong

**FIGURE 8.33 *N*-Methylmesoporphyrin is a transition-state analog used to generate catalytic antibodies.** The insertion of a metal ion into a porphyrin by ferrochelatase proceeds through a transition state in which the porphyrin is bent. *N*-Methylmesoporphyrin, a bent porphyrin that resembles the transition state of the ferrochelatase-catalyzed reaction, was used to generate an antibody that also catalyzes the insertion of a metal ion into a porphyrin ring.

evidence that enzymes function by assuming a conformation in the active site that is complementary in structure to the transition state. *The power of transition-state analogs is now evident: (1) they are sources of insight into catalytic mechanisms, (2) they can serve as potent and specific inhibitors of enzymes, and (3) they can be used as immunogens to generate a wide range of novel catalysts.*

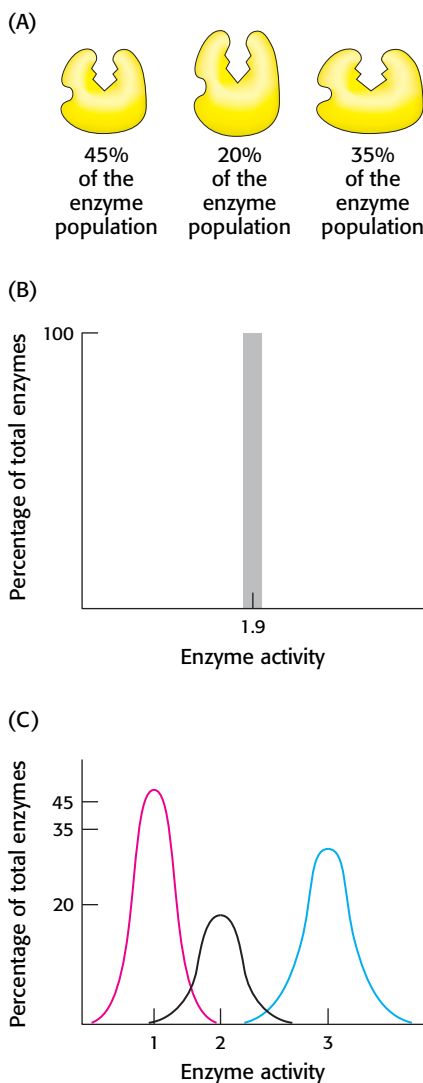

## 8.6 Enzymes Can Be Studied One Molecule at a Time

Most experiments that are performed to determine an enzyme characteristic require an enzyme preparation in a buffered solution. Even a few microliters of such a solution will contain millions of enzyme molecules. Much that we have learned about enzymes thus far has come from such experiments, called *ensemble studies*. A basic assumption of ensemble studies is that all of the enzyme molecules are the same or very similar. When we determine an enzymatic property such as the value of  $K_M$  in ensemble studies, that value is of necessity an average value of all of the enzyme molecules present. However, as discussed in Chapter 2, we now know that molecular heterogeneity, the ability of a molecule, over time, to assume several different structures that differ slightly in stability, is an inherent property of all large biomolecules (p. 53). How can we tell if this molecular heterogeneity affects enzyme activity?

By way of example, consider a hypothetical situation. A Martian visits Earth to learn about higher education. The spacecraft hovers high above a university, and our Martian meticulously records how the student population moves about campus. Much information can be gathered from such studies: where students are likely to be at certain times on certain days, which buildings are used when and by how many. Now, suppose our visitor developed a high-magnification camera that could follow one student throughout the day. Such data would provide a much different perspective on college life: What does this student eat? To whom does she talk? How much time does she spend studying? This new *in singulo* method, examining one individual at a time, yields a great deal of new information but also illustrates a potential pitfall of studying individuals, be they students or enzymes: How can we be certain that the student or molecule is representative and not an outlier? This pitfall can be overcome by studying enough individuals to satisfy statistical analysis for validity.

Let us leave our Martian to his observations, and consider a more biochemical situation. Figure 8.34A shows an enzyme that displays molecular heterogeneity, with three active forms that catalyze the same reaction but at different rates. These forms have slightly different stabilities, but thermal noise is sufficient to interconvert the forms. Each form is present as a fraction of the total enzyme population as indicated. If we were to perform an experiment to determine enzyme activity under a particular set of conditions with the use of ensemble methods, we would get a single value, which would represent the average of the heterogeneous assembly (Figure 8.34B). However, were we to perform a sufficient number of single-molecule experiments, we would discover that the enzyme has three different molecular forms with very different activities (Figure 8.34C). Moreover, these different forms would most likely correspond to important biochemical differences.

The development of powerful techniques—such as patch-clamp recording, single-molecule fluorescence, and optical tweezers—has enabled biochemists to look into the workings of individual molecules.

**FIGURE 8.34** Single molecule studies can reveal molecular heterogeneity.

(A) Complex biomolecules, such as enzymes, display molecular heterogeneity. (B) When measuring an enzyme property using ensemble methods, an average value of all of the enzymes present is the result. (C) Single enzyme studies reveal molecular heterogeneity, with the various forms showing different properties.

We will examine single-molecule studies of membrane channels with the use of patch-clamp recording (Section 13.4), ATP-synthesizing complexes with the use of single-molecule fluorescence (Section 18.4) and molecular motors with the use of an optical trap (Section 34.2). We are now able to observe events at a molecular level that reveal rare or transient structures and fleeting events in a reaction sequence, as well as to measure mechanical forces affecting or generated by an enzyme. Single-molecule studies open a new vista on the function of enzymes in particular and on all large biomolecules in general.

## SUMMARY

### 8.1 Enzymes Are Powerful and Highly Specific Catalysts

Most catalysts in biological systems are enzymes, and nearly all enzymes are proteins. Enzymes are highly specific and have great catalytic power. They can enhance reaction rates by factors of  $10^6$  or more. Many enzymes require cofactors for activity. Such cofactors can be metal ions or small, vitamin-derived organic molecules called coenzymes.

### 8.2 Gibbs Free Energy Is a Useful Thermodynamic Function for Understanding Enzymes

Free energy ( $G$ ) is the most valuable thermodynamic function for understanding the energetics of catalysis. A reaction can take place spontaneously only if the change in free energy ( $\Delta G$ ) is negative. The free-energy change of a reaction that takes place when reactants and products are at unit activity is called the standard free-energy change ( $\Delta G^\circ$ ). Biochemists use  $\Delta G^{\circ'}$ , the standard free-energy change at pH 7. Enzymes do not alter reaction equilibria; rather, they increase the rate at which equilibrium is attained.

### 8.3 Enzymes Accelerate Reactions by Facilitating the Formation of the Transition State

Enzymes serve as catalysts by decreasing the free energy of activation of chemical reactions. Enzymes accelerate reactions by providing a reaction pathway in which the transition state (the highest-energy species) has a lower free energy and hence is more rapidly formed than in the uncatalyzed reaction.

The first step in catalysis is the formation of an enzyme–substrate complex. Substrates are bound to enzymes at active-site clefts from which water is largely excluded when the substrate is bound. The specificity of enzyme–substrate interactions arises mainly from hydrogen bonding, which is directional, and from the shape of the active site, which rejects molecules that do not have a sufficiently complementary shape. Enzymes facilitate formation of the transition state by a dynamic process in which the substrate binds to specific conformations of the enzyme, accompanied by conformational changes at active sites that result in catalysis.

### 8.4 The Michaelis–Menten Model Accounts for the Kinetic Properties of Many Enzymes

The kinetic properties of many enzymes are described by the Michaelis–Menten model. In this model, an enzyme (E) combines with a substrate (S) to form an enzyme–substrate (ES) complex, which can proceed to form a product (P) or to dissociate into E and S.

The rate of formation of product  $V_0$  is given by the Michaelis–Menten equation:

$$V_0 = V_{\max} \frac{[S]}{[S] + K_M}$$

in which  $V_{\max}$  is the reaction rate when the enzyme is fully saturated with substrate and  $K_M$ , the Michaelis constant, is the substrate concentration at which the reaction rate is half maximal. The maximal rate,  $V_{\max}$ , is equal to the product of  $k_2$ , or  $k_{\text{cat}}$ , and the total concentration of enzyme. The kinetic constant  $k_{\text{cat}}$  called the turnover number, is the number of substrate molecules converted into product per unit time at a single catalytic site when the enzyme is fully saturated with substrate. Turnover numbers for most enzymes are between 1 and  $10^4$  per second. The ratio of  $k_{\text{cat}}/K_M$  provides a measure of enzyme efficiency and specificity.

Allosteric enzymes constitute an important class of enzymes whose catalytic activity can be regulated. These enzymes, which do not conform to Michaelis–Menten kinetics, have multiple active sites. These active sites display cooperativity, as evidenced by a sigmoidal dependence of reaction velocity on substrate concentration.

### 8.5 Enzymes Can Be Inhibited by Specific Molecules

Specific small molecules or ions can inhibit even nonallosteric enzymes. In irreversible inhibition, the inhibitor is covalently linked to the enzyme or bound so tightly that its dissociation from the enzyme is very slow. Covalent inhibitors provide a means of mapping the enzyme's active site. In contrast, reversible inhibition is characterized by a more rapid and less stable interaction between enzyme and inhibitor. A competitive inhibitor prevents the substrate from binding to the active site. It reduces the reaction velocity by diminishing the proportion of enzyme molecules that are bound to substrate. Competitive inhibition can be overcome by raising the substrate concentration. In uncompetitive inhibition, the inhibitor combines only with the enzyme–substrate complex. In noncompetitive inhibition, the inhibitor decreases the turnover number. Uncompetitive and noncompetitive inhibition cannot be overcome by raising the substrate concentration.

The essence of catalysis is selective stabilization of the transition state. Hence, an enzyme binds the transition state more tightly than it binds the substrate. Transition-state analogs are stable compounds that mimic key features of this highest-energy species. They are potent and specific inhibitors of enzymes. Proof that transition-state stabilization is a key aspect of enzyme activity comes from the generation of catalytic antibodies. Transition-state analogs are used as antigens, or immunogens, in generating catalytic antibodies.

### 8.6 Enzymes Can Be Studied One Molecule at a Time

Many enzymes are now being studied *in singulo*, at the level of a single molecule. Such studies are important because they yield information that is difficult to obtain in studies of populations of molecules. Single-molecule methods reveal a distribution of enzyme characteristics rather than an average value as is acquired with the use of ensemble methods.

## APPENDIX: Enzymes are Classified on the Basis of the Types of Reactions That They Catalyze

Many enzymes have common names that provide little information about the reactions that they catalyze. For example, a proteolytic enzyme secreted by the pancreas is called trypsin. Most other enzymes are named for their substrates and for the reactions that they catalyze, with the suffix “ase” added. Thus, a peptide hydrolase is an enzyme that hydrolyzes peptide bonds, whereas ATP synthase is an enzyme that synthesizes ATP.

To bring some consistency to the classification of enzymes, in 1964 the International Union of Biochemistry established an Enzyme Commission to develop a nomenclature for enzymes. Reactions were divided into six major groups numbered 1 through 6 (Table 8.8). These groups were subdivided and further subdivided so that a four-number code preceded by the letters *EC* for Enzyme Commission could precisely identify all enzymes.

Consider as an example nucleoside monophosphate (NMP) kinase, an enzyme that we will examine in detail in Section 9.4. It catalyzes the following reaction:

NMP kinase transfers a phosphoryl group from ATP to any nucleotide monophosphate (NMP) to form a nucleoside diphosphate (NDP) and ADP. Consequently, it is a transferase, or member of group 2. Many groups other than phosphoryl groups, such as sugars and single-carbon units, can be transferred. Transferases that shift a phosphoryl group are designated 2.7. Various functional groups can accept the phosphoryl group. If a phosphate is the acceptor, the transferase is designated 2.7.4. The final number designates the acceptor more precisely. In regard to NMP kinase, a nucleoside monophosphate is the acceptor, and the enzyme’s designation is EC 2.7.4.4. Although the common names are used routinely, the classification number is used when the precise identity of the enzyme is not clear from the common name alone.

**TABLE 8.8** Six major classes of enzymes

Class	Type of reaction	Example	Chapter
1. Oxidoreductases	Oxidation–reduction	Lactate dehydrogenase	16
2. Transferases	Group transfer	Nucleoside monophosphate kinase (NMP kinase)	9
3. Hydrolases	Hydrolysis reactions (transfer of functional groups to water)	Chymotrypsin	9
4. Lyases	Addition or removal of groups to form double bonds	Fumarase	17
5. Isomerases	Isomerization (intramolecular group transfer)	Triose phosphate isomerase	16
6. Ligases	Ligation of two substrates at the expense of ATP hydrolysis	Aminoacyl-tRNA synthetase	30

## KEY TERMS

enzyme (p. 216)	$K_M$ (the Michaelis constant) (p. 227)	allosteric enzyme (p. 233)
substrate (p. 216)	$V_{\max}$ (maximal rate) (p. 228)	competitive inhibition (p. 234)
cofactor (p. 217)	Michaelis–Menten equation (p. 228)	uncompetitive inhibition (p. 234)
apoenzyme (p. 217)	Lineweaver–Burk equation (double-reciprocal plot) (p. 229)	noncompetitive inhibition (p. 234)
holoenzyme (p. 217)	turnover number (p. 230)	group-specific reagent (p. 237)
coenzyme (p. 217)	$k_{\text{cat}}/K_M$ ratio (the specificity constant) (p. 230)	affinity label (reactive substrate analog) (p. 237)
prosthetic group (p. 217)	sequential reaction (p. 232)	mechanism-based (suicide) inhibition (p. 238)
free energy (p. 218)	double-displacement (ping-pong) reaction (p. 233)	transition-state analog (p. 240)
transition state (p. 221)		catalytic antibody (abzyme) (p. 241)
free energy of activation (p. 221)		
active site (p. 222)		
induced fit (p. 224)		

## PROBLEMS

- Raisons d'être.* What are the two properties of enzymes that make them especially useful catalysts?
- Partners.* What does an apoenzyme require to become a holoenzyme?
- Different partners.* What are the two main types of cofactors?
- One a day.* Why are vitamins necessary for good health?
- A function of state.* What is the fundamental mechanism by which enzymes enhance the rate of chemical reactions?
- Nooks and crannies.* What is the structural basis for enzyme specificity?
- Give with one hand, take with the other.* Why does the activation energy of a reaction not appear in the final  $\Delta G$  of the reaction?
- The more things change, the more they stay the same.* Suppose that, in the absence of enzyme, the forward rate constant ( $k_F$ ) for the conversion of S into P is  $10^{-4} \text{ s}^{-1}$  and the reverse rate constant ( $k_R$ ) for the conversion of P into S is  $10^{-6} \text{ s}^{-1}$ .

- What is the equilibrium for the reaction? What is the  $\Delta G^\circ$ ?
  - Suppose an enzyme enhances the rate of the reaction 100 fold. What are the rate constants for the enzyme-catalyzed reaction? The equilibrium constant? The  $\Delta G^\circ$ ?
- Mountain climbing.* Proteins are thermodynamically unstable. The  $\Delta G$  of the hydrolysis of proteins is quite negative, yet proteins can be quite stable. Explain this apparent paradox. What does it tell you about protein synthesis?
  - Protection.* Suggest why the enzyme lysozyme, which degrades cell walls of some bacteria, is present in tears.
  - Mutual attraction.* What is meant by the term *binding energy*?
  - Catalytically binding.* What is the role of binding energy in enzyme catalysis?
  - Sticky situation.* What would be the result of an enzyme having a greater binding energy for the substrate than for the transition state?
  - Stability matters.* Transition-state analogs, which can be used as enzyme inhibitors and to generate catalytic antibodies, are often difficult to synthesize. Suggest a reason.

- Match'em.* Match the  $K'_{\text{eq}}$  values with the appropriate  $\Delta G^\circ$  values.

$K'_{\text{eq}}$	$\Delta G^\circ (\text{kJ mol}^{-1})$
(a) 1	28.53
(b) $10^{-5}$	-11.42
(c) $10^4$	5.69
(d) $10^2$	0
(e) $10^{-1}$	-22.84

- Free energy!* Assume that you have a solution of 0.1 M glucose 6-phosphate. To this solution, you add the enzyme phosphoglucosmutase, which catalyzes the following reaction:

The  $\Delta G^\circ$  for the reaction is  $+7.5 \text{ kJ mol}^{-1}$  ( $+1.8 \text{ kcal mol}^{-1}$ ).

- Does the reaction proceed as written? If so, what are the final concentrations of glucose 6-phosphate and glucose 1-phosphate?
- Under what cellular conditions could you produce glucose 1-phosphate at a high rate?

- Free energy, too!* Consider the following reaction:

After reactant and product were mixed and allowed to reach equilibrium at  $25^\circ\text{C}$ , the concentration of each compound was measured:

$$[\text{Glucose 1-phosphate}]_{\text{eq}} = 0.01 \text{ M}$$

$$[\text{Glucose 6-phosphate}]_{\text{eq}} = 0.19 \text{ M}$$

Calculate  $K_{\text{eq}}$  and  $\Delta G^\circ$ .

- Keeping busy.* Many isolated enzymes, if incubated at  $37^\circ\text{C}$ , will be denatured. However, if the enzymes are incubated at  $37^\circ\text{C}$  in the presence of substrate, the enzymes are catalytically active. Explain this apparent paradox.
- Active yet responsive.* What is the biochemical advantage of having a  $K_M$  approximately equal to the substrate concentration normally available to an enzyme?
- Affinity or not affinity? That is the question.* The affinity between a protein and a molecule that binds to the protein is frequently expressed in terms of a dissociation constant  $K_d$ .

$$K_d = \frac{[\text{protein}][\text{small molecule}]}{[\text{Protein} - \text{small molecule complex}]}$$

Does  $K_M$  measure the affinity of the enzyme complex? Under what circumstances might  $K_M$  approximately equal  $K_d$ ?

21. *Angry biochemists.* Many biochemists go bananas, and justifiably, when they see a Michaelis–Menten plot like the one shown below. To see why, determine the  $V_0$  as a fraction of  $V_{\max}$  when the substrate concentration is equal to  $10 K_M$  and  $20 K_M$ . Please control your outrage.

22. *Hydrolytic driving force.* The hydrolysis of pyrophosphate to orthophosphate is important in driving forward biosynthetic reactions such as the synthesis of DNA. This hydrolytic reaction is catalyzed in *E. coli* by a pyrophosphatase that has a mass of 120 kDa and consists of six identical subunits. For this enzyme, a unit of activity is defined as the amount of enzyme that hydrolyzes 10  $\mu\text{mol}$  of pyrophosphate in 15 minutes at  $37^\circ\text{C}$  under standard assay conditions. The purified enzyme has a  $V_{\max}$  of 2800 units per milligram of enzyme.

- How many moles of substrate is hydrolyzed per second per milligram of enzyme when the substrate concentration is much greater than  $K_M$ ?
- How many moles of active sites are there in 1 mg of enzyme? Assume that each subunit has one active site.
- What is the turnover number of the enzyme? Compare this value with others mentioned in this chapter.

23. *Destroying the Trojan horse.* Penicillin is hydrolyzed and thereby rendered inactive by penicillinase (also known as  $\beta$ -lactamase), an enzyme present in some penicillin-resistant bacteria. The mass of this enzyme in *Staphylococcus aureus* is 29.6 kDa. The amount of penicillin hydrolyzed in 1 minute in a 10-ml solution containing  $10^{-9}$  g of purified penicillinase was measured as a function of the concentration of penicillin. Assume that the concentration of penicillin does not change appreciably during the assay.

[Penicillin] $\mu\text{M}$	Amount hydrolyzed (nmol)
1	0.11
3	0.25
5	0.34
10	0.45
30	0.58
50	0.61

(a) Plot  $V_0$  versus  $[S]$  and  $1/V_0$  versus  $1/[S]$  for these data. Does penicillinase appear to obey Michaelis–Menten kinetics? If so, what is the value of  $K_M$ ?

(b) What is the value of  $V_{\max}$ ?

(c) What is the turnover number of penicillinase under these experimental conditions? Assume one active site per enzyme molecule.

24. *Counterpoint.* Penicillinase ( $\beta$ -lactamase) hydrolyzes penicillin. Compare penicillinase with glycopeptide transpeptidase.

25. *A different mode.* The kinetics of an enzyme is measured as a function of substrate concentration in the presence and absence of 100  $\mu\text{M}$  inhibitor.

- What are the values of  $V_{\max}$  and  $K_M$  in the presence of this inhibitor?
- What type of inhibition is it?
- What is the dissociation constant of this inhibitor?

[S] ( $\mu\text{M}$ )	Velocity ( $\mu\text{mol minute}^{-1}$ )	
	No inhibitor	Inhibitor
3	10.4	2.1
5	14.5	2.9
10	22.5	4.5
30	33.8	6.8
90	40.5	8.1

(d) If  $[S] = 30 \mu\text{M}$ , what fraction of the enzyme molecules have a bound substrate in the presence and in the absence of 100  $\mu\text{M}$  inhibitor?

26. *A fresh view.* The plot of  $1/V_0$  versus  $1/[S]$  is sometimes called a Lineweaver–Burk plot. Another way of expressing the kinetic data is to plot  $V_0$  versus  $V_0/[S]$ , which is known as an Eadie–Hofstee plot.

- Rearrange the Michaelis–Menten equation to give  $V_0$  as a function of  $V_0/[S]$ .
- What is the significance of the slope, the y-intercept, and the x-intercept in a plot of  $V_0$  versus  $V_0/[S]$ ?
- Sketch a plot of  $V_0$  versus  $V_0/[S]$  in the absence of an inhibitor, in the presence of a competitive inhibitor, and in the presence of a noncompetitive inhibitor.

27. *Defining attributes.* What is the defining characteristic for an enzyme catalyzing a sequential reaction? A double-displacement reaction?

28. *Competing substrates.* Suppose that two substrates, A and B, compete for an enzyme. Derive an expression relating the ratio of the rates of utilization of A and B,  $V_A/V_B$ , to the concentrations of these substrates and their values of  $k_{\text{cat}}$  and  $K_M$ . (Hint: Express  $V_A$  as a function of  $k_{\text{cat}}/K_M$  for

substrate A, and do the same for  $V_B$ .) Is specificity determined by  $K_M$  alone?

29. *A tenacious mutant.* Suppose that a mutant enzyme binds a substrate 100 times as tightly as does the native enzyme. What is the effect of this mutation on catalytic rate if the binding of the transition state is unaffected?

30. *More Michaelis–Menten.* For an enzyme that follows simple Michaelis–Menten kinetics, what is the value of  $V_{\max}$  if  $V_0$  is equal to  $1 \mu\text{mol min}^{-1}$  at  $10 K_M$ ?

31. *Controlled paralysis.* Succinylcholine is a fast-acting, short-duration muscle relaxant that is used when a tube is inserted into a patient's trachea or when a bronchoscope is used to examine the trachea and bronchi for signs of cancer. Within seconds of the administration of succinylcholine, the patient experiences muscle paralysis and is placed on a respirator while the examination proceeds. Succinylcholine is a competitive inhibitor of acetylcholinesterase, a nervous system enzyme, and this inhibition causes paralysis. However, succinylcholine is hydrolyzed by blood-serum cholinesterase, which shows a broader substrate specificity than does the nervous system enzyme. Paralysis lasts until the succinylcholine is hydrolyzed by the serum cholinesterase, usually several minutes later.

(a) As a safety measure, serum cholinesterase is measured before the examination takes place. Explain why this measurement is good idea.

(b) What would happen to the patient if the serum cholinesterase activity were only 10 units of activity per liter rather than the normal activity of about 80 units?

(c) Some patients have a mutant form of the serum cholinesterase that displays a  $K_M$  of 10 mM, rather than the normal 1.4 mM. What will be the effect of this mutation on the patient?

### Data Interpretation Problems

32. *A natural attraction, but more complicated.* You have isolated two versions of the same enzyme, a wild type and a mutant differing from the wild type at a single amino acid. Working carefully but expeditiously, you then establish the following kinetic characteristics of the enzymes.

	Maximum velocity	$K_M$
Wild type	$100 \mu\text{mol/min}$	10 mM
Mutant	$1 \mu\text{mol/min}$	0.1 mM

(a) With the assumption that the reaction occurs in two steps in which  $k_{-1}$  is much larger than  $k_2$ , which enzyme has the higher affinity for substrate?

(b) What is the initial velocity of the reaction catalyzed by the wild-type enzyme when the substrate concentration is 10 mM?

(c) Which enzyme alters the equilibrium more in the direction of product?

33.  *$K_M$  matters.* The amino acid asparagine is required by cancer cells to proliferate. Treating patients with the enzyme asparaginase is sometimes used as a chemotherapy treatment. Asparaginase hydrolyzes asparagine to aspartate and ammonia. The adjoining illustration shows the Michaelis–Menten curves for two asparaginases from different sources, as well as the concentration of asparagine in the environment (indicated by the arrow). Which enzyme would make a better chemotherapeutic agent?

34. *Enzyme specificity.* Catalysis of the cleavage of peptide bonds in small peptides by a proteolytic enzyme is described in the following table.

Substrate	$K_M$ (mM)	$k_{\text{cat}}$ ( $\text{s}^{-1}$ )
EMTA↓G	4.0	24
EMTA↓A	1.5	30
EMTA↓F	0.5	18

The arrow indicates the peptide bond cleaved in each case.

(a) If a mixture of these peptides were presented to the enzyme with the concentration of each peptide being the same, which peptide would be digested most rapidly? Most slowly? Briefly explain your reasoning, if any.

(b) The experiment is performed again on another peptide with the following results.

EMTI↓F	9	18
--------	---	----

On the basis of these data, suggest the features of the amino acid sequence that dictate the specificity of the enzyme.

35. *Varying the enzyme.* For a one-substrate, enzyme-catalyzed reaction, double-reciprocal plots were determined for three different enzyme concentrations. Which of the following three families of curve would you expect to be obtained? Explain.

36. *Mental experiment.* Picture in your mind the velocity vs. substrate concentration curve for a typical Michaelis-Menten enzyme. Now, imagine that the experimental conditions are altered as described below. For each of the conditions described, fill in the table indicating precisely (when possible) the effect on  $V_{\max}$  and  $K_M$  of the imagined Michaelis-Menten enzyme.

Experimental condition	$V_{\max}$	$K_M$
a. Twice as much enzyme is used.		
b. Half as much enzyme is used		
c. A competitive inhibitor is present.		
d. An uncompetitive inhibitor is present.		
e. A pure non-competitive inhibitor is present.		

37. *Too much of a good thing.* A simple Michaelis-Menten enzyme, in the absence of any inhibitor, displayed the following kinetic behavior.

(a) Draw a double-reciprocal plot that corresponds to the velocity-versus-substrate curve.

(b) Suggest a plausible explanation for these kinetic results.

38. *Rate-limiting step.* In the conversion of A into D in the following biochemical pathway, enzymes  $E_A$ ,  $E_B$ , and  $E_C$  have the  $K_M$  values indicated under each enzyme. If all of the substrates and products are present at a concentration of  $10^{-4}$  M and the enzymes have approximately the same  $V_{\max}$ , which step will be rate limiting and why?

39. *Colored luminosity* Tryptophan synthetase, a bacterial enzyme that contains a pyridoxal phosphate (PLP) prosthetic group, catalyzes the synthesis of L-tryptophan from L-serine and an indole derivative. The addition of L-serine to the enzyme produces a marked increase in the fluorescence of the PLP group, as the adjoining graph shows. The subsequent addition of indole, the second substrate, reduces this fluorescence to a level even lower than that produced by the enzyme alone. How do these changes in fluorescence

support the notion that the enzyme interacts directly with its substrates?

### Chapter Integration Problems

40. *Titration experiment.* The effect of pH on the activity of an enzyme was examined. At its active site, the enzyme has an ionizable group that must be negatively charged for substrate binding and catalysis to take place. The ionizable group has a  $pK_a$  of 6.0. The substrate is positively charged throughout the pH range of the experiment.

(a) Draw the  $V_0$ -versus-pH curve when the substrate concentration is much greater than the enzyme  $K_M$ .

(b) Draw the  $V_0$ -versus-pH curve when the substrate concentration is much less than the enzyme  $K_M$ .

(c) At which pH will the velocity equal one-half of the maximal velocity attainable under these conditions?

41. *A question of stability.* Pyridoxal phosphate (PLP) is a coenzyme for the enzyme ornithine aminotransferase. The enzyme was purified from cells grown in PLP-deficient media as well as from cells grown in media that contained pyridoxal phosphate. The stability of the two different enzyme preparations was then measured by incubating the enzyme at  $37^\circ\text{C}$  for different lengths of time and then assaying for the amount of enzyme activity remaining. The following results were obtained.

- (a) Why does the amount of active enzyme decrease with the time of incubation?
- (b) Why does the amount of enzyme from the PLP-deficient cells decline more rapidly?

42. *Not just for enzymes.* Kinetics is useful for studying reactions of all types, not just those catalyzed by enzymes. In Chapters 4 and 5, we learned that DNA could be reversibly melted. When melted double-stranded DNA is allowed to renature, the process can be described as consisting of two steps, a slow second order reaction followed by a rapid first order reaction. Explain what is occurring in each step.

# Catalytic Strategies

Chess and enzymes have in common the use of strategy, consciously thought out in the game of chess and selected by evolution for the action of an enzyme. The three amino acid residues at the right, denoted by the white bonds, constitute a catalytic triad found in the active site of a class of enzymes that cleave peptide bonds. The substrate, represented by the molecule with the black bonds, is as hopelessly trapped as the king in the photograph of a chess match at the left and is sure to be cleaved. [Photograph courtesy of Wendie Berg.]

**W**hat are the sources of the catalytic power and specificity of enzymes? This chapter presents the catalytic strategies used by four classes of enzymes: serine proteases, carbonic anhydrases, restriction endonucleases, and myosins. Each class catalyzes reactions that require the addition of water to a substrate. The mechanisms of these enzymes have been revealed through the use of incisive experimental probes, including the techniques of protein structure determination (Chapter 3) and site-directed mutagenesis (Chapter 5). The mechanisms illustrate many important principles of catalysis. We shall see how these enzymes facilitate the formation of the transition state through the use of binding energy and induced fit as well as additional specific catalytic strategies.

Each of the four classes of enzymes in this chapter illustrates the use of such strategies to solve a different problem. For serine proteases, exemplified by chymotrypsin, the challenge is to promote a reaction that is almost immeasurably slow at neutral pH in the absence of a catalyst. For carbonic anhydrases, the challenge is to achieve a high absolute rate of reaction, suitable for integration with other rapid physiological processes. For restriction endonucleases such as EcoRV, the challenge is to attain a high degree of specificity. Finally, for myosins, the challenge is to utilize the free energy

## OUTLINE

- 9.1 Proteases Facilitate a Fundamentally Difficult Reaction
- 9.2 Carbonic Anhydrases Make a Fast Reaction Faster
- 9.3 Restriction Enzymes Catalyze Highly Specific DNA-Cleavage Reactions
- 9.4 Myosins Harness Changes in Enzyme Conformation to Couple ATP Hydrolysis to Mechanical Work

associated with the hydrolysis of adenosine triphosphate (ATP) to drive other processes. Each of the examples selected is a member of a large protein class. For each of these classes, comparison between class members reveals how enzyme active sites have evolved and been refined. Structural and mechanistic comparisons of enzyme action are thus the sources of insight into the evolutionary history of enzymes. In addition, our knowledge of catalytic strategies has been used to develop practical applications, including potent drugs and specific enzyme inhibitors. Finally, although we shall not consider catalytic RNA molecules explicitly in this chapter, the principles also apply to these catalysts.

### A few basic catalytic principles are used by many enzymes

In Chapter 8, we learned that enzymatic catalysis begins with substrate binding. The *binding energy* is the free energy released in the formation of a large number of weak interactions between the enzyme and the substrate. The use of this binding energy is the first common strategy used by enzymes. We can envision this binding energy as serving two purposes: it establishes substrate specificity and increases catalytic efficiency. Only the correct substrate can participate in most or all of the interactions with the enzyme and thus maximize binding energy, accounting for the exquisite substrate specificity exhibited by many enzymes. Furthermore, the full complement of such interactions is formed only when the combination of enzyme and substrate is in the transition state. Thus, interactions between the enzyme and the substrate stabilize the transition state, thereby lowering the free energy of activation. The binding energy can also promote structural changes in both the enzyme and the substrate that facilitate catalysis, a process referred to as *induced fit*.

In addition to the first strategy involving binding energy, enzymes commonly employ one or more of the following four additional strategies to catalyze specific reactions:

1. *Covalent Catalysis*. In covalent catalysis, the active site contains a reactive group, usually a powerful nucleophile, that becomes temporarily covalently attached to a part of the substrate in the course of catalysis. The proteolytic enzyme chymotrypsin provides an excellent example of this strategy (Section 9.1).
2. *General Acid–Base Catalysis*. In general acid–base catalysis, a molecule other than water plays the role of a proton donor or acceptor. Chymotrypsin uses a histidine residue as a base catalyst to enhance the nucleophilic power of serine (Section 9.1), whereas a histidine residue in carbonic anhydrase facilitates the removal of a hydrogen ion from a zinc-bound water molecule to generate hydroxide ion (Section 9.2). For myosins, a phosphate group of the ATP substrate serves as a base to promote its own hydrolysis (Section 9.3).
3. *Catalysis by Approximation*. Many reactions have two distinct substrates, including all four classes of hydrolases considered in detail in this chapter. In such cases, the reaction rate may be considerably enhanced by bringing the two substrates together along a single binding surface on an enzyme. For example, carbonic anhydrase binds carbon dioxide and water in adjacent sites to facilitate their reaction (Section 9.2).
4. *Metal Ion Catalysis*. Metal ions can function catalytically in several ways. For instance, a metal ion may facilitate the formation of nucleophiles such as hydroxide ion by direct coordination. A zinc(II) ion serves this purpose in catalysis by carbonic anhydrase (Section 9.2). Alternatively, a metal ion may serve as an electrophile, stabilizing a negative charge on a reaction intermediate. A magnesium(II) ion plays this role in EcoRV (Section 9.3).

Finally, a metal ion may serve as a bridge between enzyme and substrate, increasing the binding energy and holding the substrate in a conformation appropriate for catalysis. This strategy is used by myosins (Section 9.4) and, indeed, by almost all enzymes that utilize ATP as a substrate.

## 9.1 Proteases Facilitate a Fundamentally Difficult Reaction

Peptide bond hydrolysis is an important process in living systems (Chapter 23). Proteins that have served their purpose must be degraded so that their constituent amino acids can be recycled for the synthesis of new proteins. Proteins ingested in the diet must be broken down into small peptides and amino acids for absorption in the gut. Furthermore, as described in detail in Chapter 10, proteolytic reactions are important in regulating the activity of certain enzymes and other proteins.

Proteases cleave proteins by a hydrolysis reaction—the addition of a molecule of water to a peptide bond:

Although the hydrolysis of peptide bonds is thermodynamically favorable, such reactions are extremely slow. In the absence of a catalyst, the half-life for the hydrolysis of a typical peptide at neutral pH is estimated to be between 10 and 1000 years. Yet, peptide bonds must be hydrolyzed within milliseconds in some biochemical processes.

The chemical nature of peptide bonds is responsible for their kinetic stability. Specifically, the resonance structure that accounts for the planarity of peptide bonds (Section 2.2) also makes them resistant to hydrolysis. This resonance structure endows them with partial double-bond character:

The carbon–nitrogen bond is strengthened by its double-bond character. Furthermore, the carbonyl carbon atom is less electrophilic and less susceptible to nucleophilic attack than are the carbonyl carbon atoms in more reactive compounds such as carboxylate esters. Consequently, to promote peptide-bond cleavage, an enzyme must facilitate nucleophilic attack at a normally unreactive carbonyl group.

### Chymotrypsin possesses a highly reactive serine residue

A number of proteolytic enzymes participate in the breakdown of proteins in the digestive systems of mammals and other organisms. One such enzyme, chymotrypsin, cleaves peptide bonds selectively on the carboxyl-terminal side of the large hydrophobic amino acids such as tryptophan, tyrosine, phenylalanine, and methionine (Figure 9.1). Chymotrypsin is a good example of the use of *covalent catalysis*. The enzyme employs a powerful nucleophile to attack the unreactive carbonyl carbon atom of the substrate. This nucleophile becomes covalently attached to the substrate briefly in the course of catalysis.

**FIGURE 9.1 Specificity of chymotrypsin.** Chymotrypsin cleaves proteins on the carboxyl side of aromatic or large hydrophobic amino acids (shaded orange). The likely bonds cleaved by chymotrypsin are indicated in red.

What is the nucleophile that chymotrypsin employs to attack the substrate carbonyl carbon atom? A clue came from the fact that chymotrypsin contains an extraordinarily reactive serine residue. Chymotrypsin molecules treated with organofluorophosphates such as diisopropylphosphorofluoridate (DIPF) lost all activity irreversibly (Figure 9.2). Only a single residue, serine 195, was modified. This *chemical modification reaction* suggested that this unusually reactive serine residue plays a central role in the catalytic mechanism of chymotrypsin.

**FIGURE 9.2 An unusually reactive serine residue in chymotrypsin.** Chymotrypsin is inactivated by treatment with diisopropylphosphorofluoridate (DIPF), which reacts only with serine 195 among 28 possible serine residues.

### Chymotrypsin action proceeds in two steps linked by a covalently bound intermediate

A study of the kinetics of chymotrypsin provided a second clue to its catalytic mechanism. Enzyme kinetics are often easily monitored by having the enzyme act on a substrate analog that forms a colored product. For chymotrypsin, such a *chromogenic substrate* is *N*-acetyl-L-phenylalanine *p*-nitrophenyl ester. This substrate is an ester rather than an amide, but many proteases will also hydrolyze esters. One of the products formed by chymotrypsin's cleavage of this substrate is *p*-nitrophenolate, which has a yellow color (Figure 9.3). Measurements of the absorbance of light revealed the amount of *p*-nitrophenolate being produced.

Under steady-state conditions, the cleavage of this substrate obeys Michaelis–Menten kinetics with a  $K_M$  of 20  $\mu\text{M}$  and a  $k_{\text{cat}}$  of 77  $\text{s}^{-1}$ . The initial phase of the reaction was examined by using the stopped-flow method, which makes it possible to mix enzyme and substrate and monitor the results within a millisecond. This method revealed an initial rapid burst of colored product, followed by its slower formation as the reaction reached

**FIGURE 9.3 Chromogenic substrate.** *N*-Acetyl-L-phenylalanine *p*-nitrophenyl ester yields a yellow product, *p*-nitrophenolate, on cleavage by chymotrypsin. *p*-Nitrophenolate forms by deprotonation of *p*-nitrophenol at pH 7.

the steady state (Figure 9.4). These results suggest that hydrolysis proceeds in two phases. In the first reaction cycle that takes place immediately after mixing, only the first phase must take place before the colored product is released. In subsequent reaction cycles, both phases must take place. Note that the burst is observed because the first phase is substantially more rapid than the second phase for this substrate.

The two phases are explained by the formation of a covalently bound enzyme–substrate intermediate (Figure 9.5). First, the acyl group of the substrate becomes covalently attached to the enzyme as *p*-nitrophenolate (or an amine if the substrate is an amide rather than an ester) is released. The enzyme–acyl group complex is called the *acyl-enzyme intermediate*. Second, the acyl-enzyme intermediate is hydrolyzed to release the carboxylic acid component of the substrate and regenerate the free enzyme. Thus, one molecule of *p*-nitrophenolate is produced rapidly from each enzyme molecule as the acyl-enzyme intermediate is formed. However, it takes longer for the enzyme to be “reset” by the hydrolysis of the acyl-enzyme intermediate, and both phases are required for enzyme turnover.

**FIGURE 9.4 Kinetics of chymotrypsin catalysis.** Two phases are evident in the cleaving of *N*-acetyl-L-phenylalanine *p*-nitrophenyl ester by chymotrypsin: a rapid burst phase (pre-steady-state) and a steady-state phase.

**FIGURE 9.5 Covalent catalysis.** Hydrolysis by chymotrypsin takes place in two phases: (A) acylation to form the acyl-enzyme intermediate followed by (B) deacylation to regenerate the free enzyme.

### Serine is part of a catalytic triad that also includes histidine and aspartate

The three-dimensional structure of chymotrypsin revealed that this enzyme is roughly spherical and comprises three polypeptide chains, linked by disulfide bonds. It is synthesized as a single polypeptide, termed *chymotrypsinogen*, which is activated by the proteolytic cleavage of the polypeptide to yield the three chains (Section 10.4). The active site of chymotrypsin, marked by serine 195, lies in a cleft on the surface of the

**FIGURE 9.6 Location of the active site in chymotrypsin.** Chymotrypsin consists of three chains, shown in ribbon form in orange, blue, and green. The side chains of the catalytic triad residues are shown as ball-and-stick representations. Notice these side chains, including serine 195, lining the active site in the upper half of the structure. Also notice two intrastrand and two interstrand disulfide bonds in various locations throughout the molecule. [Drawn from 1GCT.pdb.]

enzyme (Figure 9.6). The structure of the active site explained the special reactivity of serine 195 (Figure 9.7). The side chain of serine 195 is hydrogen bonded to the imidazole ring of histidine 57. The —NH group of this imidazole ring is, in turn, hydrogen bonded to the carboxylate group of aspartate 102. This constellation of residues is referred to as the *catalytic triad*. How does this arrangement of residues lead to the high reactivity of serine 195? The histidine residue serves to position the serine side chain and to polarize its hydroxyl group so that it is poised for deprotonation. In the presence of the substrate, the histidine residue accepts the proton from the serine 195 hydroxyl group. In doing so, the histidine acts as a general base catalyst. The withdrawal of the proton from the hydroxyl group generates an alkoxide ion, which is a much more powerful nucleophile than is an alcohol. The aspartate residue helps orient the histidine residue and make it a better proton acceptor through hydrogen bonding and electrostatic effects.

**FIGURE 9.7 The catalytic triad.** The catalytic triad, shown on the left, converts serine 195 into a potent nucleophile, as illustrated on the right.

These observations suggest a mechanism for peptide hydrolysis (Figure 9.8). After substrate binding (step 1), the reaction begins with the oxygen atom of the side chain of serine 195 making a nucleophilic attack on the carbonyl carbon atom of the target peptide bond (step 2). There are now four atoms bonded to the carbonyl carbon, arranged as a tetrahedron, instead of three atoms in a planar arrangement. This inherently unstable *tetrahedral intermediate* bears a formal negative charge on the oxygen atom derived from the carbonyl group. This charge is stabilized by interactions

**FIGURE 9.8 Peptide hydrolysis by chymotrypsin.** The mechanism of peptide hydrolysis illustrates the principles of covalent and acid–base catalysis. The reaction proceeds in eight steps: (1) substrate binding, (2) nucleophilic attack of serine on the peptide carbonyl group, (3) collapse of the tetrahedral intermediate, (4) release of the amine component, (5) water binding, (6) nucleophilic attack of water on the acyl-enzyme intermediate, (7) collapse of the tetrahedral intermediate; and (8) release of the carboxylic acid component. The dashed green lines represent hydrogen bonds.

with NH groups from the protein in a site termed the *oxyanion hole* (Figure 9.9). These interactions also help stabilize the transition state that precedes the formation of the tetrahedral intermediate. This tetrahedral intermediate collapses to generate the acyl-enzyme (step 3). This step is facilitated by the transfer of the proton being held by the positively charged histidine residue to the amino group formed by cleavage of the peptide bond. The amine component is now free to depart from the enzyme (step 4), completing the first stage of the hydrolytic reaction—acylation of the enzyme. Such acyl-enzyme intermediates have even been observed using X-ray crystallography by trapping them through adjustment of conditions such as the nature of the substrate, pH, or temperature.

The next stage—deacylation—begins when a water molecule takes the place occupied earlier by the amine component of the substrate (step 5). The ester group of the acyl-enzyme is now hydrolyzed by a process that essentially repeats steps 2 through 4. Now acting as a general acid catalyst, histidine 57 draws a proton away from the water molecule. The resulting  $\text{OH}^-$  ion attacks the carbonyl carbon atom of the acyl group, forming a tetrahedral intermediate (step 6). This structure breaks down to form the carboxylic acid product (step 7). Finally, the release of the carboxylic acid product (step 8) readies the enzyme for another round of catalysis.

**FIGURE 9.9 The oxyanion hole.** The structure stabilizes the tetrahedral intermediate of the chymotrypsin reaction. Notice that hydrogen bonds (shown in green) link peptide NH groups and the negatively charged oxygen atom of the intermediate.

**FIGURE 9.10 Specificity pocket of chymotrypsin.** Notice that this pocket is lined with hydrophobic residues and is deep, favoring the binding of residues with long hydrophobic side chains such as phenylalanine (shown in green). The active-site serine residue (serine 195) is positioned to cleave the peptide backbone between the residue bound in the pocket and the next residue in the sequence. The key amino acids that constitute the binding site are identified.

This mechanism accounts for all characteristics of chymotrypsin action except the observed preference for cleaving the peptide bonds just past residues with large, hydrophobic side chains. Examination of the three-dimensional structure of chymotrypsin with substrate analogs and enzyme inhibitors revealed the presence of a deep hydrophobic pocket, called the  $S_1$  pocket, into which the long, uncharged side chains of residues such as phenylalanine and tryptophan can fit. *The binding of an appropriate side chain into this pocket positions the adjacent peptide bond into the active site for cleavage* (Figure 9.10). The specificity of chymotrypsin depends almost entirely on which amino acid is directly on the amino-terminal side of the peptide bond to be cleaved. Other proteases have more-complex specificity patterns. Such enzymes have additional pockets on their surfaces for the recognition of other residues in the substrate. Residues on the amino-terminal side of the scissile bond (the bond to be cleaved) are labeled  $P_1$ ,  $P_2$ ,  $P_3$ , and so forth, heading away from the scissile bond (Figure 9.11). Likewise, residues on the carboxyl side of the scissile bond are labeled  $P_1'$ ,  $P_2'$ ,  $P_3'$ , and so forth. The corresponding sites on the enzyme are referred to as  $S_1$ ,  $S_2$  or  $S_1'$ ,  $S_2'$ , and so forth.

**FIGURE 9.11 Specificity nomenclature for protease–substrate interactions.** The potential sites of interaction of the substrate with the enzyme are designated P (shown in red), and corresponding binding sites on the enzyme are designated S. The scissile bond (also shown in red) is the reference point.

**FIGURE 9.12 Structural similarity of trypsin and chymotrypsin.** An overlay of the structure of chymotrypsin (red) on that of trypsin (blue) is shown. Notice the high degree of similarity. Only  $\alpha$ -carbon-atom positions are shown. The mean deviation in position between corresponding  $\alpha$ -carbon atoms is 1.7 Å. [Drawn from 5PTP.pdb and 1GCT.pdb.]

### Catalytic triads are found in other hydrolytic enzymes

Many other peptide-cleaving proteins have subsequently been found to contain catalytic triads similar to that discovered in chymotrypsin. Some, such as trypsin and elastase, are obvious homologs of chymotrypsin. The sequences of these proteins are approximately 40% identical with that of chymotrypsin, and their overall structures are quite similar (Figure 9.12). These proteins operate by mechanisms identical with that of chymotrypsin. However, the three enzymes differ markedly in substrate specificity. Chymotrypsin cleaves at the peptide bond after residues with an aromatic or long nonpolar side chain. Trypsin cleaves at the peptide bond after residues with long, positively charged side chains—namely, arginine and lysine. Elastase cleaves at the peptide bond after amino acids with small side chains—such as alanine and serine. Comparison of the  $S_1$  pockets of these enzymes reveals that *these different specificities are due to small structural differences*. In trypsin, an aspartate residue (Asp 189) is present at the bottom of the  $S_1$  pocket in place of a serine residue in chymotrypsin. The aspartate residue attracts and stabilizes a positively charged arginine or lysine residue in the substrate. In elastase, two residues at the top of the pocket in chymotrypsin and trypsin are replaced by much bulkier valine residues (Val 190 and Val 216). These residues close off the mouth of the pocket so that only small side chains can enter (Figure 9.13).

**FIGURE 9.13** The  $S_1$  pockets of chymotrypsin, trypsin, and elastase. Certain residues play key roles in determining the specificity of these enzymes. The side chains of these residues, as well as those of the active-site serine residues, are shown in color.

Other members of the chymotrypsin family include a collection of proteins that take part in blood clotting, to be discussed in Chapter 10, as well as the tumor marker protein prostate-specific antigen (PSA). In addition, a wide range of proteases found in bacteria, viruses, and plants belong to this clan.

Other enzymes that are not homologs of chymotrypsin have been found to contain very similar active sites. As noted in Chapter 6, the presence of very similar active sites in these different protein families is a consequence of convergent evolution. Subtilisin, a protease in bacteria such as *Bacillus amyloliquefaciens*, is a particularly well characterized example. The active site of this enzyme includes both the catalytic triad and the oxyanion hole. However, one of the NH groups that forms the oxyanion hole comes from the side chain of an asparagine residue rather than from the peptide backbone (Figure 9.14). Subtilisin is the founding member of another large family of proteases that includes representatives from Archaea, Bacteria, and Eukarya.

Finally, other proteases have been discovered that contain an active-site serine or threonine residue that is activated not by a histidine–aspartate pair but by a primary amino group from the side chain of lysine or by the N-terminal amino group of the polypeptide chain.

Thus, the catalytic triad in proteases has emerged at least three times in the course of evolution. We can conclude that this catalytic strategy

**FIGURE 9.14** The catalytic triad and oxyanion hole of subtilisin. Notice the two enzyme NH groups (both in the backbone and in the side chain of Asn 155) located in the oxyanion hole. The NH groups will stabilize a negative charge that develops on the peptide bond attacked by nucleophilic serine 221 of the catalytic triad.

**FIGURE 9.15 Site-directed mutagenesis of subtilisin.** Residues of the catalytic triad were mutated to alanine, and the activity of the mutated enzyme was measured. Mutations in any component of the catalytic triad cause a dramatic loss of enzyme activity. Note that the activity is displayed on a logarithmic scale. The mutations are identified as follows: the first letter is the one-letter abbreviation for the amino acid being altered; the number identifies the position of the residue in the primary structure; and the second letter is the one-letter abbreviation for the amino acid replacing the original one. Uncat. refers to the estimated rate for the uncatalyzed reaction.

must be an especially effective approach to the hydrolysis of peptides and related bonds.

### The catalytic triad has been dissected by site-directed mutagenesis

How can we test the validity of the mechanism proposed for the catalytic triad? One way is to test the contribution of individual amino acid residues to the catalytic power of a protease by using site-directed mutagenesis (Section 5.2). Subtilisin has been extensively studied by this method. Each of the residues within the catalytic triad, consisting of aspartic acid 32, histidine 64, and serine 221, has been individually converted into alanine, and the ability of each mutant enzyme to cleave a model substrate has been examined (Figure 9.15).

As expected, the conversion of active-site serine 221 into alanine dramatically reduced catalytic power; the value of  $k_{\text{cat}}$  fell to less than *one millionth* of its value for the wild-type enzyme. The value of  $K_{\text{M}}$  was essentially unchanged; its increase by no more than a factor of two indicated that substrate continued to bind normally. The mutation of histidine 64 to alanine reduced catalytic power to a similar degree. The conversion of aspartate 32 into alanine reduced catalytic power by less, although the value of  $k_{\text{cat}}$  still fell to less than 0.005% of its wild-type value. The simultaneous conversion of all three residues into alanine was no more deleterious than the conversion of serine or histidine alone. These observations support the notion that the catalytic triad and, particularly, the serine–histidine pair act together to generate a nucleophile of sufficient power to attack the carbonyl carbon atom of a peptide bond. Despite the reduction in their catalytic power, the mutated enzymes still hydrolyze peptides a thousand times as fast as buffer at pH 8.6.

Site-directed mutagenesis also offered a way to probe the importance of the oxyanion hole for catalysis. The mutation of asparagine 155 to glycine eliminated the side-chain NH group from the oxyanion hole of subtilisin. The elimination of the NH group reduced the value of  $k_{\text{cat}}$  to 0.2% of its wild-type value but increased the value of  $K_{\text{M}}$  by only a factor of two. These observations demonstrate that the NH group of the asparagine residue plays a significant role in stabilizing the tetrahedral intermediate and the transition state leading to it.

### Cysteine, aspartyl, and metalloproteases are other major classes of peptide-cleaving enzymes

Not all proteases utilize strategies based on activated serine residues. Classes of proteins have been discovered that employ three alternative

**FIGURE 9.16 Three classes of proteases and their active sites.** These examples of a cysteine protease, an aspartyl protease, and a metalloprotease use a histidine-activated cysteine residue, an aspartate-activated water molecule, and a metal-activated water molecule, respectively, as the nucleophile. The two halves of renin are in blue and red to highlight the approximate twofold symmetry of aspartyl proteases. *Notice* how different these active sites are despite the similarity in the reactions they catalyze. [Drawn from 1PPN.pdb.; 1HRN.pdb; 1LND.pdb.]

approaches to peptide-bond hydrolysis (Figure 9.16). These classes are the (1) cysteine proteases, (2) aspartyl proteases, and (3) metalloproteases. In each case, the strategy is to generate a nucleophile that attacks the peptide carbonyl group (Figure 9.17).

The strategy used by the *cysteine proteases* is most similar to that used by the chymotrypsin family. In these enzymes, a cysteine residue, activated by a histidine residue, plays the role of the nucleophile that attacks the peptide bond (Figure 9.17) in a manner quite analogous to that of the serine residue in serine proteases. Because the sulfur atom in cysteine is inherently a better

**FIGURE 9.17 The activation strategies for three classes of proteases.** The peptide carbonyl group is attacked by (A) a histidine-activated cysteine in the cysteine proteases, (B) an aspartate-activated water molecule in the aspartyl proteases, and (C) a metal-activated water molecule in the metalloproteases. For the metalloproteases, the letter B represents a base (often glutamate) that helps deprotonate the metal-bound water.

(A) CYSTEINE PROTEASES

(B) ASPARTYL PROTEASES

(C) METALLOPROTEASES

nucleophile than is the oxygen atom in serine, cysteine proteases appear to require only this histidine residue in addition to cysteine and not the full catalytic triad. A well-studied example of these proteins is papain, an enzyme purified from the fruit of the papaya. Mammalian proteases homologous to papain have been discovered, most notably the cathepsins, proteins having a role in the immune system and other systems. The cysteine-based active site arose independently at least twice in the course of evolution; the caspases, enzymes that play a major role in apoptosis (a genetically programmed cell death pathway), have active sites similar to that of papain, but their overall structures are unrelated.

The second class comprises the *aspartyl proteases*. The central feature of the active sites is a pair of aspartic acid residues that act together to allow a water molecule to attack the peptide bond. One aspartic acid residue (in its deprotonated form) activates the attacking water molecule by poisoning it for deprotonation. The other aspartic acid residue (in its protonated form) polarizes the peptide carbonyl group so that it is more susceptible to attack (Figure 9.17). Members of this class include renin, an enzyme involved in the regulation of blood pressure, and the digestive enzyme pepsin. These proteins possess approximate twofold symmetry. A likely scenario is that two copies of a gene for the ancestral enzyme fused to form a single gene that encoded a single-chain enzyme. Each copy of the gene would have contributed an aspartate residue to the active site. The individual chains are now joined to make a single chain in most aspartyl proteases, whereas the proteases present in human immunodeficiency virus (HIV) and other retroviruses comprise dimers of identical chains (Figure 9.18). This observation is consistent with the idea that larger aspartyl proteases may have evolved by fusion of separate subunits.

The *metalloproteases* constitute the final major class of peptide-cleaving enzymes. The active site of such a protein contains a bound metal ion, almost always zinc, that activates a water molecule to act as a nucleophile to attack the peptide carbonyl group. The bacterial enzyme thermolysin and the digestive enzyme carboxypeptidase A are classic examples of the zinc proteases. Thermolysin, but not carboxypeptidase A, is a member of a large and diverse family of homologous zinc proteases that includes the matrix metalloproteases, enzymes that catalyze the reactions in tissue remodeling and degradation.

In each of these three classes of enzymes, the active site includes features that act to (1) activate a water molecule or another nucleophile, (2) polarize the peptide carbonyl group, and (3) stabilize a tetrahedral intermediate (Figure 9.17).

**FIGURE 9.18 HIV protease, a dimeric aspartyl protease.** The protease is a dimer of identical subunits, shown in blue and yellow, consisting of 99 amino acids each. Notice the placement of active-site aspartic acid residues, one from each chain, which are shown as ball-and-stick structures. The flaps will close down on the binding pocket after substrate has been bound. [Drawn from 3PHV.pdb.]

## Protease inhibitors are important drugs

 Several important drugs are protease inhibitors. For example, captopril, used to regulate blood pressure, is one of many inhibitors of the angiotensin-converting enzyme (ACE), a metalloprotease. Indinavir (Crixivan), retrovir, and more than 20 other compounds used in the treatment of AIDS are inhibitors of HIV protease (Figure 9.18), an aspartyl protease. HIV protease cleaves multidomain viral proteins into their active forms; blocking this process completely prevents the virus from being infectious. HIV protease inhibitors, in combination with inhibitors of other key HIV enzymes, dramatically reduced deaths due to AIDS, assuming that the cost of the treatment could be covered (Figure 36.21). In many cases, these drugs have converted AIDS from a death sentence to a treatable chronic disease.

**FIGURE 9.19 Indinavir, an HIV protease inhibitor.** The structure of indinavir (Crixivan) is shown in comparison with that of a peptide substrate of HIV protease. The scissile bond in the substrate is highlighted in red.

Indinavir resembles the peptide substrate of the HIV protease. Indinavir is constructed around an alcohol that mimics the tetrahedral intermediate; other groups are present to bind into the  $S_2$ ,  $S_1$ ,  $S_1'$ , and  $S_2'$  recognition sites on the enzyme (Figure 9.19). X-ray crystallographic studies revealed that, in the active site, indinavir adopts a conformation that approximates the twofold symmetry of the enzyme (Figure 9.20).

**FIGURE 9.20 HIV protease–indinavir complex.** (Left) The HIV protease is shown with the inhibitor indinavir bound at the active site. Notice the twofold symmetry of the enzyme structure. (Right) The drug has been rotated to reveal its approximately twofold symmetric conformation. [Drawn from 1HSH.pdb.]

The active site of HIV protease is covered by two flexible flaps that fold down on top of the bound inhibitor. The OH group of the central alcohol interacts with the two aspartate residues of the active site. In addition, two carbonyl groups of the inhibitor are hydrogen bonded to a water molecule (not shown in Figure 9.20), which, in turn, is hydrogen bonded to a peptide NH group in each of the flaps. This interaction of the inhibitor with water and the enzyme is not possible within cellular aspartyl proteases such as renin. Thus, the interaction may contribute to the specificity of indinavir for HIV protease. To prevent side effects, protease inhibitors used as drugs must be specific for one enzyme without inhibiting other proteins within the body.

## 9.2 Carbonic Anhydrases Make a Fast Reaction Faster

Carbon dioxide is a major end product of aerobic metabolism. In mammals, this carbon dioxide is released into the blood and transported to the lungs for exhalation. While in the red blood cells, carbon dioxide reacts with water (Section 7.3). The product of this reaction is a moderately strong acid, carbonic acid ( $pK_a = 3.5$ ), which is converted into bicarbonate ion ( $\text{HCO}_3^-$ ) on the loss of a proton.

Even in the absence of a catalyst, this hydration reaction proceeds at a moderately fast pace. At  $37^\circ\text{C}$  near neutral pH, the second-order rate constant  $k_1$  is  $0.0027 \text{ M}^{-1} \text{ s}^{-1}$ . This value corresponds to an effective first-order rate constant of  $0.15 \text{ s}^{-1}$  in water ( $[\text{H}_2\text{O}] = 55.5 \text{ M}$ ). The reverse reaction, the dehydration of  $\text{HCO}_3^-$ , is even more rapid, with a rate constant of  $k_{-1} = 50 \text{ s}^{-1}$ . These rate constants correspond to an equilibrium constant of  $K_1 = 5.4 \times 10^{-5}$  and a ratio of  $[\text{CO}_2]$  to  $[\text{H}_2\text{CO}_3]$  of 340 : 1 at equilibrium.

Carbon dioxide hydration and  $\text{HCO}_3^-$  dehydration are often coupled to rapid processes, particularly transport processes. Thus, almost all organisms contain enzymes, referred to as *carbonic anhydrases*, that increase the rate of reaction beyond the already reasonable spontaneous rate. For example, carbonic anhydrases dehydrate  $\text{HCO}_3^-$  in the blood to form  $\text{CO}_2$  for exhalation as the blood passes through the lungs. Conversely, they convert  $\text{CO}_2$  into  $\text{HCO}_3^-$  to generate the aqueous humor of the eye and other secretions. Furthermore, both  $\text{CO}_2$  and  $\text{HCO}_3^-$  are substrates and products for a variety of enzymes, and the rapid interconversion of these species may be necessary to ensure appropriate substrate levels. So important are these enzymes in human beings that mutations in some carbonic anhydrases have been found to be associated with osteopetrosis (excessive formation of dense bones accompanied by anemia) and mental retardation.

Carbonic anhydrases accelerate  $\text{CO}_2$  hydration dramatically. The most-active enzymes hydrate  $\text{CO}_2$  at rates as high as  $k_{\text{cat}} = 10^6 \text{ s}^{-1}$ , or a million times a second per enzyme molecule. Fundamental physical processes such as diffusion and proton transfer ordinarily limit the rate of hydration, and so the enzymes employ special strategies to attain such prodigious rates.

## Carbonic anhydrase contains a bound zinc ion essential for catalytic activity

Less than 10 years after the discovery of carbonic anhydrase in 1932, this enzyme was found to contain a bound zinc ion. Moreover, the zinc ion appeared to be necessary for catalytic activity. This discovery, remarkable at the time, made carbonic anhydrase the first known zinc-containing enzyme. At present, hundreds of enzymes are known to contain zinc. In fact, more than one-third of all enzymes either contain bound metal ions or require the addition of such ions for activity. Metal ions have several properties that increase chemical reactivity: their positive charges, their ability to form strong yet kinetically labile bonds, and, in some cases, their capacity to be stable in more than one oxidation state. The chemical reactivity of metal ions explains why catalytic strategies that employ metal ions have been adopted throughout evolution.

X-ray crystallographic studies have supplied the most-detailed and direct information about the zinc site in carbonic anhydrase. At least seven carbonic anhydrases, each with its own gene, are present in human beings. They are all clearly homologous, as revealed by substantial sequence identity. Carbonic anhydrase II, a major protein component of red blood cells, has been the most extensively studied (Figure 9.21). It is also one of the most active carbonic anhydrases.

**FIGURE 9.21** The structure of human carbonic anhydrase II and its zinc site. (Left) Notice that the zinc ion is bound to the imidazole rings of three histidine residues as well as to a water molecule. (Right) Notice the location of the zinc site in a cleft near the center of the enzyme. [Drawn from 1CA2.pdb.]

Zinc is found only in the +2 state in biological systems. A zinc atom is essentially always bound to four or more ligands; in carbonic anhydrase, three coordination sites are occupied by the imidazole rings of three histidine residues and an additional coordination site is occupied by a water molecule (or hydroxide ion, depending on pH). Because the molecules occupying the coordination sites are neutral, the overall charge on the  $\text{Zn}(\text{His})_3$  unit remains +2.

### Catalysis entails zinc activation of a water molecule

How does this zinc complex facilitate carbon dioxide hydration? A major clue comes from the pH profile of enzymatically catalyzed carbon dioxide hydration (Figure 9.22).

At pH 8, the reaction proceeds near its maximal rate. As the pH decreases, the rate of the reaction drops. The midpoint of this transition is

**FIGURE 9.22** Effect of pH on carbonic anhydrase activity. Changes in pH alter the rate of carbon dioxide hydration catalyzed by carbonic anhydrase II. The enzyme is maximally active at high pH.

**FIGURE 9.23** The  $\text{p}K_a$  of zinc-bound water. Binding to zinc lowers the  $\text{p}K_a$  of water from 15.7 to 7.

**FIGURE 9.24** Carbon dioxide binding site. Crystals of carbonic anhydrase were exposed to carbon dioxide gas at high pressure and low temperature, and x-ray diffraction data were collected. The electron density for carbon dioxide, clearly visible adjacent to the zinc and its bound water, reveals the carbon dioxide binding site. [Information from J. F. Domsic, et al., *J. Biol. Chem.* 283:30766–30771, 2008.]

near pH 7, suggesting that a group that loses a proton at pH 7 ( $\text{p}K_a = 7$ ) plays an important role in the activity of carbonic anhydrase. Moreover, the curve suggests that the deprotonated (high pH) form of this group participates more effectively in catalysis. Although some amino acids, notably histidine, have  $\text{p}K_a$  values near 7, a variety of evidence suggests that the group responsible for this transition is not an amino acid but is the zinc-bound water molecule.

The binding of a water molecule to the positively charged zinc center reduces the  $\text{p}K_a$  of the water molecule from 15.7 to 7 (Figure 9.23). With the  $\text{p}K_a$  lowered, the water molecule can more easily lose a proton at neutral pH, generating a substantial concentration of hydroxide ion (bound to the zinc atom). A zinc-bound hydroxide ion ( $\text{OH}^-$ ) is a potent nucleophile able to attack carbon dioxide much more readily than water does. Adjacent to the zinc site, carbonic anhydrase also possesses a hydrophobic patch that serves as a binding site for carbon dioxide (Figure 9.24). Based on these

**FIGURE 9.25** Mechanism of carbonic anhydrase. The zinc-bound hydroxide mechanism for the hydration of carbon dioxide reveals one aspect of metal ion catalysis. The reaction proceeds in four steps: (1) water deprotonation, (2) carbon dioxide binding, (3) nucleophilic attack by hydroxide on carbon dioxide, and (4) displacement of bicarbonate ion by water.

observations, a simple mechanism for carbon dioxide hydration can be proposed (Figure 9.25):

1. The zinc ion facilitates the release of a proton from a water molecule, which generates a hydroxide ion.
2. The carbon dioxide substrate binds to the enzyme's active site and is positioned to react with the hydroxide ion.
3. The hydroxide ion attacks the carbon dioxide, converting it into bicarbonate ion,  $\text{HCO}_3^-$ .
4. The catalytic site is regenerated with the release of  $\text{HCO}_3^-$  and the binding of another molecule of water.

Thus, the binding of a water molecule to the zinc ion favors the formation of the transition state by facilitating proton release and by positioning the water molecule to be in close proximity to the other reactant.

Studies of a *synthetic analog model system* provide evidence for the mechanism's plausibility. A simple synthetic ligand binds zinc through four

**FIGURE 9.26 A synthetic analog model system for carbonic anhydrase.** (A) An organic compound, capable of binding zinc, was synthesized as a model for carbonic anhydrase. The zinc complex of this ligand accelerates the hydration of carbon dioxide more than 100-fold under appropriate conditions. (B) The structure of the presumed active complex showing zinc bound to the ligand and to one water molecule.

nitrogen atoms (compared with three histidine nitrogen atoms in the enzyme), as shown in Figure 9.26. One water molecule remains bound to the zinc ion in the complex. Direct measurements reveal that this water molecule has a  $pK_a$  value of 8.7, not as low as the value for the water molecule in carbonic anhydrase but substantially lower than the value for free water. At pH 9.2, this complex accelerates the hydration of carbon dioxide more than 100-fold. Although its rate of catalysis is much less efficient than catalysis by carbonic anhydrase, the model system strongly suggests that the zinc-bound hydroxide mechanism is likely to be correct. Carbonic anhydrases have evolved to employ the reactivity intrinsic to a zinc-bound hydroxide ion as a potent catalyst.

### A proton shuttle facilitates rapid regeneration of the active form of the enzyme

As noted earlier, some carbonic anhydrases can hydrate carbon dioxide at rates as high as a million times a second ( $10^6 \text{ s}^{-1}$ ). The magnitude of this rate can be understood from the following observations. In the first step of a carbon dioxide hydration reaction, the zinc-bound water molecule must lose a proton to regenerate the active form of the enzyme (Figure 9.27). The rate of the reverse reaction, the protonation of the zinc-bound hydroxide ion, is limited by the rate of proton diffusion. Protons diffuse very rapidly

**FIGURE 9.27 Kinetics of water deprotonation.** The kinetics of deprotonation and protonation of the zinc-bound water molecule in carbonic anhydrase.

with second-order rate constants near  $10^{11} \text{ M}^{-1} \text{ s}^{-1}$ . Thus, the backward rate constant  $k_{-1}$  must be less than  $10^{11} \text{ M}^{-1} \text{ s}^{-1}$ . Because the equilibrium constant  $K$  is equal to  $k_1/k_{-1}$ , the forward rate constant is given by  $k_1 = K \cdot k_{-1}$ . Thus, if  $k_{-1} \leq 10^{11} \text{ M}^{-1} \text{ s}^{-1}$  and  $K = 10^{-7} \text{ M}$  (because  $pK_a = 7$ ), then  $k_1$  must be less than or equal to  $10^4 \text{ s}^{-1}$ . In other words, the rate of proton diffusion limits the rate of proton release to less than  $10^4 \text{ s}^{-1}$  for a group with  $pK_a = 7$ . However, if carbon dioxide is hydrated at a rate of  $10^6 \text{ s}^{-1}$ , then every step in the mechanism (Figure 9.25) must take place at least this fast. How is this apparent paradox resolved?

The answer became clear with the realization that *the highest rates of carbon dioxide hydration require the presence of buffer, suggesting that the buffer components participate in the reaction.* The buffer can bind or release protons. The advantage is that, whereas the concentrations of

**FIGURE 9.28 The effect of buffer on deprotonation.** The deprotonation of the zinc-bound water molecule in carbonic anhydrase is aided by buffer component B.

protons and hydroxide ions are limited to  $10^{-7}$  M at neutral pH, the concentration of buffer components can be much higher, of the order of several millimolar. If the buffer component  $\text{BH}^+$  has a  $\text{p}K_a$  of 7 (matching that for the zinc-bound water molecule), then the equilibrium constant for the reaction in Figure 9.28 is 1. The rate of proton abstraction is given by  $k_1' \cdot [\text{B}]$ . The second-order rate constants  $k_1'$  and  $k_{-1}'$  will be limited by buffer diffusion to values less than approximately  $10^9 \text{ M}^{-1} \text{ s}^{-1}$ . Thus, buffer concentrations greater than  $[\text{B}] = 10^{-3} \text{ M}$  (or 1 mM) may be high enough to support carbon dioxide hydration rates of  $10^6 \text{ M}^{-1} \text{ s}^{-1}$  because  $k_1' \cdot [\text{B}] = (10^9 \text{ M}^{-1} \text{ s}^{-1}) \cdot (10^{-3} \text{ M}) = 10^6 \text{ s}^{-1}$ . The prediction that the rate increases with increasing buffer concentration has been confirmed experimentally (Figure 9.29).

**FIGURE 9.29 The effect of buffer concentration on the rate of carbon dioxide hydration.** The rate of carbon dioxide hydration increases with the concentration of the buffer 1,2-dimethylbenzimidazole. The buffer enables the enzyme to achieve its high catalytic rates.

The molecular components of many buffers are too large to reach the active site of carbonic anhydrase. Carbonic anhydrase II has evolved a *proton shuttle* to allow buffer components to participate in the reaction from solution. The primary component of this shuttle is histidine 64. This residue transfers protons from the zinc-bound water molecule to the protein surface and then to the buffer (Figure 9.30). Thus, catalytic function has been enhanced through the evolution of an apparatus for controlling proton transfer from and to the active site. Because protons participate in many biochemical reactions, the manipulation of the proton inventory within active sites is crucial to the function of many enzymes and explains the prominence of acid–base catalysis.

**FIGURE 9.30 Histidine proton shuttle.** (1) Histidine 64 abstracts a proton from the zinc-bound water molecule, generating a nucleophilic hydroxide ion and a protonated histidine. (2) The buffer (B) removes a proton from the histidine, regenerating the unprotonated form.

### 9.3 Restriction Enzymes Catalyze Highly Specific DNA-Cleavage Reactions

We next consider a hydrolytic reaction that results in the cleavage of DNA. Bacteria and archaea have evolved mechanisms to protect themselves from viral infections. Many viruses inject their DNA genomes into cells; once inside, the viral DNA hijacks the cell's machinery to drive the production of viral proteins and, eventually, of progeny virus. Often, a viral infection results in the death of the host cell. A major protective strategy for the host is to use *restriction endonucleases* (restriction enzymes) to degrade the viral DNA on its introduction into a cell. These enzymes recognize particular base sequences, called *recognition sequences* or *recognition sites*, in their target DNA and cleave that DNA at defined positions. We have already considered the utility of these important enzymes for dissecting genes and genomes (Section 5.1). The most well-studied class of restriction enzymes comprises the type II restriction enzymes, which cleave DNA *within* their recognition sequences. Other types of restriction enzymes cleave DNA at positions somewhat distant from their recognition sites.

Restriction endonucleases must show tremendous specificity at two levels. First, they must not degrade host DNA containing the recognition sequences. Second, they must cleave only DNA molecules that contain recognition sites (hereafter referred to as *cognate DNA*) without cleaving DNA molecules that lack these sites. How do these enzymes manage to degrade viral DNA while sparing their own? In *E. coli*, the restriction endonuclease EcoRV cleaves double-stranded viral DNA molecules that contain the sequence 5'-GATATC-3' but leaves intact host DNA containing hundreds of such sequences. We shall return to the strategy by which host cells protect their own DNA at the end of this section.

Restriction enzymes must cleave DNA only at recognition sites, without cleaving at other sites. Suppose that a recognition sequence is six base pairs long. Because there are  $4^6$ , or 4096, sequences having six base pairs, the concentration of sites that must not be cleaved will be approximately 4000-fold higher than the concentration of sites that should be cleaved. Thus, to keep from damaging host-cell DNA, restriction enzymes must cleave cognate DNA molecules much more than 4000 times as efficiently as they cleave non-specific sites. We shall return to the mechanism used to achieve the necessary high specificity after considering the chemistry of the cleavage process.

#### Cleavage is by in-line displacement of 3'-oxygen from phosphorus by magnesium-activated water

A restriction endonuclease catalyzes the hydrolysis of the phosphodiester backbone of DNA. Specifically, the bond between the 3'-oxygen atom and the phosphorus atom is broken. The products of this reaction are DNA strands with a free 3'-hydroxyl group and a 5'-phosphoryl group at the cleavage site (Figure 9.31). This reaction proceeds by nucleophilic attack at the phosphorus atom. We will consider two alternative mechanisms,

**FIGURE 9.31 Hydrolysis of a phosphodiester bond.** All restriction enzymes catalyze the hydrolysis of DNA phosphodiester bonds, leaving a phosphoryl group attached to the 5' end. The bond that is cleaved is shown in red.

suggested by analogy with the proteases. The restriction endonuclease might cleave DNA by mechanism 1 through a covalent intermediate, employing a potent nucleophile (Nu), or by mechanism 2 through direct hydrolysis:

Mechanism 1 (covalent intermediate)

Mechanism 2 (direct hydrolysis)

Each mechanism postulates a different nucleophile to attack the phosphorus atom. In either case, each reaction takes place by *in-line displacement*:

The incoming nucleophile attacks the phosphorus atom, and a pentacoordinate transition state is formed. This species has a trigonal bipyramidal geometry centered at the phosphorus atom, with the incoming nucleophile at one apex of the two pyramids and the group that is displaced (the leaving group, L) at the other apex. Note that the displacement inverts the stereochemical conformation at the tetrahedral phosphorous atom, analogous to the interconversion of the R and S configurations around a tetrahedral carbon center (Section 2.1).

The two mechanisms differ in the number of times that the displacement takes place in the course of the reaction. In the first type of mechanism, a nucleophile in the enzyme (analogous to serine 195 in chymotrypsin) attacks the phosphate group to form a covalent intermediate. In a second step, this intermediate is hydrolyzed to produce the final products. In this case, two displacement reactions take place at the phosphorus atom. Consequently, the stereochemical configuration at the phosphorus atom would be inverted and then inverted again, and the overall configuration would be *retained*. In the second type of mechanism, analogous to that used by the aspartyl- and metalloproteases, an activated water molecule attacks the phosphorus atom directly. In this mechanism, a single displacement reaction takes place at the phosphorus atom. Hence, the stereochemical configuration at the phosphorus atom is *inverted* after cleavage. To determine which mechanism is correct, we examine the stereochemistry at the phosphorus atom after cleavage.

A difficulty is that the stereochemistry is not easily observed, because two of the groups bound to the phosphorus atom are simple oxygen atoms, identical with each other. This difficulty can be circumvented by replacing one oxygen atom with sulfur (producing a species called a phosphorothioate).

**FIGURE 9.32 Labeling with phosphorothioates.** Phosphorothioate groups, in which one of the nonbridging oxygen atoms is replaced by a sulfur atom, can be used to label specific sites in the DNA backbone to determine the overall stereochemical course of a displacement reaction. Here, a phosphorothioate is placed at sites that can be cleaved by EcoRV endonuclease.

Let us consider EcoRV endonuclease. This enzyme cleaves the phosphodiester bond between the T and the A at the center of the recognition sequence 5'-GATATC-3'. The first step is to synthesize an appropriate substrate for EcoRV containing phosphorothioates at the sites of cleavage (Figure 9.32). The reaction is then performed in water that has been greatly enriched in  $^{18}\text{O}$  to allow the incoming oxygen atom to be marked. The location of the  $^{18}\text{O}$  label with respect to the sulfur atom indicates whether the reaction proceeds with inversion or retention of stereochemistry. *This experiment revealed that the stereochemical configuration at the phosphorus atom was inverted only once with cleavage.* This result is consistent with a direct attack by water at the phosphorus atom and rules out the formation of any covalently bound intermediate (Figure 9.33).

### Restriction enzymes require magnesium for catalytic activity

Many enzymes that act on phosphate-containing substrates require  $\text{Mg}^{2+}$  or some other similar divalent cation for activity. One or more  $\text{Mg}^{2+}$  (or similar) cations are essential to the function of restriction endonucleases. What are the functions of these metal ions?

Direct visualization of the complex between EcoRV endonuclease and cognate DNA molecules in the presence of  $\text{Mg}^{2+}$  by crystallization has not been possible, because the enzyme cleaves the substrate under these circumstances. Nonetheless, metal ion complexes can be visualized through several approaches. In one approach, crystals of EcoRV endonuclease are prepared bound to oligonucleotides that contain the enzyme's recognition sequence. These crystals are grown in the absence of magnesium to prevent cleavage; after their preparation, the crystals are soaked in solutions containing the metal. Alternatively, crystals have been grown with the use of a mutated form of the enzyme that is less active. Finally,  $\text{Mg}^{2+}$  can be replaced by

**FIGURE 9.33 Stereochemistry of cleaved DNA.** Cleavage of DNA by EcoRV endonuclease results in overall inversion of the stereochemical configuration at the phosphorus atom, as indicated by the stereochemistry of the phosphorus atom bound to one bridging oxygen atom, one  $^{16}\text{O}$ , one  $^{18}\text{O}$ , and one sulfur atom. Two possible products are shown, only one of which is observed, indicating direct attack of water at the phosphorous atom.

**FIGURE 9.34** A magnesium ion-binding site in *EcoRV* endonuclease. The magnesium ion helps to activate a water molecule and positions it so that it can attack the phosphorus atom.

metal ions such as  $\text{Ca}^{2+}$  that bind but do not result in much catalytic activity. In all cases, no cleavage takes place, and so the locations of the metal ion-binding sites are readily determined.

As many as three metal ions have been found to be present per active site. The roles of these multiple metal ions are still under investigation. One ion-binding site is occupied in essentially all structures. This metal ion is coordinated to the protein through two aspartate residues and to one of the phosphate-group oxygen atoms near the site of cleavage. This metal ion binds the water molecule that attacks the phosphorus atom, helping to position and activate it in a manner similar to that for the  $\text{Zn}^{2+}$  ion of carbonic anhydrase (Figure 9.34).

### The complete catalytic apparatus is assembled only within complexes of cognate DNA molecules, ensuring specificity

We now return to the question of specificity, the defining feature of restriction enzymes. The recognition sequences for most restriction endonucleases are *inverted repeats*. This arrangement gives the three-dimensional structure of the recognition site a *twofold rotational symmetry* (Figure 9.35).

The restriction enzymes display a corresponding symmetry: they are dimers whose two subunits are related by twofold rotational symmetry. The matching symmetry of the recognition sequence and the enzyme facilitates the recognition of cognate DNA by the enzyme. This similarity in structure has been confirmed by the determination of the structure of the complex between *EcoRV* endonuclease and DNA fragments containing its

**FIGURE 9.35** Structure of the recognition site of *EcoRV* endonuclease. (A) The sequence of the recognition site, which is symmetric around the axis of rotation designated in green. (B) The inverted repeat within the recognition sequence of *EcoRV* (and most other restriction endonucleases) endows the DNA site with twofold rotational symmetry.

**FIGURE 9.36 EcoRV embracing a cognate DNA molecule.** (A) This view of the structure of EcoRV endonuclease bound to a cognate DNA fragment is down the helical axis of the DNA. The two protein subunits are in yellow and blue, and the DNA backbone is in red. Notice that the twofold axes of the enzyme dimer and the DNA are aligned. One of the DNA-binding loops (in green) of EcoRV endonuclease is shown interacting with the base pairs of its cognate DNA-binding site. Key amino acid residues are shown hydrogen bonding with (B) a CG base pair and (C) an AT base pair. [Drawn from 1RVB.pdb.]

recognition sequence (Figure 9.36). The enzyme surrounds the DNA in a tight embrace.

An enzyme's binding affinity for substrates often determines specificity. Surprisingly, however, binding studies performed in the absence of magnesium have demonstrated that the EcoRV endonuclease binds to all sequences, both cognate and noncognate, with approximately equal affinity. Why, then, does the enzyme cleave only cognate sequences? The answer lies in a unique set of interactions between the enzyme and a cognate DNA sequence.

Within the 5'-GATATC-3' sequence, the G and A bases at the 5' end of each strand and their Watson-Crick partners directly contact the enzyme by hydrogen bonding with residues that are located in two loops, one projecting from the surface of each enzyme subunit (Figure 9.36). The most striking feature of this complex is the *distortion of the DNA*, which is substantially kinked in the center (Figure 9.37). The central two TA base pairs in the recognition sequence play a key role in producing the kink. They do not make contact with the enzyme but appear to be required because of their ease of distortion. The 5'-TA-3' sequence is known to be among the most easily deformed base pairs.

The structures of complexes formed with noncognate DNA fragments are strikingly different from those formed with cognate DNA:

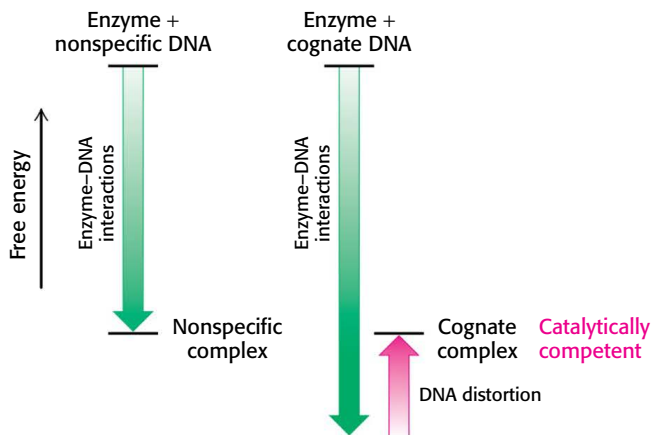

**FIGURE 9.37 Distortion of the recognition site.** The DNA is represented as a ball-and-stick model. The path of the DNA helical axis, shown in red, is substantially distorted on binding to the enzyme. For the B form of DNA, the axis is straight (not shown).

**FIGURE 9.38 Nonspecific and cognate DNA within EcoRV endonuclease.** A comparison of the positions of the nonspecific (orange) and the cognate DNA (red) within EcoRV. Notice that, in the nonspecific complex, the DNA backbone is too far from the enzyme to complete the magnesium ion-binding sites. [Drawn from 1RVB.pdb.]

the noncognate DNA conformation is not substantially distorted (Figure 9.38). This lack of distortion has important consequences with regard to catalysis. No phosphate is positioned sufficiently close to the active-site aspartate residues to complete a magnesium ion-binding site (Figure 9.34). Hence, the nonspecific complexes do not bind the magnesium ions and the complete catalytic apparatus is never assembled. The distortion of the substrate and the subsequent binding of the magnesium ion account for the catalytic specificity of more than a millionfold that is observed for EcoRV endonuclease. Thus, enzyme specificity may be determined by the specificity of enzyme action rather than the specificity of substrate binding.

We can now see the role of binding energy in this strategy for attaining catalytic specificity. The distorted DNA makes additional contacts with the enzyme, increasing the binding energy. However, the increase in binding energy is canceled by the energetic cost of distorting the DNA from its relaxed conformation (Figure 9.39). Thus, for EcoRV endonuclease, there is little difference in binding affinity for cognate and nonspecific DNA fragments. However, the distortion in the cognate complex dramatically affects catalysis by completing the magnesium ion-binding site. This example illustrates how enzymes can utilize available binding energy to deform substrates and poise them for chemical transformation. Interactions that take place within the distorted substrate complex stabilize the transition state leading to DNA hydrolysis.

**FIGURE 9.39 Greater binding energy of EcoRV endonuclease bound to cognate versus noncognate DNA.** The additional interactions between EcoRV endonuclease and cognate DNA increase the binding energy, which can be used to drive DNA distortions necessary for forming a catalytically competent complex.

### Host-cell DNA is protected by the addition of methyl groups to specific bases

How does a host cell harboring a restriction enzyme protect its own DNA? The host DNA is methylated on specific adenine bases within host recognition sequences by other enzymes called *methylases* (Figure 9.40). An endonuclease will not cleave DNA if its recognition sequence is methylated. For each restriction endonuclease, the host cell produces a corresponding methylase that marks the host DNA at the appropriate methylation site. These pairs of enzymes are referred to as *restriction-modification systems*.

The distortion in the DNA explains how methylation blocks catalysis and protects host-cell DNA. The host *E. coli* adds a methyl group to the amino group of the adenine nucleotide at the 5' end of the recognition sequence. The presence of the methyl group blocks the formation of a hydrogen bond between the amino group and the side-chain

**FIGURE 9.40 Protection by methylation.** The recognition sequence for EcoRV endonuclease (left) and the sites of methylation (right) in DNA protected from the catalytic action of the enzyme.

carbonyl group of asparagine 185 (Figure 9.41). This asparagine residue is closely linked to the other amino acids that form specific contacts with the DNA. The absence of the hydrogen bond disrupts other interactions between the enzyme and the DNA substrate, and the distortion necessary for cleavage will not take place.

### Type II restriction enzymes have a catalytic core in common and are probably related by horizontal gene transfer

 Type II restriction enzymes are prevalent in Archaea and Bacteria. What can we tell of the evolutionary history of these enzymes? Comparison of the amino acid sequences of a variety of type II restriction endonucleases did not reveal significant sequence similarity between most pairs of enzymes. However, a careful examination of three-dimensional structures, taking into account the location of the active sites, revealed the presence of a core structure conserved in the different enzymes.

These observations indicate that many type II restriction enzymes are indeed evolutionarily related. Analyses of the sequences in greater detail suggest that bacteria may have obtained genes encoding these enzymes from other species by *horizontal gene transfer*, the passing of pieces of DNA (such as plasmids) between species that provide a selective advantage in a particular environment. For example, EcoRI (from *E. coli*) and RsrI (from *Rhodobacter sphaeroides*) are 50% identical in sequence over 266 amino acids, clearly indicative of a close evolutionary relationship. However, these species of bacteria are not closely related. Thus, *these species appear to have obtained the gene for these restriction endonucleases from a common source more recently than the time of their evolutionary divergence*. Moreover, the codons used by the gene encoding EcoRI endonuclease to specify given amino acids are strikingly different from the codons used by most *E. coli* genes, which suggests that the gene did not originate in *E. coli*.

Horizontal gene transfer may be a common event. For example, genes that inactivate antibiotics are often transferred, leading to the transmission of antibiotic resistance from one species to another. For restriction-modification systems, protection against viral infections may have favored horizontal gene transfer.

**FIGURE 9.41 Methylation of adenine.**

The methylation of adenine blocks the formation of hydrogen bonds between EcoRV endonuclease and cognate DNA molecules and prevents their hydrolysis.

## 9.4 Myosins Harness Changes in Enzyme Conformation to Couple ATP Hydrolysis to Mechanical Work

The final enzymes that we will consider are the myosins. These enzymes catalyze the hydrolysis of adenosine triphosphate (ATP) to form adenosine diphosphate (ADP) and inorganic phosphate ( $P_i$ ) and use the energy associated with this thermodynamically favorable reaction to drive the motion of molecules within cells.

For example, when we lift a book, the energy required comes from ATP hydrolysis catalyzed by myosin in our muscles. Myosins are found in all

Globular ATPase domains

**FIGURE 9.42 Elongated structure of muscle myosin.** An electron micrograph showing myosin from mammalian muscle. This dimeric protein has an elongated structure with two globular ATPase domains per dimer. [Courtesy of Dr. Paula Flicker, Dr. Theo Walliman, and Dr. Peter Vibert.]

eukaryotes and the human genome encodes more than 40 different myosins. Myosins generally have elongated structures with globular domains that actually carry out ATP hydrolysis (Figure 9.42). In this chapter, we will focus on the globular ATPase domains, particularly the strategies that allow myosins to hydrolyze ATP in a controlled manner and to use the free energy associated with this reaction to promote substantial conformational changes within the myosin molecule. These conformational changes are amplified by other structures in the elongated myosin molecules to transport proteins or other cargo substantial distances within cells. In Chapter 35, we will examine the action of myosins and other molecular-motor proteins in much more detail.

As will be discussed in Chapter 15, ATP is used as the major currency of energy inside cells. Many enzymes use ATP hydrolysis to drive other reactions and processes. In almost all cases, an enzyme that hydrolyzed ATP without any such coupled processes would simply drain the energy reserves of a cell without benefit.

### ATP hydrolysis proceeds by the attack of water on the gamma phosphoryl group

In our examination of the mechanism of restriction enzymes, we learned that an activated water molecule performs a nucleophilic attack on phosphorus to cleave the phosphodiester backbone of DNA. The cleavage of ATP by myosins follows an analogous mechanism. To understand the myosin mechanism in more detail, we must first examine the structure of the myosin *ATPase* domain.

The structures of the ATPase domains of several different myosins have been examined. One such domain, that from the soil-living amoeba *Dictyostelium discoideum*, an organism that has been extremely useful for studying cell movement and molecular-motor proteins, has been studied in great detail. The crystal structure of this protein fragment in the absence of nucleotides revealed a single globular domain comprising approximately 750 amino acids. A water-filled pocket is present toward the center of the structure, suggesting a possible nucleotide-binding site. Crystals of this protein were soaked in a solution containing ATP and the structure was examined again. Remarkably, this structure revealed intact ATP bound in the active site with very little change in the overall structure and without evidence of significant hydrolysis (Figure 9.43). The ATP is also bound to a  $Mg^{2+}$  ion.

Kinetic studies of myosins, as well as many other enzymes having ATP or other nucleoside triphosphates as a substrate, reveal that these enzymes are essentially inactive in the absence of divalent metal ions such as magnesium ( $Mg^{2+}$ ) or manganese ( $Mn^{2+}$ ) but acquire activity on the addition of these ions. In contrast with the enzymes discussed so far, the metal is not a component of the active site. Rather, nucleotides such as ATP bind these ions, and it is the metal ion–nucleotide complex that is the true substrate for the enzymes. The dissociation constant for the ATP– $Mg^{2+}$  complex is approximately 0.1 mM, and thus, given that intracellular  $Mg^{2+}$  concentrations are typically in the millimolar range, essentially all nucleoside triphosphates are present as NTP– $Mg^{2+}$  complexes. *Magnesium or manganese complexes of nucleoside triphosphates are the true substrates for essentially all NTP-dependent enzymes.*

The nucleophilic attack by a water molecule on the  $\gamma$ -phosphoryl group requires some mechanism to activate the water, such as a basic residue or a bound metal ion. Examination

**FIGURE 9.43 Myosin–ATP complex structure.** An overlay of the structures of the ATPase domain from *Dictyostelium discoideum* myosin with no ligands bound (blue) and the complex of this protein with ATP and magnesium bound (red). Notice that the two structures are extremely similar to one another. [Drawn from 1FMV.pdb and 1FMW.pdb].

of the myosin–ATP complex structure shows no basic residue in an appropriate position and reveals that the bound  $Mg^{2+}$  ion is too far away from the phosphoryl group to play this role. These observations suggest why this ATP complex is relatively stable; the enzyme is not in a conformation that is competent to catalyze the reaction. This observation suggests that the domain must undergo a conformational change to catalyze the ATP-hydrolysis reaction.

### Formation of the transition state for ATP hydrolysis is associated with a substantial conformational change

The catalytically competent conformation of the myosin ATPase domain must bind and stabilize the transition state of the reaction. In analogy with restriction enzymes, we expect that ATP hydrolysis includes a pentacoordinate transition state.

Such pentacoordinate structures based on phosphorus are too unstable to be readily observed. However, transition-state analogs in which other atoms replace phosphorus are more stable. The transition metal vanadium, in particular, forms similar structures. The myosin ATPase domain can be crystallized in the presence of ADP and vanadate,  $VO_4^{3-}$ . The result is the formation of a complex that closely matches the expected transition-state structure (Figure 9.44). As expected, the vanadium atom is coordinated to five oxygen atoms, including one oxygen atom from ADP diametrically opposite an oxygen atom that is analogous to the attacking water molecule in the transition state. The  $Mg^{2+}$  ion is coordinated to one oxygen atom from the vanadate, one oxygen atom from the ADP, two hydroxyl groups from the enzyme, and two water molecules. In this position, this ion does not appear to play any direct role in activating the attacking water. However, an additional residue from the enzyme, Ser 236, is well positioned to play a role in catalysis (Figure 9.44). In the proposed mechanism of ATP hydrolysis based on this structure, the water molecule attacks the  $\gamma$ -phosphoryl group, with the hydroxyl group of Ser 236 facilitating the transfer of a proton from the attacking water to the hydroxyl group of Ser 236, which, in turn, is deprotonated by one of the oxygen atoms of the  $\gamma$ -phosphoryl group (Figure 9.45). Thus, in effect, the ATP serves as a base to promote its own hydrolysis.

**FIGURE 9.44 Myosin ATPase Transition-State Analog.** The structure of the transition-state analog formed by treating the myosin ATPase domain with ADP and vanadate ( $VO_4^{3-}$ ) in the presence of magnesium. Notice that the vanadium ion is coordinated to five oxygen atoms including one from ADP. The positions of two residues that bind magnesium as well as Ser 236, a residue that appears to play a direct role in catalysis, are shown. [Drawn from 1VOM.pdb]

**FIGURE 9.45 Facilitating water attack.** The water molecule attacking the  $\gamma$ -phosphoryl group of ATP is deprotonated by the hydroxyl group of Ser 236, which, in turn, is deprotonated by one of the oxygen atoms of the  $\gamma$ -phosphoryl group forming the  $H_2PO_4^-$  product.

**FIGURE 9.46 Myosin conformational changes.** A comparison of the overall structures of the myosin ATPase domain with ATP bound (shown in red) and that with the transition-state analog ADP–vanadate (shown in blue). Notice the large conformational change of a region at the carboxyl-terminus of the domain, some parts of which move as much as 25 Å. [Drawn from 1FMW.pdb and 1VOM.pdb].

Comparison of the overall structures of the myosin ATPase domain complexed with ATP and with the ADP–vanadate reveals some remarkable differences. Relatively modest structural changes occur in and around the active site. In particular, a stretch of amino acids moves closer to the nucleotide by approximately 2 Å and interacts with the oxygen atom that corresponds to the attacking water molecule. These changes help facilitate the hydrolysis reaction by stabilizing the transition state. However, examination of the overall structure shows even more striking changes.

A region comprising approximately 60 amino acids at the carboxyl-terminus of the domain adopts a different configuration in the ADP–vanadate complex, displaced by as much as 25 Å from its position in the ATP complex (Figure 9.46). This displacement tremendously amplifies the relatively subtle changes that take place in the active site. The effect of this motion is amplified even more as this carboxyl-terminal domain is connected to other structures within the elongated structures typical of myosin molecules (Figure 9.42). Thus, the conformation that is capable of promoting the ATP hydrolysis reaction is itself substantially different from other conformational changes that take place in the course of the catalytic cycle.

### The altered conformation of myosin persists for a substantial period of time

Myosins are slow enzymes, typically turning over approximately once per second. What steps limit the rate of turnover? In an experiment that was particularly revealing, the hydrolysis of ATP was catalyzed by the myosin ATPase domain from mammalian muscle. The reaction took place in water labeled with  $^{18}\text{O}$  to track the incorporation of solvent oxygen into the reaction products. The fraction of oxygen in the phosphate product was analyzed. In the simplest case, the phosphate would be expected to contain one oxygen atom derived from water and three initially present in the terminal phosphoryl group of ATP.

**FIGURE 9.47** Reversible hydrolysis of ATP within the myosin active site. For myosin, more than one atom of oxygen from water is incorporated in inorganic phosphate. The oxygen atoms are incorporated in cycles of hydrolysis of ATP to ADP and inorganic phosphate, phosphate rotation within the active site, and reformation of ATP now containing oxygen from water.

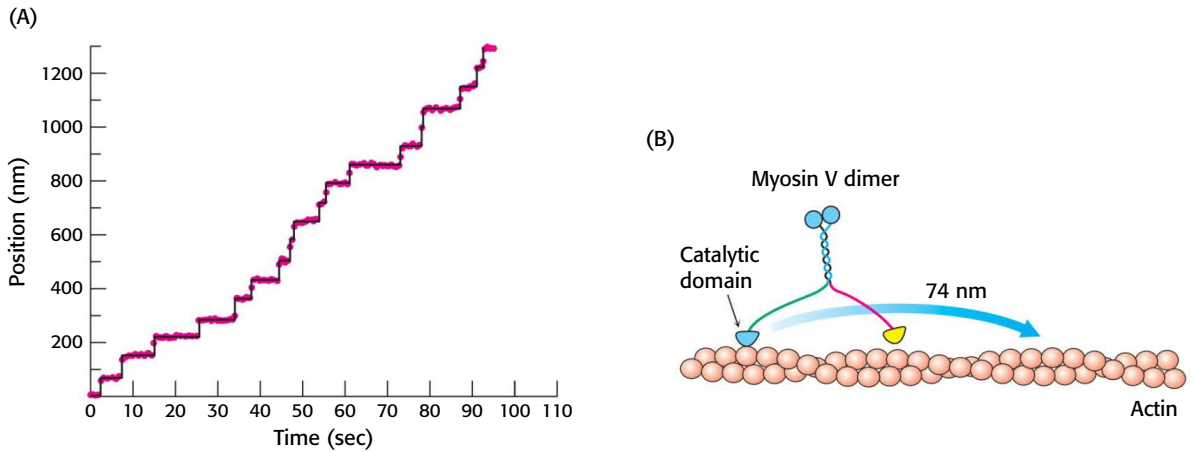

Instead, between two and three of the oxygen atoms in the phosphate were found, on average, to be derived from water. These observations indicate that the ATP hydrolysis reaction within the enzyme active site is reversible. Each molecule of ATP is cleaved to ADP and  $P_i$  and then re-formed from these products several times before the products are released from the enzyme (Figure 9.47). At first glance, this observation is startling because ATP hydrolysis is a very favorable reaction with an equilibrium constant of approximately 140,000. However, this equilibrium constant applies to the molecules free in solution, not within the active site of an enzyme. Indeed, more-extensive analysis suggests that this equilibrium constant on the enzyme is approximately 10, indicative of a general strategy used by enzymes. Enzymes catalyze reactions by stabilizing the transition state. The structure of this transition state is intermediate between the enzyme-bound reactants and the enzyme-bound products. Many of the interactions that stabilize the transition state will help equalize the stabilities of the reactants and the products. Thus, *the equilibrium constant between enzyme-bound reactants and products is often close to 1, regardless of the equilibrium constant for the reactants and products free in solution.*

These observations reveal that the hydrolysis of ATP to ADP and  $P_i$  is not the rate-limiting step for the reaction catalyzed by myosin. Instead, the release of the products, particularly  $P_i$ , from the enzyme is rate limiting. The fact that a conformation of myosin with ATP hydrolyzed but still bound to the enzyme persists for a significant period of time is critical for coupling conformational changes that take place in the course of the reaction to other processes.

### Scientists can watch single molecules of myosin move

Myosin molecules function to use the free energy of hydrolysis of ATP to drive macroscopic motion. Myosin molecules move along a filamentous protein termed actin, as we will discuss in more detail in Chapter 35. Using a variety of physical methods, scientists have been able to watch *single myosin in action*. For example, a myosin family member termed myosin V can be labelled with fluorescent tags so that it can be localized when fixed on a surface with a precision of less than 15 Å. When this myosin is placed on a surface coated with actin filaments, each molecule remains in a fixed position. However, when ATP is added, each molecule moves along the surface.

**FIGURE 9.48 Single molecule motion.** (A) A trace of the position of a single dimeric myosin V molecule as it moves across a surface coated with actin filaments. (B) A model of how the dimeric molecule moves in discrete steps with an average size of  $74 \pm 5$  nm. [Data from A. Yildiz, et al., *Science* 300(5628):2061–2065, 2003.]

**FIGURE 9.49 The core domain of NMP kinases.** Notice the P-loop shown in green. The dashed lines represent the remainder of the protein structure. [Drawn from 1GKY.pdb.]

Tracking individual molecules reveals that each moves in steps of approximately 74 nm as shown in Figure 9.48. The observation of steps of a fixed size as well as the determination of this step size helps reveal details of the mechanism of action of these tiny molecular motors.

### Myosins are a family of enzymes containing P-loop structures

X-ray crystallography has yielded the three-dimensional structures of a number of different enzymes that share key structural characteristics and, almost certainly, an evolutionary history with myosin. In particular, a conserved NTP-binding core domain is present. This domain consists of a central  $\beta$  sheet, surrounded on both sides by  $\alpha$  helices (Figure 9.49). A characteristic feature of this domain is a loop between the first  $\beta$  strand and the first helix. This loop typically has several glycine residues that are often conserved between more closely related members of this large and diverse

**FIGURE 9.50 Three proteins containing P-loop NTPase domains.** Notice the conserved domains shown with the inner surfaces of the ribbons in purple and the P-loops in green. [Drawn from 4AKE.pdb; 1TND.pdb; 1BMF.pdb.]

family. The loop is often referred to as the *P-loop* because it interacts with phosphoryl groups on the bound nucleotide. P-loop NTPase domains are present in a remarkably wide array of proteins, many of which participate in essential biochemical processes. Examples include ATP synthase, the key enzyme responsible for ATP generation; signal-transduction proteins such as G proteins; proteins essential for translating mRNA into proteins, such as elongation factor Tu; and DNA- and RNA-unwinding helicases. The wide utility of P-loop NTPase domains is perhaps best explained by their ability to undergo substantial conformational changes on nucleoside triphosphate binding and hydrolysis. We shall encounter these domains throughout the book and shall observe how they function as springs, motors, and clocks. To allow easy recognition of these domains in the book, they will be depicted with the inner surfaces of the ribbons in a ribbon diagram shown in purple and the P-loop shown in green (Figure 9.50).

## SUMMARY

Enzymes adopt conformations that are structurally and chemically complementary to the transition states of the reactions that they catalyze. Sets of interacting amino acid residues make up sites with the special structural and chemical properties necessary to stabilize the transition state. Enzymes use five basic strategies to form and stabilize the transition state. The first (1) involves the use of binding energy to promote both specificity and catalysis. The others are (2) covalent catalysis, (3) general acid–base catalysis, (4) catalysis by approximation, and (5) metal ion catalysis. The four classes of enzymes examined in this chapter catalyze the addition of water to their substrates but have different requirements for catalytic speed, specificity, and coupling to other processes.

### 9.1 Proteases Facilitate a Fundamentally Difficult Reaction

The cleavage of peptide bonds by chymotrypsin is initiated by the attack by a serine residue on the peptide carbonyl group. The attacking hydroxyl group is activated by interaction with the imidazole group of a histidine residue, which is, in turn, linked to an aspartate residue. This Ser-His-Asp catalytic triad generates a powerful nucleophile. The product of this initial reaction is a covalent intermediate formed by the enzyme and an acyl group derived from the bound substrate. The hydrolysis of this acyl-enzyme intermediate completes the cleavage process. The tetrahedral intermediates for these reactions have a negative charge on the peptide carbonyl oxygen atom. This negative charge is stabilized by interactions with peptide NH groups in a region on the enzyme termed the oxyanion hole.

Other proteases employ the same catalytic strategy. Some of these proteases, such as trypsin and elastase, are homologs of chymotrypsin. Other proteases, such as subtilisin, contain a very similar catalytic triad that has arisen by convergent evolution. Active-site structures that differ from the catalytic triad are present in a number of other classes of proteases. These classes employ a range of catalytic strategies but, in each case, a nucleophile is generated that is sufficiently powerful to attack the peptide carbonyl group. In some enzymes, the nucleophile is derived from a side chain whereas, in others, an activated water molecule attacks the peptide carbonyl directly.

### 9.2 Carbonic Anhydrases Make a Fast Reaction Faster

Carbonic anhydrases catalyze the reaction of water with carbon dioxide to generate carbonic acid. The catalysis can be extremely

fast: some carbonic anhydrases hydrate carbon dioxide at rates as high as 1 million times per second. A tightly bound zinc ion is a crucial component of the active sites of these enzymes. Each zinc ion binds a water molecule and promotes its deprotonation to generate a hydroxide ion at neutral pH. This hydroxide ion attacks carbon dioxide to form bicarbonate ion,  $\text{HCO}_3^-$ . Because of the physiological roles of carbon dioxide and bicarbonate ions, speed is of the essence for this enzyme. To overcome limitations imposed by the rate of proton transfer from the zinc-bound water molecule, the most-active carbonic anhydrases have evolved a proton shuttle to transfer protons to a buffer.

### 9.3 Restriction Enzymes Catalyze Highly Specific DNA-Cleavage Reactions

A high level of substrate specificity is often the key to biological function. Restriction endonucleases that cleave DNA at specific recognition sequences discriminate between molecules that contain these recognition sequences and those that do not. Within the enzyme–substrate complex, the DNA substrate is distorted in a manner that generates a magnesium ion-binding site between the enzyme and DNA. The magnesium ion binds and activates a water molecule, which attacks the phosphodiester backbone.

Some enzymes discriminate between potential substrates by binding them with different affinities. Others may bind many potential substrates but promote chemical reactions efficiently only on specific molecules. Restriction endonucleases such as EcoRV endonuclease employ the latter mechanism. Only molecules containing the proper recognition sequence are distorted in a manner that allows magnesium ion binding and, hence, catalysis. Restriction enzymes are prevented from acting on the DNA of a host cell by the methylation of key sites within its recognition sequences. The added methyl groups block specific interactions between the enzymes and the DNA such that the distortion necessary for cleavage does not take place.

### 9.4 Myosins Harness Changes in Enzyme Conformation to Couple ATP Hydrolysis to Mechanical Work

Finally, myosins catalyze the hydrolysis of adenosine triphosphate (ATP) to form adenosine diphosphate (ADP) and inorganic phosphate ( $\text{P}_i$ ). The conformations of myosin ATPase domains free of bound nucleotides and with bound ATP are quite similar. Through the use of ADP and vanadate ( $\text{VO}_4^{3-}$ ), an excellent mimic of the transition state for ATP hydrolysis bound to the myosin ATPase domain can be produced. The structure of this complex reveals that dramatic conformational changes take place on formation of this species from the ATP complex. These conformational changes are used to drive substantial motions in molecular motors. The rate of ATP hydrolysis by myosin is relatively low and is limited by the rate of product release from the enzyme. The hydrolysis of ATP to ADP and  $\text{P}_i$  within the enzyme is reversible with an equilibrium constant of approximately 10, compared with an equilibrium constant of 140,000 for these species free in solution. Myosins are examples of P-loop NTPase enzymes, a large collection of protein families that play key roles in a range of biological processes by virtue of the conformational changes that they undergo with various nucleotides bound.

## PROBLEMS

1. *No burst.* Examination of the cleavage of the amide substrate, A, by chymotrypsin with the use of stopped-flow kinetic methods reveals no burst. The reaction is monitored by noting the color produced by the release of the amino part of the substrate (highlighted in orange). Why is no burst observed?

2. *Contributing to your own demise.* Consider the subtilisin substrates A and B.

**A**

**B**

These substrates are cleaved (between Phe and X) by native subtilisin at essentially the same rate. However, the His 64-to-Ala mutant of subtilisin cleaves substrate B more than 1000-fold as rapidly as it cleaves substrate A. Propose an explanation.

3.  $1 + 1 \neq 2$ . Consider the following argument. In subtilisin, mutation of Ser 221 to Ala results in a  $10^6$ -fold decrease in activity. Mutation of His 64 to Ala results in a similar  $10^6$ -fold decrease. Therefore, simultaneous mutation of Ser 221 to Ala and His 64 to Ala should result in a  $10^6 \times 10^6 = 10^{12}$ -fold reduction in activity. Is this reduction correct? Why or why not?

4. *Adding a charge.* In chymotrypsin, a mutant was constructed with Ser 189, which is in the bottom of the substrate-specificity pocket, changed to Asp. What effect would you predict for this Ser 189→Asp 189 mutation?

5. *Conditional results.* In carbonic anhydrase II, mutation of the proton-shuttle residue His 64 to Ala was expected to result in a decrease in the maximal catalytic rate. However, in buffers such as imidazole with relatively small molecular components, no rate reduction was observed. In buffers with larger molecular components, significant rate reductions were observed. Propose an explanation.

6. *How many sites?* A researcher has isolated a restriction endonuclease that cleaves at only one particular 10-base-pair site. Would this enzyme be useful in protecting cells from viral infections, given that a typical viral genome is 50,000 base pairs long? Explain.

7. *Is faster better?* Restriction endonucleases are, in general, quite slow enzymes with typical turnover numbers of  $1 \text{ s}^{-1}$ . Suppose that endonucleases were faster, with turnover numbers similar to those for carbonic anhydrase ( $10^6 \text{ s}^{-1}$ ), such that they act faster than do methylases. Would this increased rate be beneficial to host cells, assuming that the fast enzymes have similar levels of specificity?

8. *Adopting a new gene.* Suppose that one species of bacteria obtained one gene encoding a restriction endonuclease by horizontal gene transfer. Would you expect this acquisition to be beneficial?

9. *Chelation therapy.* Treatment of carbonic anhydrase with high concentrations of the metal chelator EDTA (ethylenediaminetetraacetic acid) results in the loss of enzyme activity. Propose an explanation.

10. *An aldehyde inhibitor.* Elastase is specifically inhibited by an aldehyde derivative of one of its substrates:

(a) Which residue in the active site of elastase is most likely to form a covalent bond with this aldehyde?

(b) What type of covalent link would be formed?

11. *Identify the enzyme.* Consider the structure of molecule A. Which enzyme discussed in the chapter do you think molecule A will most effectively inhibit?

12. *Acid test.* At pH 7.0, carbonic anhydrase exhibits a  $k_{\text{cat}}$  of  $600,000 \text{ s}^{-1}$ . Estimate the value expected for  $k_{\text{cat}}$  at pH 6.0.

13. *Restriction.* To terminate a reaction in which a restriction enzyme cleaves DNA, researchers often add high concentrations of the metal chelator EDTA (ethylenediaminetetraacetic acid). Why does the addition of EDTA terminate the reaction?

14. *Labeling strategy.* ATP is added to the myosin ATPase domain in water labeled with  $^{18}\text{O}$ . After 50% of the ATP has been hydrolyzed, the remaining ATP is isolated and found to contain  $^{18}\text{O}$ . Explain.

15. *Viva la resistance.* Many patients become resistant to HIV protease inhibitors with the passage of time owing to

mutations in the HIV gene that encodes the protease. Mutations are not found in the aspartate residue that interacts with the drugs. Why not?

16. *More than one way to skin  $k_{\text{cat}}$ .* Serine 236 in *Dictyostelium discoideum* myosin has been mutated to alanine. The mutated protein showed modestly reduced ATPase activity. Analysis of the crystal structure of the mutated protein revealed that a water molecule occupied the position of the hydroxyl group of the serine residue in the wild-type protein. Propose a mechanism for the ATPase activity of the mutated enzyme.

17. *A power struggle.* The catalytic power of an enzyme can be defined as the ratio of the rate of the enzyme catalyzed reaction to that for the uncatalyzed reaction. Using the information in Figure 9.15 for subtilisin and in Figure 9.22 for carbonic anhydrase, calculate the catalytic powers for these two enzymes.

18. *Wounded but not dead.* How much activity (in terms of relative  $k_{\text{cat}}$  values) does the version of subtilisin with all three residues in the catalytic triad mutated have compared to uncatalyzed reaction? Propose an explanation.

#### Mechanism Problem

19. *Complete the mechanism.* On the basis of the information provided in Figure 9.17, complete the mechanisms for peptide-bond cleavage by (a) a cysteine protease, (b) an aspartyl protease, and (c) a metalloprotease.

## Regulatory Strategies

Like motor traffic, metabolic pathways flow more efficiently when regulated by signals. Cytidine triphosphate (CTP), the final product of a multistep pathway, controls flux through the pathway by inhibiting the committed step catalyzed by aspartate transcarbamoylase (ATCase). [(Left) Michael Winokur Photography/Getty Images.]

The activity of enzymes must often be regulated so that they function at the proper time and place. This regulation is essential for coordination of the vast array of biochemical processes taking place at any instant in an organism. Enzymatic activity is regulated in five principal ways:

1. *Allosteric Control.* Allosteric proteins contain distinct regulatory sites and multiple functional sites. The binding of small signal molecules at regulatory sites controls the activity of these proteins. Moreover, allosteric proteins show the property of *cooperativity*: activity at one functional site affects the activity at others. Proteins displaying allosteric control are thus information transducers: their activity can be modified in response to signal molecules or to information shared among active sites. This chapter examines one of the best-understood allosteric proteins: the enzyme *aspartate transcarbamoylase* (ATCase). Catalysis by aspartate transcarbamoylase of the first step in pyrimidine biosynthesis is inhibited by cytidine triphosphate, the final product of that biosynthesis, in an example of *feedback inhibition*. We have already examined an allosteric protein—hemoglobin, the oxygen transport protein in the blood (Chapter 7).

2. *Multiple Forms of Enzymes.* Isozymes, or isoenzymes, provide an avenue for varying regulation of the same reaction to meet the specific physiological needs in the particular tissue at a particular time. Isozymes are homologous enzymes within a single organism that catalyze the same reaction but differ

## OUTLINE

- 10.2 Isozymes Provide a Means of Regulation Specific to Distinct Tissues and Developmental Stages
- 10.3 Covalent Modification Is a Means of Regulating Enzyme Activity
- 10.4 Many Enzymes Are Activated by Specific Proteolytic Cleavage

slightly in structure and more obviously in  $K_M$  and  $V_{max}$  values as well as in regulatory properties. Often, isozymes are expressed in a distinct tissue or organelle or at a distinct stage of development.

3. *Reversible Covalent Modification.* The catalytic properties of many enzymes are markedly altered by the covalent attachment of a modifying group, commonly a phosphoryl group. ATP serves as the phosphoryl donor in these reactions, which are catalyzed by *protein kinases*. The removal of phosphoryl groups by hydrolysis is catalyzed by *protein phosphatases*. This chapter considers the structure, specificity, and control of *protein kinase A* (PKA), a ubiquitous eukaryotic enzyme that regulates diverse target proteins.

4. *Proteolytic Activation.* The enzymes controlled by some of these regulatory mechanisms cycle between active and inactive states. A different regulatory strategy is used to *irreversibly* convert an inactive enzyme into an active one. Many enzymes are activated by the hydrolysis of a few peptide bonds or even one such bond in inactive precursors called *zymogens* or *proenzymes*. This regulatory mechanism generates digestive enzymes such as chymotrypsin, trypsin, and pepsin. Blood clotting is due to a remarkable cascade of zymogen activations. Active digestive and clotting enzymes are switched off by the irreversible binding of specific inhibitory proteins that are irresistible lures to their molecular prey.

5. *Controlling the Amount of Enzyme Present.* Enzyme activity can also be regulated by adjusting the amount of enzyme present. This important form of regulation usually takes place at the level of transcription. We will consider the control of gene transcription in Chapters 29, 30, and 31.

To begin, we will consider the principles of allostery by examining the enzyme aspartate transcarbamoylase.

## 10.1 Aspartate Transcarbamoylase Is Allosterically Inhibited by the End Product of Its Pathway

Aspartate transcarbamoylase catalyzes the first step in the biosynthesis of pyrimidines: the condensation of aspartate and carbamoyl phosphate to form *N*-carbamoylaspartate and orthophosphate (Figure 10.1). This reaction is the committed step in the pathway, which consists of 10 reactions, that will ultimately yield the pyrimidine nucleotides uridine triphosphate (UTP)

**FIGURE 10.1 ATCase reaction.** Aspartate transcarbamoylase catalyzes the committed step, the condensation of aspartate and carbamoyl phosphate to form *N*-carbamoylaspartate, in pyrimidine synthesis.

and cytidine triphosphate (CTP). How is this enzyme regulated to generate precisely the amount of pyrimidines needed by the cell?

ATCase is inhibited by CTP, the final product of the ATCase-initiated pathway. The rate of the reaction catalyzed by ATCase is fast at low concentrations of CTP but slows as CTP concentration increases (Figure 10.2). Thus, the pathway continues to make new pyrimidines until sufficient quantities of CTP have accumulated. The inhibition of ATCase by CTP is an example of *feedback inhibition*, the inhibition of an enzyme by the end product of the pathway. Feedback inhibition by CTP ensures that *N*-carbamoylaspartate and subsequent intermediates in the pathway are not needlessly formed when pyrimidines are abundant.

The inhibitory ability of CTP is remarkable because *CTP is structurally quite different from the substrates of the reaction* (Figure 10.1). Thus CTP must bind to a site distinct from the active site at which substrate binds. Such sites are called *allosteric* or *regulatory sites*. CTP is an example of an *allosteric inhibitor*. In ATCase (but not all allosterically regulated enzymes), the catalytic sites and the regulatory sites are on separate polypeptide chains.

### Allosterically regulated enzymes do not follow Michaelis–Menten kinetics

Allosteric enzymes are distinguished by their response to changes in substrate concentration in addition to their susceptibility to regulation by other molecules. Let us examine the rate of product formation as a function of substrate concentration for ATCase (Figure 10.3). The curve differs from that expected for an enzyme that follows Michaelis–Menten kinetics. The observed curve is referred to as sigmoidal because it resembles the letter “S.” The vast majority of allosteric enzymes display sigmoidal kinetics. Recall from the discussion of hemoglobin that sigmoidal curves result from cooperation between subunits: the binding of substrate to one active site in a molecule increases the likelihood that substrate will bind to other active sites. To understand the basis of sigmoidal enzyme kinetics and inhibition by CTP, we need to examine the structure of ATCase.

### ATCase consists of separable catalytic and regulatory subunits

What is the evidence that ATCase has distinct regulatory and catalytic sites? ATCase can be literally separated into regulatory (r) and catalytic (c) subunits by treatment with a mercurial compound such as *p*-hydroxymercuribenzoate, which reacts with sulfhydryl groups (Figure 10.4). Ultracentrifugation (p. 74) following treatment with mercurials revealed that ATCase is composed of two kinds of subunits (Figure 10.5). The subunits can be readily separated by ion-exchange chromatography because they differ markedly in charge (p. 67) or by centrifugation in a sucrose density gradient because they differ in size (p. 67). These size differences are manifested in the sedimentation coefficients: that of the native enzyme is 11.6S, whereas those of the dissociated subunits are 2.8S and 5.8S. The attached *p*-mercuribenzoate groups can be removed from the separated subunits by adding an excess of mercaptoethanol, providing isolated subunits for study.

The larger subunit is the *catalytic subunit*. This subunit has catalytic activity but displays the hyperbolic kinetics of Michaelis–Menten enzymes rather than sigmoidal kinetics. Furthermore, the isolated catalytic subunit is unresponsive to CTP. The isolated smaller subunit can bind CTP, but has no catalytic activity. Hence, that subunit is the *regulatory subunit*. The catalytic subunit ( $c_3$ ) consists of three chains (34 kDa each), and the regulatory subunit ( $r_2$ ) consists of two chains (17 kDa each). The catalytic and regulatory subunits combine

**FIGURE 10.2 CTP inhibits ATCase.** Cytidine triphosphate, an end product of the pyrimidine-synthesis pathway, inhibits aspartate transcarbamoylase despite having little structural similarity to reactants or products.

**FIGURE 10.3 ATCase displays sigmoidal kinetics.** A plot of product formation as a function of substrate concentration produces a sigmoidal curve because the binding of substrate to one active site increases the activity at the other active sites. Thus, the enzyme shows cooperativity.

**FIGURE 10.4 Modification of cysteine residues.** *p*-Hydroxymercuribenzoate reacts with crucial cysteine residues in aspartate transcarbamoylase.

**FIGURE 10.5 Ultracentrifugation studies of ATCase.** Sedimentation velocity patterns of (A) native ATCase and (B) the enzyme after treatment with *p*-hydroxymercuribenzoate show that the enzyme can be dissociated into regulatory (r) and catalytic (c) subunits. [Data from J. C. Gerhart and H. K. Schachman, *Biochemistry* 4:1054–1062, 1965.]

rapidly when they are mixed. The resulting complex has the same structure,  $c_6r_6$ , as the native enzyme: two catalytic trimers and three regulatory dimers.

Most strikingly, the reconstituted enzyme has the same allosteric and kinetic properties as those of the native enzyme. Thus, ATCase is composed of discrete catalytic and regulatory subunits, and *the interaction of the subunits in the native enzyme produces its regulatory and catalytic properties*. The fact that the enzyme can be separated into isolated catalytic and regulatory subunits, which can be reconstituted back to the functional enzyme, allows for a variety of experiments to characterize the allosteric properties of the enzyme (Problems 33 and 34).

### Allosteric interactions in ATCase are mediated by large changes in quaternary structure

What are the subunit interactions that account for the properties of ATCase? Significant clues have been provided by the three-dimensional structure of ATCase in various forms. Two catalytic trimers are stacked one on top of the other, linked by three dimers of the regulatory chains (Figure 10.6). There are significant contacts between the catalytic and the regulatory

**FIGURE 10.6 Structure of ATCase.** (A) The quaternary structure of aspartate transcarbamoylase as viewed from the top. The drawing in the center is a simplified representation of the relations between subunits. A single catalytic trimer [catalytic (c) chains, shown in yellow] is visible; in this view, the second trimer is hidden below the one visible. *Notice* that each r chain interacts with a c chain through the zinc domain. (B) A side view of the complex. [Drawn from 1RA1.pdb.]

**FIGURE 10.7 PALA, a bisubstrate analog.** (Top) Nucleophilic attack by the amino group of aspartate on the carbonyl carbon atom of carbamoyl phosphate generates an intermediate on the pathway to the formation of *N*-carbamoylaspartate. (Bottom) *N*-(Phosphonacetyl)-L-aspartate (PALA) is an analog of the reaction intermediate and a potent competitive inhibitor of aspartate transcarbamoylase.

subunits: each r chain within a regulatory dimer interacts with a c chain within a catalytic trimer. The c chain makes contact with a structural domain in the r chain that is stabilized by a zinc ion bound to four cysteine residues. The zinc ion is critical for the interaction of the r chain with the c chain. The mercurial compound *p*-hydroxymercuribenzoate is able to dissociate the catalytic and regulatory subunits because mercury binds strongly to the cysteine residues, displacing the zinc and preventing interaction with the c chain.

To locate the active sites, the enzyme is crystallized in the presence of *N*-(phosphonacetyl)-L-aspartate (PALA), a bisubstrate analog (an analog of the two substrates) that resembles an intermediate along the pathway of catalysis (Figure 10.7). PALA is a potent competitive inhibitor of ATCase that binds to and blocks the active sites. The structure of the ATCase–PALA complex reveals that PALA binds at sites lying at the boundaries between pairs of c chains within a catalytic trimer (Figure 10.8). Each catalytic trimer contributes three active sites to the complete enzyme. Further examination of the ATCase–PALA complex reveals a remarkable change in

**FIGURE 10.8 The active site of ATCase.** Some of the crucial active-site residues are shown binding to the inhibitor PALA (shaded gray). Notice that the active site is composed mainly of residues from one c chain, but an adjacent c chain also contributes important residues (boxed in green). [Drawn from 8ATC.pdb.]

**FIGURE 10.9 The T-to-R state transition in ATCase.** Aspartate transcarbamoylase exists in two conformations: a compact, relatively inactive form called the tense (T) state and an expanded form called the relaxed (R) state. Notice that the structure of ATCase changes dramatically in the transition from the T state to the R state. PALA binding stabilizes the R state.

quaternary structure on binding of PALA. The two catalytic trimers move 12 Å farther apart and rotate approximately 10 degrees about their common threefold axis of symmetry. Moreover, the regulatory dimers rotate approximately 15 degrees to accommodate this motion (Figure 10.9). The enzyme literally expands on PALA binding. In essence, ATCase has two distinct quaternary forms: one that predominates in the absence of substrate or substrate analogs and another that predominates when substrates or analogs are bound. We call these forms the T (for tense) state and the R (for relaxed) state, respectively, as we did for the two quaternary states of hemoglobin.

How can we explain the enzyme's sigmoidal kinetics in light of the structural observations? Like hemoglobin, the enzyme exists in an equilibrium between the T state and the R state.

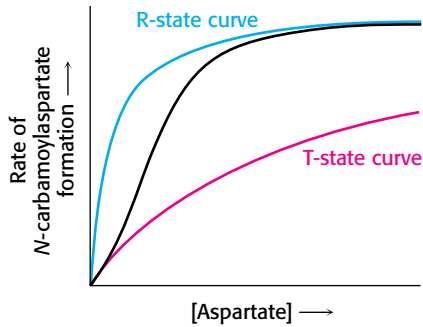

In the absence of substrate, almost all the enzyme molecules are in the T state because the T state is more stable than the R state. The ratio of the concentration of enzyme in the T state to that in the R state is called the allosteric constant ( $L$ ). For most allosteric enzymes,  $L$  is on the order of  $10^2$  to  $10^3$ .

$$L = \frac{T}{R}$$

The T state has a low affinity for substrate and hence shows a low catalytic activity. The occasional binding of a substrate molecule to one active site in an enzyme increases the likelihood that the entire enzyme shifts to the R state with its higher binding affinity. The addition of more substrate has two effects. First, it increases the probability that each enzyme molecule will bind at least one substrate molecule. Second, it increases the average number of substrate molecules bound to each enzyme. The presence of additional substrate will increase the fraction of enzyme molecules in the more active R state because *the position of the equilibrium depends on the number of active sites that are occupied by substrate*. We considered this property, called *cooperativity* because the subunits cooperate with one another, when we discussed the sigmoidal oxygen-binding curve of hemoglobin. The effects of substrates on allosteric enzymes are referred to as *homotropic effects* (from the Greek *homós*, "same").

This mechanism for allosteric regulation is referred to as the *concerted model* because the change in the enzyme is "all or none"; the entire enzyme is converted from T into R, affecting all of the catalytic sites equally. In contrast, the *sequential model* assumes that the binding of ligand to one site on the complex can affect neighboring sites without causing all subunits

**FIGURE 10.10 Basis for the sigmoidal curve.** The generation of the sigmoidal curve by the property of cooperativity can be understood by imagining an allosteric enzyme as a mixture of two Michaelis–Menten enzymes, one with a high value of  $K_M$  that corresponds to the T state and another with a low value of  $K_M$  that corresponds to the R state. As the concentration of substrate is increased, the equilibrium shifts from the T state to the R state, which results in a steep rise in activity with respect to substrate concentration.

to undergo the T-to-R transition (p. 199). Although the concerted model explains the behavior of ATCase well, most other allosteric enzymes have features of both models.

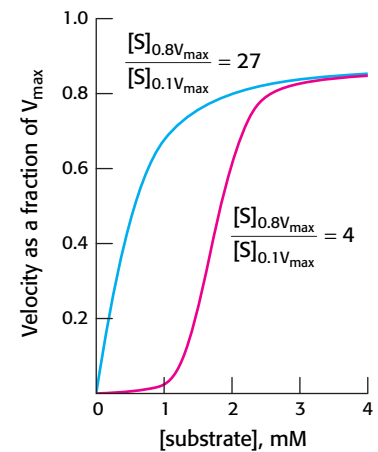

The sigmoidal curve for ATCase can be pictured as a composite of two Michaelis–Menten curves, one corresponding to the less-active T state and the other to the more-active R state. At low concentrations of substrate, the curve closely resembles that of the T state enzyme. As the substrate concentration is increased, the curve progressively shifts to resemble that of the R state enzyme (Figure 10.10).

What is the biochemical advantage of sigmoidal kinetics? Allosteric enzymes transition from a less active state to a more active state within a narrow range of substrate concentration. The benefit of this behavior is illustrated in Figure 10.11, which compares the kinetics of a Michaelis–Menten enzyme (blue curve) to that of an allosteric enzyme (red curve). In this example, the Michaelis–Menten enzyme requires an approximately 27-fold increase in substrate concentration to increase  $V_o$  from  $0.1 V_{max}$  to  $0.8 V_{max}$ . In contrast, the allosteric enzyme requires only about a 4-fold increase in substrate concentration to attain the same increase in velocity. *The activity of allosteric enzymes is more sensitive to changes in substrate concentration near  $K_M$  than are Michaelis–Menten enzymes with the same  $V_{max}$ .* This sensitivity is called a *threshold effect*: below a certain substrate concentration, there is little enzyme activity. However, after the threshold has been reached, enzyme activity increases rapidly. In other words, much like an “on or off” switch, cooperativity ensures that most of the enzyme is either on (R state) or off (T state). The vast majority of allosteric enzymes display sigmoidal kinetics.

### Allosteric regulators modulate the T-to-R equilibrium

We now turn our attention to the effects of pyrimidine nucleotides. As noted earlier, CTP inhibits the action of ATCase. X-ray studies of ATCase in the presence of CTP reveal (1) that the enzyme is in the T state when bound to CTP and (2) that a binding site for this nucleotide exists in each regulatory chain in a domain that does not interact with the catalytic subunit (Figure 10.12). Each active site is more than  $50 \text{ \AA}$  from the nearest CTP-binding site. The question naturally arises, How can CTP inhibit the catalytic activity of the enzyme when it does not interact with the catalytic chain?

The quaternary structural changes observed on substrate-analog binding suggest a mechanism for inhibition by CTP (Figure 10.13). *The binding of the inhibitor CTP to the T state shifts the T-to-R equilibrium in favor of the T state, decreasing net enzyme activity.* CTP increases the allosteric coefficient from 200 in its absence to 1250 when all of the regulatory sites are occupied by CTP. The binding of CTP makes it more difficult for substrate binding to convert the enzyme into the R state.

**FIGURE 10.11 Allosteric enzymes display threshold effects.** As the T-to-R transition occurs, the velocity increases over a narrower range of substrate concentration for an allosteric enzyme (red curve) than for a Michaelis–Menten enzyme (blue curve).

**FIGURE 10.12 CTP stabilizes the T state.** The binding of CTP to the regulatory subunit of aspartate transcarbamoylase stabilizes the T state.

**FIGURE 10.13 The R state and the T state are in equilibrium.** Even in the absence of any substrate or regulators, aspartate transcarbamoylase exists in equilibrium between the R and the T states. Under these conditions, the T state is favored by a factor of approximately 200.

**FIGURE 10.14 Effect of CTP and ATP on ATCase kinetics.** CTP stabilizes the T state of aspartate transcarbamoylase, making it more difficult for substrate binding to convert the enzyme into the R state. As a result, the curve is shifted to the right, as shown in red. ATP is an allosteric activator of aspartate transcarbamoylase because it stabilizes the R state, making it easier for substrate to bind. As a result, the curve is shifted to the left, as shown in blue.

Consequently, CTP increases the initial phase of the sigmoidal curve (Figure 10.14). More substrate is required to attain a given reaction rate. UTP, the immediate precursor to CTP, also regulates ATCase. While unable to inhibit the enzyme alone, UTP synergistically inhibits ATCase in the presence of CTP.

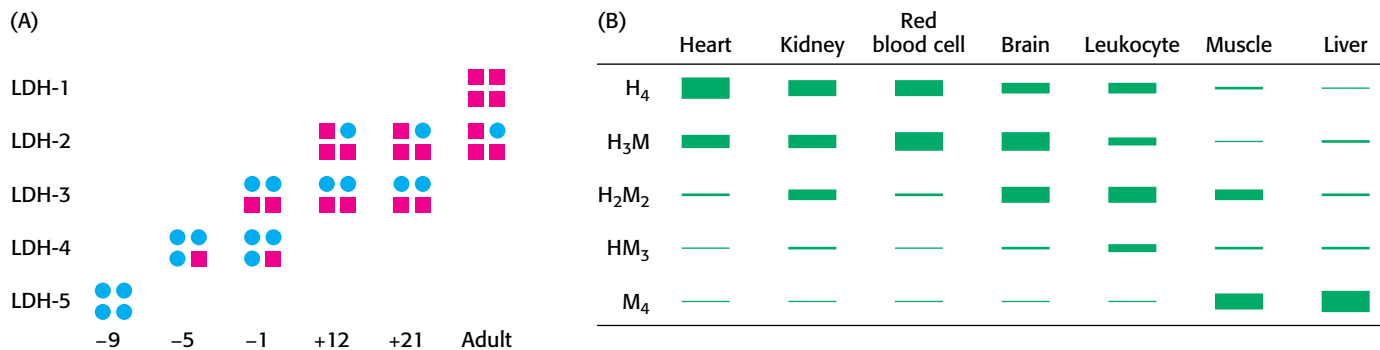

Interestingly, ATP, too, is an allosteric effector of ATCase, binding to the same site as CTP. However, ATP binding stabilizes the R state, lowering the allosteric coefficient from 200 to 70 and thus *increasing* the reaction rate at a given aspartate concentration (Figure 10.14). At high concentrations of ATP, the kinetic profile shows a less-pronounced sigmoidal behavior. Because ATP and CTP bind at the same site, high levels of ATP prevent CTP from inhibiting the enzyme. The effects of nonsubstrate molecules on allosteric enzymes (such as those of CTP and ATP on ATCase) are referred to as *heterotropic effects* (from the Greek *hēteros*, “different”). Substrates generate the sigmoidal curve (homotropic effects), whereas regulators shift the  $K_M$  (heterotropic effects). Note, however, that both types of effect are generated by altering the T/R ratio.

The increase in ATCase activity in response to increased ATP concentration has two potential physiological ramifications. First, high ATP concentration signals a high concentration of purine nucleotides in the cell; the increase in ATCase activity will tend to balance the purine and pyrimidine pools. Second, a high concentration of ATP indicates that energy is available for mRNA synthesis and DNA replication and leads to the synthesis of pyrimidines needed for these processes.

## 10.2 Isozymes Provide a Means of Regulation Specific to Distinct Tissues and Developmental Stages

*Isozymes*, or *isoenzymes*, are enzymes that differ in amino acid sequence yet catalyze the same reaction. Typically, these enzymes display different kinetic parameters, such as  $K_M$ , or respond to different regulatory molecules. They are encoded by different genes, which usually arise through gene duplication and divergence. Isozymes can often be distinguished from one another by physical properties such as electrophoretic mobility. *Isoform* is a more generic term used when the protein in question is not an enzyme.

*The existence of isozymes permits the fine-tuning of metabolism to meet the needs of a given tissue or developmental stage.* Consider the example of lactate dehydrogenase (LDH), an enzyme that catalyzes a step in anaerobic

**FIGURE 10.15 Isozymes of lactate dehydrogenase.** (A) The rat heart lactate dehydrogenase (LDH) isozyme profile changes in the course of development. The H isozyme is represented by squares and the M isozyme by circles. The negative and positive numbers denote the days before and after birth, respectively. (B) LDH isozyme content varies by tissue. [(A) Data from W.-H. Li, *Molecular Evolution* (Sinauer, 1997), p. 283; (B) after K. Urich, *Comparative Animal Biochemistry* (Springer Verlag, 1990), p. 542.]

glucose metabolism and glucose synthesis. Human beings have two isozymic polypeptide chains for this enzyme: the H isozyme is highly expressed in heart muscle and the M isozyme is expressed in skeletal muscle. The amino acid sequences are 75% identical. Each functional enzyme is tetrameric, and many different combinations of the two isozymic polypeptide chains are possible. The H<sub>4</sub> isozyme, found in the heart, has a higher affinity for substrates than does the M<sub>4</sub> isozyme. The two isozymes also differ in that high levels of pyruvate allosterically inhibit the H<sub>4</sub> but not the M<sub>4</sub> isozyme. The other combinations, such as H<sub>3</sub>M, have intermediate properties. We will consider these isozymes in their biological context in Chapter 16.

The M<sub>4</sub> isozyme functions optimally in the anaerobic environment of hard-working skeletal muscle, whereas the H<sub>4</sub> isozyme does so in the aerobic environment of heart muscle. Indeed, the proportions of these isozymes change throughout the development of the rat heart as the tissue switches from an anaerobic environment to an aerobic one (Figure 10.15A). Figure 10.15B shows the tissue-specific forms of lactate dehydrogenase in adult rat tissues. *Essentially all of the enzymes that we will encounter in later chapters, including allosteric enzymes, exist in isozymic forms.*

The appearance of some isozymes in the blood is a sign of tissue damage, useful for clinical diagnosis. For instance, an increase in serum levels of H<sub>4</sub> relative to H<sub>3</sub>M is an indication that a myocardial infarction, or heart attack, has damaged heart-muscle cells, leading to the release of cellular material.

### 10.3 Covalent Modification Is a Means of Regulating Enzyme Activity

The covalent attachment of a molecule to an enzyme or protein can modify its activity. In these instances, a donor molecule provides the functional moiety being attached. Most modifications are reversible. Phosphorylation and dephosphorylation are common means of covalent modification. The attachment of acetyl groups to lysine residues by acetyltransferases and their removal by deacetylases are another example. Histones—proteins that are packaged with DNA into chromosomes—are extensively acetylated and deacetylated *in vivo* on lysine residues (Section 31.3). More heavily acetylated histones are associated with genes that are being actively transcribed. Although protein acetylation was originally discovered as a modification of histones, we now know that it is a major means of regulation, with more than 2000 different proteins in mammalian cells regulated by acetylation.

**TABLE 10.1** Common covalent modifications of protein activity

Modification	Donor molecule	Example of modified protein	Protein function
Phosphorylation	ATP	Glycogen phosphorylase	Glucose homeostasis; energy transduction
Acetylation	Acetyl CoA	Histones	DNA packing; transcription
Myristoylation	Myristoyl CoA	Src	Signal transduction
ADP ribosylation	NAD <sup>+</sup>	RNA polymerase	Transcription
Farnesylation	Farnesyl pyrophosphate	Ras	Signal transduction
γ-Carboxylation	HCO <sub>3</sub> <sup>-</sup>	Thrombin	Blood clotting
Sulfation	3'-Phosphoadenosine-5'-phosphosulfate	Fibrinogen	Blood-clot formation
Ubiquitination	Ubiquitin	Cyclin	Control of cell cycle

Protein acetylation appears to be especially important in the regulation of metabolism. The acetyltransferase and deacetylase enzymes are themselves regulated by phosphorylation, showing that the covalent modification of a protein can be controlled by the covalent modification of the modifying enzymes.

Modification is not readily reversible in some cases. The irreversible attachment of a lipid group causes some proteins in signal-transduction pathways, such as Ras (a GTPase) and Src (a protein tyrosine kinase), to become affixed to the cytoplasmic face of the plasma membrane. Fixed in this location, the proteins are better able to receive and transmit information that is being passed along their signaling pathways (Chapter 14). Mutations in both Ras and Src are seen in a wide array of cancers. The attachment of the small protein ubiquitin can signal that a protein is to be destroyed, the ultimate means of regulation (Chapter 23). The protein cyclin must be ubiquitinated and destroyed before a cell can enter anaphase and proceed through the cell cycle.

Virtually all the metabolic processes that we will examine are regulated in part by covalent modification. Indeed, the allosteric properties of many enzymes are altered by covalent modification. Table 10.1 lists some of the common covalent modifications.

### Kinases and phosphatases control the extent of protein phosphorylation

We will see phosphorylation used as a regulatory mechanism in virtually every metabolic process in eukaryotic cells. Indeed, as much as 30% of eukaryotic proteins are phosphorylated. The enzymes catalyzing phosphorylation reactions are called *protein kinases*. These enzymes constitute one of the largest protein families known: there are more than 500 homologous kinases in human beings. This multiplicity of enzymes allows regulation to be fine-tuned according to a specific tissue, time, or substrate.

ATP is the most common donor of phosphoryl groups. The terminal (γ) phosphoryl group of ATP is transferred to a specific amino acid of the acceptor protein or enzyme. In eukaryotes, the acceptor residue is commonly one of the three containing a hydroxyl group in its side chain. Transfers to *serine* and *threonine* residues are handled by one class of protein kinases and to *tyrosine* residues by another. Tyrosine kinases, which are unique to multicellular organisms, play pivotal roles in growth regulation, and mutations in these enzymes are commonly observed in cancer cells.

Table 10.2 lists a few of the known serine and threonine protein kinases. The acceptors in protein-phosphorylation reactions are located inside cells, where the phosphoryl-group donor ATP is abundant. Proteins that are entirely extracellular are not regulated by reversible phosphorylation.

Protein kinases vary in their degree of specificity. *Dedicated protein kinases* phosphorylate a single protein or several closely related ones. *Multifunctional protein kinases* modify many different targets; they have a wide reach and can coordinate diverse processes. Comparisons of amino acid sequences of many phosphorylation sites show that a multifunctional kinase recognizes related sequences. For example, the *consensus sequence* recognized by protein kinase A is Arg-Arg-X-Ser-Z or Arg-Arg-X-Thr-Z, in which X is a small residue, Z is a large hydrophobic one, and Ser or Thr is the site of phosphorylation. However, this sequence is not absolutely required. Lysine, for example, can substitute for one of the arginine residues but with some loss of affinity. Thus, *the primary determinant of specificity is the amino acid sequence surrounding the serine or threonine phosphorylation site*. However, distant residues can contribute to specificity. For instance, a change in protein conformation can open or close access to a possible phosphorylation site.

*Protein phosphatases* reverse the effects of kinases by catalyzing the removal of phosphoryl groups attached to proteins. The enzyme hydrolyzes the bond attaching the phosphoryl group.

**TABLE 10.2** Examples of serine and threonine kinases and their activating signals

Signal	Enzyme
Cyclic nucleotides	Cyclic AMP-dependent protein kinase Cyclic GMP-dependent protein kinase
Ca <sup>2+</sup> and calmodulin	Ca <sup>2+</sup> – calmodulin protein kinase Phosphorylase kinase or glycogen synthase kinase 2
AMP	AMP-activated kinase
Diacylglycerol	Protein kinase C
Metabolic intermediates and other “local” effectors	Many target-specific enzymes, such as pyruvate dehydrogenase kinase and branched-chain ketoacid dehydrogenase kinase

Source: Information from D. Fell, *Understanding the Control of Metabolism* (Portland Press, 1997), Table 7.2.

The unmodified hydroxyl-containing side chain is regenerated and orthophosphate ( $\text{P}_i$ ) is produced. This family of enzymes, of which there are about 200 members in human beings, plays a vital role in cells because the enzymes turn off the signaling pathways that are activated by kinases. One class of highly conserved phosphatase called PP2A suppresses the cancer-promoting activity of certain kinases.

Importantly, the phosphorylation and dephosphorylation reactions are not the reverse of one another; each is essentially irreversible under physiological conditions. Furthermore, both reactions take place at negligible rates in the absence of enzymes. Thus, phosphorylation of a protein substrate will take place only through the action of a specific protein kinase and at the expense of ATP cleavage, and dephosphorylation will take place only through the action of a phosphatase. The result is that target proteins cycle unidirectionally between unphosphorylated and phosphorylated forms. The rate of cycling between the phosphorylated and the dephosphorylated states depends on the relative activities of kinases and phosphatases.

### Phosphorylation is a highly effective means of regulating the activities of target proteins

Phosphorylation is a common covalent modification of proteins in all forms of life, which leads to the question, What makes protein phosphorylation so valuable in regulating protein function that its use is ubiquitous? Phosphorylation is a highly effective means of controlling the activity of proteins for several reasons:

1. *The free energy of phosphorylation is large.* Of the  $-50 \text{ kJ mol}^{-1}$  ( $-12 \text{ kcal mol}^{-1}$ ) provided by ATP, about half is consumed in making phosphorylation irreversible; the other half is conserved in the phosphorylated protein. A free-energy change of  $5.69 \text{ kJ mol}^{-1}$  ( $1.36 \text{ kcal mol}^{-1}$ ) corresponds to a factor of 10 in an equilibrium constant. Hence, phosphorylation can change the conformational equilibrium between different functional states by a large factor, of the order of  $10^4$ . In essence, the energy expenditure allows for a stark shift from one conformation to another.
2. *A phosphoryl group adds two negative charges to a modified protein.* These new charges may disrupt electrostatic interactions in the unmodified protein and allow new electrostatic interactions to be formed. Such structural changes can markedly alter substrate binding and catalytic activity.
3. *A phosphoryl group can form three or more hydrogen bonds.* The tetrahedral geometry of a phosphoryl group makes these bonds highly directional, allowing for specific interactions with hydrogen-bond donors.
4. *Phosphorylation and dephosphorylation can take place in less than a second or over a span of hours.* The kinetics can be adjusted to meet the timing needs of a physiological process.
5. *Phosphorylation often evokes highly amplified effects.* A single activated kinase can phosphorylate hundreds of target proteins in a short interval. If the target protein is an enzyme, it can in turn transform a large number of substrate molecules.

6. *ATP is the cellular energy currency* (Chapter 15). The use of this compound as a phosphoryl-group donor links the energy status of the cell to the regulation of metabolism.

### Cyclic AMP activates protein kinase A by altering the quaternary structure

Let us examine a specific protein kinase that helps animals cope with stressful situations. The “flight or fight” response is common to many animals presented with a dangerous or exciting situation. Muscle becomes primed for action. This priming is the result of the activity of a particular protein kinase. In this case, the hormone epinephrine (adrenaline) triggers the formation of cyclic AMP (cAMP), an intracellular messenger formed by the cyclization of ATP. Cyclic AMP subsequently activates a key enzyme: *protein kinase A* (PKA). The kinase alters the activities of target proteins by phosphorylating specific serine or threonine residues. The striking finding is that *most effects of cAMP in eukaryotic cells are achieved through the activation of PKA by cAMP*.

PKA provides a clear example of the integration of allosteric regulation and phosphorylation. PKA is activated by cAMP concentrations near 10 nM. The quaternary structure is reminiscent of that of ATCase. Like that enzyme, PKA in muscle consists of two kinds of subunits: a 49-kDa regulatory (R) subunit and a 38-kDa catalytic (C) subunit. In the absence of cAMP, the regulatory and catalytic subunits form an  $R_2C_2$  complex that is enzymatically inactive (Figure 10.16). The binding of two molecules of cAMP to each of the regulatory subunits leads to the dissociation of  $R_2C_2$  into an  $R_2$  subunit and two C subunits. These free catalytic subunits are enzymatically active. Thus, *the binding of cAMP to the regulatory subunit relieves its inhibition of the catalytic subunit*. PKA, like most other kinases, exists in isozymic forms for fine-tuning regulation to meet the needs of a specific cell or developmental stage. In mammals, four isoforms of the R subunit and three of the C subunit are encoded in the genome.

How does the binding of cAMP activate the kinase? Each R chain contains the sequence Arg-Arg-Gly-Ala-Ile, which matches the consensus sequence for phosphorylation except for the presence of alanine in place of serine. In the  $R_2C_2$  complex, this *pseudosubstrate sequence* of R occupies the catalytic site of C, thereby preventing the entry of protein substrates (Figure 10.16). The binding of cAMP to the R chains allosterically moves the pseudosubstrate sequences out of the catalytic sites. The released C chains are then free to bind and phosphorylate substrate proteins. Interestingly, the cAMP-binding domain of the R subunit is highly conserved and found in all organisms.

**FIGURE 10.16**  
**Regulation of protein kinase A.** The binding of four molecules of cAMP activates protein kinase A by dissociating the inhibited holoenzyme ( $R_2C_2$ ) into a regulatory subunit ( $R_2$ ) and two catalytically active subunits (C). Each R chain includes cAMP-binding domains and a pseudosubstrate sequence.

**FIGURE 10.17 Protein kinase A bound to an inhibitor.** This ribbon model shows a complex of the catalytic subunit of protein kinase A with an inhibitor (yellow) bearing a pseudosubstrate sequence. Notice that the inhibitor binds to the active site, a cleft between the domains of the enzyme. The bound ATP (purple)-Mn<sup>2+</sup> (green) is in the active site adjacent to the site to which the inhibitor is bound. [Drawn from 1ATP.pdb.]

### ATP and the target protein bind to a deep cleft in the catalytic subunit of protein kinase A

X-ray crystallography reveals the three-dimensional structure of the catalytic subunit of PKA bound to ATP and a 20-residue peptide inhibitor. The 350-residue catalytic subunit of PKA has two lobes, an amino terminal N-lobe and a carboxyl terminal C-lobe (Figure 10.17). ATP and part of the inhibitor fill a deep cleft between the lobes. The N-lobe makes many contacts with ATP-Mn<sup>2+</sup>, whereas the C-lobe binds the peptide and contributes the key catalytic residues. As with other kinases, the two lobes move closer to one another on substrate binding; mechanisms that restrict this domain closure provide a means of regulating protein kinase activity. The PKA structure has broad significance because residues 40 to 280 constitute a conserved catalytic core, called the *kinase fold*, that is common to essentially all known protein kinases. We see here an example of a successful biochemical solution to a problem (in this case, protein phosphorylation) being employed many times in the course of evolution.

The bound peptide in this crystal occupies the active site because it contains the pseudosubstrate sequence Arg-Arg-Asn-Ala-Ile (Figure 10.18). The structure of the complex reveals the interactions by which the enzyme recognizes the consensus sequence. The guanidinium group of the first arginine residue forms an ion pair with the carboxylate side chain of a glutamate residue (Glu 127) of the enzyme. The second arginine likewise interacts with two other carboxylate groups. The nonpolar side chain of isoleucine, which matches Z in the consensus sequence (p. 295), fits snugly in a hydrophobic groove formed by two leucine residues of the enzyme.

**FIGURE 10.18 Binding of pseudosubstrate to protein kinase A.** Notice that the inhibitor makes multiple contacts with the enzyme. The two arginine side chains of the pseudosubstrate ionically interact with three glutamate carboxylate groups (green dashed lines). Hydrophobic interactions also are important in the recognition of substrate. The isoleucine residue of the pseudosubstrate is in contact with a pair of leucine residues of the enzyme.

## 10.4 Many Enzymes are Activated by Specific Proteolytic Cleavage

We turn now to a different mechanism of enzyme regulation. Many enzymes acquire full enzymatic activity as they spontaneously fold into their characteristic three-dimensional forms. In contrast, the folded forms of other enzymes are inactive until the cleavage of one or a few specific peptide bonds. The inactive precursor is called a *zymogen* or a *proenzyme*. An energy source such as ATP is not needed for cleavage. Therefore, in contrast with reversible regulation by phosphorylation, even proteins located outside cells can be activated by this means. Another noteworthy difference is that proteolytic activation, in contrast with allosteric control and reversible covalent modification, is irreversible, taking place just once in the life of an enzyme molecule.

Specific proteolysis is a common means of activating enzymes and other proteins in biological systems. For example:

1. The *digestive enzymes* that hydrolyze foodstuffs are synthesized as zymogens in the stomach and pancreas (Table 10.3).

**TABLE 10.3** Gastric and pancreatic zymogens

Site of synthesis	Zymogen	Active enzyme
Stomach	Pepsinogen	Pepsin
Pancreas	Chymotrypsinogen	Chymotrypsin
Pancreas	Trypsinogen	Trypsin
Pancreas	Procarboxypeptidase	Carboxypeptidase

2. *Blood clotting* is mediated by a cascade of proteolytic activations that ensures a rapid and amplified response to trauma.

3. Some protein hormones are synthesized as inactive precursors. For example, *insulin* is derived from *proinsulin* by proteolytic removal of a peptide.

4. The fibrous protein *collagen*, the major constituent of skin and bone, is derived from *procollagen*, a soluble precursor.

5. Many *developmental processes* are controlled by the activation of zymogens. For example, in the metamorphosis of a tadpole into a frog, large amounts of collagen are resorbed from the tail in the course of a few days. Likewise, much collagen is broken down in a mammalian uterus after delivery. The conversion of *procollagenase* into *collagenase*, the active protease responsible for collagen breakdown, is precisely timed in these remodeling processes.

6. *Programmed cell death*, or *apoptosis*, is mediated by proteolytic enzymes called *caspases*, which are synthesized in precursor form as *procaspases*. When activated by various signals, caspases function to cause cell death in most organisms, ranging from *C. elegans* to human beings. Apoptosis provides a means of sculpting the shapes of body parts in the course of development and a means of eliminating damaged or infected cells.

We next examine the activation and control of zymogens, using enzymes responsible for digestion and blood-clot formation as examples.

### Chymotrypsinogen is activated by specific cleavage of a single peptide bond

*Chymotrypsin* is a digestive enzyme that hydrolyzes proteins. Chymotrypsin, whose mechanism of action was described in detail in Chapter 9, specifically cleaves peptide bonds on the carboxyl side of amino acid residues with large, hydrophobic R groups (Table 8.6). Its inactive precursor, *chymotrypsinogen*,

**FIGURE 10.19 Secretion of zymogens by an acinar cell of the pancreas.** Zymogens are synthesized on ribosomes attached to the endoplasmic reticulum. They are subsequently processed in the Golgi apparatus and packaged into zymogen or secretory granules. With the proper signal, the granules fuse with the plasma membrane, discharging their contents into the lumen of the pancreatic ducts. Cell cytoplasm is depicted as pale green. Membranes and lumen are shown as dark green.

**FIGURE 10.20 Proteolytic activation of chymotrypsinogen.** The three chains of  $\alpha$ -chymotrypsin are linked by two interchain disulfide bonds (A to B, and B to C). The approximate positions of disulfide bonds are shown.

is synthesized in the pancreas, as are several other zymogens and digestive enzymes. Indeed, the pancreas is one of the most active organs in synthesizing and secreting proteins. The enzymes and zymogens are synthesized in the acinar cells of the pancreas and stored inside membrane-bounded granules (Figure 10.19). The zymogen granules accumulate at the apex of the acinar cell; when the cell is stimulated by a hormonal signal or a nerve impulse, the contents of the granules are released into a duct leading into the duodenum.

Chymotrypsinogen, a single polypeptide chain consisting of 245 amino acid residues, is virtually devoid of enzymatic activity. It is converted into a fully active enzyme when the peptide bond joining arginine 15 and isoleucine 16 is cleaved by trypsin (Figure 10.20). The resulting active enzyme, called  $\pi$ -chymotrypsin, then acts on other  $\pi$ -chymotrypsin molecules by removing two dipeptides to yield  $\alpha$ -chymotrypsin, the stable form of the enzyme. The three resulting chains in  $\alpha$ -chymotrypsin remain linked to one another by two interchain disulfide bonds. The striking feature of this activation process is that *cleavage of a single specific peptide bond transforms the protein from a catalytically inactive form into one that is fully active.*

### Proteolytic activation of chymotrypsinogen leads to the formation of a substrate-binding site

How does cleavage of a single peptide bond activate the zymogen? The cleavage of the peptide bond between amino acids 15 and 16 triggers key conformational changes, which were revealed by the elucidation of the three-dimensional structure of chymotrypsinogen.

1. The newly formed *amino-terminal group of isoleucine 16 turns inward and forms an ionic bond with aspartate 194* in the interior of the chymotrypsin molecule (Figure 10.21).
2. This electrostatic interaction triggers a number of conformational changes. Methionine 192 moves from a deeply buried position in the zymogen to the surface of the active enzyme, and residues 187 and 193 move farther apart from

each other. These changes result in the formation of the *substrate-specificity site* for aromatic and bulky nonpolar groups. One side of this site is made up of residues 189 through 192. *This cavity for binding part of the substrate is not fully formed in the zymogen.*

3. The tetrahedral transition state generated by chymotrypsin has an oxyanion (a negatively charged carbonyl oxygen atom) that is stabilized by hydrogen bonds with two NH groups of the main chain of the enzyme (Figure 9.9). One of these NH groups is not appropriately located in chymotrypsinogen, and so the site stabilizing the oxyanion (the oxyanion hole, p. 257) is incomplete in the zymogen.

4. The conformational changes elsewhere in the molecule are very small. Thus, *the switching on of enzymatic activity in a protein can be accomplished by discrete, highly localized conformational changes that are triggered by the hydrolysis of a single peptide bond.*

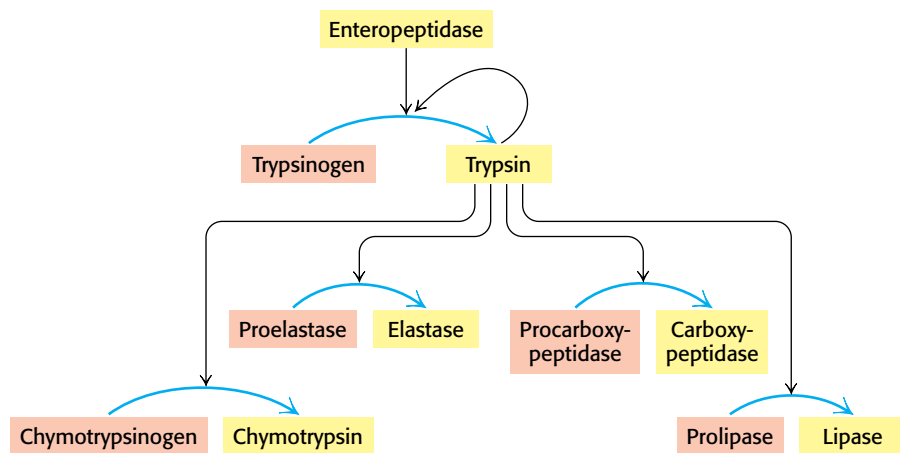

### The generation of trypsin from trypsinogen leads to the activation of other zymogens

The structural changes accompanying the activation of *trypsinogen*, the precursor of the proteolytic enzyme *trypsin*, are different from those in the activation of chymotrypsinogen. Four regions of the polypeptide are very flexible in the zymogen, whereas they have a well-defined conformation in trypsin. The resulting structural changes also complete the formation of the oxyanion hole.

The digestion of proteins and other molecules in the duodenum requires the concurrent action of several enzymes, because each is specific for a limited number of side chains. Thus, the zymogens must be switched on at the same time. Coordinated control is achieved by the action of *trypsin as the common activator of all the pancreatic zymogens*—trypsinogen, chymotrypsinogen, proelastase, procarboxypeptidase, and prolipase, the inactive precursor of a lipid-degrading enzyme. To produce active trypsin, the cells that line the duodenum display a membrane-embedded enzyme, *enteropeptidase*, which hydrolyzes a unique lysine–isoleucine peptide bond in trypsinogen as the zymogen enters the duodenum from the pancreas. The small amount of trypsin produced in this way activates more trypsinogen and the other zymogens (Figure 10.22). Thus, *the formation of trypsin by enteropeptidase is the master activation step.*

**FIGURE 10.21 Conformations of chymotrypsinogen and chymotrypsin.** The electrostatic interaction between the  $\alpha$ -amino group of isoleucine 16 and the carboxylate of aspartate 194, essential for the structure of active chymotrypsin, is possible only after cleavage of the peptide bond between isoleucine and arginine in chymotrypsinogen. [Information from Gregory A. Petsko and Dagmar Ringe, *Protein Structure and Function* (Sinauer, 2003), p. 3-16, Figure 3-31.]

**FIGURE 10.22 Zymogen activation by proteolytic cleavage.** Enteropeptidase initiates the activation of the pancreatic zymogens by activating trypsin, which then activates other zymogens. Active enzymes are shown in yellow; zymogens are shown in orange.

### Some proteolytic enzymes have specific inhibitors

The conversion of a zymogen into a protease by cleavage of a single peptide bond is a precise means of switching on enzymatic activity. However, this activation step is irreversible, and so a different mechanism is needed to terminate proteolysis. Specific protease inhibitors accomplish this task. *Serpins*, *serine protease inhibitors*, are an example of one such family of inhibitors. For example, *pancreatic trypsin inhibitor*, a 6-kDa protein, inhibits trypsin by binding very tightly to its active site. The dissociation constant of the complex is 0.1 pM, which corresponds to a standard free energy of binding of about  $-75 \text{ kJ mol}^{-1}$  ( $-18 \text{ kcal mol}^{-1}$ ). In contrast with nearly all known protein assemblies, this complex is not dissociated into its constituent chains by treatment with denaturing agents such as 8 M urea or 6 M guanidine hydrochloride (p. 47).

The reason for the exceptional stability of the complex is that pancreatic trypsin inhibitor is a very effective substrate analog. X-ray analyses show that the inhibitor lies in the active site of the enzyme, positioned such that the side chain of lysine 15 of this inhibitor interacts with the aspartate side chain in the specificity pocket of trypsin. In addition, there are many hydrogen bonds between the main chain of trypsin and that of its inhibitor. Furthermore, the carbonyl group of lysine 15 and the surrounding atoms of the inhibitor fit snugly in the active site of the enzyme. Comparison of the structure of the inhibitor bound to the enzyme with that of the free inhibitor reveals that *the structure is essentially unchanged on binding to the enzyme* (Figure 10.23). Thus, the inhibitor is preorganized into a structure that is highly complementary to the enzyme's active site. Indeed, the peptide bond between lysine 15 and alanine 16 in pancreatic trypsin inhibitor is cleaved but at a very slow rate: the half-life of the trypsin–inhibitor complex is several months. In essence, the inhibitor is a substrate, but its intrinsic structure is so nicely complementary to the enzyme's active site that it binds very tightly, rarely progressing to the transition state and is turned over slowly.

**FIGURE 10.23 Interaction of trypsin with its inhibitor.** Structure of a complex of trypsin (yellow) and pancreatic trypsin inhibitor (red). Notice that lysine 15 of the inhibitor penetrates into the active site of the enzyme. There it forms an ionic bond with aspartate 189 in the active site. Also notice that bound inhibitor and the free inhibitor are almost identical in structure. [Drawn from 1BPI.pdb.]

The amount of trypsin is much greater than the amount of inhibitor. Why does trypsin inhibitor exist? Recall that trypsin activates other zymogens. Consequently, the prevention of even small amounts of trypsin from initiating the cascade while the zymogens are still in the pancreas or

pancreatic ducts is vital. Trypsin inhibitor binds to any prematurely activated trypsin molecules in the pancreas or pancreatic ducts. This inhibition prevents severe damage to those tissues, which could lead to acute pancreatitis.

 Pancreatic trypsin inhibitor is not the only important protease inhibitor. A 53-kDa plasma protein,  $\alpha_1$ -antitrypsin (also called  $\alpha_1$ -antiprotease), protects tissues from digestion by elastase, a secretory product of neutrophils (white blood cells that engulf bacteria). *Antielastase* would be a more accurate name for this inhibitor, because it blocks *elastase* much more effectively than it blocks trypsin. Like pancreatic trypsin inhibitor,  $\alpha_1$ -antitrypsin blocks the action of target enzymes by binding nearly irreversibly to their active sites. Genetic disorders leading to a deficiency of  $\alpha_1$ -antitrypsin illustrate the physiological importance of this inhibitor. For example, the substitution of lysine for glutamate at residue 53 in the type Z mutant slows the secretion of this inhibitor from liver cells. Serum levels of the inhibitor are about 15% of normal in people homozygous for this defect. The consequence is that excess elastase destroys alveolar walls in the lungs by digesting elastic fibers and other connective-tissue proteins.

The resulting clinical condition is called *emphysema* (also known as *chronic obstructive pulmonary disease* [COPD]). People with emphysema must breathe much harder than normal people to exchange the same volume of air because their alveoli are much less resilient than normal. Cigarette smoking markedly increases the likelihood that even a type Z heterozygote will develop emphysema. The reason is that smoke oxidizes methionine 358 of the inhibitor (Figure 10.24), a residue essential for binding elastase. Indeed, this methionine side chain is the bait that selectively traps elastase. The *methionine sulfoxide* oxidation product, in contrast, does not lure elastase, a striking consequence of the insertion of just one oxygen atom into a protein and a remarkable example of the effect of human behavior on biochemistry. We will consider another protease inhibitor, antithrombin III, when we examine the control of blood clotting.

### Blood clotting is accomplished by a cascade of zymogen activations

 *Enzymatic cascades* are often employed in biochemical systems to achieve a rapid response. In a cascade, an initial signal institutes a series of steps, each of which is catalyzed by an enzyme. At each step, the signal is amplified. For instance, if a signal molecule activates an enzyme that in turn activates 10 enzymes and each of the 10 enzymes in turn activates 10 additional enzymes, after four steps the original signal will have been amplified 10,000-fold. *Hemostasis*, the process of blood clot formation and dissolution, requires a *cascade of zymogen activations*: the activated form of one clotting factor catalyzes the activation of the next (Figure 10.25). Thus, very small amounts of the initial factors suffice to trigger the cascade, ensuring a rapid response to trauma.

### 10.4 Activation by Proteolytic Cleavage

FIGURE 10.24 Oxidation of methionine to methionine sulfoxide.

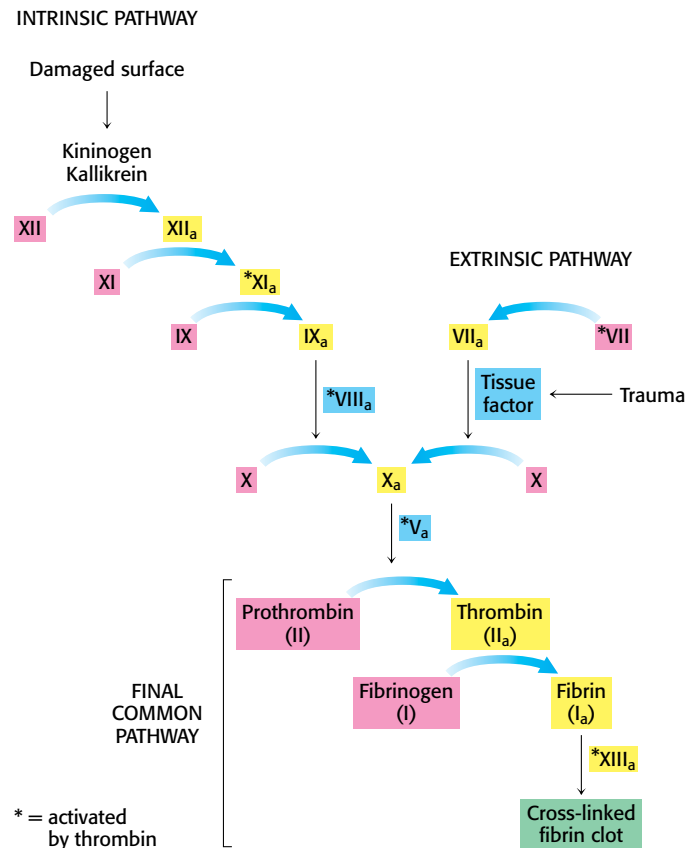

FIGURE 10.25 Blood-clotting cascade. A fibrin clot is formed by the interplay of the intrinsic, extrinsic, and final common pathways. The intrinsic pathway begins with the activation of factor XII (Hageman factor) by contact with abnormal surfaces produced by injury. The extrinsic pathway is triggered by trauma, which releases tissue factor (TF). TF forms a complex with VII, which initiates a cascade-activating thrombin. Inactive forms of clotting factors are shown in red; their activated counterparts (indicated by the subscript "a") are in yellow. Stimulatory proteins that are not themselves enzymes are shown in blue boxes. A striking feature of this process is that the activated form of one clotting factor catalyzes the activation of the next factor.

The second kringle domain of prothrombin

Kringle pastry

Calcium ions

**FIGURE 10.27** The calcium-binding region of prothrombin. Prothrombin binds calcium ions with the modified amino acid  $\gamma$ -carboxyglutamate (red). [Drawn from 2PF2.pdb.]

Two means of initiating blood clotting have been described, the *intrinsic pathway* and the *extrinsic pathway*. The intrinsic clotting pathway is activated by exposure of anionic surfaces upon rupture of the endothelial lining of the blood vessels. The extrinsic pathway, which appears to be most crucial in blood clotting, is initiated when trauma exposes *tissue factor* (TF), an integral membrane glycoprotein. Upon exposure to the blood, tissue factor binds to factor VII to activate factor X. Both the intrinsic and extrinsic pathways lead to the activation of factor X (a serine protease), which in turn converts *prothrombin* into *thrombin*, the key protease in clotting. Thrombin then amplifies the clotting process by activating enzymes and factors that lead to the generation of yet more thrombin, an example of positive feedback. Note that the active forms of the clotting factors are designated with a subscript “a,” whereas factors that are activated by thrombin are designated with an asterisk.

### Prothrombin requires a vitamin K-dependent modification for activation

Thrombin is synthesized as a zymogen called *prothrombin*. The inactive molecule comprises four major domains, with the serine protease domain at its carboxyl terminus (Figure 10.26). The first domain, called the *gla domain*, is rich in  $\gamma$  carboxyglutamate residues (abbreviation gla), and the second and third domains are called *kringle domains* (named after a Danish pastry that they resemble). Vitamin K is required for the synthesis of  $\gamma$  carboxyglutamate, a strong chelator of  $\text{Ca}^{2+}$ . These three domains work in concert to keep prothrombin in an inactive form. Moreover, because it is rich in  $\gamma$  carboxyglutamate, the gla domain is able to bind  $\text{Ca}^{2+}$  (Figure 10.27). What is the effect of this binding? The binding of  $\text{Ca}^{2+}$  by prothrombin anchors the zymogen to phospholipid membranes derived from blood platelets after injury. This binding is crucial because it brings prothrombin into close proximity to two clotting proteins, factor  $\text{X}_a$  and factor  $\text{V}_a$  (a stimulatory protein), that catalyze its conversion into thrombin. Activation is begun by proteolytic cleavage of the bond between arginine 274 and threonine 275 to release a fragment containing the first three domains. Cleavage of the bond between arginine 323 and isoleucine 324 yields active thrombin.

**FIGURE 10.26** Modular structure of prothrombin. Cleavage of two peptide bonds yields thrombin. All the  $\gamma$ -carboxyglutamate residues are in the gla domain.

### Fibrinogen is converted by thrombin into a fibrin clot

The best-characterized part of the clotting process is the final step in the cascade: the conversion of *fibrinogen* into fibrin by thrombin. Fibrinogen is made up of three globular units connected by two rods (Figure 10.28). This 340-kDa protein consists of six chains: two each of  $\text{A}\alpha$ ,  $\text{B}\beta$ , and  $\gamma$ . The rod regions are triple-stranded  $\alpha$ -helical coiled coils, a recurring motif in proteins (Section 2.3). Thrombin cleaves four *arginine–glycine peptide bonds* in the central globular region of fibrinogen (p. 217). On cleavage, an A peptide of 18 residues is released from each of the two  $\text{A}\alpha$  chains, as is a B peptide of 20 residues from each of the two  $\text{B}\beta$  chains. These A and B peptides are called *fibrinopeptides*. A fibrinogen molecule

**FIGURE 10.28 Structure of a fibrinogen molecule.** (A) A ribbon diagram. The two rod regions are  $\alpha$ -helical coiled coils, connected to a globular region at each end. The structure of the central globular region has not been determined. (B) A schematic representation showing the positions of the fibrinopeptides A and B. [Part A drawn from 1DEQ.pdb.]

devoid of these fibrinopeptides is called a *fibrin monomer* and has the subunit structure  $(\alpha\beta\gamma)_2$ .

Fibrin monomers spontaneously assemble into ordered fibrous arrays called *fibrin*. Electron micrographs and low-angle x-ray patterns show that fibrin has a periodic structure that repeats every 23 nm (Figure 10.29). Higher-resolution images reveal how the removal of the fibrinopeptides permits the fibrin monomers to come together to form fibrin. The homologous  $\beta$  and  $\gamma$  chains have globular domains at the carboxyl-terminal ends (Figure 10.30). These domains have binding “holes” that interact with peptides. The  $\beta$  domain is specific for sequences of the form  $\text{H}_3\text{N}^+\text{-Gly-His-Arg-}$ , whereas the  $\gamma$  domain binds  $\text{H}_3\text{N}^+\text{-Gly-Pro-Arg-}$ . Exactly these sequences (sometimes called “knobs”) are exposed at the amino-terminal ends of the  $\beta$  and  $\alpha$  chains, respectively, on thrombin cleavage. The knobs of the  $\alpha$  subunits fit into the holes on the  $\gamma$  subunits of another monomer to form a protofibril. This protofibril is extended when the knobs of the  $\beta$  subunits fit into the holes of  $\beta$  subunits of other protofibrils. Thus, analogous to the activation of chymotrypsinogen, peptide-bond cleavage exposes new amino termini that can participate in specific interactions. The newly formed “soft clot” is stabilized by the formation of amide bonds between the side chains of lysine and glutamine residues in different monomers.

**FIGURE 10.29 Electron micrograph of fibrin.** The 23-nm period along the fiber axis is half the length of a fibrinogen molecule. [From John L. Woodhead et al., “The Ultrastructure of Fibrinogen Caracas II Molecules, Fibers, and Clots,” *J. Biol. Chem.* 271(9):4946–4953, 1996, Mar 1. © American Society for Biochemistry and Molecular Biology.]

**FIGURE 10.30 Formation of a fibrin clot.** (1) Thrombin cleaves fibrinopeptides A and B from the central globule of fibrinogen. (2) Globular domains at the carboxyl-terminal ends of the  $\beta$  and  $\gamma$  chains interact with “knobs” exposed at the amino-terminal ends of the  $\beta$  and  $\gamma$  chains to form clots.

This cross-linking reaction is catalyzed by *transglutaminase* (*factor XIII<sub>a</sub>*), which itself is activated from the protransglutaminase form by thrombin.

### Vitamin K is required for the formation of $\gamma$ -carboxyglutamate

 Vitamin K (Figure 10.31) has been known for many years to be essential for the synthesis of prothrombin and several other clotting factors. Indeed, it is called vitamin K because a deficiency in this vitamin results in defective blood *koagulation* (Scandinavian spelling). After ingestion, vitamin K is reduced to a dihydro derivative that is required by  $\gamma$ -glutamyl carboxylase to convert the first 10 glutamate residues in the amino-terminal region of prothrombin into  $\gamma$ -carboxyglutamate (Figure 10.32).

**FIGURE 10.31** Structures of vitamin K and two antagonists, dicoumarol and warfarin.

**FIGURE 10.32** Synthesis of  $\gamma$ -carboxyglutamate by  $\gamma$ -glutamyl carboxylase. The formation of  $\gamma$ -carboxyglutamate requires the hydroquinone derivative of vitamin K, which is regenerated from the epoxide derivative by the sequential action of epoxide reductase and quinone reductase, both of which are inhibited by warfarin.

Recall that  $\gamma$ -carboxyglutamate, a strong chelator of  $\text{Ca}^{2+}$ , is required for the activation of prothrombin (p. 304). *Dicoumarol*, which is found in spoiled sweet clover, causes a fatal hemorrhagic disease in cattle fed on this hay. Cows fed dicoumarol synthesize an abnormal prothrombin that does not bind  $\text{Ca}^{2+}$ , in contrast with normal prothrombin. Dicoumarol was the first *anticoagulant* used to prevent thromboses in patients prone to clot formation. However, it is seldom used now because of poor absorption and gastrointestinal side effects. *Warfarin*, another vitamin K antagonist, is commonly administered as an anticoagulant. Warfarin inhibits the keto reductase and quinone reductase that are required to regenerate the dihydro derivative of vitamin K (Figure 10.32). Dicoumarol, warfarin, and their chemical derivatives serve as effective rat poisons.

### The clotting process must be precisely regulated

There is a fine line between hemorrhage and thrombosis, the formation of blood clots in blood vessels. Clots must form rapidly yet remain confined to the area of injury. What are the mechanisms that normally limit clot formation to the site of injury? The lability of clotting factors contributes significantly to the control of clotting. Activated factors are short-lived because they are diluted by blood flow, removed by the liver, and degraded by proteases. For example, the stimulatory protein factors  $\text{V}_a$  and  $\text{VIII}_a$  are digested by protein C, a protease that is switched on by the action of thrombin. Thus, *thrombin has a dual function: it catalyzes the formation of fibrin and it initiates the deactivation of the clotting cascade.*

Specific inhibitors of clotting factors are also critical in the termination of clotting. For instance, *tissue factor pathway inhibitor* (TFPI) inhibits the complex of  $\text{TF-VII}_a\text{-X}_a$  that activates thrombin. Another key inhibitor is *antithrombin III*, a member of the serpin family of protease inhibitors (p. 302) that forms an irreversible inhibitory complex with thrombin. Antithrombin III resembles  $\alpha_1$ -antitrypsin except that it inhibits thrombin much more strongly than it inhibits elastase (Figure 10.23). Antithrombin III also blocks other serine proteases in the clotting cascade—namely, factors  $\text{XII}_a$ ,  $\text{XI}_a$ ,  $\text{IX}_a$ , and  $\text{X}_a$ . The inhibitory action of antithrombin III is enhanced by *heparin*, a negatively charged polysaccharide (Section 11.3) found in mast cells near the walls of blood vessels and on the surfaces of endothelial cells (Figure 10.33). Heparin acts as an *anticoagulant* by increasing the rate of formation of irreversible complexes between antithrombin III and the serine protease clotting factors.

 The importance of the ratio of thrombin to antithrombin is illustrated in the case of a 14-year-old boy who died of a bleeding disorder because of a mutation in his  $\alpha_1$ -antitrypsin, which normally inhibits elastase. Methionine 358 in  $\alpha_1$ -antitrypsin's binding pocket for elastase was replaced by arginine, resulting in a change in specificity from an elastase inhibitor to a thrombin inhibitor. Activity of  $\alpha_1$ -antitrypsin normally increases markedly after injury to counteract excess elastase arising from stimulated neutrophils. The mutant  $\alpha_1$ -antitrypsin caused the patient's thrombin activity to drop to such a low level that hemorrhage ensued. We see here a striking example of how a change of a single residue in a protein can dramatically alter specificity and an example of the critical importance of having the right amount of a protease inhibitor.

Antithrombin limits the extent of clot formation, but what happens to the clots themselves? Clots are not permanent structures but are designed to

### An account of a hemorrhagic disposition existing in certain families

"About seventy or eighty years ago, a woman by the name of Smith settled in the vicinity of Plymouth, New Hampshire, and transmitted the following idiosyncrasy to her descendants. It is one, she observed, to which her family is unfortunately subject and has been the source not only of great solicitude, but frequently the cause of death. If the least scratch is made on the skin of some of them, as mortal a hemorrhage will eventually ensue as if the largest wound is inflicted. . . . It is a surprising circumstance that the males only are subject to this strange affection, and that all of them are not liable to it. . . . Although the females are exempt, they are still capable of transmitting it to their male children."

John Otto (1803)

**FIGURE 10.35 The effect of tissue-type plasminogen activator.** Angiographic images demonstrate the effect of TPA administration. The top left image shows an occluded cerebral artery (arrow) prior to TPA injection. The middle image indicates the site of injection. The lower right image, made several hours after injection, reveals the restoration of blood flow to the cerebral artery. [Medical Body Scans/Science Source.]

**FIGURE 10.36 Action of antihemophilic factor.** Antihemophilic factor (Factor VIII) stimulates the activation of factor X by factor IX<sub>a</sub>. Interestingly, the activity of factor VIII is markedly increased by limited proteolysis by thrombin. This positive feedback amplifies the clotting signal and accelerates clot formation after a threshold has been reached.

dissolve when the structural integrity of damaged areas is restored. Fibrin is degraded by *plasmin*, a serine protease that hydrolyzes peptide bonds in the coiled-coil regions. Plasmin molecules can diffuse through aqueous channels in the porous fibrin clot to cut the accessible connector rods. Plasmin is formed by the proteolytic activation of *plasminogen*, an inactive precursor that has a high affinity for the fibrin clots. This conversion is carried out by *tissue-type plasminogen activator* (TPA), a 72-kDa protein that has a domain structure closely related to that of prothrombin (Figure 10.34). However, a domain that targets TPA to fibrin clots replaces the membrane-targeting gla domain of prothrombin. The TPA bound to fibrin clots swiftly activates adhering plasminogen. In contrast, TPA activates free plasminogen very slowly. The gene for TPA has been cloned and expressed in cultured mammalian cells. TPA administered at the onset of a heart attack or a stroke caused by a blood clot increases the likelihood of survival without physical or cognitive disabilities (Figure 10.35).

### Hemophilia revealed an early step in clotting

Some important breakthroughs in the elucidation of clotting pathways have come from studies of patients with bleeding disorders. *Classic hemophilia*, or *hemophilia A*, is the best-known clotting defect. This disorder is genetically transmitted as a sex-linked recessive characteristic. In *classic hemophilia*, *factor VIII (antihemophilic factor) of the intrinsic pathway is missing or has markedly reduced activity*. Although factor VIII is not itself a protease, it markedly stimulates the activation of factor X, the final protease of the intrinsic pathway, by factor IX<sub>a</sub>, a serine protease (Figure 10.36). Thus, activation of the intrinsic pathway is severely impaired in hemophilia.

In the past, hemophiliacs were treated with transfusions of a concentrated plasma fraction containing factor VIII. This therapy carried the risk of infection. Indeed, many hemophiliacs contracted hepatitis and, more recently, AIDS. A safer source of factor VIII was urgently needed. With the use of biochemical purification and recombinant DNA techniques, the gene for factor VIII was isolated and expressed in cells grown in culture. Recombinant factor VIII purified from these cells has largely replaced plasma concentrates in treating hemophilia.

## SUMMARY

### 10.1 Aspartate Transcarbamoylase Is Allosterically Inhibited by the End Product of Its Pathway

Allosteric proteins constitute an important class of proteins whose biological activity can be regulated. Specific regulatory molecules can modulate the activity of allosteric proteins by binding to distinct regulatory sites, separate from the functional sites. These proteins have multiple functional sites, which display cooperativity as evidenced by a

sigmoidal dependence of function on substrate concentration. Aspartate transcarbamoylase (ATCase), one of the best-understood allosteric enzymes, catalyzes the synthesis of *N*-carbamoylaspartate, the first intermediate in the synthesis of pyrimidines. ATCase is feedback inhibited by CTP, the final product of the pathway. ATP reverses this inhibition. ATCase consists of separable catalytic ( $c_3$ ) subunits (which bind the substrates) and regulatory ( $r_2$ ) subunits (which bind CTP and ATP). The inhibitory effect of CTP, the stimulatory action of ATP, and the cooperative binding of substrates are mediated by large changes in quaternary structure. On binding substrates, the  $c_3$  subunits of the  $c_6r_6$  enzyme move apart and reorient themselves. This allosteric transition is highly concerted. All subunits of an ATCase molecule simultaneously interconvert from the T (low-affinity) to the R (high-affinity) state.

### 10.2 Isozymes Provide a Means of Regulation Specific to Distinct Tissues and Developmental Stages

Isozymes differ in structural characteristics but catalyze the same reaction. They provide a means of fine-tuning metabolism to meet the needs of a given tissue or developmental stage. The results of gene-duplication events provide the means for subtle regulation of enzyme function.

### 10.3 Covalent Modification Is a Means of Regulating Enzyme Activity

The covalent modification of proteins is a potent means of controlling the activity of enzymes and other proteins. Phosphorylation is a common type of reversible covalent modification. Signals can be highly amplified by phosphorylation because a single kinase can act on many target molecules. The regulatory actions of protein kinases are reversed by protein phosphatases, which catalyze the hydrolysis of attached phosphoryl groups.

Cyclic AMP serves as an intracellular messenger in the transduction of many hormonal and sensory stimuli. Cyclic AMP switches on protein kinase A, a major multifunctional kinase, by binding to the regulatory subunit of the enzyme, thereby releasing the active catalytic subunits of PKA. In the absence of cAMP, the catalytic sites of PKA are occupied by pseudosubstrate sequences of the regulatory subunit.

### 10.4 Many Enzymes Are Activated by Specific Proteolytic Cleavage

The activation of an enzyme by the proteolytic cleavage of one or a few peptide bonds is a recurring control mechanism seen in processes as diverse as the activation of digestive enzymes and blood clotting. The inactive precursor is a zymogen (proenzyme). Trypsinogen is activated by enteropeptidase or trypsin, and trypsin then activates a host of other zymogens, leading to the digestion of foodstuffs. For instance, trypsin converts chymotrypsinogen, a zymogen, into active chymotrypsin by hydrolyzing a single peptide bond.

A striking feature of the clotting process is that it is accomplished by a cascade of zymogen conversions, in which the activated form of one clotting factor catalyzes the activation of the next precursor. Many of the activated clotting factors are serine proteases. In the final step of clot formation, fibrinogen, a highly soluble molecule in the plasma, is converted by thrombin into fibrin by the hydrolysis of four arginine–glycine bonds. The resulting fibrin monomer spontaneously forms long, insoluble fibers called fibrin. Zymogen activation is also essential in the lysis of clots. Plasminogen is converted into plasmin, a serine protease that cleaves fibrin, by tissue-type plasminogen activator. Although zymogen activation is irreversible, specific inhibitors of some proteases exert control. The irreversible protein inhibitor antithrombin III holds blood clotting in check in the clotting cascade.

## KEY TERMS

cooperativity (p. 285)	isozyme (isoenzyme) (isoform) (p. 292)	zymogen (proenzyme) (p. 299)
feedback (end-product) inhibition (p. 287)	covalent modification (p. 293)	enzymatic cascade (p. 303)
allosteric (regulatory) site (p. 287)	protein kinase (p. 294)	hemostasis (p. 303)
homotropic effect (p. 290)	consensus sequence (p. 295)	intrinsic pathway (p. 304)
concerted model (p. 290)	protein phosphatase (p. 295)	extrinsic pathway (p. 304)
sequential model (p. 290)	protein kinase A (PKA) (p. 297)	
heterotropic effect (p. 292)	pseudosubstrate sequence (p. 297)	

## PROBLEMS

- Context please.* The allosteric properties of aspartate transcarbamoylase have been discussed in detail in this chapter. What is the function of aspartate transcarbamoylase?
- Activity profile.* A histidine residue in the active site of aspartate transcarbamoylase is thought to be important in stabilizing the transition state of the bound substrates. Predict the pH dependence of the catalytic rate, assuming that this interaction is essential and dominates the pH-activity profile of the enzyme. (See equations on p. 16.)
- Knowing when to say when.* What is feedback inhibition? Why is it a useful property?
- Knowing when to get going.* What is the biochemical rationale for ATP serving as a positive regulator of ATCase?
- No T.* What would be the effect of a mutation in an allosteric enzyme that resulted in a T/R ratio of 0?
- Turned upside down.* An allosteric enzyme that follows the concerted model has a T/R ratio of 300 in the absence of substrate. Suppose that a mutation reversed the ratio. How would this mutation affect the relation between the rate of the reaction and the substrate concentration?
- Partners.* As shown in Figure 10.2, CTP inhibits ATCase; however, the inhibition is not complete. Can you suggest another molecule that might enhance the inhibition of ATCase? Hint: See Figure 25.2.
- RT equilibrium.* Differentiate between homotropic and heterotropic effectors.
- Restoration project.* If isolated regulatory subunits and catalytic subunits of ATCase are mixed, the native enzyme is reconstituted. What is the biological significance of the observation?
- Because it's an enzyme.* X-ray crystallographic studies of ATCase in the R form required the use of the bisubstrate analog PALA. Why was this analog, a competitive inhibitor, used instead of the actual substrates?
- Allosteric switching.* A substrate binds 100 times as tightly to the R state of an allosteric enzyme as to its T state. Assume that the concerted (MWC) model applies to this enzyme. (See equations for the Concerted Model in the Appendix to Chapter 7.)
  - By what factor does the binding of one substrate molecule per enzyme molecule alter the ratio of the concentrations of enzyme molecules in the R and T states?
  - Suppose that  $L$ , the ratio of [T] to [R] in the absence of substrate, is  $10^7$  and that the enzyme contains four binding sites for substrate. What is the ratio of enzyme molecules in the R state to those in the T state in the presence of saturating amounts of substrate, assuming that the concerted model is obeyed?
- Allosteric transition.* Consider an allosteric protein that obeys the concerted model. Suppose that the ratio of T to R formed in the absence of ligand is  $10^5$ ,  $K_T = 2$  mM, and  $K_R = 5$   $\mu$ M. The protein contains four binding sites for ligand. What is the fraction of molecules in the R form when 0, 1, 2, 3, and 4 ligands are bound? (See equations for the Concerted Model in the Appendix to Chapter 7.)
- Negative cooperativity.* You have isolated a dimeric enzyme that contains two identical active sites. The binding of substrate to one active site decreases the substrate affinity of the other active site. Can the concerted model account for this negative cooperativity? Hint: See Section 7.2.
- A new view of cooperativity.* Draw a double-reciprocal plot for a typical Michaelis–Menten enzyme and an allosteric enzyme that have the same  $V_{\max}$  and  $K_M$ . Draw a double reciprocal plot for the same allosteric enzyme in the presence of an allosteric inhibitor and an allosteric stimulator.
- Paradoxical at first glance.* Recall that phosphonacetyl-L-aspartate (PALA) is a potent inhibitor of ATCase because

it mimics the two physiological substrates. However, in the presence of substrates, low concentrations of this unreactive bisubstrate analog *increase* the reaction velocity. On the addition of PALA, the reaction rate increases until an average of three molecules of PALA are bound per molecule of enzyme. This maximal velocity is 17-fold greater than it is in the absence of PALA. The reaction rate then decreases to nearly zero on the addition of three more molecules of PALA per molecule of enzyme. Why do low concentrations of PALA activate ATCase?

16. *Regulation energetics.* The phosphorylation and dephosphorylation of proteins is a vital means of regulation. Protein kinases attach phosphoryl groups, whereas only a phosphatase will remove the phosphoryl group from the target protein. What is the energy cost of this means of covalent regulation?

17. *Vive la différence.* What is an isozyme?

18. *Fine-tuning biochemistry.* What is the advantage for an organism to have isozymic forms of an enzyme?

19. *Making matches.*

20. *Powering change.* Phosphorylation is a common covalent modification of proteins in all forms of life. What energetic advantages accrue from the use of ATP as the phosphoryl donor?

21. *No going back.* What is the key difference between regulation by covalent modification and specific proteolytic cleavage?

22. *Zymogen activation.* When very low concentrations of pepsinogen are added to acidic media, how does the half-time for activation depend on zymogen concentration?

23. *No protein shakes advised.* Predict the physiological effects of a mutation that resulted in a deficiency of enteropeptidase.

24. *A revealing assay.* Suppose that you have just examined a young boy with a bleeding disorder highly suggestive of classic hemophilia (factor VIII deficiency). Because of the late hour, the laboratory that carries out specialized coagulation assays is closed. However, you happen to have a sample of blood from a classic hemophiliac whom you admitted to the hospital an hour earlier. What is the simplest and most rapid test that you can perform to determine whether your present patient also is deficient in factor VIII activity?

25. *Counterpoint.* The synthesis of factor X, like that of prothrombin, requires vitamin K. Factor X also contains  $\gamma$ -carboxyglutamate residues in its amino-terminal region. However, activated factor X, in contrast with thrombin, retains this region of the molecule. What is a likely functional consequence of this difference between the two activated species?

26. *A discerning inhibitor.* Antithrombin III forms an irreversible complex with thrombin but not with prothrombin. What is the most likely reason for this difference in reactivity?

27. *Drug design.* A drug company has decided to use recombinant DNA methods to prepare a modified  $\alpha_1$ -anti-trypsin that will be more resistant to oxidation than is the naturally occurring inhibitor. Which single amino acid substitution would you recommend?

28. *Blood must flow.* Why is inappropriate blood-clot formation dangerous?

29. *Hemostasis.* Thrombin functions in both coagulation and fibrinolysis. Explain.

30. *Dissolution row.* What is tissue-type plasminogen activator and what is its role in preventing heart attacks?

31. *Joining together.* What differentiates a soft clot from a mature clot?

### Data Interpretation Problems

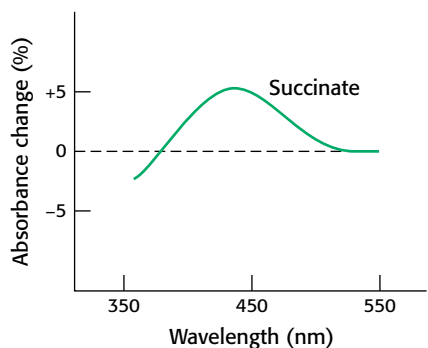

32. *Distinguishing between models.* The following graph shows the fraction of an allosteric enzyme in the R state ( $f_R$ ) and the fraction of active sites bound to substrate ( $Y$ ) as a function of substrate concentration. Which model, the concerted or sequential, best explains these results?

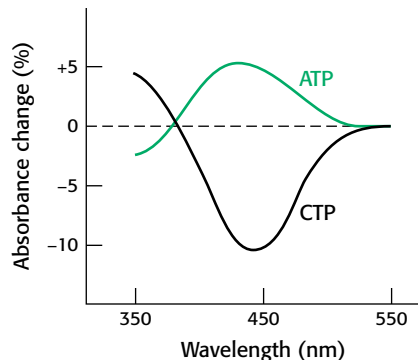

[Data from M. W. Kirschner and H. K. Schachman. *Biochemistry* 12:2997–3004, 1966.]

33. *Reporting live from ATCase 1.* ATCase underwent reaction with tetranitromethane to form a colored nitrotyrosine group ( $\lambda_{\max} = 430$  nm) in each of its catalytic chains. The absorption by this reporter group depends on its immediate environment. An essential lysine residue at each catalytic site also was modified to block the binding of substrate. Catalytic trimers from this doubly modified enzyme were then combined with native trimers to form a hybrid enzyme. The absorption by the nitrotyrosine group was measured on addition of the substrate analog succinate. What is the significance of the alteration in the absorbance at 430 nm?

[Data from H. K. Schachman. *J. Biol. Chem.* 263:18583–18586, 1988.]

34. *Reporting live from ATCase 2.* A different ATCase hybrid was constructed to test the effects of allosteric activators and inhibitors. Normal regulatory subunits were combined with nitrotyrosine-containing catalytic subunits. The addition of ATP in the absence of substrate increased the absorbance at 430 nm, the same change elicited by the addition of succinate (see the graph in Problem 33). Conversely, CTP in the absence of substrate decreased the absorbance at 430 nm. What is the significance of the changes in absorption of the reporter groups?

[Data from H. K. Schachman. *J. Biol. Chem.* 263:18583–18586, 1988.]

35. *Conviviality and PKA.* Recent studies have suggested that protein kinase A may be important in establishing behaviors in many organisms, including humans. One study investigated the role of PKA in locust behavior. Certain species of locust live solitary lives until crowded, at which point they become gregarious—they prefer the crowded life.

[Data from S. R. Ott, et al., *Proc. Natl. Acad. Sci. U. S. A.* 109(7):E381–7, 2012.]

Locusts were grouped together for one hour, and then allowed to stay with the group or move away. Prior to crowding, some insects were injected with a PKA inhibitor, a cyclic GMP-dependent kinase inhibitor or no inhibitor, as indicated. The results are shown above.

- What is the response of the control group to crowding?
- What is the result if the insects are first treated with PKA inhibitor? PKG inhibitor?
- What was the purpose of the experiment with the PKG inhibitor?

(d) What do these results suggest about the role of PKA in the transition from a solitary to a gregarious life style?

The above experiments were repeated on a different species of insect that is always gregarious. The results are shown below.

[Data from S. R. Ott, et al., *Proc. Natl. Acad. Sci. U. S. A.* 109(7):E381–7, 2012.]

(e) What do these results suggest about the role of PKA in insects that are always gregarious?

### Chapter Integration Problems

36. *Repeating heptads.* Each of the three types of fibrin chains contains repeating heptapeptide units (*abcdefg*) in which residues *a* and *d* are hydrophobic. Propose a reason for this regularity.

37. *Density matters.* The sedimentation value of aspartate transcarbamoylase decreases when the enzyme switches to the R state. On the basis of the allosteric properties of the enzyme, explain why the sedimentation value decreases.

38. *Too tight a grip.* Trypsin cleaves proteins on the carboxyl side of lysine. Trypsin inhibitor has a lysine residue, and binds to trypsin, yet it is not a substrate. Explain.

39. *Apparently not the four-leaf variety.* Cows that graze on spoiled sweet clover, which contains dicoumarol, die from hemorrhagic disease. The cause of death is defective prothrombin. However, the amino acid composition of the defective prothrombin is identical to that of normal prothrombin. What is the mechanism of action of dicoumarol? Why are the amino acid compositions of the defective and normal prothrombin the same?

### Mechanism Problems

40. *Aspartate transcarbamoylase.* Write the mechanism (in detail) for the conversion of aspartate and carbamoyl phosphate into *N*-carbamoylaspartate. Include a role for the histidine residue present in the active site.

41. *Protein kinases.* Write a mechanism (in detail) for phosphorylation of a serine residue by ATP catalyzed by protein kinase. What groups might you expect to find in the enzyme's active site?

## Carbohydrates

Carbohydrates are important fuel molecules, but they play many other biochemical roles, including protection against high-impact forces. The cartilage of a runner's foot cushions the impact of each step she takes. A key component of cartilage are molecules called glycosaminoglycans, large polymers made up of many repeats of dimers such as the pair shown at the right. [Untitled x-ray/Nick Veasey/Getty Images.]

For years, the study of carbohydrates was considered less exciting than many if not most topics of biochemistry. Carbohydrates were recognized as important fuels and structural components but were thought to be peripheral to most key activities of the cell. In essence, they were considered the underlying girders and fuel for a magnificent piece of biochemical architecture. This view has changed dramatically in the past few years. We have learned that cells of all organisms are coated in a dense and complex coat of carbohydrates. Secreted proteins are often extensively decorated with carbohydrates essential to a protein's function. The extracellular matrix in higher eukaryotes—the environment in which the cells live—is rich in secreted carbohydrates central to cell survival and cell-to-cell communication. Carbohydrates, carbohydrate-containing proteins, and specific carbohydrate-binding proteins are required for interactions that allow cells to form tissues, are the basis of human blood groups, and are used by

## OUTLINE

- 11.1 Monosaccharides Are the Simplest Carbohydrates
- 11.2 Monosaccharides Are Linked to Form Complex Carbohydrates

a variety of pathogens to gain access to their hosts. Indeed, rather than being mere infrastructure components, carbohydrates supply details and enhancements to the biochemical architecture of the cell, helping to define the functionality and uniqueness of the cell.

A key property of carbohydrates that allows their many functions is the tremendous structural *diversity* possible within this class of molecules. Carbohydrates are built from monosaccharides, which are small molecules—typically containing from three to nine carbon atoms that are bound to hydroxyl groups—that vary in size and in the stereochemical configuration at one or more carbon centers. These monosaccharides can be linked together to form a large variety of oligosaccharide structures. The sheer number of possible oligosaccharides makes this class of molecules information rich. This information, when attached to proteins, can augment the already immense diversity of proteins.

The realization of the importance of carbohydrates to so many aspects of biochemistry has spawned a field of study called *glycobiology*. Glycobiology is the study of the synthesis and structure of carbohydrates and how carbohydrates are attached to and recognized by other molecules such as proteins. Along with a new field comes a new “omics” to join genomics and proteomics—*glycomics*. Glycomics is the study of the glycome, all of the carbohydrates and carbohydrate-associated molecules that cells produce. Like the proteome, the glycome is dynamic, depending on cellular and environmental conditions. Unraveling oligosaccharide structures and elucidating the effects of their attachment to other molecules constitutes a tremendous challenge in the field of biochemistry.

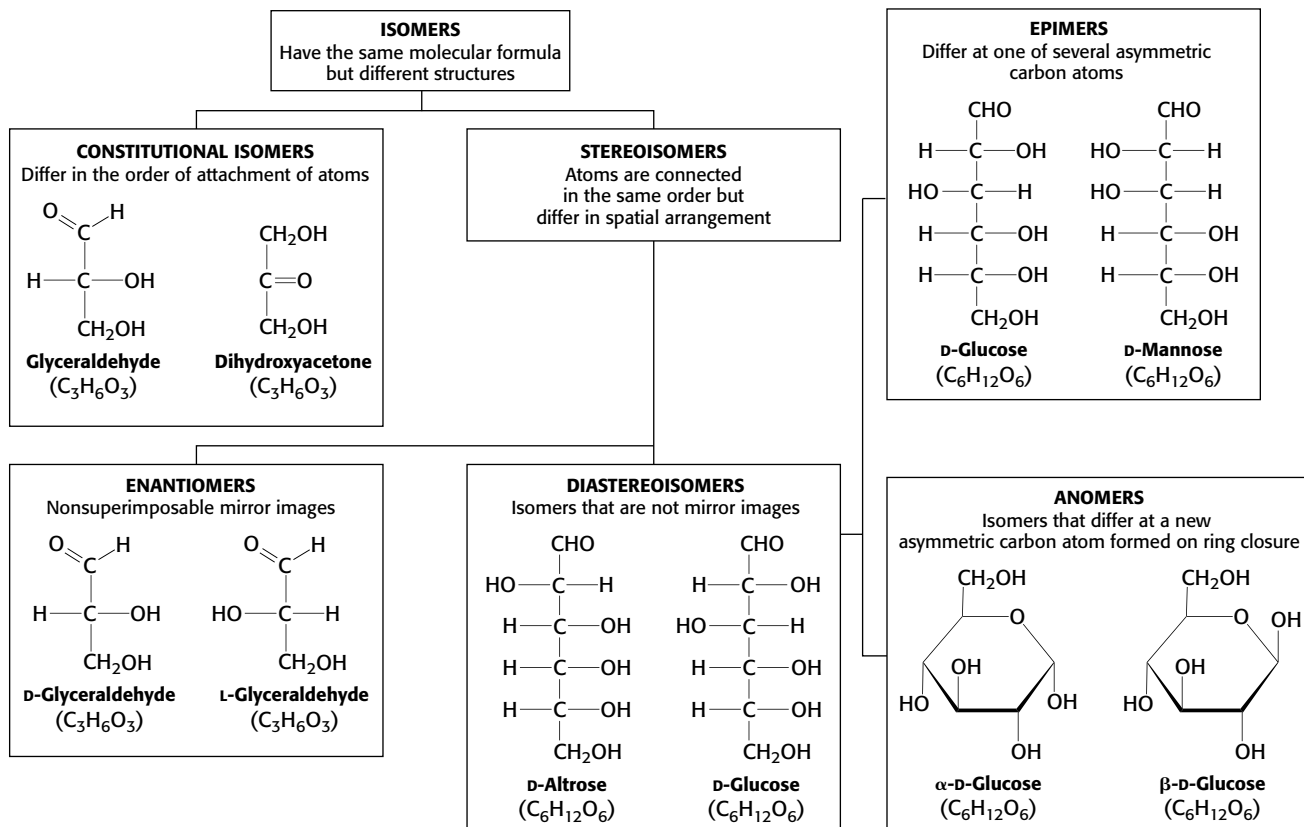

## 11.1 Monosaccharides Are the Simplest Carbohydrates

Carbohydrates are carbon-based molecules that are rich in hydroxyl groups. Indeed, the empirical formula for many carbohydrates is  $(\text{CH}_2\text{O})_n$ —literally, a carbon hydrate. Simple carbohydrates are called *monosaccharides*. These simple sugars serve not only as fuel molecules but also as fundamental constituents of living systems. For instance, DNA has a backbone consisting of alternating phosphoryl groups and deoxyribose, a cyclic five-carbon sugar.

Monosaccharides are aldehydes or ketones that have two or more hydroxyl groups. The smallest monosaccharides, composed of three carbon atoms, are dihydroxyacetone and D- and L-glyceraldehyde.

Dihydroxyacetone is called a *ketose* because it contains a keto group (in red above), whereas glyceraldehyde is called an *aldose* because it contains an aldehyde group (also in red). They are referred to as *trioses* (tri- for three, referring to the three carbon atoms that they contain). Similarly, simple monosaccharides with four, five, six, and seven carbon atoms are called *tetroses*, *pentoses*, *hexoses*, and *heptoses*, respectively. Perhaps the monosaccharides of which we are most aware are the hexoses, such as glucose and

**ANOMERS**  
Isomers that differ at a new asymmetric carbon atom formed on ring closure

 <p><b>α-D-Glucose</b> (C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>)</p>	 <p><b>β-D-Glucose</b> (C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>)</p>

FIGURE 11.1 Isomeric forms of carbohydrates.

fructose. Glucose is an essential energy source for virtually all forms of life. Fructose is commonly used as a sweetener that is converted into glucose derivatives inside the cell.

Carbohydrates can exist in a dazzling variety of isomeric forms (Figure 11.1). Dihydroxyacetone and glyceraldehyde are *constitutional isomers* because they have identical molecular formulas but differ in how the atoms are ordered. *Stereoisomers* are isomers that differ in spatial arrangement. Recall from the discussion of amino acids (p. 29) that stereoisomers are designated as having either D or L configuration. Glyceraldehyde has a single asymmetric carbon atom and, thus, there are two stereoisomers of this sugar: D-glyceraldehyde and L-glyceraldehyde. These molecules are a type of stereoisomer called *enantiomers*, which are mirror images of each other. Most vertebrate monosaccharides have the D configuration. According to convention, the D and L isomers are determined by the configuration of the asymmetric carbon atom farthest from the aldehyde or keto group. Dihydroxyacetone is the only monosaccharide without at least one asymmetric carbon atom.

Monosaccharides made up of more than three carbon atoms have multiple asymmetric carbons, and so they can exist not only as enantiomers but also as *diastereoisomers*, isomers that are not mirror images of each other. The number of possible stereoisomers equals  $2^n$ , where  $n$  is the number of asymmetric carbon atoms. Thus, a six-carbon aldose with 4 asymmetric carbon atoms can exist as 16 possible diastereoisomers, of which glucose is one such isomer.

Figure 11.2 shows the common sugars that we will see most frequently in our study of biochemistry. D-Ribose, the carbohydrate component of RNA, is a five-carbon aldose, as is deoxyribose, the monosaccharide component of deoxynucleotides. D-Glucose, D-mannose, and D-galactose are

**FIGURE 11.2 Common monosaccharides.**

Aldoses contain an aldehyde (shown in blue), whereas ketoses, such as fructose, contain a ketone (shown in red). The asymmetric carbon atom farthest from the aldehyde or ketone (shown in green) designates the structures as being in the D configuration.

abundant six-carbon aldoses. Note that D-glucose and D-mannose differ in configuration only at C-2, the carbon atom in the second position. Sugars that are diastereoisomers differing in configuration at only a single asymmetric center are *epimers*. Thus, D-glucose and D-mannose are epimeric at C-2; D-glucose and D-galactose are epimeric at C-4.

Note that ketoses have one less asymmetric center than aldoses with the same number of carbon atoms. D-Fructose is the most abundant ketohexose.

### Many common sugars exist in cyclic forms

The predominant forms of ribose, glucose, fructose, and many other sugars in solution, as is the case inside the cell, are not open chains. Rather, the open-chain forms of these sugars cyclize into rings. The chemical basis for ring formation is that an aldehyde can react with an alcohol to form a *hemiacetal*.

**Pyran**

For an aldohexose such as glucose, a single molecule provides both the aldehyde and the alcohol: the C-1 aldehyde in the open-chain form of glucose reacts with the C-5 hydroxyl group to form an *intramolecular hemiacetal* (Figure 11.3). The resulting cyclic hemiacetal, a six-membered ring, is called *pyranose* because of its similarity to *pyran*.

Similarly, a ketone can react with an alcohol to form a *hemiketal*.

**Furan**

The C-2 keto group in the open-chain form of a ketohexose, such as fructose, can form an *intramolecular hemiketal* by reacting with either the

**FIGURE 11.3 Pyranose formation.** The open-chain form of glucose cyclizes when the C-5 hydroxyl group attacks the oxygen atom of the C-1 aldehyde group to form an intramolecular hemiacetal. Two anomeric forms, designated  $\alpha$  and  $\beta$ , can result.

C-6 hydroxyl group to form a six-membered cyclic hemiketal or the C-5 hydroxyl group to form a five-membered cyclic hemiketal (Figure 11.4). The five-membered ring is called a *furanose* because of its similarity to *furan*.

**FIGURE 11.4 Furanose formation.** The open-chain form of fructose cyclizes to a five-membered ring when the C-5 hydroxyl group attacks the C-2 ketone to form an intramolecular hemiketal. Two anomers are possible, but only the  $\alpha$  anomer is shown.

The depictions of glucopyranose (glucose) and fructofuranose (fructose) shown in Figures 11.3 and 11.4 are *Haworth projections*. In such projections, the carbon atoms in the ring are not written out. The approximate plane of the ring is perpendicular to the plane of the paper, with the heavy line on the ring projecting toward the reader.

We have seen that carbohydrates can contain many asymmetric carbon atoms. An additional asymmetric center is created when a cyclic hemiacetal is formed, generating yet another diastereoisomeric form of sugars called *anomers*. In glucose, C-1 (the carbonyl carbon atom in the open-chain form) becomes an asymmetric center. Thus, two ring structures can be formed:  $\alpha$ -D-glucopyranose and  $\beta$ -D-glucopyranose (Figure 11.3). For D sugars drawn as Haworth projections in the standard orientation as shown in Figure 11.3, the designation  $\alpha$  means that the hydroxyl group attached to C-1 is on the opposite side of the ring as C-6;  $\beta$  means that the hydroxyl group is on the same side of the ring as C-6. The C-1 carbon atom is called the *anomeric carbon atom*. An equilibrium mixture of glucose contains approximately one-third  $\alpha$  anomer, two-thirds  $\beta$  anomer, and  $<1\%$  of the open-chain form.

The furanose-ring form of fructose also has anomeric forms, in which  $\alpha$  and  $\beta$  refer to the hydroxyl groups attached to C-2, the anomeric carbon atom (Figure 11.4). Fructose forms both pyranose and furanose rings. The

**FIGURE 11.5** Ring structures of fructose. Fructose can form both five-membered furanose (top) and six-membered pyranose (bottom) rings. In each case, both  $\alpha$  and  $\beta$  anomers are possible.

pyranose form predominates in fructose that is free in solution, and the furanose form predominates in many fructose derivatives (Figure 11.5).

$\beta$ -D-Fructopyranose, found in honey, is one of the sweetest chemicals known. The  $\beta$ -D-fructofuranose form is not nearly as sweet. Heating converts  $\beta$ -fructopyranose into the  $\beta$ -fructofuranose form, reducing the sweetness of the solution. For this reason, corn syrup with a high concentration of fructose in the  $\beta$ -D-pyranose form is used as a sweetener in cold, but not hot, drinks. Figure 11.6 shows the common sugars discussed previously in their ring forms.

**FIGURE 11.6** Common monosaccharides in their ring forms.

### Pyranose and furanose rings can assume different conformations

The six-membered pyranose ring is not planar because of the tetrahedral geometry of its saturated carbon atoms. Instead, pyranose rings adopt two classes of conformations, termed chair and boat because of the resemblance to these objects (Figure 11.7). In the chair form, the substituents on the ring carbon atoms have two orientations: axial and equatorial. Axial bonds are nearly perpendicular to the average plane of the ring, whereas equatorial bonds are nearly parallel to this plane. Axial substituents sterically hinder each other if they emerge on the same side of the ring (e.g., 1,3-diaxial groups). In contrast, equatorial substituents are less

crowded. The chair form of  $\beta$ -D-glucopyranose predominates because all axial positions are occupied by hydrogen atoms. The bulkier —OH and —CH<sub>2</sub>OH groups emerge at the less-hindered periphery. The boat form of glucose is disfavored because it is quite sterically hindered.

Furanose rings, like pyranose rings, are not planar. They can be puckered so that four atoms are nearly coplanar and the fifth is about 0.5 Å away from this plane (Figure 11.8). This conformation is called an *envelope form* because the structure resembles an opened envelope with the back flap raised. In the ribose moiety of most biomolecules, either C-2 or C-3 is out of the plane on the same side as C-5. These conformations are called C-2-endo and C-3-endo, respectively.

**FIGURE 11.8** Envelope conformations of  $\beta$ -D-ribose.

The C-3-endo and C-2-endo forms of  $\beta$ -D-ribose are shown. The color indicates the four atoms that lie approximately in a plane.

**FIGURE 11.7** Chair and boat forms of  $\beta$ -D-glucose. The chair form is more stable because hydrogen atoms occupy the axial positions, resulting in less steric hindrance. Abbreviations: a, axial; e, equatorial.

### Glucose is a reducing sugar

Because the  $\alpha$  and  $\beta$  isomers of glucose are in an equilibrium that passes through the open-chain form, glucose has some of the chemical properties of free aldehydes, such as the ability to react with oxidizing agents. For example, glucose can react with cupric ion ( $\text{Cu}^{2+}$ ), reducing it to cuprous ion ( $\text{Cu}^+$ ), while being oxidized to gluconic acid.

 Solutions of cupric ion (known as Fehling's solution) provide a simple test for the presence of sugars such as glucose. Sugars that react are called *reducing sugars*; those that do not are called *nonreducing sugars*. Reducing sugars can often nonspecifically react with a free amino group to form a stable covalent bond. For instance, as a reducing sugar, glucose reacts with hemoglobin to form glycosylated hemoglobin (hemoglobin A1c). Monitoring changes in the amount of glycosylated hemoglobin is an especially useful means of assessing the effectiveness of treatments for diabetes mellitus, a condition characterized by high levels of blood glucose (Section 27.3). Because the glycosylated hemoglobin remains in circulation, the amount of the modified hemoglobin corresponds to the long-term regulation—over several months—of glucose levels. In nondiabetic individuals, less than 6% of the hemoglobin is glycosylated, whereas, in uncontrolled diabetics, almost 10% of the hemoglobin is glycosylated. Although the glycosylation of hemoglobin has no effect on oxygen binding and is thus

benign, similar reducing reactions are often detrimental because the glycosylations alter the normal biochemical function of the modified proteins. These modifications, known as *advanced glycation end products (AGE)*, have been implicated in aging, arteriosclerosis, and diabetes, as well as other pathological conditions.

### Monosaccharides are joined to alcohols and amines through glycosidic bonds

The biochemical properties of monosaccharides can be modified by reaction with other molecules. These modifications increase the biochemical versatility of carbohydrates, enabling them to serve as signal molecules or facilitating their metabolism. Three common reactants are alcohols, amines, and phosphates. A bond formed between the anomeric carbon atom of a carbohydrate and the oxygen atom of an alcohol is called a *glycosidic bond*—specifically, an *O-glycosidic bond*. *O-Glycosidic bonds* are prominent when carbohydrates are linked together to form long polymers and when they are attached to proteins (Figure 11.9). In addition, the anomeric carbon atom of

**FIGURE 11.9 O- and N-glycosidic linkages.** (A) An O-glycosidic bond links glucose to a methyl group in  $\alpha$ -D-methylglucose. (B) An N-glycosidic bond joins ribose to the base adenine in adenosine monophosphate.

a sugar can be linked to the nitrogen atom of an amine to form an *N-glycosidic bond*, such as when nitrogenous bases are attached to ribose units to form nucleosides. Carbohydrates can also be modified by the attachment of functional groups to carbons other than the anomeric carbon (Figure 11.10).

**FIGURE 11.10 Modified monosaccharides.** Carbohydrates can be modified by the addition of substituents (shown in red) other than hydroxyl groups. Such modified carbohydrates are often expressed on cell surfaces.

### Phosphorylated sugars are key intermediates in energy generation and biosyntheses

One sugar modification deserves special note because of its prominence in metabolism. The addition of phosphoryl groups is a common modification of sugars. For instance, the first step in the breakdown of glucose to obtain energy is its conversion into glucose 6-phosphate. Several subsequent

intermediates in this metabolic pathway, such as dihydroxyacetone phosphate and glyceraldehyde 3-phosphate, are phosphorylated sugars.

*Phosphorylation makes sugars anionic*; the negative charge not only prevents these sugars from spontaneously leaving the cell by crossing lipid-bilayer membranes, but also prevents them from interacting with transporters of the unmodified sugar. Moreover, phosphorylation *creates reactive intermediates* that will more readily undergo metabolism. For example, a multiply phosphorylated derivative of ribose plays key roles in the biosyntheses of purine and pyrimidine nucleotides (Chapter 25).

## 11.2 Monosaccharides Are Linked to Form Complex Carbohydrates

Because sugars contain hydroxyl groups, glycosidic bonds can join one monosaccharide to another. *Oligosaccharides* are built by the linkage of two or more monosaccharides by *O*-glycosidic bonds (Figure 11.11). In the disaccharide maltose, for example, two D-glucose residues are joined by a glycosidic linkage between the  $\alpha$ -anomeric form of C-1 on one sugar and the hydroxyl oxygen atom on C-4 of the adjacent sugar. Such a linkage is called an  $\alpha$ -1,4-glycosidic bond. Just as proteins have a directionality defined by the amino and carboxyl termini, oligosaccharides have a directionality defined by their reducing and nonreducing ends. The carbohydrate unit at the reducing end has a free anomeric carbon atom that has reducing activity because it can form the open-chain form, as discussed earlier (p. 321). By convention, this end of the oligosaccharide is still called the reducing end even when it is bound to another molecule such as a protein and thus no longer has reducing properties.

The fact that monosaccharides have multiple hydroxyl groups means that many different glycosidic linkages are possible. For example, consider three monosaccharides: glucose, mannose, and galactose. These molecules can be linked together in the laboratory to form more than 12,000 structures differing in the order of the monosaccharides and the hydroxyl groups participating in the glycosidic linkages. In this section, we will look at some of the most common oligosaccharides found in nature.

### Sucrose, lactose, and maltose are the common disaccharides

A *disaccharide* consists of two sugars joined by an *O*-glycosidic bond. Three abundant disaccharides that we encounter frequently are sucrose, lactose, and maltose (Figure 11.12). *Sucrose* (common table sugar) is obtained commercially from sugar cane or sugar beets. The anomeric carbon atoms of a glucose unit and a fructose unit are joined in this disaccharide; the configuration of this glycosidic linkage is  $\alpha$  for glucose and  $\beta$  for fructose. Sucrose can be cleaved into its component monosaccharides by the enzyme *sucrase*. *Lactose*, the disaccharide of milk, consists of galactose joined to

**FIGURE 11.11 Maltose, a disaccharide.**

Two molecules of glucose are linked by an  $\alpha$ -1,4-glycosidic bond to form the disaccharide maltose. The angles in the bonds to the central oxygen atom do not denote carbon atoms. The angles are added only for ease of illustration. The glucose molecule on the right is capable of assuming the open-chain form, which can act as a reducing agent. The glucose molecule on the left cannot assume the open-chain form, because the C-1 carbon atom is bound to another molecule.

**FIGURE 11.12 Common disaccharides.**

Sucrose, lactose, and maltose are common dietary components. As in Figure 11.11, the angles in the bonds to the central oxygen atoms do not denote carbon atoms.

glucose by a  $\beta$ -1,4-glycosidic linkage. Lactose is hydrolyzed to these monosaccharides by *lactase* in human beings and by  $\beta$ -*galactosidase* in bacteria. In *maltose*, two glucose units are joined by an  $\alpha$ -1,4-glycosidic linkage. Maltose comes from the hydrolysis of large polymeric oligosaccharides such as starch and glycogen and is in turn hydrolyzed to glucose by *maltase*. Sucrase, lactase, and maltase are located on the outer surfaces of epithelial cells lining the small intestine. The cleavage products of sucrose, lactose, and maltose can be further processed to provide energy in the form of ATP.

### Glycogen and starch are storage forms of glucose

Glucose is an important energy source in virtually all life forms. However, free glucose molecules cannot be stored because in high concentrations, glucose will disturb the osmotic balance of the cell, potentially resulting in cell death. The solution is to store glucose as units in a large polymer, which is not osmotically active.

**FIGURE 11.13 Branch point in glycogen.** Two chains of glucose molecules joined by  $\alpha$ -1,4-glycosidic bonds are linked by an  $\alpha$ -1,6-glycosidic bond to create a branch point. Such an  $\alpha$ -1,6-glycosidic bond forms at approximately every 10 glucose units, making glycogen a highly branched molecule.

Large polymeric oligosaccharides, formed by the linkage of multiple monosaccharides, are called *polysaccharides* and play vital roles in energy storage and in maintaining the structural integrity of an organism. If all of the monosaccharide units in a polysaccharide are the same, the polymer is called a *homopolymer*. The most common homopolymer in animal cells is *glycogen*, the storage form of glucose. Glycogen is present in most of our tissues but is most abundant in muscle and liver. As will be considered in detail in Chapter 21, glycogen is a large, branched polymer of glucose residues. Most of the glucose units in glycogen are linked by  $\alpha$ -1,4-glycosidic bonds. The branches are formed by  $\alpha$ -1,6-glycosidic bonds, present about once in 10 units (Figure 11.13).

The nutritional reservoir in plants is the homopolymer *starch*, of which there are two forms. *Amylose*, the unbranched type of starch, consists of glucose residues in  $\alpha$ -1,4 linkage. *Amylopectin*, the branched form, has about 1  $\alpha$ -1,6 linkage per 30  $\alpha$ -1,4 linkages, in similar fashion to glycogen except for its lower degree of branching. More than half the carbohydrate ingested by human beings is starch found in wheat, potatoes, and rice, to name just a few sources.

*Amylopectin*, *amylose*, and *glycogen* are rapidly hydrolyzed by  $\alpha$ -*amylase*, an enzyme secreted by the salivary glands and the pancreas.

### Cellulose, a structural component of plants, is made of chains of glucose

*Cellulose*, the other major polysaccharide of glucose found in plants, serves a structural rather than a nutritional role as an important component of the plant cell wall. *Cellulose is among the most abundant organic compounds in the biosphere*. Some  $10^{15}$  kg of cellulose is synthesized and degraded on Earth each year, an amount 1000 times as great as the

**FIGURE 11.14** Glycosidic bonds determine polysaccharide structure. The  $\beta$ -1,4 linkages favor straight chains, which are optimal for structural purposes. The  $\alpha$ -1,4 linkages favor bent structures, which are more suitable for storage.

combined weight of the human race. Cellulose is an unbranched polymer of glucose residues joined by  $\beta$ -1,4 linkages, in contrast with the  $\alpha$ -1,4 linkage seen in starch and glycogen. This simple difference in stereochemistry yields two molecules with very different properties and biological functions. The  $\beta$  configuration allows cellulose to form very long, straight chains. Fibrils are formed by parallel chains that interact with one another through hydrogen bonds, generating a rigid, supportive structure. The straight chains formed by  $\beta$  linkages are optimal for the construction of fibers having a high tensile strength. The  $\alpha$ -1,4 linkages in glycogen and starch produce a very different molecular architecture: a hollow helix is formed instead of a straight chain (Figure 11.14). The hollow helix formed by  $\alpha$  linkages is well suited to the formation of a more-compact, accessible store of sugar. Although mammals lack cellulases and therefore cannot digest wood and vegetable fibers, cellulose and other plant fibers are still an important constituent of the mammalian diet as a component of dietary fiber. Soluble fiber such as *pectin* (polygalacturonic acid) slows the movement of food through the gastrointestinal tract, allowing improved digestion and the absorption of nutrients. Insoluble fibers, such as cellulose, increase the rate at which digestion products pass through the large intestine. This increase in rate can minimize exposure to toxins in the diet.

We have considered only homopolymers of glucose. However, given the variety of different monosaccharides that can be put together in any number of arrangements, the number of possible polysaccharides is huge. We will consider some of these polysaccharides shortly.

**Galacturonic acid**

### 11.3 Carbohydrates Can Be Linked to Proteins to Form Glycoproteins

A carbohydrate group can be covalently attached to a protein to form a *glycoprotein*. Such modifications are not rare, as 50% of the proteome consists of glycoproteins. We will examine three classes of glycoproteins. The first class is simply referred to as glycoproteins. In glycoproteins of this class, the protein constituent is the largest component by weight. This versatile class plays a variety of biochemical roles. Many glycoproteins

are components of cell membranes, where they take part in processes such as cell adhesion and the binding of sperm to eggs. Other glycoproteins are formed by linking carbohydrates to soluble proteins. Many of the proteins secreted from cells are glycosylated, or modified by the attachment of carbohydrates, including most proteins present in the serum component of blood.

The second class of glycoproteins comprises the *proteoglycans*. The protein component of proteoglycans is conjugated to a particular type of polysaccharide called a *glycosaminoglycan*. Carbohydrates make up a much larger percentage by weight of the proteoglycan compared with simple glycoproteins. Proteoglycans function as structural components and lubricants.

*Mucins*, or *mucoproteins*, are, like proteoglycans, predominantly carbohydrate. *N*-Acetylgalactosamine is usually the carbohydrate moiety bound to the protein in mucins. *N*-Acetylgalactosamine is an example of an *amino sugar*, so named because an amino group replaces a hydroxyl group. Mucins, a key component of mucus, serve as lubricants.

Glycosylation greatly increases the complexity of the proteome. A given protein with several potential glycosylation sites can have many different glycosylated forms (called *glycoforms*), each of which can be generated only in a specific cell type or developmental stage.

### Carbohydrates can be linked to proteins through asparagine (*N*-linked) or through serine or threonine (*O*-linked) residues

Sugars in glycoproteins are attached either to the amide nitrogen atom in the side chain of asparagine (termed an *N-linkage*) or to the oxygen atom in the side chain of serine or threonine (termed an *O-linkage*), as shown in Figure 11.15. An asparagine residue can accept an oligosaccharide only if the residue is part of an Asn-X-Ser or Asn-X-Thr sequence, in which X can be any residue, except proline. However, not all potential sites are glycosylated. Which sites are glycosylated depends on other aspects of the protein structure and on the cell type in which the protein is expressed. All *N*-linked oligosaccharides have in common a pentasaccharide core consisting of three mannose and two *N*-acetylglucosamine residues. Additional sugars are attached to this core to form the great variety of oligosaccharide patterns found in glycoproteins (Figure 11.16).

**FIGURE 11.15 Glycosidic bonds between proteins and carbohydrates.** A glycosidic bond links a carbohydrate to the side chain of asparagine (*N*-linked) or to the side chain of serine or threonine (*O*-linked). The glycosidic bonds are shown in red.

Glc	● Glucose
GlcNAc	■ <i>N</i> -Acetylglucosamine
Man	● Mannose
Sia	◆ Sialic acid

**FIGURE 11.16 *N*-linked oligosaccharides.** A pentasaccharide core (shaded gray) is common to all *N*-linked oligosaccharides and serves as the foundation for a wide variety of *N*-linked oligosaccharides, two of which are illustrated: (A) high-mannose type; (B) complex type.

## The glycoprotein erythropoietin is a vital hormone

Let us look at a glycoprotein present in the blood serum that has dramatically improved treatment for anemia, particularly that induced by cancer chemotherapy. The glycoprotein hormone *erythropoietin* (EPO) is secreted by the kidneys and stimulates the production of red blood cells. EPO is composed of 165 amino acids and is *N*-glycosylated at three asparagine residues and *O*-glycosylated on a serine residue (Figure 11.17). The mature EPO is 40% carbohydrate by weight, and glycosylation enhances the stability of the protein in the blood. Unglycosylated protein has only about 10% of the bioactivity of the glycosylated form because the protein is rapidly removed from the blood by the kidneys. The availability of recombinant human EPO has greatly aided the treatment of anemias. However, some endurance athletes have used recombinant human EPO to increase the red-blood-cell count and hence their oxygen-carrying capacity. Drug-testing laboratories are able to distinguish some forms of prohibited human recombinant EPO from natural EPO in athletes by detecting differences in their glycosylation patterns through the use of isoelectric focusing (p. 73).

Erythropoietin has oligosaccharides linked to three asparagine residues and one serine residue. The structures shown are approximately to scale. See Figure 11.16 for the carbohydrate key. [Drawn from 1BUY.pdf.]

## Glycosylation functions in nutrient sensing

An especially important glycosylation reaction is the covalent attachment of *N*-acetylglucosamine (GlcNAc) to serine or threonine residues of cellular proteins, a reaction catalyzed by *GlcNAc transferase*. The concentration of GlcNAc reflects the active metabolism of carbohydrates, amino acids and fats, indicating that nutrients are abundant (Figure 11.18). More than one thousand proteins are modified by GlcNAcylation, including transcription factors and components of signaling pathways. Interestingly, because the GlcNAcylation sites are also potential phosphorylation sites, *O*-GlcNAc transferase and protein kinases may be involved in cross talk to modulate one another's signaling activity. Like phosphorylation, GlcNAcylation is reversible, with *GlcNAcase* catalyzing the removal of the carbohydrate. Dysregulation of *GlcNAc transferase* has been linked to insulin resistance, diabetes, cancer and neurological pathologies.

## Proteoglycans, composed of polysaccharides and protein, have important structural roles

As stated earlier, proteoglycans are proteins attached to glycosaminoglycans. The glycosaminoglycan makes up as much as 95% of the biomolecule by weight, and so the proteoglycan resembles a polysaccharide more than a protein. Proteoglycans not only function as lubricants and structural components in connective tissue, but also mediate the adhesion of cells to the extracellular matrix, and bind factors that regulate cell proliferation.

The properties of proteoglycans are determined primarily by the glycosaminoglycan component. Many glycosaminoglycans are made of repeating units of disaccharides containing a derivative of an

**FIGURE 11.18** Glycosylation as a nutrient sensor. *N*-acetylglucosamine is attached to proteins when nutrients are abundant.

**FIGURE 11.19 Repeating units in glycosaminoglycans.** Structural formulas for five repeating units of important glycosaminoglycans illustrate the variety of modifications and linkages that is possible. Amino groups are shown in blue and negatively charged groups in red. Hydrogen atoms have been omitted for clarity. The right-hand structure is a glucosamine derivative in each case.

amino sugar, either glucosamine or galactosamine (Figure 11.19). At least one of the two sugars in the repeating unit has a *negatively charged carboxylate or sulfate group*. The major glycosaminoglycans in animals are chondroitin sulfate, keratan sulfate, heparin, dermatan sulfate, and hyaluronate. Recall that heparin acts as an anticoagulant to assist the termination of blood clotting (p. 307). *Mucopolysaccharidoses* are a collection of diseases, such as Hurler disease, that result from the inability to degrade glycosaminoglycans (Figure 11.20). Although precise clinical features vary with the disease, all mucopolysaccharidoses result in skeletal deformities and reduced life expectancies.

**FIGURE 11.20 Hurler disease.** Formerly called gargoylism, Hurler disease is a mucopolysaccharidosis having symptoms that include wide nostrils, a depressed nasal bridge, thick lips and earlobes, and irregular teeth. In Hurler disease, glycosaminoglycans cannot be degraded. The excess of these molecules are stored in the soft tissue of the facial regions, resulting in the characteristic facial features. [Courtesy National MPS Society, [www.mppsociety.org](http://www.mppsociety.org).]

### Proteoglycans are important components of cartilage

Among the best-characterized members of this diverse class is the proteoglycan in the extracellular matrix of cartilage. The proteoglycan *aggrecan* and the protein *collagen* are key components of cartilage. The triple helix of collagen (p. 45) provides structure and tensile strength, whereas aggrecan serves as a shock absorber. The protein component of aggrecan is a large molecule composed of 2397 amino acids. The protein has three globular domains, and the site of glycosaminoglycan attachment is the extended region between globular domains 2 and 3. This linear region contains highly repetitive amino acid sequences, which are sites for the attachment of keratan sulfate and chondroitin sulfate. Many molecules of aggrecan are in turn noncovalently bound through the first globular domain to a very long filament formed by linking together molecules of the glycosaminoglycan hyaluronate (Figure 11.21). Water is bound to the glycosaminoglycans, attracted by the many negative charges. Aggrecan can cushion compressive forces because the absorbed water enables it to spring back after having been deformed. When pressure is exerted, as when the foot hits the ground while walking, water is squeezed from the glycosaminoglycan, cushioning the impact. When the pressure is released, the water rebinds. *Osteoarthritis*, the most common form of arthritis, results when water is lost from proteoglycan with aging. Other forms of arthritis can result from the proteolytic degradation of aggrecan and collagen in the cartilage.

**FIGURE 11.21 Structure of proteoglycan from cartilage.** (A) Electron micrograph of a proteoglycan from cartilage (with false color added). Proteoglycan monomers emerge laterally at regular intervals from opposite sides of a central filament of hyaluronate. (B) Schematic representation. G = globular domain. [(A) Courtesy of Dr. Lawrence Rosenberg. From J. A. Buckwalter and L. Rosenberg. *Collagen Relat. Res.* 3:489–504, 1983.]

In addition to being a key component of structural tissues, glycosaminoglycans are common throughout the biosphere. Chitin is a glycosaminoglycan found in the exoskeleton of insects, crustaceans, and arachnids and is, next to cellulose, the second most abundant polysaccharide in nature (Figure 11.22). Cephalopods such as squid use their razor sharp beaks, which are made of extensively crosslinked chitin, to disable and consume prey.

### Mucins are glycoprotein components of mucus

A third class of glycoproteins is the *mucins* (mucoproteins). In mucins, the protein component is extensively glycosylated at serine or threonine residues by *N*-acetylgalactosamine (Figure 11.10). Mucins are capable of forming large polymeric structures and are common in mucous secretions. These glycoproteins are synthesized by specialized cells in the tracheobronchial, gastrointestinal, and genitourinary tracts. Mucins are abundant in saliva where they function as lubricants.

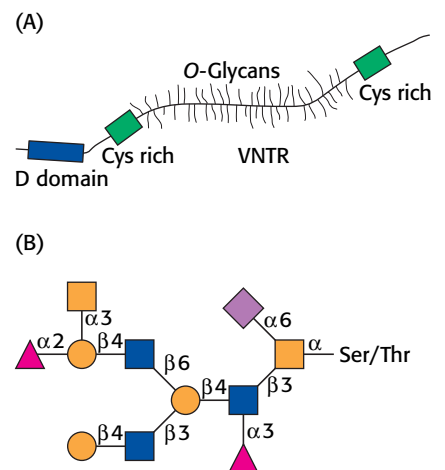

A model of a mucin is shown in Figure 11.23A. The defining feature of the mucins is a region of the protein backbone termed the *variable number of tandem repeats* (VNTR) region, which is rich in serine and threonine residues that are *O*-glycosylated. Indeed, the carbohydrate moiety can account for as much as 80% of the molecule by weight. A number of core carbohydrate structures are conjugated to the protein component of mucin. Figure 11.23B shows one such structure.

Mucins adhere to epithelial cells and act as a protective barrier; they also hydrate the underlying cells. In addition to protecting cells from environmental insults, such as stomach acid, inhaled chemicals in the lungs, and bacterial infections, mucins have roles in fertilization, the immune response, and cell adhesion. Mucins are overexpressed in bronchitis and cystic fibrosis, and the overexpression of mucins is characteristic of adenocarcinomas—cancers of the glandular cells of epithelial origin.

**FIGURE 11.22 Chitin, a glycosaminoglycan, is present in insect wings and the exoskeleton.** Glycosaminoglycans are components of the exoskeletons of insects, crustaceans, and arachnids. [FLPA/Alamy.]

**FIGURE 11.23 Mucin structure.** (A) A schematic representation of a mucoprotein. The VNTR region is highly glycosylated, forcing the molecule into an extended conformation. The Cys-rich domains and the D domain facilitate the polymerization of many such molecules. (B) An example of an oligosaccharide that is bound to the VNTR region of the protein. See Figure 11.16 for the carbohydrate key. [Information from A. Varki et al. (Eds.), *Essentials of Glycobiology*, 2d ed. (Cold Spring Harbor Press, 2009), pp. 117, 118.]

**FIGURE 11.24 Golgi complex and endoplasmic reticulum.** The electron micrograph shows the Golgi complex and adjacent endoplasmic reticulum. The black dots on the cytoplasmic surface of the ER membrane are ribosomes. [Micrograph courtesy of Lynne Mercer.]

## Protein glycosylation takes place in the lumen of the endoplasmic reticulum and in the Golgi complex

The major pathway for protein glycosylation takes place inside the lumen of the *endoplasmic reticulum* (ER) and in the *Golgi complex*, organelles that play central roles in protein trafficking (Figure 11.24). The protein is synthesized by ribosomes attached to the cytoplasmic face of the ER membrane, and the peptide chain is inserted into the lumen of the ER (Section 30.6). The *N*-linked glycosylation begins in the ER and continues in the Golgi complex, whereas the *O*-linked glycosylation takes place exclusively in the Golgi complex.

A large oligosaccharide destined for attachment to the asparagine residue of a protein is assembled on *dolichol phosphate*, a specialized lipid molecule located in the ER membrane and containing about 20 isoprene ( $C_5$ ) units.

The terminal phosphate group of the dolichol phosphate is the site of attachment of the oligosaccharide. This activated (energy-rich) form of the oligosaccharide is subsequently transferred to a specific asparagine residue of the growing polypeptide chain by an enzyme located on the luminal side of the ER.

Proteins in the lumen of the ER and in the ER membrane are transported to the Golgi complex, which is a stack of flattened membranous sacs. *Carbohydrate units of glycoproteins are altered and elaborated in the Golgi complex.* The *O*-linked sugar units are fashioned there, and the *N*-linked sugars, arriving from the ER as a component of a glycoprotein, are modified in many different ways. *The Golgi complex is the major sorting center of the cell.* Proteins proceed from the Golgi complex to lysosomes, secretory granules, or the plasma membrane, according to signals encoded within their amino acid sequences and three-dimensional structures (Figure 11.25).

**FIGURE 11.25 Golgi complex as sorting center.** The Golgi complex is the sorting center in the targeting of proteins to lysosomes, secretory vesicles, and the plasma membrane. The cis face of the Golgi complex receives vesicles from the endoplasmic reticulum, and the trans face sends a different set of vesicles to target sites. Vesicles also transfer proteins from one compartment of the Golgi complex to another. [Courtesy of Dr. Marilyn Farquhar.]

## Specific enzymes are responsible for oligosaccharide assembly

How are the complex carbohydrates formed, be they unconjugated molecules such as glycogen or components of glycoproteins? Complex carbohydrates are synthesized through the action of specific enzymes, *glycosyltransferases*, which catalyze the formation of glycosidic bonds. Given the diversity of known glycosidic linkages, many different enzymes are required. Indeed, glycosyltransferases account for 1% to 2% of gene products in all organisms examined.

While dolichol phosphate-linked oligosaccharides are substrates for some glycosyltransferases, the most common carbohydrate donors for glycosyltransferases are activated sugar nucleotides, such as UDP-glucose (UDP is the abbreviation for uridine diphosphate) (Figure 11.26). The attachment of a nucleotide to enhance the energy content of a molecule is a common strategy in biosynthesis that we will see many times in our study of biochemistry. The acceptor substrates for glycosyltransferases are quite varied and include carbohydrates, serine, threonine, and asparagine residues of proteins, lipids, and even nucleic acids.

## Blood groups are based on protein glycosylation patterns

The human ABO blood groups illustrate the effects of glycosyltransferases on the formation of glycoproteins. Each blood group is designated by the presence of one of the three different carbohydrates, termed A, B, or O, attached to glycoproteins and glycolipids on the surfaces of red blood cells (Figure 11.27). These structures have in common an oligosaccharide foundation called the O (or sometimes H) antigen. The A and B antigens differ from the O antigen by the addition of one extra monosaccharide, either *N*-acetylgalactosamine (for A) or galactose (for B) through an  $\alpha$ -1,3 linkage to a galactose moiety of the O antigen.

Specific glycosyltransferases add the extra monosaccharide to the O antigen. Each person inherits the gene for one glycosyltransferase of this type from each parent. The type A transferase specifically adds *N*-acetylgalactosamine, whereas the type B transferase adds galactose. These enzymes are identical in all but 4 of 354 positions. The O phenotype is the result of a mutation in the O transferase that results in the synthesis of an inactive enzyme.

These structures have important implications for blood transfusions and other transplantation procedures. If an antigen not normally present in a person is introduced, the person's immune system recognizes it as foreign. Red-blood-cell lysis occurs rapidly, leading to a severe drop in blood pressure (hypotension), shock, kidney failure, and death from circulatory collapse.

Why are different blood types present in the human population? Suppose that a pathogenic organism such as a parasite expresses on its cell surface a carbohydrate antigen similar to one of the blood-group antigens. This antigen may not be readily detected as foreign in a person whose blood type matches the parasite antigen, and the parasite will flourish. However, other people with different blood types will be protected. Hence, there will be selective pressure on human beings to vary blood type

**FIGURE 11.26** General form of a glycosyltransferase reaction. The sugar to be added comes from a sugar nucleotide—in this case, UDP-glucose. The acceptor, designated X in this illustration, can be one of a variety of biomolecules, including other carbohydrates or proteins.

**FIGURE 11.27** Structures of A, B, and O oligosaccharide antigens. The carbohydrate structures shown are depicted symbolically by employing a scheme (see the key in Figure 11.16) that is becoming widely used.

**FIGURE 11.28 Formation of a mannose 6-phosphate marker.** A glycoprotein destined for delivery to lysosomes acquires a phosphate marker in the Golgi compartment in a two-step process. First, GlcNAc phosphotransferase adds a phospho-*N*-acetylglucosamine unit to the 6-OH group of a mannose, and then an *N*-acetylglucosaminidase removes the added sugar to generate a mannose 6-phosphate residue in the core oligosaccharide.

to prevent parasitic mimicry and a corresponding selective pressure on parasites to enhance mimicry. The constant “arms race” between pathogenic microorganisms and human beings drives the evolution of diversity of surface antigens within the human population.

### Errors in glycosylation can result in pathological conditions

Although the role of carbohydrate attachment to proteins is not known in detail in most cases, data indicate that this glycosylation is important for the processing and stability of these proteins, as it is for EPO. Certain types of muscular dystrophy can be traced to improper glycosylation of dystroglycan, a membrane protein that links the extracellular matrix with the cytoskeleton. Indeed, an entire family of severe inherited human diseases called *congenital disorders of glycosylation* has been identified. These pathological conditions reveal the importance of proper modification of proteins by carbohydrates and their derivatives.

An especially clear example of the role of glycosylation is provided by *I-cell disease* (also called *mucopolipidosis II*), a lysosomal storage disease. Normally, a carbohydrate marker directs certain digestive enzymes from the Golgi complex to lysosomes. *Lysosomes* are organelles that degrade and recycle damaged cellular components or material brought into the cell by endocytosis. In patients with *I-cell disease*, lysosomes contain large *inclusions* of undigested glycosaminoglycans and glycolipids—hence the “I” in the name of the disease. These inclusions are present because the enzymes normally responsible for the degradation of glycosaminoglycans are missing from affected lysosomes. Remarkably, the enzymes are present at very high levels in the blood and urine. Thus, active enzymes are synthesized, but, in the absence of appropriate glycosylation, they are exported instead of being sequestered in lysosomes. In other words, *in I-cell disease, a whole series of enzymes are incorrectly addressed and delivered to the wrong location*. Normally, these enzymes contain a mannose 6-phosphate residue as a component of an *N*-oligosaccharide that serves as the marker directing the enzymes from the Golgi complex to lysosomes. In *I-cell disease*, however, the attached mannose lacks a phosphate. *I-cell disease* causes the patient to suffer severe psychomotor retardation and skeletal deformities, similar to those in Hurler disease. Remarkably, mutations in the phosphotransferase have also been linked to stuttering. Why some mutations cause stuttering while other cause *I-cell disease* is a mystery.

### Oligosaccharides can be “sequenced”

How is it possible to determine the structure of a glycoprotein—the oligosaccharide structures and their points of attachment? Most approaches make use of enzymes that cleave oligosaccharides at specific types of linkages.

The first step is to detach the oligosaccharide from the protein. For example, *N*-linked oligosaccharides can be released from proteins by an enzyme such as *peptide N-glycosidase F*, which cleaves the *N*-glycosidic bonds linking the oligosaccharide to the protein. The oligosaccharides can then be isolated and analyzed. Matrix-assisted laser desorption/ionization/time-of-flight (MALDI-TOF) or other mass spectrometric techniques (Section 3.3) provide the mass of an oligosaccharide fragment. However, many possible oligosaccharide structures are consistent with a given mass. More-complete information can be obtained by cleaving the oligosaccharide with enzymes of varying specificities. For example,  $\beta\text{-1,4-galactosidase}$

**FIGURE 11.29** Mass spectrometric “sequencing” of oligosaccharides. Carbohydrate-cleaving enzymes were used to release and specifically cleave the oligosaccharide component of the glycoprotein fetuin from bovine serum. Parts A and B show the masses obtained with MALDI-TOF spectrometry as well as the corresponding structures of the oligosaccharide-digestion products: (A) digestion with peptide *N*-glycosidase F (to release the oligosaccharide from the protein) and neuraminidase; (B) digestion with peptide *N*-glycosidase F, neuraminidase, and  $\beta$ -1,4-galactosidase. Knowledge of the enzyme specificities and the masses of the products permits the characterization of the oligosaccharide. See Figure 11.16 for the carbohydrate key. [Data from A. Varki, R. D. Cummings, J. D. Esko, H. H. Freeze, G. W. Hart, and J. Marth (Eds.), *Essentials of Glycobiology* (Cold Spring Harbor Laboratory Press, 1999), p. 596.]

cleaves  $\beta$ -glycosidic bonds exclusively at galactose residues. The products can again be analyzed by mass spectrometry (Figure 11.29). The repetition of this process with the use of an array of enzymes of different specificity will eventually reveal the structure of the oligosaccharide.

Proteases applied to glycoproteins can reveal the points of oligosaccharide attachment. Cleavage by a specific protease yields a characteristic pattern of peptide fragments that can be analyzed chromatographically. Fragments attached to oligosaccharides can be picked out because their chromatographic properties will change on glycosidase treatment. Mass spectrometric analysis or direct peptide sequencing can reveal the identity of the peptide in question and, with additional effort, the exact site of oligosaccharide attachment.

While the sequencing of the human genome is complete, the characterization of the much more complex proteome, including the biological roles of glycosylated proteins, presents a challenge to biochemistry.

## 11.4 Lectins Are Specific Carbohydrate-Binding Proteins

The diversity and complexity of the carbohydrate units and the variety of ways in which they can be joined in oligosaccharides and polysaccharides suggest that they are functionally important. Nature does not construct complex patterns when simple ones suffice. Why all this intricacy and diversity? It is now clear that these carbohydrate structures are the recognition

sites for a special class of proteins. Such proteins, termed *glycan-binding proteins*, bind specific carbohydrate structures on neighboring cell surfaces. Originally discovered in plants, glycan-binding proteins are ubiquitous, and no living organisms have been found that lack these key proteins. We will focus on a particular class of glycan-binding proteins termed *lectins* (from Latin *legere*, “to select”). The interaction of lectins with their carbohydrate partners is another example of carbohydrates being information-rich molecules that guide many biological processes. The diverse carbohydrate structures displayed on cell surfaces are well-suited to serving as sites of interaction between cells and their environments. Interestingly, the partners for lectin binding are often the carbohydrate moiety of glycoproteins.

### Lectins promote interactions between cells

Cell–cell contact is a vital interaction in a host of biochemical functions, ranging from building a tissue from isolated cells to facilitating the transmission of information. The chief function of lectins is to facilitate cell–cell contact. A lectin usually contains two or more carbohydrate-binding sites. The lectins on the surface of one cell interact with arrays of carbohydrates displayed on the surface of another cell. Lectins and carbohydrates are linked by a number of weak noncovalent interactions that ensure specificity yet permit unlinking as needed. The weak interactions between one cell surface and another resemble the action of Velcro; each interaction is weak, but the composite is strong.

We have already met a lectin obliquely. Recall that, in I-cell disease, lysosomal enzymes lack the appropriate mannose 6-phosphate, a molecule that directs the enzymes to the lysosome. Under normal circumstances, the *mannose 6-phosphate receptor*, a lectin, binds the enzymes in the Golgi apparatus and directs them to the lysosome.

### Lectins are organized into different classes

Lectins can be divided into classes on the basis of their amino acid sequences and biochemical properties. One large class is the C type (for calcium-requiring) found in animals. These proteins each have a homologous domain of 120 amino acids that is responsible for carbohydrate binding. The structure of one such domain bound to a carbohydrate target is shown in Figure 11.30.

A calcium ion on the protein acts as a bridge between the protein and the sugar through direct interactions with sugar OH groups. In addition, two glutamate residues in the protein bind to both the calcium ion and the sugar, and other protein side chains form hydrogen bonds with other

**FIGURE 11.30** Structure of a carbohydrate-binding domain of an animal C-type lectin. Notice that a calcium ion links a mannose residue to the lectin. Selected interactions are shown, with some hydrogen atoms omitted for clarity. [Drawn from 2MSC. pdb.]

OH groups on the carbohydrate. The carbohydrate-binding specificity of a particular lectin is determined by the amino acid residues that bind the carbohydrate. C-type lectins function in a variety of cellular activities, including receptor-mediated endocytosis, a process by which soluble molecules are bound to the cell surface and subsequently internalized (Section 26.3), and cell–cell recognition.

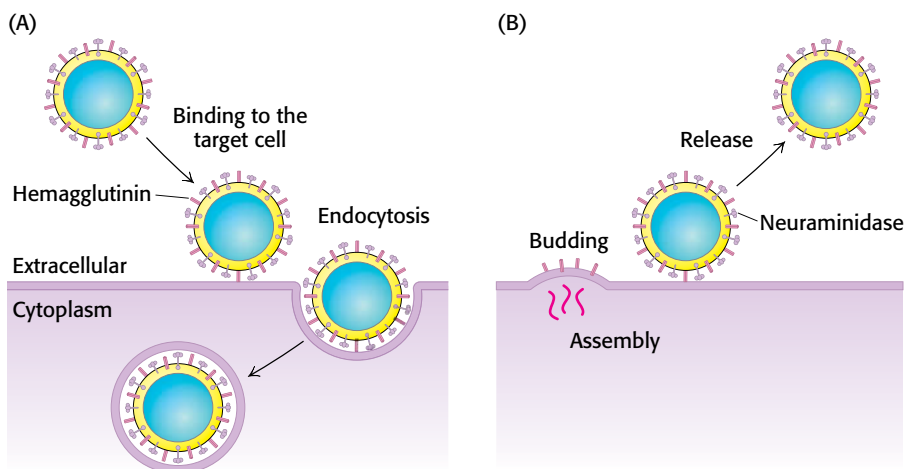

Proteins termed *selectins* are members of the C-type family. Selectins bind immune-system cells to sites of injury in the inflammatory response. The L, E, and P forms of selectins bind specifically to carbohydrates on lymph-node vessels, endothelium, or activated blood platelets, respectively. New therapeutic agents that control inflammation may emerge from a deeper understanding of how selectins bind and distinguish different carbohydrates. *L*-Selectin, originally thought to participate only in the immune response, is produced by embryos when they are ready to attach to the endometrium of the mother's uterus. For a short period of time, the endometrial cells present an oligosaccharide on the cell surface. When the embryo attaches through lectins, the attachment activates signal pathways in the endometrium to make implantation of the embryo possible.

Another large class of lectins comprises the *L*-lectins. These lectins are especially rich in the seeds of leguminous plants, and many of the initial biochemical characterizations of lectins were performed on this readily available lectin. Although the exact role of lectins in plants is unclear, they can serve as potent insecticides. Other *L*-type lectins, such as *calnexin* and *calreticulin*, are prominent chaperones in the eukaryotic endoplasmic reticulum. Recall that chaperones are proteins that facilitate the folding of other proteins (p. 51).

### Influenza virus binds to sialic acid residues

Many pathogens gain entry into specific host cells by adhering to cell-surface carbohydrates. For example, influenza virus recognizes sialic acid residues linked to galactose residues that are present on cell-surface glycoproteins. The viral protein that binds to these sugars is called *hemagglutinin* (Figure 11.31A).

After binding hemagglutinin, the virus is engulfed by the cell and begins to replicate. To exit the cell, a process essentially the reverse of viral entry occurs (Figure 11.31B). Viral assembly results in the budding of the viral particle from the cell. Upon complete assembly, the viral particle is still attached to sialic acid residues of the cell membrane by hemagglutinin on the surface of the new virions. Another viral protein, neuraminidase (sialidase),

**FIGURE 11.31** Viral receptors.

(A) Influenza virus targets cells by binding to sialic acid residues located at the termini of oligosaccharides present on cell-surface glycoproteins and glycolipids. These carbohydrates are bound by hemagglutinin, one of the major proteins expressed on the surface of the virus. (B) When viral replication is complete and the viral particle buds from the cell, the other major viral-surface protein, neuraminidase, cleaves oligosaccharide chains to release the viral particle.

cleaves the glycosidic bonds between the sialic acid residues and the rest of the cellular glycoprotein, freeing the virus to infect new cells, and thus spreading the infection throughout the respiratory tract. Inhibitors of this enzyme such as oseltamivir (Tamiflu) and zanamivir (Relenza) are important anti-influenza agents.

Viral hemagglutinin's carbohydrate-binding specificity may play an important role in species specificity of infection and ease of transmission. For instance, avian influenza H5N1 (bird flu) is especially lethal and is readily spread from bird to bird. Although human beings can be infected by this virus, infection is rare and human-to-human transmission is rarer still. The biochemical basis of these characteristics is that the avian-virus hemagglutinin recognizes a different carbohydrate sequence from that recognized in human influenza. Although human beings have the sequence to which the avian virus binds, it is located deep in the lungs. Infection by the avian virus is thus difficult, and, when it does occur, the avian virus is not readily transmitted by sneezing or coughing.

*Plasmodium falciparum*, the parasitic protozoan that causes malaria, also relies on glycan binding to infect and colonize its host. Glycan-binding proteins of the parasitic form initially injected by the mosquito bind to the glycosaminoglycan heparin sulfate on the liver, initiating the parasite's entry into the cell. On exiting from the liver later in its life cycle, the parasite invades red blood cells by using another glycan-binding protein to bind to the carbohydrate moiety of *glycophorin*, a prominent membrane glycoprotein in red blood cells. Developing means to disrupt the carbohydrate interactions between pathogens and host cells may prove to be clinically useful.

## SUMMARY

### 11.1 Monosaccharides Are the Simplest Carbohydrates

Carbohydrates are aldoses or ketoses that are rich in hydroxyl groups. An aldose is a carbohydrate with an aldehyde group (as in glyceraldehyde and glucose), whereas a ketose contains a keto group (as in dihydroxyacetone and fructose). A sugar belongs to the D series if the absolute configuration of its asymmetric carbon atom farthest from the aldehyde or keto group is the same as that of D-glyceraldehyde. Most naturally occurring sugars belong to the D series. The C-1 aldehyde in the open-chain form of glucose reacts with the C-5 hydroxyl group to form a six-membered pyranose ring. The C-2 keto group in the open-chain form of fructose reacts with the C-5 hydroxyl group to form a five-membered furanose ring. Pentoses such as ribose and deoxyribose also form furanose rings. An additional asymmetric center is formed at the anomeric carbon atom (C-1 in aldoses and C-2 in ketoses) in these cyclizations. The hydroxyl group attached to the anomeric carbon atom is on the opposite side of the ring from the CH<sub>2</sub>OH group attached to the chiral center in the  $\alpha$  anomer, whereas it is on the same side of the ring as the CH<sub>2</sub>OH group in the  $\beta$  anomer. Not all atoms in the ring lie in the same plane. Rather, pyranose rings usually adopt the chair conformation, and furanose rings usually adopt the envelope conformation. Sugars are joined to alcohols and amines by glycosidic bonds from the anomeric carbon atom. For example, N-glycosidic bonds link sugars to purines and pyrimidines in nucleotides, RNA, and DNA.

### 11.2 Monosaccharides Are Linked to Form Complex Carbohydrates

Sugars are linked to one another in disaccharides and polysaccharides by O-glycosidic bonds. Sucrose, lactose, and maltose are the common

disaccharides. Sucrose (common table sugar) consists of  $\alpha$ -glucose and  $\beta$ -fructose joined by a glycosidic linkage between their anomeric carbon atoms. Lactose (in milk) consists of galactose joined to glucose by a  $\beta$ -1,4 linkage. Maltose (from starch) consists of two glucoses joined by an  $\alpha$ -1,4 linkage. Starch is a polymeric form of glucose in plants, and glycogen serves a similar role in animals. Most of the glucose units in starch and glycogen are in  $\alpha$ -1,4 linkage. Cellulose, the major structural polymer of plant cell walls, consists of glucose units joined by  $\beta$ -1,4 linkages. These  $\beta$  linkages give rise to long straight chains that form fibrils with high tensile strength. In contrast, the  $\alpha$  linkages in starch and glycogen lead to open helices, in keeping with their roles as mobilizable energy stores.

### 11.3 Carbohydrates Can Be Linked to Proteins to Form Glycoproteins

Carbohydrates are commonly conjugated to proteins. If the protein component is predominant, the conjugate of protein and carbohydrate is called a glycoprotein. Most secreted proteins, such as the signal molecule erythropoietin, are glycoproteins. Glycoproteins are also prominent on the external surface of the plasma membrane. Proteins bearing covalently linked glycosaminoglycans are proteoglycans. Glycosaminoglycans are polymers of repeating disaccharides. One of the units in each repeat is a derivative of glucosamine or galactosamine. These highly anionic carbohydrates have a high density of carboxylate or sulfate groups. Proteoglycans are found in the extracellular matrices of animals and are key components of cartilage. Mucoproteins, like proteoglycans, are predominantly carbohydrate by weight. The protein component is heavily *O*-glycosylated with *N*-acetylgalactosamine joining the oligosaccharide to the protein. Mucoproteins serve as lubricants.

Glycosyltransferases link the oligosaccharide units on proteins either to the side-chain oxygen atom of a serine or threonine residue or to the side-chain amide nitrogen atom of an asparagine residue. Protein glycosylation takes place in the lumen of the endoplasmic reticulum. The *N*-linked oligosaccharides are synthesized on dolichol phosphate and subsequently transferred to the protein acceptor. Additional sugars are attached in the Golgi complex to form diverse patterns.

### 11.4 Lectins Are Specific Carbohydrate-Binding Proteins

Carbohydrates on cell surfaces are recognized by proteins called lectins. In animals, the interplay of lectins and their sugar targets guides cell–cell contact. The viral protein hemagglutinin on the surface of the influenza virus recognizes sialic acid residues on the surfaces of cells invaded by the virus.

## KEY TERMS

glycobiology (p. 316)

glycomics (p. 316)

monosaccharide (p. 316)

ketose (p. 316)

aldose (p. 316)

constitutional isomer (p. 317)

stereoisomer (p. 317)

enantiomer (p. 317)

diastereoisomer (p. 317)

epimer (p. 318)

hemiacetal (p. 318)

pyranose (p. 318)

hemiketal (p. 318)

furanose (p. 319)

anomer (p. 319)

reducing sugar (p. 321)

nonreducing sugar (p. 321)

advanced glycation end product (AGE)  
(p. 322)

glycosidic bond (p. 322)

oligosaccharide (p. 323)

disaccharide (p. 323)

polysaccharide (p. 324)

glycogen (p. 324)

starch (p. 324)

cellulose (p. 324)

glycoprotein (p. 325)

proteoglycan (p. 326)

glycosaminoglycan (p. 326)

glycoform (p. 326)

mucin (mucoprotein) (p. 329)

endoplasmic reticulum (p. 330)

Golgi complex (p. 330)

dolichol phosphate (p. 330)

glycosyltransferase (p. 331)

glycan-binding protein (p. 334)

lectin (p. 334)

selectin (p. 335)

## PROBLEMS

1. *Word origin.* Account for the origin of the term *carbohydrate*.

2. *Diversity.* How many different oligosaccharides can be made by linking one glucose, one mannose, and one galactose? Assume that each sugar is in its pyranose form. Compare this number with the number of tripeptides that can be made from three different amino acids.

3. *They go together like a horse and carriage.* Match each term with its description.

- |                                |  |
|--------------------------------|--|
| (a) Enantiomers _____          | 1. Has the molecular formula of $(\text{CH}_2\text{O})_n$                |
| (b) Cellulose _____            | 2. Monosaccharides that differ at a single asymmetric carbon atom        |
| (c) Lectins _____              | 3. The storage form of glucose in animals                                |
| (d) Glycosyltransferases _____ | 4. The storage form of glucose in plants                                 |
| (e) Epimers _____              | 5. Glycoprotein containing glycosaminoglycans                            |
| (f) Starch _____               | 6. The most abundant organic molecule in the biosphere                   |
| (g) Carbohydrates _____        | 7. <i>N</i> -Acetylgalactosamine is a key component of this glycoprotein |
| (h) Proteoglycan _____         | 8. Carbohydrate-binding proteins   |
| (i) Mucoprotein _____          | 9. Enzymes that synthesize oligosaccharides                              |
| (j) Glycogen _____             | 10. Stereoisomers that are mirror images of each other                   |

4. *Couples.* Indicate whether each of the following pairs of sugars consists of anomers, epimers, or an aldose–ketose pair:

- D-glyceraldehyde and dihydroxyacetone
- D-glucose and D-mannose
- D-glucose and D-fructose
- $\alpha$ -D-glucose and  $\beta$ -D-glucose

(e) D-ribose and D-ribulose

(f) D-galactose and D-glucose

5. *Carbons and carbonyls.* To which classes of sugars do the monosaccharides shown here belong?

6. *Chemical cousins.* Although an aldose with 4 asymmetric carbon atoms is capable of forming 16 diastereoisomers, only 8 of the isomers are commonly observed, including glucose. They are listed below with their structural relation to glucose. Using the structure of glucose as a reference, draw the structures.

- D-Allose: Epimeric at C-3
- D-Altrose: Isomeric at C-2 and C-3
- D-Mannose: Epimeric at C-2
- D-Gulose: Isomeric at C-3 and C-4
- D-Idose: Isomeric at C-2, C-3 and C-4
- D-Galactose: Epimeric at C-4
- D-Talose: Isomeric at C-2 and C-4

7. *An art project.* Draw the structure of the disaccharide  $\alpha$ -glycosyl-(1 $\rightarrow$ 6)-galactose in the  $\beta$  anomeric form.

8. *Mutarotation.* The specific rotations of the  $\alpha$  and  $\beta$  anomers of D-glucose are +112 degrees and +18.7 degrees, respectively. Specific rotation,  $[\alpha]_D$ , is defined as the observed rotation of light of wavelength 589 nm (the D line of a sodium lamp) passing through 10 cm of a 1 g ml<sup>-1</sup> solution of a sample. When a crystalline sample of  $\alpha$ -D-glucose is dissolved in water, the specific rotation decreases from 112 degrees to an equilibrium value of 52.7 degrees. On the basis of this result, what are the proportions of the  $\alpha$  and  $\beta$  anomers at equilibrium? Assume that the concentration of the open-chain form is negligible.

9. *Telltale marker.* Glucose reacts slowly with hemoglobin and other proteins to form covalent compounds. Why is glucose reactive? What is the nature of the adduct formed?

10. *Periodate cleavage.* Compounds containing hydroxyl groups on adjacent carbon atoms undergo carbon-carbon bond cleavage when treated with periodate ion (IO<sub>4</sub><sup>-</sup>). How can this reaction be used to distinguish between pyranosides and furanosides?

11. *Sugar lineup.* Identify the following four sugars.

12. *Cellular glue.* A trisaccharide unit of a cell-surface glycoprotein is postulated to play a critical role in mediating cell-cell adhesion in a particular tissue. Design a simple experiment to test this hypothesis.

13. *Mapping the molecule.* Each of the hydroxyl groups of glucose can be methylated with reagents such as dimethyl sulfate under basic conditions. Explain how exhaustive methylation followed by the complete digestion of a known amount of glycogen would enable you to determine the number of branch points and reducing ends.

14. *Component parts.* Raffinose is a trisaccharide and a minor constituent in sugar beets.

- Is raffinose a reducing sugar? Explain.
- What are the monosaccharides that compose raffinose?
- $\beta$ -Galactosidase is an enzyme that will remove galactose residues from an oligosaccharide. What are the products of  $\beta$ -galactosidase treatment of raffinose?

15. *Anomeric differences.*  $\alpha$ -D-Mannose is a sweet-tasting sugar.  $\beta$ -D-Mannose, on the other hand, tastes bitter. A pure solution of  $\alpha$ -D-mannose loses its sweet taste with time as it is converted into the  $\beta$  anomer. Draw the  $\beta$  anomer and explain how it is formed from the  $\alpha$  anomer.

16. *A taste of honey.* Fructose in its  $\beta$ -D-pyranose form accounts for the powerful sweetness of honey. The  $\beta$ -D-furanose form, although sweet, is not as sweet as the pyranose form. The furanose form is the more stable form. Draw the two forms and explain why it may not always be wise to cook with honey.

17. *Making ends meet.*

(a) Compare the number of reducing ends to nonreducing ends in a molecule of glycogen.

(b) As we will see in Chapter 21, glycogen is an important fuel-storage form that is rapidly mobilized. At which end—the reducing or nonreducing—would you expect most metabolism to take place?

18. *A lost property.* Glucose and fructose are reducing sugars. Sucrose, or table sugar, is a disaccharide consisting of both fructose and glucose. Is sucrose a reducing sugar? Explain.

19. *Meat and potatoes.* Compare the structures of glycogen and starch.

20. *Straight or with a twist?* Account for the different structures of glycogen and cellulose.

21. *Sweet proteins.* List the key classes of glycoproteins, their defining characteristics, and their biological functions.

22. *Life extender.* What is the function of the carbohydrate moiety that is attached to EPO?

23. *Cushioning.* What is the role of the glycosaminoglycan in the cushioning provided by cartilage?

24. *Undelivered mail. Not returned to sender.* I-cell disease results when proteins normally destined to the lysosomes lack the appropriate carbohydrate-addressing molecule (p. 332). Suggest another possible means by which I-cell disease might arise.

25. *Appropriate peg.* Which amino acids are used for the attachment of carbohydrates to proteins?
26. *From one, many.* What is meant by a glycoform?
27. *Ome.* What is meant by the glycome?
28. *Exponential expansion?* Compare the amount of information inherent in the genome, the proteome, and the glycome.
29. *Attachments.* Suppose, one Sunday afternoon, you are relaxing by reading amino acid sequences of various proteins. Being a bit hungry, you are also thinking of sweet snacks. Combining your interests, you wonder whether you can detect *N*-glycosylation sites by simply looking at amino acid sequence. Your roommate, who is taking a biochemistry course, says “You sure can, to some degree at least, and here’s how.” What did your roommate say to explain?
30. *Locks and keys.* What does the fact that all organisms contain lectins suggest about the role of carbohydrates?
31. *Carbohydrates—not just for breakfast anymore.* Differentiate between a glycoprotein and a lectin.
32. *Carbohydrates and proteomics.* Suppose that a protein contains six potential *N*-linked glycosylation sites. How many possible proteins can be generated, depending on which of these sites is actually glycosylated? Do not include the effects of diversity within the carbohydrate added.

### Chapter Integration Problems

33. *Like a jigsaw puzzle.* Why is it more difficult to determine the structure of the oligosaccharides compared to amino acid sequences or nucleotide sequences?
34. *Stereospecificity.* Sucrose, a major product of photosynthesis in green leaves, is synthesized by a battery of enzymes. The substrates for sucrose synthesis, *D*-glucose and *D*-fructose, are a mixture of  $\alpha$  and  $\beta$  anomers as well as acyclic compounds in solution. Nonetheless, sucrose consists of  $\alpha$ -*D*-glucose linked by its carbon-1 atom to the carbon-2 atom of  $\beta$ -*D*-fructose. How can the specificity of sucrose be explained in light of the potential substrates?
35. *Specific recognition.* How might the technique of affinity chromatography be used to purify lectins?

### Data Interpretation Problem

36. *Sore joints.* A contributing factor to the development of arthritis is the inappropriate proteolytic destruction of the aggrecan component of cartilage by the proteolytic enzyme aggrecanase. The immune-system signal molecule interleukin 2 (IL-2) activates aggrecanase; in fact, IL-2 blockers are sometimes used to treat arthritis. Studies were undertaken to determine whether inhibitors of aggrecanase can counteract the effects of IL-2. Pieces of cartilage were incubated in media with various additions and the amount of aggrecan destruction was measured as a function of time.

[Data from M.A. Pratta et al., *J. Biol. Chem.* 278:45539–45545, 2003, Fig. 7B.]

- (a) Aggrecan degradation was measured by the release of glycosaminoglycan. What is the rationale for this assay?
- (b) Why might glycosaminoglycan release not indicate aggrecan degradation?
- (c) What is the purpose of the control—cartilage incubated with no additions?
- (d) What is the effect of adding IL-2 to the system?
- (e) What is the response when an aggrecanase inhibitor is added in addition to IL-2?
- (f) Why is there some aggrecan destruction in the control with the passage of time?

## Lipids and Cell Membranes

An HIV particle exits an infected cell by membrane budding. Cellular membranes are highly dynamic structures that spontaneously self-assemble. Driven by hydrophobic interactions, as shown in the diagram at right, the fatty acid tails of membrane lipids pack together (green), while the polar heads (red) remain exposed on the surfaces. [Micrographs from Eye of Science/Photo Researchers.]

The boundaries of all cells are defined by *biological membranes* (Figure 12.1), dynamic structures in which proteins float in a sea of lipids. The lipid component prevents molecules generated inside the cell from leaking out and unwanted molecules from diffusing in, while the protein components act as transport systems that allow the cell to take up specific molecules and remove unwanted ones. Such transport systems confer on membranes the important property of *selective permeability*. We will consider these transport systems in greater detail in the next chapter.

In addition to an external cell membrane (called the *plasma membrane*), eukaryotic cells also contain internal membranes that form the boundaries of organelles such as mitochondria, chloroplasts, peroxisomes, and lysosomes. Functional specialization in the course of evolution has been closely linked to the formation of such compartments. Specific systems have evolved to allow the targeting of selected proteins into or through particular internal membranes and, hence, into specific organelles. External and internal membranes share essential properties; these features are the subject of this chapter.

Biological membranes serve several additional functions indispensable for life, such as energy storage and information transduction, that are dictated by the proteins associated with them. In this chapter, we will examine the properties of membrane proteins that enable them to exist in the hydrophobic environment of the membrane while connecting two hydrophilic environments. In the next chapter, we will discuss the functions of these proteins.

## OUTLINE

- 12.1 Fatty Acids Are Key Constituents of Lipids
- 12.2 There Are Three Common Types of Membrane Lipids
- 12.3 Phospholipids and Glycolipids Readily Form Bimolecular Sheets in Aqueous Media
- 12.4 Proteins Carry Out Most Membrane Processes
- 12.5 Lipids and Many Membrane Proteins Diffuse Rapidly in the Plane of the Membrane
- 12.6 Eukaryotic Cells Contain Compartments Bounded by Internal Membranes

**FIGURE 12.1** Electron micrograph of a plasma cell. This image has been colored to indicate the distinct boundary of the cell, formed by its plasma membrane. [Steve Gschmeissner/Photo Researchers.]

## Many Common Features Underlie the Diversity of Biological Membranes

Membranes are as diverse in structure as they are in function. However, they do have in common a number of important attributes:

1. Membranes are *sheetlike structures*, only two molecules thick, that form *closed boundaries* between different compartments. The thickness of most membranes is between 60 Å (6 nm) and 100 Å (10 nm).
2. Membranes consist mainly of *lipids* and *proteins*. The mass ratio of lipids to proteins ranges from 1:4 to 4:1. Membranes also contain *carbohydrates* that are linked to lipids and proteins.
3. Membrane lipids are small molecules that have both *hydrophilic* and *hydrophobic* moieties. These lipids spontaneously form *closed bimolecular sheets* in aqueous media. These *lipid bilayers* are barriers to the flow of polar molecules.
4. *Specific proteins mediate distinctive functions of membranes*. Proteins serve as pumps, channels, receptors, energy transducers, and enzymes. Membrane proteins are embedded in lipid bilayers, which create suitable environments for their action.
5. Membranes are *noncovalent assemblies*. The constituent protein and lipid molecules are held together by many noncovalent interactions, which act cooperatively.
6. Membranes are *asymmetric*. The two faces of biological membranes always differ from each other.
7. Membranes are *fluid structures*. Lipid molecules diffuse rapidly in the plane of the membrane, as do proteins, unless they are anchored by specific interactions. In contrast, lipid molecules and proteins do not readily rotate across the membrane. Membranes can be regarded as *two-dimensional solutions of oriented proteins and lipids*.
8. Most cell membranes are *electrically polarized*, such that the inside is negative [typically  $-60$  millivolts (mV)]. Membrane potential plays a key role in transport, energy conversion, and excitability (Chapter 13).

---

## 12.1 Fatty Acids Are Key Constituents of Lipids

The hydrophobic properties of lipids are essential to their ability to form membranes. Most lipids owe their hydrophobic properties to one component, their fatty acids.

### Fatty acid names are based on their parent hydrocarbons

*Fatty acids* are long hydrocarbon chains of various lengths and degrees of unsaturation that terminate with carboxylic acid groups. The systematic name for a fatty acid is derived from the name of its parent hydrocarbon by the substitution of *oic* for the final *e*. For example, the  $C_{18}$  saturated fatty acid is called *octadecanoic acid* because the parent hydrocarbon is octadecane. A  $C_{18}$  fatty acid with one double bond is called *octadecenoic acid*; with two double bonds, *octadecadienoic acid*; and with three double bonds, *octadecatrienoic acid*. The notation 18:0 denotes a  $C_{18}$  fatty acid with no double bonds, whereas 18:2 signifies that there are two double bonds. The structures of the ionized forms of two common fatty acids—palmitic acid (16:0) and oleic acid (18:1)—are shown in Figure 12.2.

**FIGURE 12.2 Structures of two fatty acids.** Palmitate is a 16-carbon, saturated fatty acid, and oleate is an 18-carbon fatty acid with a single cis double bond.

Fatty acid carbon atoms are numbered starting at the carboxyl terminus, as shown in the margin. Carbon atoms 2 and 3 are often referred to as  $\alpha$  and  $\beta$ , respectively. The methyl carbon atom at the distal end of the chain is called the  $\omega$ -carbon atom. The position of a double bond is represented by the symbol  $\Delta$  followed by a superscript number. For example, *cis*- $\Delta^9$  means that there is a cis double bond between carbon atoms 9 and 10; *trans*- $\Delta^2$  means that there is a trans double bond between carbon atoms 2 and 3. Alternatively, the position of a double bond can be denoted by counting from the distal end, with the  $\omega$ -carbon atom (the methyl carbon) as number 1. An  $\omega$ -3 fatty acid, for example, has the structure shown in the margin. Fatty acids are ionized at physiological pH, and so it is appropriate to refer to them according to their carboxylate form: for example, palmitate or hexadecanoate.

### Fatty acids vary in chain length and degree of unsaturation

Fatty acids in biological systems usually contain an even number of carbon atoms, typically between 14 and 24 (Table 12.1). The 16- and 18-carbon fatty acids are most common. The dominance of fatty acid chains containing an even number of carbon atoms reflects the manner in which fatty acids are biosynthesized (Chapter 26). The hydrocarbon chain is almost invariably unbranched in animal fatty acids. The alkyl chain may be saturated or it may contain one or more double bonds. The configuration of the double bonds in most unsaturated fatty acids is *cis*. The double

**TABLE 12.1** Some naturally occurring fatty acids in animals

Number of carbons	Number of double bonds	Common name	Systematic name	Formula
12	0	Laurate	<i>n</i> -Dodecanoate	$\text{CH}_3(\text{CH}_2)_{10}\text{COO}^-$
14	0	Myristate	<i>n</i> -Tetradecanoate	$\text{CH}_3(\text{CH}_2)_{12}\text{COO}^-$
16	0	Palmitate	<i>n</i> -Hexadecanoate	$\text{CH}_3(\text{CH}_2)_{14}\text{COO}^-$
18	0	Stearate	<i>n</i> -Octadecanoate	$\text{CH}_3(\text{CH}_2)_{16}\text{COO}^-$
20	0	Arachidate	<i>n</i> -Eicosanoate	$\text{CH}_3(\text{CH}_2)_{18}\text{COO}^-$

18	2	Linoleate	<i>cis, cis</i> - $\Delta^9, \Delta^{12}$ -Octadecadienoate	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_2(\text{CH}_2)_6\text{COO}^-$
18	3	Linolenate	all- <i>cis</i> - $\Delta^9, \Delta^{12}, \Delta^{15}$ -Octadecatrienoate	$\text{CH}_3\text{CH}_2(\text{CH}=\text{CHCH}_2)_3(\text{CH}_2)_6\text{COO}^-$
20	4	Arachidonate	all- <i>cis</i> $\Delta^5, \Delta^8, \Delta^{11}, \Delta^{14}$ -Eicosatetraenoate	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_4(\text{CH}_2)_2\text{COO}^-$

bonds in polyunsaturated fatty acids are separated by at least one methylene group.

The properties of fatty acids and of lipids derived from them are markedly dependent on chain length and degree of saturation. Unsaturated fatty acids have lower melting points than do saturated fatty acids of the same length. For example, the melting point of stearic acid is 69.6°C, whereas that of oleic acid (which contains one cis double bond) is 13.4°C. The melting points of polyunsaturated fatty acids of the C<sub>18</sub> series are even lower. Chain length also affects the melting point, as illustrated by the fact that the melting temperature of palmitic acid (C<sub>16</sub>) is 6.5 degrees lower than that of stearic acid (C<sub>18</sub>). Thus, *short chain length and unsaturation enhance the fluidity of fatty acids and of their derivatives.*

## 12.2 There Are Three Common Types of Membrane Lipids

By definition, *lipids are water-insoluble biomolecules that are highly soluble in organic solvents such as chloroform.* Lipids have a variety of biological roles: they serve as fuel molecules, highly concentrated energy stores, signal molecules and messengers in signal-transduction pathways, and components of membranes. The first three roles of lipids will be considered in later chapters. Here, our focus is on lipids as membrane constituents. The three major kinds of membrane lipids are *phospholipids*, *glycolipids*, and *cholesterol*. We begin with lipids found in eukaryotes and bacteria. The lipids in archaea are distinct, although they have many features related to membrane formation in common with lipids of other organisms.

**FIGURE 12.3** Schematic structure of a phospholipid.

### Phospholipids are the major class of membrane lipids

*Phospholipids* are abundant in all biological membranes. A phospholipid molecule is constructed from four components: one or more fatty acids, a platform to which the fatty acids are attached, a phosphate, and an alcohol attached to the phosphate (Figure 12.3). The fatty acid components provide a hydrophobic barrier, whereas the remainder of the molecule has hydrophilic properties that enable interaction with the aqueous environment.

The platform on which phospholipids are built may be *glycerol*, a three-carbon alcohol, or *sphingosine*, a more complex alcohol. Phospholipids derived from glycerol are called *phosphoglycerides*. A phosphoglyceride consists of a glycerol backbone to which are attached two fatty acid chains and a phosphorylated alcohol.

In phosphoglycerides, the hydroxyl groups at C-1 and C-2 of glycerol are esterified to the carboxyl groups of the two fatty acid chains. The C-3 hydroxyl group of the glycerol backbone is esterified to phosphoric acid. When no further additions are made, the resulting compound is *phosphatidate (diacylglycerol 3-phosphate)*, the simplest phosphoglyceride. Only small amounts of phosphatidate are present in membranes. However, the molecule is a key intermediate in the biosynthesis of the other phosphoglycerides (Section 26.1). The absolute configuration of the glycerol 3-phosphate moiety of membrane lipids is shown in Figure 12.4.

**FIGURE 12.4** Structure of phosphatidate (diacylglycerol 3-phosphate). The absolute configuration of the center carbon (C-2) is shown.

The major phosphoglycerides are derived from phosphatidate by the formation of an ester bond between the phosphate group of phosphatidate and the hydroxyl group of one of several alcohols. The common alcohol moieties of phosphoglycerides are the amino acid serine, ethanolamine, choline, glycerol, and inositol.

The structural formulas of phosphatidylcholine and the other principal phosphoglycerides—namely, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, and diphosphatidylglycerol—are given in Figure 12.5.

FIGURE 12.5 Some common phosphoglycerides found in membranes.

*Sphingomyelin* is a phospholipid found in membranes that is not derived from glycerol. Instead, the backbone in sphingomyelin is *sphingosine*, an amino alcohol that contains a long, unsaturated hydrocarbon chain (Figure 12.6). In sphingomyelin, the amino group of the sphingosine backbone is linked to a fatty acid by an amide bond. In addition, the primary hydroxyl group of sphingosine is esterified to phosphorylcholine.

### Membrane lipids can include carbohydrate moieties

The second major class of membrane lipids, *glycolipids*, are *sugar-containing lipids*. Like sphingomyelin, the glycolipids in animal cells are derived

FIGURE 12.6 Structures of sphingosine and sphingomyelin. The sphingosine moiety of sphingomyelin is highlighted in blue.

from sphingosine. The amino group of the sphingosine backbone is acylated by a fatty acid, as in sphingomyelin. Glycolipids differ from sphingomyelin in the identity of the unit that is linked to the primary hydroxyl group of the sphingosine backbone. In glycolipids, one or more sugars (rather than phosphorylcholine) are attached to this group. The simplest glycolipid, called a *cerebroside*, contains a single sugar residue, either glucose or galactose.

More-complex glycolipids, such as *gangliosides*, contain a branched chain of as many as seven sugar residues. Glycolipids are oriented in a completely asymmetric fashion with the *sugar residues always on the extracellular side of the membrane*.

### Cholesterol Is a Lipid Based on a Steroid Nucleus

*Cholesterol*, the third major type of membrane lipid, has a structure that is quite different from that of phospholipids. It is a steroid, built from four linked hydrocarbon rings.

A hydrocarbon tail is linked to the steroid at one end, and a hydroxyl group is attached at the other end. In membranes, the orientation of the molecule is parallel to the fatty acid chains of the phospholipids, and the hydroxyl group interacts with the nearby phospholipid head groups. Cholesterol is absent from prokaryotes but is found to varying degrees in virtually all animal membranes. It constitutes almost 25% of the membrane lipids in certain nerve cells but is essentially absent from some intracellular membranes.

### Archaeal membranes are built from ether lipids with branched chains

The membranes of archaea differ in composition from those of eukaryotes or bacteria in three important ways. Two of these differences clearly relate to the hostile living conditions of many archaea (Figure 12.7). First, the nonpolar chains are joined to a glycerol backbone by ether rather than ester linkages. The ether linkage is more resistant to hydrolysis. Second, the alkyl chains are branched rather than linear. They are built up from repeats of a fully saturated five-carbon fragment. These

**FIGURE 12.7 An archaeon and its environment.** Archaea can thrive in habitats as harsh as a volcanic vent. Here, the archaea form an orange mat surrounded by yellow sulfurous deposits. [Krafft-Explorer/Photo Researchers.]

branched, saturated hydrocarbons are more resistant to oxidation than the unbranched chains of eukaryotic and bacterial membrane lipids. The ability of archaeal lipids to resist hydrolysis and oxidation may help these organisms to withstand the extreme conditions, such as high temperature, low pH, or high salt concentration, under which some of these archaea grow. Finally, the stereochemistry of the central glycerol is inverted compared with that shown in Figure 12.4.

### A membrane lipid is an amphipathic molecule containing a hydrophilic and a hydrophobic moiety

The repertoire of membrane lipids is extensive. However, these lipids possess a critical common structural theme: *membrane lipids are amphipathic molecules* (amphiphilic molecules), that is, they contain both a *hydrophilic* and a *hydrophobic* moiety.

Let us look at a model of a phosphoglyceride, such as phosphatidylcholine. Its overall shape is roughly rectangular (Figure 12.8A). The two hydrophobic fatty acid chains are approximately parallel to each other, whereas the hydrophilic phosphorylcholine moiety points in the opposite direction. Sphingomyelin has a similar conformation, as does the archaeal lipid depicted. Therefore, the following shorthand has been adopted to represent these membrane lipids: the hydrophilic unit, also called the *polar head group*, is represented by a circle, and the hydrocarbon tails are depicted by straight or wavy lines (Figure 12.8B).

**FIGURE 12.9** Diagram of a section of a micelle. Ionized fatty acids readily form such structures, but most phospholipids do not.

**FIGURE 12.10** Diagram of a section of a bilayer membrane.

## 12.3 Phospholipids and Glycolipids Readily Form Bimolecular Sheets in Aqueous Media

What properties enable phospholipids to form membranes? *Membrane formation is a consequence of the amphipathic nature of the molecules.* Their polar head groups favor contact with water, whereas their hydrocarbon tails interact with one another in preference to water. How can molecules with these preferences arrange themselves in aqueous solutions? One way is to form a globular structure called a *micelle*. The polar head groups form the outside surface of the micelle, which is surrounded by water, and the hydrocarbon tails are sequestered inside, interacting with one another (Figure 12.9).

Alternatively, the strongly opposed preferences of the hydrophilic and hydrophobic moieties of membrane lipids can be satisfied by forming a *lipid bilayer*, composed of two lipid sheets (Figure 12.10). A lipid bilayer is also called a *bimolecular sheet*. The hydrophobic tails of each individual sheet interact with one another, forming a hydrophobic interior that acts as a permeability barrier. The hydrophilic head groups interact with the aqueous medium on each side of the bilayer. The two opposing sheets are called leaflets.

*The favored structure for most phospholipids and glycolipids in aqueous media is a bimolecular sheet rather than a micelle.* The reason is that the two fatty acid chains of a phospholipid or a glycolipid are too bulky to fit into the interior of a micelle. In contrast, salts of fatty acids (such as sodium palmitate, a constituent of soap) readily form micelles because they contain only one chain. *The formation of bilayers instead of micelles by phospholipids is of critical biological importance.* A micelle is a limited structure, usually less than 200 Å (20 nm) in diameter. In contrast, a bimolecular sheet can extend to macroscopic dimensions, as much as a millimeter ( $10^7$  Å, or  $10^6$  nm) or more. Phospholipids and related molecules are important membrane constituents because they readily form extensive bimolecular sheets.

Lipid bilayers form spontaneously by a *self-assembly process*. In other words, the structure of a bimolecular sheet is inherent in the structure of the constituent lipid molecules. The growth of lipid bilayers from phospholipids is rapid and spontaneous in water. *Hydrophobic interactions are the major driving force for the formation of lipid bilayers.* Recall that hydrophobic interactions also play a dominant role in the stacking of bases in nucleic acids and in the folding of proteins (Sections 1.3 and 2.4). Water molecules are released from the hydrocarbon tails of membrane lipids as these tails become sequestered in the nonpolar interior of the bilayer. Furthermore, *van der Waals attractive forces between the hydrocarbon tails favor close packing of the tails.* Finally, there are *electrostatic and hydrogen-bonding attractions between the polar head groups and water molecules.* Thus, lipid bilayers are stabilized by the full array of forces that mediate molecular interactions in biological systems. Because lipid bilayers are held together by many *reinforcing, noncovalent interactions (predominantly hydrophobic)*, they are *cooperative structures*. These hydrophobic interactions have three significant biological consequences: (1) lipid bilayers have an inherent tendency to be *extensive*; (2) lipid bilayers will tend to *close on themselves* so that there are no edges with exposed hydrocarbon chains, and so they form compartments; and (3) lipid bilayers are *self-sealing* because a hole in a bilayer is energetically unfavorable.

### Lipid vesicles can be formed from phospholipids

The propensity of phospholipids to form membranes has been used to create an important experimental and clinical tool. *Lipid vesicles, or liposomes,* are aqueous compartments enclosed by a lipid bilayer (Figure 12.11). These structures can be used to study membrane permeability or to deliver chemicals

**FIGURE 12.11 Liposome.** A liposome, or lipid vesicle, is a small aqueous compartment surrounded by a lipid bilayer.

to cells. Liposomes are formed by suspending a suitable lipid, such as phosphatidylcholine, in an aqueous medium, and then *sonicating* (i.e., agitating by high-frequency sound waves) to give a dispersion of closed vesicles that are quite uniform in size. Vesicles formed by this method are nearly spherical and have a diameter of about 500 Å (50 nm). Larger vesicles (of the order of 1 μm or 10<sup>4</sup> Å in diameter) can be prepared by slowly evaporating the organic solvent from a suspension of phospholipid in a mixed-solvent system.

Ions or molecules can be trapped in the aqueous compartments of lipid vesicles by forming the vesicles in the presence of these substances (Figure 12.12). For example, 500-Å-diameter vesicles formed in a 0.1 M glycine solution will trap about 2000 molecules of glycine in each inner aqueous compartment. These glycine-containing vesicles can be separated from the surrounding solution of glycine by dialysis or by gel-filtration chromatography (Section 3.1). The permeability of the bilayer membrane to glycine can then be determined by measuring the rate of efflux of glycine from the inner compartment of the vesicle to the ambient solution. Liposomes can be formed with specific membrane proteins embedded in them by solubilizing the proteins in the presence of detergents and then adding them to the phospholipids from which liposomes will be formed. Protein–liposome complexes provide valuable experimental tools for examining a range of membrane-protein functions.

 Therapeutic applications for liposomes are currently under active investigation. For example, liposomes containing drugs or DNA can be injected into patients. These liposomes fuse with the plasma membrane of many kinds of cells, introducing into the cells the molecules that they contain. Drug delivery with liposomes often lessens its toxicity. Less of the drug is distributed to normal tissues because long-circulating liposomes concentrate in regions of increased blood circulation, such as solid tumors and sites of inflammation. Moreover, the selective fusion of lipid vesicles with particular kinds of cells is a promising means of controlling the delivery of drugs to target cells.

Another well-defined synthetic membrane is a *planar bilayer membrane*. This structure can be formed across a 1-mm hole in a partition between two aqueous compartments by dipping a fine paintbrush into a membrane-forming solution, such as phosphatidylcholine in decane, and stroking the tip of the brush across the hole. The lipid film across the hole thins spontaneously into a lipid bilayer. The electrical conduction properties of this macroscopic bilayer membrane are readily studied by inserting electrodes into each aqueous compartment (Figure 12.13). For example, the permeability of the membrane to ions is determined by measuring the current across the membrane as a function of the applied voltage.

### Lipid bilayers are highly impermeable to ions and most polar molecules

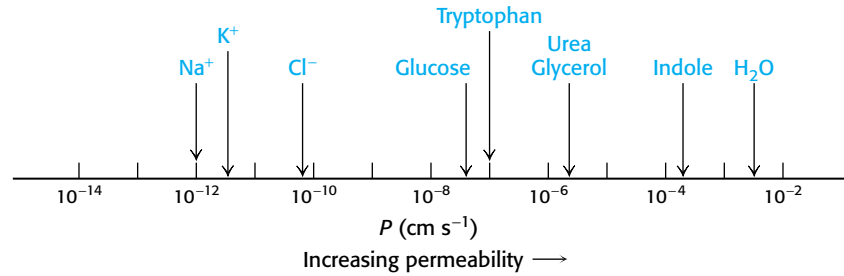

Permeability studies of lipid vesicles and electrical-conductance measurements of planar bilayers have shown that *lipid bilayer membranes have a very low permeability for ions and most polar molecules*. Water is a conspicuous

**FIGURE 12.12 Preparation of glycine-containing liposomes.** Liposomes containing glycine are formed by the sonication of phospholipids in the presence of glycine. Free glycine is removed by gel filtration.

**FIGURE 12.13 Experimental arrangement for the study of a planar bilayer membrane.** A bilayer membrane is formed across a 1-mm hole in a septum that separates two aqueous compartments. This arrangement permits measurements of the permeability and electrical conductance of lipid bilayers.

**FIGURE 12.14** Permeability coefficients ( $P$ ) of ions and molecules in a lipid bilayer. The ability of molecules to cross a lipid bilayer spans a wide range of values.

exception to this generalization; it traverses such membranes relatively easily because of its low molecular weight, high concentration, and lack of a complete charge. The range of measured permeability coefficients is very wide (Figure 12.14). For example,  $\text{Na}^+$  and  $\text{K}^+$  traverse these membranes  $10^9$  times as slowly as does  $\text{H}_2\text{O}$ . Tryptophan, a zwitterion at pH 7, crosses the membrane  $10^3$  times as slowly as does indole, a structurally related molecule that lacks ionic groups. In fact, *the permeability of small molecules is correlated with their solubility in a nonpolar solvent relative to their solubility in water*. This relation suggests that a small molecule might traverse a lipid bilayer membrane in the following way: first, it sheds its solvation shell of water; then, it is dissolved in the hydrocarbon core of the membrane; and, finally, it diffuses through this core to the other side of the membrane, where it becomes resolvated by water. An ion such as  $\text{Na}^+$  traverses membranes very slowly because the replacement of its coordination shell of polar water molecules by nonpolar interactions with the membrane interior is highly unfavorable energetically.

## 12.4 Proteins Carry Out Most Membrane Processes

We now turn to membrane proteins, which are responsible for most of the dynamic processes carried out by membranes. Membrane lipids form a permeability barrier and thereby establish compartments, whereas *specific proteins mediate nearly all other membrane functions*. In particular, proteins transport chemicals and information across a membrane. Membrane lipids create the appropriate environment for the action of such proteins.

Membranes differ in their protein content. Myelin, a membrane that serves as an electrical insulator around certain nerve fibers, has a low content of protein (18%). Relatively pure lipids are well suited for insulation. In contrast, the plasma membranes, or exterior membranes, of most other cells are much more metabolically active. They contain many pumps, channels, receptors, and enzymes. The protein content of these plasma membranes is typically 50%. Energy-transduction membranes, such as the internal membranes of mitochondria and chloroplasts, have the highest content of protein, around 75%.

The protein components of a membrane can be readily visualized by *SDS-polyacrylamide gel electrophoresis*. As stated earlier (p. 73), the electrophoretic mobility of many proteins in SDS-containing gels depends on the mass rather than on the net charge of the protein. The gel-electrophoresis patterns of three membranes—the plasma membrane of erythrocytes, the photoreceptor membrane of retinal rod cells, and the sarcoplasmic reticulum membrane of muscle—are shown in Figure 12.15. It is evident that each of these three membranes contains many proteins but has a distinct protein composition. In general, *membranes performing different functions contain different repertoires of proteins*.

**FIGURE 12.15** SDS-acrylamide gel patterns of membrane proteins.

## Proteins associate with the lipid bilayer in a variety of ways

The ease with which a protein can be dissociated from a membrane indicates how intimately it is associated with the membrane. Some membrane proteins can be solubilized by relatively mild means, such as extraction by a solution of high ionic strength (e.g., 1 M NaCl). Other membrane proteins are bound much more tenaciously; they can be solubilized only by using a detergent or an organic solvent. Membrane proteins can be classified as being either *peripheral* or *integral* on the basis of this difference in dissociability (Figure 12.16). *Integral membrane proteins* interact extensively with the hydrocarbon chains of membrane lipids, and they can be released only by agents that compete for these nonpolar interactions. In fact, most integral membrane proteins span the lipid bilayer. In contrast, *peripheral membrane proteins* are bound to membranes primarily by electrostatic and hydrogen-bond interactions with the head groups of lipids. These polar interactions can be disrupted by adding salts or by changing the pH. Many peripheral membrane proteins are bound to the surfaces of integral proteins, on either the cytoplasmic or the extracellular side of the membrane. Others are anchored to the lipid bilayer by a covalently attached hydrophobic chain, such as a fatty acid.

## Proteins interact with membranes in a variety of ways

Membrane proteins are more difficult to purify and crystallize than are water-soluble proteins. Nonetheless, researchers using x-ray crystallographic or electron microscopic methods have determined the three-dimensional structures of more than 2000 such proteins at sufficiently high resolution to discern the molecular details. As noted in Chapter 2, membrane proteins differ from soluble proteins in the distribution of hydrophobic and hydrophilic groups. We will consider the structures of three membrane proteins in some detail.

**Proteins can span the membrane with alpha helices.** The first membrane protein that we consider is the archaeal protein *bacteriorhodopsin*, shown in Figure 12.17. This protein uses light energy to transport protons from inside to outside the cell, generating a proton gradient used to form ATP.

**FIGURE 12.16 Integral and peripheral membrane proteins.** Integral membrane proteins (*a* and *b*) interact extensively with the hydrocarbon region of the bilayer. Most known integral membrane proteins traverse the lipid bilayer. Peripheral membrane proteins interact with the polar head groups of the lipids (*c*) or bind to the surfaces of integral proteins (*d*). Other proteins are tightly anchored to the membrane by a covalently attached lipid molecule (*e*).

**FIGURE 12.17 Structure of bacteriorhodopsin.** Notice that bacteriorhodopsin consists largely of membrane-spanning  $\alpha$  helices (represented by yellow cylinders). **FIGURE 12.18 Amino acid sequence of bacteriorhodopsin.** The seven helical regions are highlighted in yellow and the charged residues in red.

Bacteriorhodopsin is built almost entirely of  $\alpha$  helices; seven closely packed  $\alpha$  helices, nearly perpendicular to the plane of the cell membrane, span its 45-Å width. Examination of the primary structure of bacteriorhodopsin reveals that most of the amino acids in these membrane-spanning  $\alpha$  helices are nonpolar and only a very few are charged (Figure 12.18). This distribution of nonpolar amino acids is sensible because these residues are either in contact with the hydrocarbon core of the membrane or with one another. *Membrane-spanning  $\alpha$  helices are the most common structural motif in membrane proteins.* As will be considered in Section 12.5, such regions can often be detected by examining amino acid sequence alone.

**A channel protein can be formed from beta strands.** Porin, a protein from the outer membranes of bacteria such as *E. coli* and *Rhodobacter capsulatus*, represents a class of membrane proteins with a completely different type of structure. Structures of this type are built from  $\beta$  strands and contain essentially no  $\alpha$  helices (Figure 12.19).

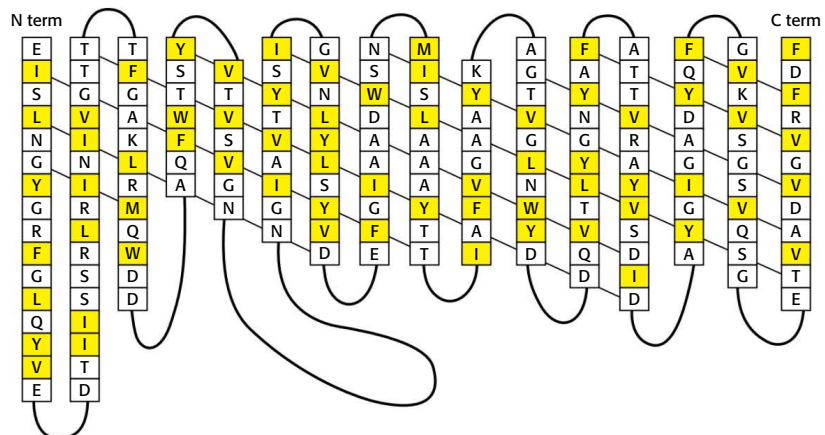

The arrangement of  $\beta$  strands is quite simple: each strand is hydrogen bonded to its neighbor in an antiparallel arrangement, forming a single  $\beta$  sheet. The  $\beta$  sheet curls up to form a hollow cylinder that, as its name suggests, forms a pore, or channel, in the membrane. The outside surface of porin is appropriately

nonpolar, given that it interacts with the hydrocarbon core of the membrane. In contrast, the inside of the channel is quite hydrophilic and is filled with water. This arrangement of nonpolar and polar surfaces is accomplished by the alternation of hydrophobic and hydrophilic amino acids along each  $\beta$  strand (Figure 12.20).

**FIGURE 12.19 Structure of bacterial porin (from *Rhodopseudomonas blastica*).** Notice that this membrane protein is built entirely of  $\beta$  strands. (A) Side view. (B) View from the periplasmic space. Only one monomer of the trimeric protein is shown. [Drawn from 1PRN.pdb.]

**FIGURE 12.20 Amino acid sequence of a porin.** Some membrane proteins, such as porins, are built from  $\beta$  strands that tend to have hydrophobic and hydrophilic amino acids in adjacent positions. The secondary structure of porin from *Rhodopseudomonas blastica* is shown, with the diagonal lines indicating the direction of hydrogen bonding along the  $\beta$  sheet. Hydrophobic residues (F, I, L, M, V, W, and Y) are shown in yellow. These residues tend to lie on the outside of the structure, in contact with the hydrophobic core of the membrane.

**Embedding part of a protein in a membrane can link the protein to the membrane surface.** The structure of the endoplasmic reticulum membrane-bound enzyme prostaglandin H<sub>2</sub> synthase-1 reveals a rather different role for  $\alpha$  helices in protein–membrane associations. This enzyme catalyzes the conversion of arachidonic acid into prostaglandin H<sub>2</sub> in two steps: (1) a cyclooxygenase reaction and (2) a peroxidase reaction (Figure 12.21). Prostaglandin H<sub>2</sub> promotes inflammation and modulates gastric acid secretion. The enzyme that produces prostaglandin H<sub>2</sub> is a homodimer with a rather complicated structure consisting primarily of  $\alpha$  helices. Unlike bacteriorhodopsin, this protein is not largely embedded in the membrane. Instead, it lies along the outer surface of the membrane, firmly bound by a set of  $\alpha$  helices with hydrophobic surfaces that extend from the bottom of the protein into the membrane (Figure 12.22). This linkage is sufficiently strong that only the action of detergents can release the protein from the membrane. Thus, this enzyme is classified as an integral membrane protein, although it does not span the membrane.

**FIGURE 12.22 Attachment of prostaglandin H<sub>2</sub> synthase-1 to the membrane.** Notice that prostaglandin H<sub>2</sub> synthase-1 is held in the membrane by a set of  $\alpha$  helices (orange) coated with hydrophobic side chains. One monomer of the dimeric enzyme is shown. [Drawn from 1PTH.pdb.]

The localization of prostaglandin H<sub>2</sub> synthase-1 in the membrane is crucial to its function. The substrate for this enzyme, arachidonic acid, is a hydrophobic molecule generated by the hydrolysis of membrane lipids. Arachidonic acid reaches the active site of the enzyme from the membrane without entering an aqueous environment by traveling through a hydrophobic channel in the protein (Figure 12.23). Indeed, nearly all of us have experienced the importance of this channel: drugs such as aspirin and ibuprofen block the channel and prevent prostaglandin synthesis by inhibiting the cyclooxygenase activity of the synthase. In particular, aspirin acts through the transfer of its acetyl group to a serine residue (Ser 530) that lies along the path to the active site (Figure 12.24).

Two important features emerge from our examination of these three examples of membrane-protein structure.

**FIGURE 12.21 Formation of prostaglandin H<sub>2</sub>.** Prostaglandin H<sub>2</sub> synthase-1 catalyzes the formation of prostaglandin H<sub>2</sub> from arachidonic acid in two steps.

**FIGURE 12.23 Hydrophobic channel of prostaglandin H<sub>2</sub> synthase-1.** A view of prostaglandin H<sub>2</sub> synthase-1 from the membrane shows the hydrophobic channel that leads to the active site. The membrane-anchoring helices are shown in orange. [Drawn from 1PTH.pdb.]

**Aspirin**  
(Acetylsalicylic acid)

**FIGURE 12.24 Aspirin's effects on prostaglandin H<sub>2</sub> synthase-1.** Aspirin acts by transferring an acetyl group to a serine residue in prostaglandin H<sub>2</sub> synthase-1.

First, the parts of the protein that interact with the hydrophobic parts of the membrane are coated with nonpolar amino acid side chains, whereas those parts that interact with the aqueous environment are much more hydrophilic. Second, the structures positioned within the membrane are quite regular and, in particular, all backbone hydrogen-bond donors and acceptors participate in hydrogen bonds. *Breaking a hydrogen bond within a membrane is quite unfavorable, because little or no water is present to compete for the polar groups.*

### Some proteins associate with membranes through covalently attached hydrophobic groups

The membrane proteins considered thus far associate with the membrane through surfaces generated by hydrophobic amino acid side chains. However, even otherwise soluble proteins can associate with membranes if hydrophobic groups are attached to the proteins. Three such groups are shown in Figure 12.25: (1) a palmitoyl group attached to a specific cysteine residue by a thioester bond, (2) a farnesyl group attached to a cysteine residue at the carboxyl terminus, and (3) a glycolipid structure termed a glycosylphosphatidylinositol (GPI) anchor attached to the carboxyl terminus. These modifications are attached by enzyme systems that recognize specific signal sequences near the site of attachment.

**S-Palmitoylcysteine**

**C-terminal S-farnesylcysteine methyl ester**

**Glycosylphosphatidylinositol (GPI) anchor**

**FIGURE 12.25 Membrane anchors.** Membrane anchors are hydrophobic groups that are covalently attached to proteins (in blue) and tether the proteins to the membrane. The green circles and blue square correspond to mannose and  $\beta$ -D-acetylglucosamine (GlcNAc), respectively. R groups represent points of additional modification.

### Transmembrane helices can be accurately predicted from amino acid sequences

Many membrane proteins, like bacteriorhodopsin, employ  $\alpha$  helices to span the hydrophobic part of a membrane. As noted earlier, most of the residues in these  $\alpha$  helices are nonpolar and almost none of them are charged. Can we use this information to identify likely membrane-spanning regions from sequence data alone? One approach to identifying transmembrane helices is to ask whether a postulated helical segment is likely to be more stable in a hydrocarbon environment or in water. Specifically, we want to estimate the

free-energy change when a helical segment is transferred from the interior of a membrane to water. Free-energy changes for the transfer of individual amino acid residues from a hydrophobic to an aqueous environment are given in Table 12.2. For example, the transfer of a helix formed entirely of L-arginine residues, a positively charged amino acid, from the interior of a membrane to water would be highly favorable [ $-51.5 \text{ kJ mol}^{-1}$  ( $-12.3 \text{ kcal mol}^{-1}$ ) per arginine residue in the helix]. In contrast, the transfer of a helix formed entirely of L-phenylalanine, a hydrophobic amino acid, would be unfavorable [ $+15.5 \text{ kJ mol}^{-1}$  ( $+3.7 \text{ kcal mol}^{-1}$ ) per phenylalanine residue in the helix].

The hydrocarbon core of a membrane is typically  $30 \text{ \AA}$  wide, a length that can be traversed by an  $\alpha$  helix consisting of 20 residues. We can take the amino acid sequence of a protein and estimate the free-energy change that takes place when a hypothetical  $\alpha$  helix formed of residues 1 through 20 is transferred from the membrane interior to water. The same calculation can be made for residues 2 through 21, 3 through 22, and so forth, until we reach the end of the sequence. The span of 20 residues chosen for this calculation is called a *window*. The free-energy change for each window is plotted against the first amino acid at the window to create a *hydropathy plot*. Empirically, a peak of  $+84 \text{ kJ mol}^{-1}$  ( $+20 \text{ kcal mol}^{-1}$ ) or more in a hydropathy plot based on a window of 20 residues indicates that a polypeptide segment could be a membrane-spanning  $\alpha$  helix. For example, glycophorin, a protein found in the membranes of red blood cells, is predicted by this criterion to have one membrane-spanning helix, in agreement with experimental findings (Figure 12.26). Note, however, that a peak in the hydropathy plot does not prove that a segment is a transmembrane helix. Even soluble proteins may have highly nonpolar regions. Conversely, some membrane proteins contain membrane-spanning features (such as

**TABLE 12.2** Polarity scale for identifying transmembrane helices

Amino acid residue	Transfer free energy in $\text{kJ mol}^{-1}$ ( $\text{kcal mol}^{-1}$ )
Phe	15.5 (3.7)

a set of cylinder-forming  $\beta$  strands) that escape detection by these plots (Figure 12.27).

## 12.5 Lipids and Many Membrane Proteins Diffuse Rapidly in the Plane of the Membrane

Biological membranes are not rigid, static structures. On the contrary, lipids and many membrane proteins are constantly in lateral motion, a process called *lateral diffusion*. The rapid lateral movement of membrane proteins has been visualized by means of fluorescence microscopy using the technique of *fluorescence recovery after photobleaching* (FRAP; Figure 12.28). First, a cell-surface component is specifically labeled with a fluorescent chromophore. A small region of the cell surface ( $\sim 3 \mu\text{m}^2$ ) is viewed through a fluorescence microscope. The fluorescent molecules in this region are then destroyed (bleached) by a very intense light pulse from a laser, as indicated by the pale spot in Figure 12.28B. The fluorescence of this region is subsequently monitored as a function of time by using a light level sufficiently low to prevent further bleaching. If the labeled component is mobile, bleached molecules leave and unbleached molecules enter the illuminated region, resulting in an increase in the fluorescence intensity. The rate of recovery of fluorescence depends on the lateral mobility of the fluorescence-labeled component, which can be expressed in terms of a diffusion coefficient,  $D$ . The average distance  $S$  traversed in time  $t$  depends on  $D$  according to the expression

$$S = (4Dt)^{1/2}$$

The diffusion coefficient of lipids in a variety of membranes is about  $1 \mu\text{m}^2 \text{s}^{-1}$ . Thus, a phospholipid molecule diffuses an average distance of  $2 \mu\text{m}$  in 1 s. This rate means that *a lipid molecule can travel from one end of a bacterium to the other in a second*. The magnitude of the observed diffusion coefficient indicates that the viscosity of the membrane is about 100 times that of water, rather like that of olive oil.

### FIGURE 12.28 Fluorescence recovery after photobleaching (FRAP) technique.

(A) The cell surface fluoresces because of a labeled surface component. (B) The fluorescent molecules of a small part of the surface are bleached by an intense light pulse. (C) The fluorescence intensity recovers as bleached molecules diffuse out of the region and unbleached molecules diffuse into it. (D) The rate of recovery depends on the diffusion coefficient.

In contrast, proteins vary markedly in their lateral mobility. *Some proteins are nearly as mobile as lipids, whereas others are virtually immobile.* For example, the photoreceptor protein rhodopsin (Section 33.3), a very mobile protein, has a diffusion coefficient of  $0.4 \mu\text{m}^2 \text{s}^{-1}$ . The rapid movement of rhodopsin is essential for fast signaling. At the other extreme is fibronectin, a peripheral glycoprotein that interacts with the extracellular matrix. For fibronectin,  $D$  is less than  $10^{-4} \mu\text{m}^2 \text{s}^{-1}$ . Fibronectin has a very low mobility because it is anchored to actin filaments on the inside of the plasma membrane through *integrin*, a transmembrane protein that links the extracellular matrix to the cytoskeleton.

### The fluid mosaic model allows lateral movement but not rotation through the membrane

On the basis of the mobility of proteins in membranes, in 1972 S. Jonathan Singer and Garth Nicolson proposed a *fluid mosaic model* to describe the overall organization of biological membranes. The essence of their model is that *membranes are two-dimensional solutions of oriented lipids and globular proteins.* The lipid bilayer has a dual role: it is both a *solvent* for integral membrane proteins and a *permeability barrier*. Membrane proteins are free to diffuse laterally in the lipid matrix unless restricted by special interactions.

Although the lateral diffusion of membrane components can be rapid, the spontaneous rotation of lipids from one face of a membrane to the other is a very slow process. The transition of a molecule from one membrane surface to the other is called *transverse diffusion* or *flip-flop* (Figure 12.29). The flip-flop of phospholipid molecules in phosphatidylcholine vesicles has been directly measured by electron spin resonance techniques, which show that *a phospholipid molecule flip-flops once in several hours.* Thus, a phospholipid molecule takes about  $10^9$  times as long to flip-flop across a membrane as it takes to diffuse a distance of  $50 \text{ \AA}$  in the lateral direction. The free-energy barriers to flip-flopping are even larger for protein molecules than for lipids because proteins have more-extensive polar regions. In fact, the flip-flop of a protein molecule has not been observed. Hence, *membrane asymmetry can be preserved for long periods.*

### Membrane fluidity is controlled by fatty acid composition and cholesterol content

Many membrane processes, such as transport or signal transduction, depend on the fluidity of the membrane lipids, which in turn depends on the properties of fatty acid chains. Fatty acid chains in membrane bilayers can exist in an ordered, rigid state or in a relatively disordered, fluid state. The transition from the rigid to the fluid state takes place abruptly as the temperature is raised above  $T_m$ , the melting temperature (Figure 12.30). *This transition temperature depends on the length of the fatty acid chains and on their degree of unsaturation* (Table 12.3). The presence of saturated fatty

**TABLE 12.3** The melting temperature of phosphatidylcholine containing different pairs of identical fatty acid chains

Number of carbons	Number of double bonds	Fatty acid			$T_m$ ( $^{\circ}\text{C}$ )
		Common name	Systematic name		
22	0	Behenate	<i>n</i> -Docosanoate	75	
18	0	Stearate	<i>n</i> -Octadecanoate	58	
16	0	Palmitate	<i>n</i> -Hexadecanoate	41	
14	0	Myristate	<i>n</i> -Tetradecanoate	24	
18	1	Oleate	<i>cis</i> - $\Delta^9$ -Octadecenoate	-22	

**FIGURE 12.29** Lipid movement in membranes. Lateral diffusion of lipids is much more rapid than transverse diffusion (flip-flop).

**FIGURE 12.30** The phase-transition, or melting, temperature ( $T_m$ ) for a phospholipid membrane. As the temperature is raised, the phospholipid membrane changes from a packed, ordered state to a more random one.

**FIGURE 12.31 Packing of fatty acid chains in a membrane.** The highly ordered packing of fatty acid chains is disrupted by the presence of cis double bonds. The space-filling models show the packing of (A) three molecules of stearate (C<sub>18</sub>, saturated) and (B) a molecule of oleate (C<sub>18</sub>, unsaturated) between two molecules of stearate.

acid residues favors the rigid state because their straight hydrocarbon chains interact very favorably with one another. On the other hand, a *cis* double bond produces a bend in the hydrocarbon chain. This bend interferes with a highly ordered packing of fatty acid chains, and so  $T_m$  is lowered (Figure 12.31). The length of the fatty acid chain also affects the transition temperature. Long hydrocarbon chains interact more strongly than do short ones. Specifically, each additional  $-\text{CH}_2-$  group makes a favorable contribution of about  $-2 \text{ kJ mol}^{-1}$  ( $-0.5 \text{ kcal mol}^{-1}$ ) to the free energy of interaction of two adjacent hydrocarbon chains.

*Bacteria regulate the fluidity of their membranes by varying the number of double bonds and the length of their fatty acid chains.* For example, the ratio of saturated to unsaturated fatty acid chains in the *E. coli* membrane decreases from 1.6 to 1.0 as the growth temperature is lowered from 42°C to 27°C. This decrease in the proportion of saturated residues prevents the membrane from becoming too rigid at the lower temperature.

*In animals, cholesterol is the key regulator of membrane fluidity.* Cholesterol contains a bulky steroid nucleus with a hydroxyl group at one end and a flexible hydrocarbon tail at the other end. Cholesterol inserts into bilayers with its long axis perpendicular to the plane of the membrane. The hydroxyl group of cholesterol forms a hydrogen bond with a carbonyl oxygen atom of a phospholipid head group, whereas the hydrocarbon tail of cholesterol is located in the nonpolar core of the bilayer. The different shape of cholesterol compared with that of phospholipids disrupts the regular interactions between fatty acid chains (Figure 12.32).

**FIGURE 12.32 Cholesterol disrupts the tight packing of the fatty acid chains.** [Information from S. L. Wolfe, *Molecular and Cellular Biology* (Wadsworth, 1993).]

### Lipid rafts are highly dynamic complexes formed between cholesterol and specific lipids

In addition to its nonspecific effects on membrane fluidity, cholesterol can form specific complexes with lipids that contain the sphingosine backbone, including sphingomyelin and certain glycolipids, and with GPI-anchored proteins. These complexes concentrate within small (10–200 nm) and highly dynamic regions within membranes. The resulting structures are often referred to as *lipid rafts*. One result of these interactions is the *moderation of membrane fluidity*, making membranes less fluid but at the same time less subject to phase transitions. The presence of lipid rafts thus represents a modification of the original fluid mosaic model for biological membranes. Although their small size and dynamic nature have made them very difficult to study, it appears that lipid rafts may play a role in concentrating proteins that participate in signal transduction pathways and may also serve to regulate membrane curvature and budding.

### All biological membranes are asymmetric

Membranes are structurally and functionally asymmetric. The outer and inner surfaces of *all known biological membranes have different components and different*

*enzymatic activities.* A clear-cut example is the pump that regulates the concentration of  $\text{Na}^+$  and  $\text{K}^+$  ions in cells (Figure 12.33). This transport protein is located in the plasma membrane of nearly all cells in higher organisms. The  $\text{Na}^+-\text{K}^+$  pump is oriented so that it pumps  $\text{Na}^+$  out of the cell and  $\text{K}^+$  into it. Furthermore, ATP must be on the inside of the cell to drive the pump. Ouabain, a specific inhibitor of the pump, is effective only if it is located outside. We shall consider the mechanism of this important and fascinating family of pumps in Chapter 13.

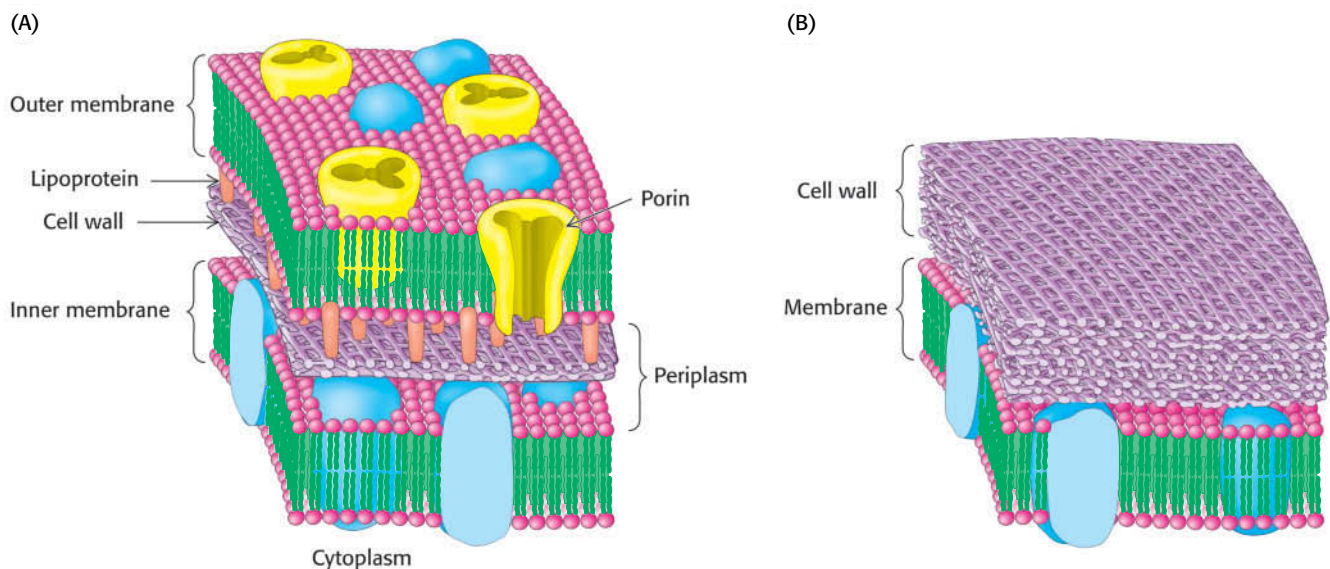

Membrane proteins have a unique orientation because, after synthesis, they are inserted into the membrane in an asymmetric manner. This absolute asymmetry is preserved because membrane proteins do not rotate from one side of the membrane to the other and because *membranes are always synthesized by the growth of preexisting membranes.* Lipids, too, are asymmetrically distributed as a consequence of their mode of biosynthesis, but this asymmetry is usually not absolute, except for glycolipids. In the red-blood-cell membrane, sphingomyelin and phosphatidylcholine are preferentially located in the outer leaflet of the bilayer, whereas phosphatidylethanolamine and phosphatidylserine are located mainly in the inner leaflet. Large amounts of cholesterol are present in both leaflets.

**FIGURE 12.33** Asymmetry of the  $\text{Na}^+-\text{K}^+$  transport system in plasma membranes. The  $\text{Na}^+-\text{K}^+$  transport system pumps  $\text{Na}^+$  out of the cell and  $\text{K}^+$  into the cell by hydrolyzing ATP on the intracellular side of the membrane.

## 12.6 Eukaryotic Cells Contain Compartments Bounded by Internal Membranes

Thus far, we have considered only the plasma membrane of cells. Some bacteria and archaea have only this single membrane, surrounded by a cell wall. Other bacteria, such as *E. coli*, have two membranes separated by a cell wall (made of proteins, peptides, and carbohydrates) lying between them (Figure 12.34). The inner membrane acts as the permeability barrier, and the outer membrane and the cell wall provide additional protection. The outer membrane is quite permeable to small molecules, owing to the presence of porins. The region between the two membranes containing the cell wall is called the *periplasm*.

**FIGURE 12.34** Cell membranes of prokaryotes. A schematic view of the membrane of bacterial cells surrounded by (A) two membranes or (B) one membrane.

**FIGURE 12.35 Nuclear envelope.** The nuclear envelope is a double membrane connected to another membrane system of eukaryotes, the endoplasmic reticulum. [Information from E. C. Schirmer and L. Gerace, *Genome Biol.* 3(4):1008.1–1008.4, 2002, reviews, Fig.1.]

Eukaryotic cells, with the exception of plant cells, do not have cell walls, and their cell membranes consist of a single lipid bilayer. In plant cells, the cell wall is on the outside of the plasma membrane. Eukaryotic cells are distinguished from prokaryotic cells by the presence of membranes inside the cell that form internal compartments. For example, peroxisomes, organelles that play a major role in the oxidation of fatty acids for energy conversion, are defined by a single membrane. Mitochondria, the organelles in which ATP is synthesized, are surrounded by two membranes. As in the case for a bacterium, the outer membrane is quite permeable to small molecules, whereas the inner membrane is not. Indeed, considerable evidence now indicates that mitochondria evolved from bacteria by *endosymbiosis* (Section 18.1). The nucleus is also surrounded by a double membrane, the *nuclear envelope*, that consists of a set of closed membranes that come together at structures called *nuclear pores* (Figure 12.35). These pores regulate transport into and out of the nucleus. The nuclear envelope is linked to another membrane-defined structure, the *endoplasmic reticulum*, which plays a host of cellular roles, including drug detoxification and the modification of proteins for secretion. Thus, a eukaryotic cell contains interacting compartments, and transport into and out of these compartments is essential to many biochemical processes.

Membranes must be able to separate or join together so that cells and compartments may take up, transport, and release molecules. Many cells take up molecules through the process of *receptor-mediated endocytosis*.

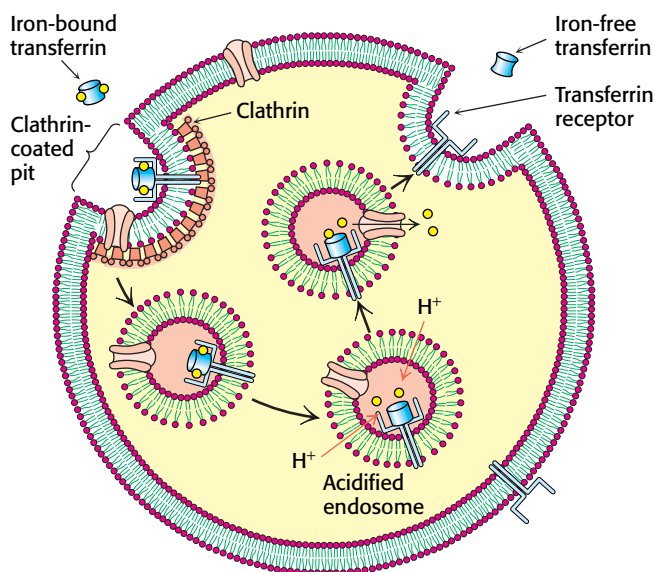

Here, a protein or larger complex initially binds to a receptor on the cell surface. After the receptor is bound, specialized proteins act to cause the membrane in this region to invaginate. One of these specialized proteins is *clathrin*, which polymerizes into a lattice network around the growing membrane bud, often referred to as a *clathrin-coated pit* (Figure 12.36). The invaginated membrane eventually breaks off and fuses to form a *vesicle*. Various hormones, transport proteins, and antibodies employ receptor-mediated endocytosis to gain entry into a cell. A less-advantageous consequence is that this pathway is available to viruses and toxins as a means of invading cells. The reverse process—the fusion of a vesicle to a membrane—is a key step in the release of neurotransmitters from a neuron into the synaptic cleft (Figure 12.37).

**FIGURE 12.36 Vesicle formation by receptor-mediated endocytosis.** Receptor binding on the surface of the cell induces the membrane to invaginate, with the assistance of specialized intracellular proteins such as clathrin. The process results in the formation of a vesicle within the cell. [M. M. Perry and A. B. Gilbert, *J. Cell Sci.* 39:266, 1979.]

Let us consider one example of receptor-mediated endocytosis. Iron is a critical element for the function and structure of many proteins, including hemoglobin and myoglobin (Chapter 7). However, free iron ions are highly toxic to cells, owing to their ability to catalyze the formation of free radicals. Hence, the transport of iron atoms from the digestive tract to the cells where they are most needed must be tightly controlled. In the bloodstream, iron is bound very tightly by the protein *transferrin*, which can bind two  $\text{Fe}^{3+}$  ions with a dissociation constant of  $10^{-23}$  M at neutral pH. Cells requiring iron express the *transferrin receptor* in their plasma membranes (Section 32.4). Formation of a complex between the transferrin receptor and iron-bound transferrin initiates receptor-mediated endocytosis, internalizing these complexes within vesicles called *endosomes* (Figure 12.38). As the endosome matures, proton pumps within the vesicle membrane lower the luminal pH to about 5.5. Under these conditions, the affinity of iron ions for transferrin is reduced; these ions are released and are free to pass through channels in the endosomal membranes into the cytoplasm. The iron-free transferrin complex is recycled to the plasma membrane, where transferrin is released back into the bloodstream and the transferrin receptor can participate in another uptake cycle.

Although budding and fusion appear deceptively simple, the structures of the intermediates in these processes and the detailed mechanisms remain ongoing areas of investigation. These processes must be highly specific in order to prevent incorrect membrane fusion events. *SNARE* (soluble *N*-ethylmaleimide-sensitive-factor attachment protein receptor) *proteins* from both membranes help draw appropriate lipid bilayers together by forming tightly coiled four-helical bundles (Figure 12.39). Once these membranes are in close apposition, the fusion process can proceed. *SNARE* proteins, encoded by gene families in all eukaryotic cells, largely determine the compartment with which a vesicle will fuse. The specificity of membrane fusion ensures the orderly trafficking of membrane vesicles and their cargos through eukaryotic cells.

**FIGURE 12.38 The transferrin receptor cycle.** Iron-bound transferrin binds to the transferrin receptor (TfR) on the surface of cells. Receptor-mediated endocytosis occurs, leading to the formation of a vesicle called an endosome. As the lumen of the endosome is acidified by the action of proton pumps, iron is released from transferrin, passes through channels in the membrane, and is utilized by the cell. The complex between iron-free transferrin and the transferrin receptor is returned to the plasma membrane for another cycle. [Information from L. Zecca et al., *Nat. Rev. Neurosci.* 5:863–873, 2004, Fig.1.]

**FIGURE 12.37 Neurotransmitter release.** Neurotransmitter-containing synaptic vesicles (indicated by the arrows) are arrayed near the plasma membrane of a nerve cell. Synaptic vesicles fuse with the plasma membrane, releasing the neurotransmitter into the synaptic cleft. [T. Reese/ Don Fawcett/Photo Researchers.]

**FIGURE 12.39 SNARE complexes initiate membrane fusion.** The SNARE protein synaptobrevin (yellow) from one membrane forms a tight four-helical bundle with the corresponding SNARE proteins syntaxin-1 (blue) and SNAP25 (red) from a second membrane. The complex brings the membranes close together, initiating the fusion event. [Drawn from 1SFC.pdb.]

## SUMMARY

Biological membranes are sheetlike structures, typically from 60 to 100 Å thick, that are composed of protein and lipid molecules held together by noncovalent interactions. Membranes are highly selective permeability barriers. They create closed compartments, which may be entire cells or organelles within a cell. Proteins in membranes regulate the molecular and ionic compositions of these compartments. Membranes also control the flow of information between cells.

### 12.1 Fatty Acids Are Key Constituents of Lipids

Fatty acids are hydrocarbon chains of various lengths and degrees of unsaturation that terminate with a carboxylic acid group. The fatty acid chains in membranes usually contain between 14 and 24 carbon atoms; they may be saturated or unsaturated. Short chain length and unsaturation enhance the fluidity of fatty acids and their derivatives by lowering the melting temperature.

### 12.2 There Are Three Common Types of Membrane Lipids

The major types of membrane lipids are phospholipids, glycolipids, and cholesterol. Phosphoglycerides, a type of phospholipid, consist of a glycerol backbone, two fatty acid chains, and a phosphorylated alcohol. Phosphatidylcholine, phosphatidylserine, and phosphatidylethanolamine are major phosphoglycerides. Sphingomyelin, a different type of phospholipid, contains a sphingosine backbone instead of glycerol. Glycolipids are sugar-containing lipids derived from sphingosine. Cholesterol, which modulates membrane fluidity, is constructed from a steroid nucleus. A common feature of these membrane lipids is that they are amphipathic molecules, having one hydrophobic and one hydrophilic end.

### 12.3 Phospholipids and Glycolipids Readily Form Bimolecular Sheets in Aqueous Media

Membrane lipids spontaneously form extensive bimolecular sheets in aqueous solutions. The driving force for membrane formation is the hydrophobic interactions among the fatty acid tails of membrane lipids. The hydrophilic head groups interact with the aqueous medium. Lipid bilayers are cooperative structures, held together by many weak bonds. These lipid bilayers are highly impermeable to ions and most polar molecules, yet they are quite fluid, which enables them to act as a solvent for membrane proteins.

## 12.4 Proteins Carry Out Most Membrane Processes

Specific proteins mediate distinctive membrane functions such as transport, communication, and energy transduction. Many integral membrane proteins span the lipid bilayer, whereas others are only partly embedded in the membrane. Peripheral membrane proteins are bound to membrane surfaces by electrostatic and hydrogen-bond interactions. Membrane-spanning proteins have regular structures, including  $\beta$  strands, although the  $\alpha$  helix is the most common membrane-spanning structure. Sequences of 20 consecutive nonpolar amino acids can be diagnostic of a membrane-spanning  $\alpha$  helical region of a protein.

## 12.5 Lipids and Many Membrane Proteins Diffuse Rapidly in the Plane of the Membrane

Membranes are structurally and functionally asymmetric, as exemplified by the restriction of sugar residues to the external surface of mammalian plasma membranes. Membranes are dynamic structures in which proteins and lipids diffuse rapidly in the plane of the membrane (lateral diffusion), unless restricted by special interactions. In contrast, the rotation of lipids from one face of a membrane to the other (transverse diffusion, or flip-flop) is usually very slow. Proteins do not rotate across bilayers; hence, membrane asymmetry can be preserved. The degree of fluidity of a membrane depends on the chain length of its lipids and on the extent to which their constituent fatty acids are unsaturated. In animals, cholesterol content also regulates membrane fluidity.

## 12.6 Eukaryotic Cells Contain Compartments Bounded by Internal Membranes

An extensive array of internal membranes in eukaryotes creates compartments within a cell for distinct biochemical functions. For instance, a double membrane surrounds the nucleus (the location of most of the cell's genetic material) and the mitochondria (the location of most ATP synthesis). A single membrane defines the other internal compartments, such as the endoplasmic reticulum. Receptor-mediated endocytosis enables the formation of intracellular vesicles when ligands bind to their corresponding receptor proteins in the plasma membrane. The reverse process—the fusion of a vesicle to a membrane—is a key step in the release of signaling molecules outside the cell.

### PROBLEMS

1. *Population density.* How many phospholipid molecules are there in a  $1\text{-}\mu\text{m}^2$  region of a phospholipid bilayer membrane? Assume that a phospholipid molecule occupies  $70\text{ \AA}^2$  of the surface area.
2. *Through the looking-glass.* Phospholipids form lipid bilayers in water. What structure might form if phospholipids were placed in an organic solvent?

3. *Lipid diffusion.* What is the average distance traversed by a membrane lipid in 1  $\mu\text{s}$ , 1 ms, and 1 s? Assume a diffusion coefficient of  $10^{-8} \text{ cm}^2 \text{ s}^{-1}$ .

4. *Protein diffusion.* The diffusion coefficient,  $D$ , of a rigid spherical molecule is given by

$$D = kT/6\pi\eta r$$

in which  $\eta$  is the viscosity of the solvent,  $r$  is the radius of the sphere,  $k$  is the Boltzmann constant ( $1.38 \times 10^{-16} \text{ erg degree}^{-1}$ ), and  $T$  is the absolute temperature. What is the diffusion coefficient at  $37^\circ\text{C}$  of a 100-kDa protein in a membrane that has an effective viscosity of 1 poise (1 poise =  $1 \text{ erg s}^{-1} \text{ cm}^{-3}$ )? What is the average distance traversed by this protein in 1  $\mu\text{s}$ , 1 ms, and 1 s? Assume that this protein is an unhydrated, rigid sphere of density  $1.35 \text{ g cm}^{-3}$ .

5. *Cold sensitivity.* Some antibiotics act as carriers that bind an ion on one side of a membrane, diffuse through the membrane, and release the ion on the other side. The conductance of a lipid-bilayer membrane containing a carrier antibiotic decreased abruptly when the temperature was lowered from  $40^\circ\text{C}$  to  $36^\circ\text{C}$ . In contrast, there was little change in conductance of the same bilayer membrane when it contained a channel-forming antibiotic. Why?

6. *Melting point 1.* Explain why oleic acid (18 carbons, one cis bond) has a lower melting point than stearic acid, which has the same number of carbon atoms but is saturated. How would you expect the melting point of *trans*-oleic acid to compare with that of *cis*-oleic acid? Why might most unsaturated fatty acids in phospholipids be in the *cis* rather than the *trans* conformation?

7. *Melting point 2.* Explain why the melting point of palmitic acid ( $\text{C}_{16}$ ) is 6.5 degrees lower than that of stearic acid ( $\text{C}_{18}$ ).

8. *A sound diet.* Small mammalian hibernators can withstand body temperatures of  $0^\circ$  to  $5^\circ\text{C}$  without injury. However, the body fats of most mammals have melting temperatures of approximately  $25^\circ\text{C}$ . Predict how the composition of the body fat of hibernators might differ from that of their nonhibernating cousins.

9. *Flip-flop 1.* The transverse diffusion of phospholipids in a bilayer membrane was investigated by using a fluorescently labeled analog of phosphatidylserine called NBD-PS.

The fluorescence signal of NBD-PS is quenched when exposed to sodium dithionite, a reducing agent that is not membrane permeable.

Lipid vesicles containing phosphatidylserine (98%) and NBD-PS (2%) were prepared by sonication and purified. Within a few minutes of the addition of sodium dithionite, the fluorescence signal of these vesicles decreased to  $\sim 45\%$  of its initial value. Immediately adding a second addition of sodium dithionite yielded no change in the fluorescence signal. However, if the vesicles were allowed to incubate for 6.5 hours, a third addition of sodium dithionite decreased the remaining fluorescence signal by 50%. How would you interpret the fluorescence changes at each addition of sodium dithionite?

10. *Flip-flop 2.* Although proteins rarely if ever flip-flop across a membrane, the distribution of membrane lipids between the membrane leaflets is not absolute except for glycolipids. Why are glycosylated lipids less likely to flip-flop?

11. *Linkages.* Platelet-activating factor (PAF) is a phospholipid that plays a role in allergic and inflammatory responses, as well as in toxic shock syndrome. The structure of PAF is shown here. How does it differ from the structures of the phospholipids discussed in this chapter?

12. *A question of competition.* Would a homopolymer of alanine be more likely to form an  $\alpha$  helix in water or in a hydrophobic medium? Explain.

13. *A false positive.* Hydrophathy plot analysis of your protein of interest reveals a single, prominent hydrophobic peak. However, you later discover that this protein is soluble and not membrane associated. Explain how the hydrophathy plot may have been misleading.

14. *Maintaining fluidity.* A culture of bacteria growing at  $37^\circ\text{C}$  was shifted to  $25^\circ\text{C}$ . How would you expect this shift to alter the fatty acid composition of the membrane phospholipids? Explain.

15. *Let me count the ways.* Each intracellular fusion of a vesicle with a membrane requires a SNARE protein on the vesicle (called the v-SNARE) and a SNARE protein on the target membrane (called the t-SNARE). Assume that a genome encodes 21 members of the v-SNARE family and 7 members of the t-SNARE family. With the assumption of no specificity, how many potential v-SNARE-t-SNARE interactions could take place?

## Data Interpretation Problems

16. *Cholesterol effects.* The red curve on the following graph shows the fluidity of the fatty acids of a phospholipid bilayer as a function of temperature. The blue curve shows the fluidity in the presence of cholesterol.

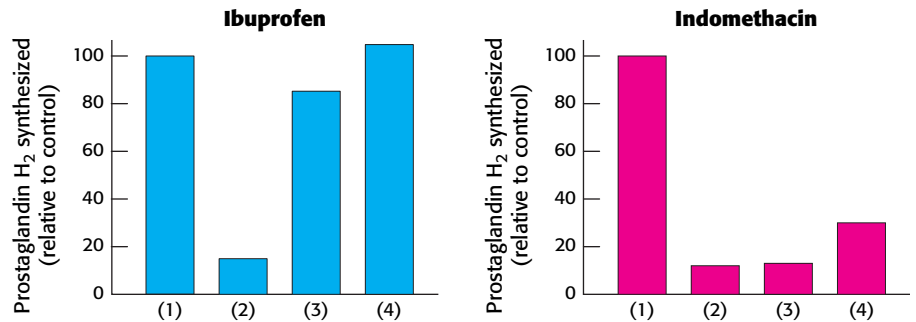

- (a) What is the effect of cholesterol?  
 (b) Why might this effect be biologically important?

17. *Hydropathy plots.* On the basis of the following hydropathy plots for three proteins (A–C), predict which would be membrane proteins. What are the ambiguities with respect to using such plots to determine if a protein is a membrane protein?

18. *Not all inhibitors are equal.* Ibuprofen and indomethacin are clinically important inhibitors of prostaglandin  $H_2$  synthase-1. Cells expressing this enzyme were incubated under the following conditions, after which the activity of the enzyme was measured by adding radiolabeled arachidonic acid and detecting newly-produced prostaglandin  $H_2$ :

- (1) 40 min *without* inhibitor (control)  
 (2) 40 min with inhibitor  
 (3) 40 min with inhibitor, after which the cells were resuspended in medium *without* inhibitor  
 (4) 40 min with inhibitor, after which the cells were resuspended in medium *without* inhibitor and incubated for an additional 30 min.

(a) Provide a hypothesis explaining the different results for these two inhibitors.

(b) How would these results look if aspirin were tested in a similar fashion?

## Chapter Integration Problem

19. *The proper environment.* An understanding of the structure and function of membrane proteins has lagged behind that of other proteins. The primary reason is that membrane proteins are more difficult to purify and crystallize. Why might this be the case?

# Membrane Channels and Pumps

The flow of ions through a single membrane channel (channels are shown in red in the illustration at the left) can be detected by the patch-clamp technique, which records current changes as the channel alternates between open and closed states. [(Left) Information from E. Neher and B. Sakmann. The patch clamp technique. Copyright © 1992 by Scientific American, Inc. All rights reserved. (Right) Courtesy of Dr. Mauricio Montal.]

The lipid bilayer of biological membranes is intrinsically impermeable to ions and polar molecules, yet these species must be able to cross these membranes for normal cell function. Permeability is conferred by three classes of membrane proteins: *pumps*, *carriers*, and *channels*. Pumps use a source of free energy such as ATP hydrolysis or light absorption to drive the thermodynamically uphill transport of ions or molecules. Pump action is an example of *active transport*. Carriers mediate the transport of ions and small molecules across the membrane without consumption of ATP. Channels provide a membrane pore through which ions can flow very rapidly in a thermodynamically downhill direction. The action of channels illustrates *passive transport*, or *facilitated diffusion*.

Pumps are energy transducers in that they convert one form of free energy into another. Two types of *ATP-driven pumps*, P-type ATPases and the ATP-binding cassette (ABC) transporters, undergo conformational changes on ATP binding and hydrolysis that cause a bound ion to be transported across the membrane. The free energy of ATP hydrolysis is used to drive the movement of ions against their concentration gradients, a process referred to as *primary active transport*. In contrast, carriers utilize the gradient of one ion to drive the transport of another against its gradient. An example of this process, termed *secondary active transport*, is mediated by the *E. coli* lactose transporter, a well-studied protein responsible for the uptake of a specific sugar from the environment of a bacterium. Many transporters of this class are present in the membranes of our cells. The expression of these transporters determines which metabolites a cell can import from the environment. Hence, adjusting the level of transporter expression is a primary means of controlling metabolism.

## OUTLINE

- 13.1 The Transport of Molecules Across a Membrane May Be Active or Passive
- 13.2 Two Families of Membrane Proteins Use ATP Hydrolysis to Pump Ions and Molecules Across Membranes
- 13.3 Lactose Permease Is an Archetype of Secondary Transporters That Use One Concentration Gradient to Power the Formation of Another
- 13.4 Specific Channels Can Rapidly Transport Ions Across Membranes
- 13.5 Gap Junctions Allow Ions and Small Molecules to Flow Between Communicating Cells
- 13.6 Specific Channels Increase the Permeability of Some Membranes to Water

Pumps can establish persistent gradients of particular ions across membranes. Specific *ion channels* can allow these ions to flow rapidly across membranes down these gradients. These channels are among the most fascinating molecules in biochemistry in their ability to allow some ions to flow freely through a membrane while blocking the flow of even closely related species. The opening, or gating, of these channels can be controlled by the presence of certain ligands or a particular membrane voltage. Gated ion channels are central to the functioning of our nervous systems, acting as elaborately switched wires that allow the rapid flow of current.

Finally, a different class of channel, the cell-to-cell channel, or *gap junction*, allows the flow of metabolites or ions *between cells*. For example, gap junctions are responsible for synchronizing muscle-cell contraction in the beating heart.

### The expression of transporters largely defines the metabolic activities of a given cell type

Each cell type expresses a specific set of transporters in its plasma membrane. This collection of expressed transporters is important because it largely determines the ionic composition inside cells and the compounds that can be taken up from the extracellular environment. In some sense, the specific array of transporters defines the cell's characteristics because a cell can execute only those biochemical reactions for which it has taken up the necessary substrates.

An example from glucose metabolism illustrates this point. As we will see in Chapter 16, tissues differ in their ability to employ different molecules as energy sources. Which tissues can utilize glucose is largely governed by the expression of members of the GLUT family of homologous glucose transporters. For example, GLUT3 is the primary glucose transporter expressed on the plasma membrane of neurons. This transporter binds glucose relatively tightly so that these cells have first call on glucose when it is present at relatively low concentrations. We will encounter many such examples of the critical role that transporter expression plays in the control and integration of metabolism.

---

## 13.1 The Transport of Molecules Across a Membrane May Be Active or Passive

We first consider some general principles of membrane transport. Two factors determine whether a molecule will cross a membrane: (1) the permeability of the molecule in a lipid bilayer and (2) the availability of an energy source.

### Many molecules require protein transporters to cross membranes

As stated in Chapter 12, some molecules can pass through cell membranes because they dissolve in the lipid bilayer. Such molecules are called *lipophilic molecules*. The steroid hormones provide a physiological example. These cholesterol relatives can pass through a membrane, but what determines the direction in which they will move? Such molecules will pass through a membrane down their concentration gradient in a process called *simple diffusion*. In accord with the Second Law of Thermodynamics, molecules spontaneously move from a region of higher concentration to one of lower concentration.

Matters become more complicated when the molecule is highly polar. For example, sodium ions are present at 143 mM outside a typical cell and

at 14 mM inside the cell. However, sodium does not freely enter the cell, because the charged ion cannot pass through the hydrophobic membrane interior. In some circumstances, as during a nerve impulse, sodium ions must enter the cell. How are they able to do so? Sodium ions pass through specific channels in the hydrophobic barrier formed by membrane proteins. This means of crossing the membrane is called *facilitated diffusion* because the diffusion across the membrane is facilitated by the channel. It is also called *passive transport* because the energy driving the ion movement originates from the ion gradient itself, without any contribution by the transport system. Channels, like enzymes, display substrate specificity in that they facilitate the transport of some ions, but not other, even closely related, ions.

How is the sodium gradient established in the first place? In this case, sodium must move, or be pumped, *against* a concentration gradient. Because moving the ion from a low concentration to a higher concentration results in a decrease in entropy, it requires an input of free energy. Protein transporters embedded in the membrane are capable of using an energy source to move the molecule up a concentration gradient. Because an input of energy from another source is required, this means of crossing the membrane is called *active transport*.

### Free energy stored in concentration gradients can be quantified

An unequal distribution of molecules is an energy-rich condition because free energy is minimized when all concentrations are equal. Consequently, to attain such an unequal distribution of molecules requires an input of free energy. How can we quantify the amount of energy required to generate a concentration gradient (Figure 13.1)? Consider an uncharged solute molecule. The free-energy change in transporting this species from side 1, where it is present at a concentration of  $c_1$ , to side 2, where it is present at concentration  $c_2$ , is

$$\Delta G = RT \ln(c_2/c_1)$$

where  $R$  is the gas constant ( $8.315 \times 10^{-3} \text{ kJ mol}^{-1} \text{ deg}^{-1}$ , or  $1.987 \times 10^{-3} \text{ kcal mol}^{-1} \text{ deg}^{-1}$ ) and  $T$  is the temperature in kelvins. For a charged species, the unequal distribution across the membrane generates an electrical potential that also must be considered because the ions will be repelled by the like charges. The sum of the concentration and electrical terms is called the *electrochemical potential* or *membrane potential*. The free-energy change is then given by

$$\Delta G = RT \ln(c_2/c_1) + ZF\Delta V$$

in which  $Z$  is the electrical charge of the transported species,  $\Delta V$  is the potential in volts across the membrane, and  $F$  is the Faraday constant ( $96.5 \text{ kJ V}^{-1} \text{ mol}^{-1}$ , or  $23.1 \text{ kcal V}^{-1} \text{ mol}^{-1}$ ).

A transport process must be active when  $\Delta G$  is positive, whereas it can be passive when  $\Delta G$  is negative. For example, consider the transport of an uncharged molecule from  $c_1 = 10^{-3} \text{ M}$  to  $c_2 = 10^{-1} \text{ M}$ .

$$\begin{aligned} \Delta G &= RT \ln(10^{-1}/10^{-3}) \\ &= (8.315 \times 10^{-3}) \times 298 \times \ln(10^2) \\ &= +11.4 \text{ kJ mol}^{-1} (+2.7 \text{ kcal mol}^{-1}) \end{aligned}$$

At 25°C (298 K),  $\Delta G$  is  $+11.4 \text{ kJ mol}^{-1}$  ( $+2.7 \text{ kcal mol}^{-1}$ ), indicating that this transport process requires an input of free energy.

**FIGURE 13.1 Free energy and transport.** The free-energy change in transporting (A) an uncharged solute from a compartment at concentration  $c_1$  to one at  $c_2$  and (B) a singly charged species across a membrane to the side having the same charge as that of the transported ion. Notice that the free-energy change imposed by a membrane potential of 59 mV is equivalent to that imposed by a concentration ratio of 10 for a singly charged ion at 25°C.

## 13.2 Two Families of Membrane Proteins Use ATP Hydrolysis to Pump Ions and Molecules Across Membranes

The extracellular fluid of animal cells has a salt concentration similar to that of seawater. However, cells must control their intracellular salt concentrations to facilitate specific processes, such as signal transduction and action potential propagation, and prevent unfavorable interactions with high concentrations of ions such as  $\text{Ca}^{2+}$ . For instance, most animal cells contain a high concentration of  $\text{K}^+$  and a low concentration of  $\text{Na}^+$  relative to the external medium. These ionic gradients are generated by a specific transport system, an enzyme that is called the  $\text{Na}^+-\text{K}^+$  pump or the  $\text{Na}^+-\text{K}^+$  ATPase. The hydrolysis of ATP by the pump provides the energy needed for the active transport of  $\text{Na}^+$  out of the cell and  $\text{K}^+$  into the cell, generating the gradients. The pump is called the  $\text{Na}^+-\text{K}^+$  ATPase because the hydrolysis of ATP takes place only when  $\text{Na}^+$  and  $\text{K}^+$  are present. This ATPase, like all such enzymes, requires  $\text{Mg}^{2+}$ .

The change in free energy accompanying the transport of  $\text{Na}^+$  and  $\text{K}^+$  can be calculated. Suppose that the concentrations of  $\text{Na}^+$  outside and inside the cell are 143 and 14 mM, respectively, and the corresponding values for  $\text{K}^+$  are 4 and 157 mM. At a membrane potential of  $-50$  mV and a temperature of  $37^\circ\text{C}$ , we can use the equation on page 369 to determine that the free-energy change in transporting 3 mol of  $\text{Na}^+$  out of the cell and 2 mol of  $\text{K}^+$  into the cell is  $3(5.99) + 2(9.46) = +36.9$  kJ mol $^{-1}$  ( $+8.8$  kcal mol $^{-1}$ ). Under typical cellular conditions, the hydrolysis of a single ATP molecule per transport cycle provides sufficient free energy, about  $-50$  kJ mol $^{-1}$  ( $-12$  kcal mol $^{-1}$ ) to drive the uphill transport of these ions. The active transport of  $\text{Na}^+$  and  $\text{K}^+$  is of great physiological significance. Indeed, more than a third of the ATP consumed by a resting animal is used to pump these ions. The  $\text{Na}^+-\text{K}^+$  gradient in animal cells controls cell volume, renders neurons and muscle cells electrically excitable, and drives the active transport of sugars and amino acids.

The purification of other ion pumps has revealed a large family of evolutionarily related ion pumps including proteins from bacteria, archaea, and all eukaryotes. Each of these pumps is specific for a particular ion or set of ions. Two are of particular interest: the *sarcoplasmic reticulum*  $\text{Ca}^{2+}$  ATPase (or *SERCA*) transports  $\text{Ca}^{2+}$  out of the cytoplasm and into the sarcoplasmic reticulum of muscle cells, and the *gastric*  $\text{H}^+-\text{K}^+$  ATPase is the enzyme responsible for pumping sufficient protons into the stomach to lower the pH to 1.0. These enzymes and the hundreds of known homologs, including the  $\text{Na}^+-\text{K}^+$  ATPase, are referred to as *P-type* ATPases because they form a key phosphorylated intermediate. In the formation of this intermediate, a phosphoryl group from ATP is linked to the side chain of a specific conserved aspartate residue in the ATPase to form phosphorylaspartate.

### P-type ATPases couple phosphorylation and conformational changes to pump calcium ions across membranes

Membrane pumps function by mechanisms that are simple in principle but often complex in detail. Fundamentally, each pump protein can exist in two principal conformational states, one with ion-binding sites open to one side of the membrane and the other with ion-binding sites open to the other side (Figure 13.2). To pump ions in a single direction across a membrane, the free energy of ATP hydrolysis must be coupled to the interconversion between these conformational states.

**FIGURE 13.2 Pump action.** A simple scheme for the pumping of a molecule across a membrane. The pump interconverts to two conformational states, each with a binding site accessible to a different side of the membrane.

We will consider the structural and mechanistic features of P-type ATPases by examining SERCA. The properties of this P-type ATPase have been established in great detail by relying on crystal structures of the pump in five different states. This enzyme, which constitutes 80% of the protein in the sarcoplasmic reticulum membrane, plays an important role in relaxation of contracted muscle. Muscle contraction is triggered by an abrupt rise in the cytoplasmic calcium ion level. Subsequent muscle relaxation depends on the rapid removal of  $\text{Ca}^{2+}$  from the cytoplasm into the sarcoplasmic reticulum, a specialized compartment for  $\text{Ca}^{2+}$  storage, by SERCA. This pump maintains a  $\text{Ca}^{2+}$  concentration of approximately  $0.1 \mu\text{M}$  in the cytoplasm compared with  $1.5 \text{ mM}$  in the sarcoplasmic reticulum.

The first structure of SERCA to be determined had  $\text{Ca}^{2+}$  bound, but no nucleotides present (Figure 13.3). SERCA is a single 110-kDa polypeptide with a transmembrane domain consisting of 10  $\alpha$  helices. The transmembrane domain includes sites for binding two calcium ions. Each calcium ion is coordinated to seven oxygen atoms coming from a combination of side-chain glutamate, aspartate, threonine, and asparagine residues, backbone carbonyl groups, and water molecules. A large cytoplasmic headpiece constitutes nearly half the molecular weight of the protein and consists of three distinct domains, each with a distinct function. One domain (N) binds the ATP nucleotide, another (P) accepts the phosphoryl group on a conserved aspartate residue, and the third (A) serves as an

**FIGURE 13.3 Calcium-pump structure.**

The overall structure of the SERCA P-type ATPase. Notice the two calcium ions (green) that lie in the center of the transmembrane domain. A conserved aspartate residue (Asp 351) that binds a phosphoryl group lies in the P domain. The designation bb refers to backbone carbonyl groups. [Drawn from 1SU4.pdb.]

**FIGURE 13.4 Conformational changes associated with calcium pumping.** This structure was determined in the absence of bound calcium but with a phosphorylaspartate analog present in the P domain. Notice how different this structure is from the calcium-bound form shown in Figure 13.3: both the transmembrane part (yellow) and the A, P, and N domains have substantially rearranged. [Drawn from 1WPG.pdb.]

actuator, linking changes in the N and P domains to the transmembrane part of the enzyme.

SERCA is a remarkably dynamic protein. For example, the structure of SERCA without bound  $\text{Ca}^{2+}$ , but with a phosphorylaspartate analog present in the P domain, is shown in Figure 13.4. The N and P domains are now closed around the phosphorylaspartate analog, and the A domain has rotated substantially relative to its position in SERCA with  $\text{Ca}^{2+}$  bound and without the phosphoryl analog. Furthermore, the transmembrane part of the enzyme has rearranged significantly and the well-organized  $\text{Ca}^{2+}$ -binding sites are disrupted. These sites are now accessible from the side of the membrane opposite the N, P, and A domains.

The structural results can be combined with other studies to construct a detailed mechanism for  $\text{Ca}^{2+}$  pumping by SERCA (Figure 13.5):

1. The catalytic cycle begins with the enzyme in its unphosphorylated state with two calcium ions bound. We will refer to the overall enzyme conformation in this state as  $E_1$ ; with  $\text{Ca}^{2+}$  bound, it is  $E_1-(\text{Ca}^{2+})_2$ . In this conformation, SERCA can bind calcium ions only on the cytoplasmic side of the membrane. This conformation is shown in Figure 13.3.
2. In the  $E_1$  conformation, the enzyme can bind ATP. The N, P, and A domains undergo substantial rearrangement as they close around the bound ATP, but there is no substantial conformational change in the transmembrane domain. The calcium ions are now trapped inside the enzyme.
3. The phosphoryl group is then transferred from ATP to Asp 351.
4. Upon ADP release, the enzyme again changes its overall conformation, including the membrane domain this time. This new conformation is referred to as  $E_2$  or  $E_2\text{-P}$  in its phosphorylated form. The process of interconverting the  $E_1$  and  $E_2$  conformations is sometimes referred to as *eversion*.

**FIGURE 13.5 Pumping calcium.**  $\text{Ca}^{2+}$ ATPase transports  $\text{Ca}^{2+}$  through the membrane by a mechanism that includes (1)  $\text{Ca}^{2+}$  binding from the cytoplasm, (2) ATP binding, (3) ATP cleavage with the transfer of a phosphoryl group to Asp 351 on the enzyme, (4) ADP release and eversion of the enzyme to release  $\text{Ca}^{2+}$  on the opposite side of the membrane, (5) hydrolysis of the phosphorylaspartate residue, and (6) eversion to prepare for the binding of  $\text{Ca}^{2+}$  from the cytoplasm.

In the  $E_2$ -P conformation, the  $Ca^{2+}$ -binding sites become disrupted and the calcium ions are released to the side of the membrane opposite that at which they entered; ion transport has been achieved. This conformation is shown in Figure 13.4.

- The phosphorylaspartate residue is hydrolyzed to release inorganic phosphate.
- With the release of phosphate, the interactions stabilizing the  $E_2$  conformation are lost, and the enzyme everts to the  $E_1$  conformation.

The binding of two calcium ions from the cytoplasmic side of the membrane completes the cycle.

This mechanism likely applies to other P-type ATPases. For example,  $Na^+$ - $K^+$  ATPase is an  $\alpha_2\beta_2$  tetramer. Its  $\alpha$  subunit is homologous to SERCA and includes a key aspartate residue analogous to Asp 351. The  $\beta$  subunit does not directly take part in ion transport. A mechanism analogous to that shown in Figure 13.5 applies, with three  $Na^+$  ions binding from the inside of the cell to the  $E_1$  conformation and two  $K^+$  ions binding from outside the cell to the  $E_2$  conformation.

### Digitalis specifically inhibits the $Na^+$ - $K^+$ pump by blocking its dephosphorylation

 Certain steroids derived from plants are potent inhibitors ( $K_i \approx 10$  nM) of the  $Na^+$ - $K^+$  pump. Digitoxigenin and ouabain are members of this class of inhibitors, which are known as *cardiotonic steroids* because of their strong effects on the heart (Figure 13.6). These compounds inhibit the dephosphorylation of the  $E_2$ -P form of the ATPase when applied on the *extracellular* face of the membrane.

*Digitalis* is a mixture of cardiotonic steroids derived from the dried leaf of the foxglove plant (*Digitalis purpurea*). The compound increases the force of contraction of heart muscle and is consequently a choice drug in the treatment of congestive heart failure. Inhibition of the  $Na^+$ - $K^+$  pump by digitalis leads to a higher level of  $Na^+$  inside the cell. The diminished  $Na^+$  gradient results in slower extrusion of  $Ca^{2+}$  by the sodium-calcium exchanger, an antiporter (Section 13.3). The subsequent increase in the intracellular level of  $Ca^{2+}$  enhances the ability of cardiac muscle to contract. It is interesting to note that digitalis was used effectively long before the discovery of the  $Na^+$ - $K^+$  ATPase. In 1785, William Withering, a British physician, heard tales of an elderly woman, known as “the old woman of Shropshire,” who cured people of “dropsy” (which today would be recognized as congestive heart failure) with an extract of foxglove. Withering conducted the first scientific study of the effects of foxglove on congestive heart failure and documented its effectiveness.

Foxglove (*Digitalis purpurea*) is the source of digitalis, one of the most widely used drugs. [Roger Hall/Shutterstock.]

**FIGURE 13.6 Digitoxigenin.** Cardiotonic steroids such as digitoxigenin inhibit the  $Na^+$ - $K^+$  pump by blocking the dephosphorylation of  $E_2$ -P.

## P-type ATPases are evolutionarily conserved and play a wide range of roles

 Analysis of the complete yeast genome revealed the presence of 16 proteins that clearly belong to the P-type ATPase family. More-detailed sequence analysis suggests that 2 of these proteins transport  $H^+$  ions, 2 transport  $Ca^{2+}$ , 3 transport  $Na^+$ , and 2 transport metals such as  $Cu^{2+}$ . In addition, 5 members of this family appear to participate in the transport of phospholipids with amino acid head groups. These 5 proteins help maintain membrane asymmetry by transporting lipids such as phosphatidylserine from the outer to the inner leaflet of the bilayer membrane. Such enzymes have been termed “flippases.” Remarkably, the human genome encodes 70 P-type ATPases. All members of this protein family employ the same fundamental mechanism: the free energy of ATP hydrolysis drives membrane transport by means of conformational changes, which are induced by the addition and removal of a phosphoryl group at an analogous aspartate site in each protein.

## Multidrug resistance highlights a family of membrane pumps with ATP-binding cassette domains

 Studies of human disease revealed another large and important family of active-transport proteins, with structures and mechanisms quite different from those of the P-type ATPase family. These pumps were identified from studies on tumor cells in culture that developed resistance to drugs that had been initially quite toxic to the cells. Remarkably, the development of resistance to one drug had made the cells less sensitive to a range of other compounds. This phenomenon is known as *multidrug resistance*. In a significant discovery, the onset of multidrug resistance was found to correlate with the expression and activity of a membrane protein with an apparent molecular mass of 170 kDa. This protein acts as an ATP-dependent pump that extrudes a wide range of small molecules from cells that express it. The protein is called the *multidrug-resistance (MDR) protein* or *P-glycoprotein* (“glyco” because it includes a carbohydrate moiety). Thus, when cells are exposed to a drug, the MDR pumps the drug out of the cell before the drug can exert its effects.

 Analysis of the amino acid sequences of MDR and homologous proteins revealed a common architecture (Figure 13.7A). Each protein comprises four domains: two membrane-spanning domains and two ATP-binding domains. The ATP-binding domains of these proteins are called *ATP-binding cassettes (ABCs)* and are homologous to domains in a large family of transport proteins in bacteria and archaea. Transporters that include these domains are called *ABC transporters*. With 79 members, the ABC transporters are the largest single family identified in the *E. coli* genome. The human genome includes more than 150 ABC transporter genes.

The ABC proteins are members of the P-loop NTPase superfamily (Section 9.4). The three-dimensional structures of several members of the ABC transporter family have now been determined, including that of the bacterial lipid transporter MsbA. In contrast with the eukaryotic MDR protein, this protein is a dimer of 62-kDa chains: the amino-terminal half of each protein contains the membrane-spanning domain, and the carboxyl-terminal half contains the ATP-binding cassette (Figure 13.7B). Prokaryotic ABC proteins are often made up of multiple subunits, such as a dimer of identical chains, as above, or as a heterotetramer of two membrane-spanning domain subunits and two ATP-binding-cassette subunits. The consolidation of the enzymatic activities of several polypeptide chains in prokaryotes to a single chain in eukaryotes is a theme that we will see again. The two

**FIGURE 13.7 Domain arrangement of ABC transporters.** ABC transporters are a large family of homologous proteins composed of two transmembrane domains and two ATP-binding domains called ATP-binding cassettes (ABCs). (A) The multidrug-resistance protein is a single polypeptide chain containing all four domains, whereas (B) the bacterial lipid transporter MsbA consists of a dimer of two identical chains, containing one of each domain.

ATP-binding cassettes are in contact, but they do not interact strongly in the absence of bound ATP (Figure 13.8). On the basis of this structure and others, as well as on other experiments, a mechanism for active transport by these proteins has been developed (Figure 13.9):

1. The catalytic cycle begins with the transporter free of both ATP and substrate. While the distance between the ATP-binding cassettes in this form may vary with the individual transporter, the substrate binding region of the transporter faces inward.
2. Substrate enters the central cavity of the transporter from inside the cell. Substrate binding induces conformational changes in the ATP-binding cassettes that increase their affinity for ATP.
3. ATP binds to the ATP-binding cassettes, changing their conformations so that the two domains interact strongly with one another. The close interaction of the ABCs reorients the transmembrane helices such that the substrate binding site is now facing outside the cell (Figure 13.8, far right).

**FIGURE 13.8 ABC transporter structure.** Two structures of the bacterial lipid transporter MsbA, a representative ABC transporter. The nucleotide-free, inward-facing form is on the left and the ATP-bound, outward-facing form is shown in two views (rotated by 90 degrees) in the center and on the right. The two ATP-binding cassettes (blue) are related to the P-loop NTPases and, like them, contain P-loops (green). The  $\alpha$  helix adjacent to the P-loop is shown in red. [Drawn from 3B5W and 3B60.pdb.]

**FIGURE 13.9 ABC transporter mechanism.** The mechanism includes the following steps: (1) opening of the channel toward the inside of the cell, (2) substrate binding and conformational changes in the ATP-binding cassettes, (3) ATP binding and opening of the channel to the opposite face of the membrane, (4) release of the substrate to the outside of the cell, and (5) ATP hydrolysis to reset the transporter to its initial state.

- The outward facing conformation of the transporter has reduced affinity for the substrate, enabling the release of the substrate on the opposite face of the membrane.
- The hydrolysis of ATP and the release of ADP and inorganic phosphate reset the transporter for another cycle.

Whereas eukaryotic ABC transporters generally act to export molecules from inside the cell, prokaryotic ABC transporters often act to import specific molecules from *outside* the cell. A specific binding protein acts in concert with the bacterial ABC transporter, delivering the substrate to the transporter and stimulating ATP hydrolysis inside the cell. These binding proteins are present in the periplasm, the compartment between the two membranes that surround some bacterial cells (Figure 12.35A).

Thus, ABC transporters use a substantially different mechanism from the P-type ATPases to couple the ATP hydrolysis reaction to conformational changes. Nonetheless, the net result is the same: the transporters are converted from one conformation capable of binding substrate from one side of the membrane to another that releases the substrate on the other side.

### 13.3 Lactose Permease Is an Archetype of Secondary Transporters That Use One Concentration Gradient to Power the Formation of Another

Carriers are proteins that transport ions or molecules across the membrane without hydrolysis of ATP. The mechanism of carriers involves both large conformational changes and the interaction of the protein with only a few molecules per transport cycle, limiting the maximum rate at which transport can occur. Although carriers cannot mediate primary active transport, owing to their inability to hydrolyze ATP, they can couple the thermodynamically unfavorable flow of one species of ion or molecule *up* a concentration gradient to the favorable flow of a different species *down* a concentration gradient, a process referred to as secondary active transport. Carriers that move ions or molecules “uphill” by this means are termed *secondary transporters* or *cotransporters*. These proteins can be classified as either *antiporters* or *symporters*. Antiporters couple the downhill flow of one species to the uphill flow of another in the *opposite direction* across the membrane; symporters use the flow of one species to drive the flow of a different species in the *same direction* across the membrane. *Uniporters*, another class of carriers, are able to transport a specific species in either direction governed only by concentrations of that species on either side of the membrane (Figure 13.10).

**FIGURE 13.10** Antiporters, symporters, and uniporters. Secondary transporters can transport two substrates in opposite directions (antiporters), two substrates in the same direction (symporters), or one substrate in either direction (uniporter).

Secondary transporters are ancient molecular machines, common today in bacteria and archaea as well as in eukaryotes. For example, approximately 160 (of around 4000) proteins encoded by the *E. coli* genome are secondary transporters. Sequence comparison and hydropathy analysis suggest that members of the largest family have 12 transmembrane helices that appear to have arisen by duplication and fusion of a membrane protein containing 6 transmembrane helices. Included in this family is the *lactose permease* of *E. coli*. This symporter uses the  $H^+$  gradient across the *E. coli* membrane (outside has higher  $H^+$  concentration) generated by the oxidation of fuel molecules to drive the uptake of lactose and other sugars against a concentration gradient. This transporter has been extensively studied for many decades and is a useful archetype for this family.

The structure of lactose permease has been determined (Figure 13.11). As expected from the sequence analysis, the protein consists of two halves, each of which comprises six membrane-spanning  $\alpha$  helices. The two halves are well separated and are joined by a single stretch of polypeptide. In this structure, a sugar molecule lies in a pocket in the center of the protein and is accessible from a path that leads from the interior of the cell. On the basis of this structure and a wide range of other experiments, a mechanism for symporter action has been developed. This mechanism (Figure 13.12) has many features similar to those for P-type ATPases and ABC transporters:

1. The cycle begins with the two halves oriented so that the opening to the binding pocket faces outside the cell, in a conformation different from that observed in the structures solved to date. A proton from outside the cell binds to a residue in the permease, quite possibly Glu 269.
2. In the protonated form, the permease binds lactose from outside the cell.
3. The structure everts to the form observed in the crystal structure (Figure 13.11).
4. The permease releases lactose to the inside of the cell.
5. The permease releases a proton to the inside of the cell.
6. The permease everts to complete the cycle.

The site of protonation likely changes in the course of this cycle.

It is believed that this eversion mechanism applies to all classes of secondary transporters, which resemble the lactose permease in overall architecture.

**FIGURE 13.11 Structure of lactose permease with a bound lactose analog.** The amino-terminal half of the protein is shown in blue and the carboxyl-terminal half in red. (A) Side view. (B) Bottom view (from inside the cell). Notice that the structure consists of two halves that surround the sugar and are linked to one another by only a single stretch of polypeptide. [Drawn from 1PV7.pdb.]

**FIGURE 13.12 Lactose permease mechanism.** The mechanism begins with the permease open to the outside of the cell (upper left). The permease binds a proton from the outside of the cell (1) and then binds its substrate (2). The permease everts (3) and then releases its substrate (4) and a proton (5) to the inside of the cell. It then everts (6) to complete the cycle.

## 13.4 Specific Channels Can Rapidly Transport Ions Across Membranes

Pumps and carriers can move ions across the membrane at rates approaching several thousand ions per second. Other membrane proteins, the passive-transport systems called *ion channels*, are capable of ion-transport rates that are more than 1000 times as fast. These rates of transport through ion channels are close to rates expected for ions diffusing freely through aqueous solution. Yet ion channels are not simply tubes that span membranes through which ions can rapidly flow. Instead, they are highly sophisticated molecular machines that respond to chemical and physical changes in their environments and undergo precisely timed conformational changes.

### Action potentials are mediated by transient changes in $\text{Na}^+$ and $\text{K}^+$ permeability

One of the most important manifestations of ion-channel action is the nerve impulse, which is the fundamental means of communication in the nervous system. A *nerve impulse* is an electrical signal produced by the flow of ions across the plasma membrane of a neuron. The interior of a neuron, like that of most other cells, contains a high concentration of  $\text{K}^+$  and a low concentration of  $\text{Na}^+$ . These ionic gradients are generated by the  $\text{Na}^+/\text{K}^+$  ATPase. The cell membrane has an electrical potential determined by the ratio of the internal to the external concentration of ions. In the resting state, the membrane potential is typically  $-60$  mV. A nerve impulse, or *action potential*, is generated when the membrane potential is depolarized beyond a critical threshold value (e.g., from  $-60$  to  $-40$  mV). The membrane potential becomes positive within about a millisecond and attains a value of about  $+30$  mV before turning negative again (repolarization). This amplified depolarization is propagated along the nerve terminal (Figure 13.13).

**FIGURE 13.13 Action potential.** Signals are sent along neurons by the transient depolarization and repolarization of the membrane.

Ingenious experiments carried out by Alan Hodgkin and Andrew Huxley revealed that action potentials arise from large, transient changes in the permeability of the axon membrane to  $\text{Na}^+$  and  $\text{K}^+$  ions. Depolarization of the membrane beyond the threshold level leads to an increase in permeability to  $\text{Na}^+$ . Sodium ions begin to flow into the cell because of the large electrochemical gradient across the plasma membrane. The entry of  $\text{Na}^+$  further depolarizes the membrane, leading to a further increase in  $\text{Na}^+$  permeability. This positive feedback yields the very rapid and large change in membrane potential described above and shown in Figure 13.13.

The membrane spontaneously becomes less permeable to  $\text{Na}^+$  and more permeable to  $\text{K}^+$ . Consequently,  $\text{K}^+$  flows outward, and so the membrane potential returns to a negative value. The resting level of  $-60$  mV is restored in a few milliseconds as the  $\text{K}^+$  conductance decreases to the value characteristic of the unstimulated state. The wave of depolarization followed by repolarization moves rapidly along a nerve cell. The propagation of these waves allows a touch at the tip of your toe to be detected in your brain in a few milliseconds.

This model for the action potential postulated the existence of ion channels specific for  $\text{Na}^+$  and  $\text{K}^+$ . These channels must open in response to changes in membrane potential and then close after having remained open for a brief period of time. This bold hypothesis predicted the existence of molecules with a well-defined set of properties long before tools existed for their direct detection and characterization.

**FIGURE 13.14 Patch-clamp modes.**

The patch-clamp technique for monitoring channel activity is highly versatile. A high-resistance seal (gigaseal) is formed between the pipette and a small patch of plasma membrane. This configuration is called *cell-attached mode*. The breaking of the membrane patch by increased suction produces a low-resistance pathway between the pipette and the interior of the cell. The activity of the channels in the entire plasma membrane can be monitored in this *whole-cell mode*. To prepare a membrane in the *excised-patch mode*, the pipette is pulled away from the cell. A piece of plasma membrane with its cytoplasmic side now facing the medium is monitored by the patch pipette.

### Patch-clamp conductance measurements reveal the activities of single channels

Direct evidence for the existence of these channels was provided by the *patch-clamp technique*, which was introduced by Erwin Neher and Bert Sakmann in 1976. This powerful technique enables the measurement of the ion conductance through a small patch of cell membrane. In this technique, a clean glass pipette with a tip diameter of about  $1\ \mu\text{m}$  is pressed against an intact cell to form a seal (Figure 13.14). Slight suction leads to the formation of a very tight seal so that the resistance between the inside of the pipette and the bathing solution is many gigaohms (1 gigaohm is equal to  $10^9$  ohms). Thus, a gigaohm seal (called a *gigaseal*) ensures that an electric current flowing through the pipette is identical with the current flowing through the membrane covered by the pipette. The gigaseal makes possible high-resolution current measurements while a known voltage is applied across the membrane. Remarkably, the flow of ions through a single channel and transitions between the open and the closed states of a channel can be monitored with a time resolution of microseconds (Figure 13.15). Furthermore, the activity of a channel in its native membrane environment, even in an intact cell, can be directly observed. Patch-clamp methods provided one of the first views of single biomolecules in action. Subsequently, other methods for observing single molecules were invented, opening new vistas on biochemistry at its most fundamental level.

### The structure of a potassium ion channel is an archetype for many ion-channel structures

With the existence of ion channels firmly established by patch-clamp methods, scientists sought to identify the molecules that form ion channels. The  $\text{Na}^+$  channel was first purified from the electric organ of electric eel,

**FIGURE 13.15 Observing single channels.**

(A) The results of a patch-clamp experiment revealing the small amount of current, measured in picoamperes (pA,  $10^{-12}$  amperes) passing through a single ion channel. The downward spikes indicate transitions between closed and open states. (B) Closer inspection of one of the spikes in (A) reveals the length of time the channel is in the open state.

which is a rich source of the protein forming this channel. The channel was purified on the basis of its ability to bind tetrodotoxin, a neurotoxin from the puffer fish that binds to  $\text{Na}^+$  channels very tightly ( $K_i \approx 1 \text{ nM}$ ). The lethal dose of this poison for an adult human being is about 10 ng.

The isolated  $\text{Na}^+$  channel is a single 260-kDa chain. Cloning and sequencing of cDNAs encoding  $\text{Na}^+$  channels revealed that the channel contains four internal repeats, each having a similar amino acid sequence, suggesting that gene duplication and divergence have produced the gene for this channel. Hydrophobicity profiles indicate that each repeat contains five hydrophobic segments (S1, S2, S3, S5, and S6). Each repeat also contains a highly positively charged S4 segment; positively charged arginine or lysine residues are present at nearly every third residue. It was proposed that segments S1 through S6 are membrane-spanning  $\alpha$  helices, while the positively charged residues in S4 act as the voltage sensors of the channel.

The purification of  $\text{K}^+$  channels proved to be much more difficult because of their low abundance and the lack of known high-affinity ligands comparable to tetrodotoxin. The breakthrough came in studies of mutant fruit flies that shake violently when anesthetized with ether. The mapping and cloning of the gene, termed *shaker*, responsible for this defect revealed the amino acid sequence encoded by a  $\text{K}^+$ -channel gene. The *shaker* gene encodes a 70-kDa protein that contains sequences corresponding to segments S1 through S6 in one of the repeated units of the  $\text{Na}^+$  channel. Thus, a  $\text{K}^+$ -channel subunit is homologous to one of the repeated units of  $\text{Na}^+$  channels. Consistent with this homology, four Shaker polypeptides come together to form a functional channel. More recently, bacterial  $\text{K}^+$  channels were discovered that contain only the two membrane-spanning regions corresponding to segments S5 and S6. This and other information suggested that S5 and S6, including the region between them, form the actual pore in the  $\text{K}^+$  channel. Segments S1 through S4 contain the apparatus that opens the pore. The sequence relations between these ion channels are summarized in Figure 13.16.

**FIGURE 13.16 Sequence relations of ion channels.** Like colors indicate structurally similar regions of the sodium, calcium, and potassium channels. Each of these channels exhibits approximate fourfold symmetry, either within one chain (sodium, calcium channels) or by forming tetramers (potassium channels).

In 1998, Roderick MacKinnon and coworkers determined the structure of a  $\text{K}^+$  channel from the bacterium *Streptomyces lividans* by x-ray crystallography. This channel contains only the pore-forming segments S5 and S6. As expected, the  $\text{K}^+$  channel is a tetramer of identical subunits, each of which includes two membrane-spanning  $\alpha$  helices (Figure 13.17). The four subunits come together to form a pore in the shape of a cone that runs through the center of the structure.

### The structure of the potassium ion channel reveals the basis of ion specificity

The structure presented in Figure 13.17 probably represents the  $\text{K}^+$  channel in a closed form. Nonetheless, it suggests how the channel is able to exclude all but  $\text{K}^+$  ions. Beginning from the inside of the cell, the pore starts with a diameter of approximately 10 Å and then constricts to a smaller cavity with a

**FIGURE 13.17 Structure of the potassium ion channel.** The  $K^+$  channel, composed of four identical subunits, is cone shaped, with the larger opening facing the inside of the cell (center). A view down the pore, looking toward the outside of the cell, shows the relations of the individual subunits (left). One of the four identical subunits of the pore is illustrated at the right, with the pore-forming region shown in gray. [Drawn from 1K4C.pdb.]

diameter of 8 Å. Both the opening to the outside and the central cavity of the pore are filled with water, and a  $K^+$  ion can fit in the pore without losing its shell of bound water molecules. Approximately two-thirds of the way through the membrane, the pore becomes more constricted (3-Å diameter). At that point, any  $K^+$  ions must give up their water molecules and interact directly with groups from the protein. The channel structure effectively reduces the thickness of the membrane from 34 Å to 12 Å by allowing the solvated ions to penetrate into the membrane before the ions must directly interact with the channel (Figure 13.18).

For  $K^+$  ions to relinquish their water molecules, other polar interactions must replace those with water. The restricted part of the pore is built from residues contributed by the two transmembrane  $\alpha$  helices. In particular, a five-amino-acid stretch within this region functions as the *selectivity filter* that determines the preference for  $K^+$  over other ions (Figure 13.19). The stretch has the sequence Thr-Val-Gly-Tyr-Gly (TVGYG), and is nearly completely conserved in all  $K^+$  channels. The region of the strand containing the conserved sequence lies in an extended conformation and is oriented such that the peptide carbonyl groups are directed into the channel, in good position to interact with the potassium ions.

**FIGURE 13.18 Path through a channel.** A potassium ion entering the  $K^+$  channel can pass a distance of 22 Å into the membrane while remaining solvated with water (blue). At this point, the pore diameter narrows to 3 Å (yellow), and potassium ions must shed their water and interact with carbonyl groups (red) of the pore amino acids.

**FIGURE 13.19 Selectivity filter of the potassium ion channel.** Potassium ions interact with the carbonyl groups of the TVGYG sequence of the selectivity filter, located at the 3-Å-diameter pore of the  $K^+$  channel. Only two of the four channel subunits are shown.

**TABLE 13.1** Properties of alkali cations

Ion	Ionic radius (Å)	Hydration free energy in kJ mol <sup>-1</sup> (kcal mol <sup>-1</sup> )
Li <sup>+</sup>	0.60	-410 (-98)
Na <sup>+</sup>	0.95	-301 (-72)
K <sup>+</sup>	1.33	-230 (-55)
Rb <sup>+</sup>	1.48	-213 (-51)
Cs <sup>+</sup>	1.69	-197 (-47)

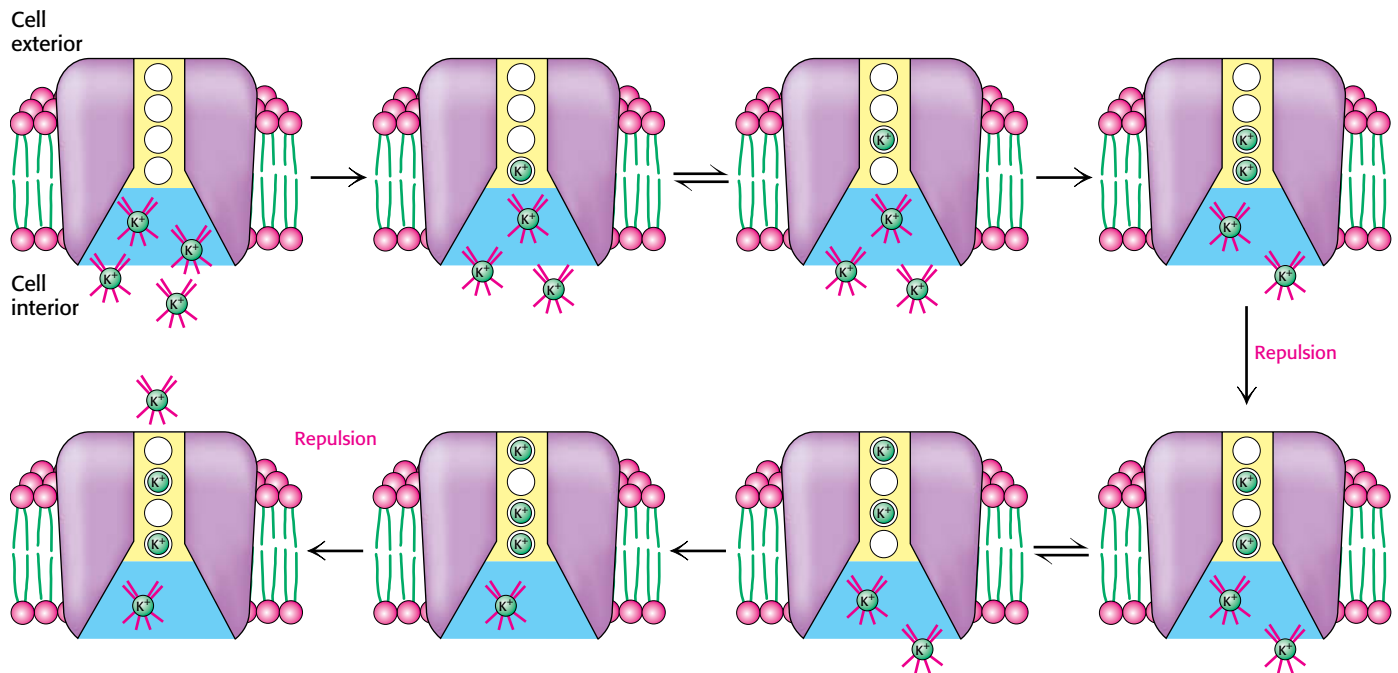

Potassium ion channels are 100-fold more permeable to K<sup>+</sup> than to Na<sup>+</sup>. How is this high degree of selectivity achieved? Ions having a radius larger than 1.5 Å cannot pass into the narrow diameter (3 Å) of the selectivity filter of the K<sup>+</sup> channel. However, a bare Na<sup>+</sup> is small enough (Table 13.1) to pass through the pore. Indeed, the ionic radius of Na<sup>+</sup> is substantially smaller than that of K<sup>+</sup>. How then is Na<sup>+</sup> rejected?

The key point is that the free-energy costs of dehydrating these ions are considerable [Na<sup>+</sup>, 301 kJ mol<sup>-1</sup> (72 kcal mol<sup>-1</sup>), and K<sup>+</sup>, 230 kJ mol<sup>-1</sup> (55 kcal mol<sup>-1</sup>)]. *The channel pays the cost of dehydrating K<sup>+</sup> by providing optimal compensating interactions with the carbonyl oxygen atoms lining the selectivity filter.* Careful studies of the potassium channel, enabled by the determination of its three-dimensional structure, have revealed that the interior of the pore is a highly dynamic, fluid environment. The favorable interactions between the carbonyl oxygen atoms, which carry a partial negative charge, with the cation are balanced by the repulsion of these oxygen atoms from one another. For this channel, the ideal balance is achieved with K<sup>+</sup>, but not with Na<sup>+</sup> (Figure 13.20). Hence, sodium ions are rejected because the higher energetic cost of dehydrating them would not be recovered.

**FIGURE 13.20 Energetic basis of ion selectivity.** The energy cost of dehydrating a potassium ion is compensated by favorable interactions with the selectivity filter. Because a sodium ion is too small to interact favorably with the selectivity filter, the free energy of desolvation cannot be compensated and the sodium ion does not pass through the channel.

 The K<sup>+</sup> channel structure enables a clearer understanding of the structure and function of Na<sup>+</sup> and Ca<sup>2+</sup> channels because of their homology to K<sup>+</sup> channels. Sequence comparisons and the results of mutagenesis experiments have implicated the region between segments S5 and S6 in ion selectivity in the Ca<sup>2+</sup> channel. In Ca<sup>2+</sup> channels, one glutamate residue of this region in each of the four repeated units plays a major role in determining ion selectivity. Residues in the positions corresponding to the glutamate residues in Ca<sup>2+</sup> channels are major components of the selectivity filter of the Na<sup>+</sup> channel. These residues—aspartate, glutamate, lysine, and alanine—are located in each of the internal repeats of the Na<sup>+</sup> channel, forming a region termed the DEKA locus. Thus, the potential fourfold symmetry of the channel is clearly broken in this region, which explains why Na<sup>+</sup> channels consist of a single large polypeptide chain rather than a noncovalent assembly of four identical subunits. The preference of the Na<sup>+</sup> channel for Na<sup>+</sup> over K<sup>+</sup> depends on ionic radius; the diameter of the pore determined by these residues and others is sufficiently restricted that small ions such as Na<sup>+</sup> and Li<sup>+</sup> can pass through the channel, but larger ions such as K<sup>+</sup> are significantly hindered.

### The structure of the potassium ion channel explains its rapid rate of transport

The tight binding sites required for ion selectivity should slow the progress of ions through a channel, yet ion channels achieve rapid rates of ion transport. How is this paradox resolved? A structural analysis of the  $K^+$  channel at high resolution provides an appealing explanation. Four  $K^+$ -binding sites crucial for rapid ion flow are present in the constricted region of the  $K^+$  channel. Consider the process of ion conductance starting from inside the cell (Figure 13.21). A hydrated potassium ion proceeds into the channel and through the relatively unrestricted part of the channel. The ion then gives up its coordinated water molecules and binds to a site within the selectivity-filter region. The ion can move between the four sites within the selectivity filter because they have similar ion affinities. As each subsequent potassium ion moves into the selectivity filter, its positive charge will repel the potassium ion at the nearest site, causing it to shift to a site farther up the channel and in turn push upward any potassium ion already bound to a site farther up. Thus, each ion that binds anew favors the release of an ion from the other side of the channel. This multiple-binding-site mechanism solves the paradox of high ion selectivity and rapid flow.

### Voltage gating requires substantial conformational changes in specific ion-channel domains

Some  $Na^+$  and  $K^+$  channels are gated by membrane potential; that is, they change conformation to a highly conducting form in response to changes in voltage across the membrane. As already noted, these *voltage-gated channels* include segments S1 through S4 in addition to the pore itself formed by S5 and S6. The structure of a voltage-gated  $K^+$  channel from *Aeropyrum pernix* has been determined by x-ray crystallography (Figure 13.22). The segments S1 through S4 form domains, termed “paddles,” that extend from the core of the channel. These paddles include the segment S4, the voltage sensor itself. Segment S4 forms an  $\alpha$  helix lined with positively charged residues. In contrast with expectations, segments S1 through S4 are not enclosed within the protein but, instead, are positioned to lie in the membrane itself.

**FIGURE 13.21 Model for  $K^+$ -channel ion transport.** The selectivity filter has four binding sites. Hydrated potassium ions can enter these sites, one at a time, losing their hydration shells. When two ions occupy adjacent sites, electrostatic repulsion forces them apart. Thus, as ions enter the channel from one side, other ions are pushed out the other side.

**FIGURE 13.22 Structure of a voltage-gated potassium channel.** (A) A view looking down through the pore. (B) A side view. Notice that the positively charged S4 region (red) lies on the outside of the structure at the bottom of the pore. [Drawn from 1ORQ.pdb.]

A model for voltage gating has been proposed by Roderick MacKinnon and coworkers on the basis of this structure and a range of other experiments (Figure 13.23). In the closed state, the paddles lie in a “down” position. On membrane depolarization, the cytoplasmic side of the membrane becomes more positively charged, and the paddles are pulled through the membrane into an “up” position. In this position, they pull the four sides of the base on the pore apart, increasing access to the selectivity filter and opening the channel.

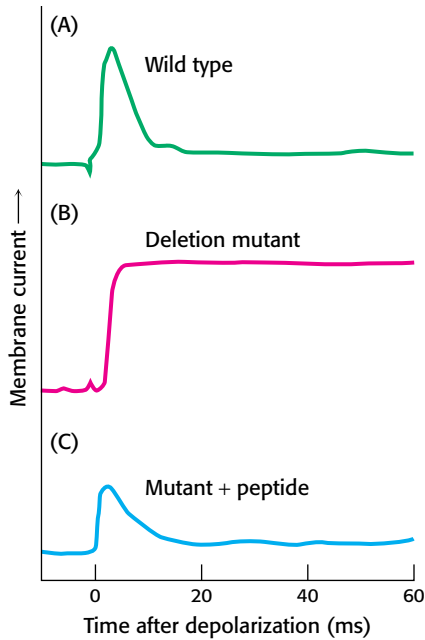

**FIGURE 13.23 A model for voltage gating of ion channels.** The voltage-sensing paddles lie in the “down” position below the closed channel (left). Membrane depolarization pulls these paddles through the membrane. The motion pulls the base of the channel apart, opening the channel (right).

### A channel can be inactivated by occlusion of the pore: the ball-and-chain model

The  $K^+$  channel and the  $Na^+$  channel undergo inactivation within milliseconds of opening (Figure 13.24). A first clue to the mechanism of inactivation came from exposing the cytoplasmic side of either channel to trypsin; cleavage by trypsin produced trimmed channels that stayed persistently open after depolarization. Furthermore, a mutant Shaker channel lacking 42 amino acids near the amino terminus opened in response to depolarization but did not inactivate. Remarkably, inactivation was restored by adding a synthetic peptide corresponding to the first 20 residues of the native channel.

These experiments strongly support the *ball-and-chain model* for channel inactivation that had been proposed years earlier (Figure 13.25). According to this model, the first 20 residues of the  $K^+$  channel form a cytoplasmic unit (the *ball*) that is attached to a flexible segment of the polypeptide (the *chain*). When the channel is closed, the ball rotates freely in

**FIGURE 13.24 Inactivation of the potassium ion channel.** The amino-terminal region of the  $K^+$  chain is critical for inactivation. (A) The wild-type Shaker  $K^+$  channel displays rapid inactivation after opening. (B) A mutant channel lacking residues 6 through 46 does not inactivate. (C) Inactivation can be restored by adding a peptide consisting of residues 1 through 20 at a concentration of  $100 \mu\text{M}$ . [Data from W. N. Zagotta, T. Hoshi, and R. W. Aldrich, *Science* 250:568–571, 1990.]

the aqueous solution. When the channel opens, the ball quickly finds a complementary site in the open pore and occludes it. Hence, the channel opens for only a brief interval before it undergoes inactivation by occlusion. Shortening the chain speeds inactivation because the ball finds its target more quickly. Conversely, lengthening the chain slows inactivation. Thus, the duration of the open state can be controlled by the length and flexibility of the tether. In some senses, the “ball” domains, which include substantial regions of positive charge, can be thought of as large, tethered cations that are pulled into the open channel but get stuck and block further ion conductance.

**FIGURE 13.25 Ball-and-chain model for channel inactivation.** The inactivation domain, or “ball” (gray), is tethered to the channel by a flexible “chain.” In the closed state, the ball is located in the cytoplasm. Depolarization opens the channel and creates a binding site for the positively charged ball in the mouth of the pore. Movement of the ball into this site inactivates the channel by occluding it.

### The acetylcholine receptor is an archetype for ligand-gated ion channels

Nerve impulses are communicated across synapses by small, diffusible molecules called *neurotransmitters*. One neurotransmitter is *acetylcholine*. The presynaptic membrane of a synapse is separated from the postsynaptic membrane by a gap of about 50 nm called the *synaptic cleft*. The arrival of a nerve impulse at the end of an axon leads to the synchronous export of the contents of some 300 membrane-bound compartments, or vesicles, of acetylcholine into the cleft (Figure 13.26). The binding of acetylcholine to the postsynaptic membrane markedly changes its ionic permeability, triggering an action potential. Acetylcholine opens a single kind of cation channel, called the *acetylcholine receptor*, which is almost equally permeable to  $\text{Na}^+$  and to  $\text{K}^+$ .

**FIGURE 13.26** Schematic representation of a synapse.

The torpedo (*Torpedo marmorata*, also known as the electric ray) has an electric organ, rich in acetylcholine receptors, that can deliver a shock of as much as 200 V for approximately 1 s. [Yves Gladu/Jacana/Photo Researchers.]

The acetylcholine receptor is the best-understood *ligand-gated channel*. This type of channel is gated not by voltage but by the presence of specific ligands. The binding of acetylcholine to the channel is followed by its transient opening. The electric organ of *Torpedo marmorata*, an electric ray, is a choice source of acetylcholine receptors for study because its electroplaxes (voltage-generating cells) are very rich in postsynaptic membranes that respond to this neurotransmitter. The receptor is very densely packed in these membranes ( $\sim 20,000 \mu\text{m}^{-2}$ ). The acetylcholine receptor of the electric organ has been solubilized by adding a nonionic detergent to a post-synaptic membrane preparation and purified by affinity chromatography on a column bearing covalently attached cobratoxin, a small protein toxin from snakes that has a high affinity for acetylcholine receptors. With the use of techniques presented in Chapter 3, the 268-kDa receptor was identified as a pentamer of four kinds of membrane-spanning subunits— $\alpha_2$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ —arranged in the form of a ring that creates a pore through the membrane.

The cloning and sequencing of the cDNAs for the four kinds of subunits (50–58 kDa) showed that they have clearly similar sequences; the genes for the  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$  subunits arose by duplication and divergence of a common ancestral gene. Each subunit has a large extracellular domain, followed at the carboxyl end by four predominantly hydrophobic segments that span the bilayer membrane. Acetylcholine binds at the  $\alpha$ - $\gamma$  and  $\alpha$ - $\delta$  interfaces. Electron microscopic studies of purified acetylcholine receptors demonstrated that the structure has approximate fivefold symmetry, in harmony with the similarity of its five constituent subunits (Figure 13.27).

What is the basis of channel opening? A comparison of the structures of the closed and open forms of the channel would be highly revealing, but such comparisons have been difficult to obtain. Cryoelectron micrographs indicate that the binding of acetylcholine to the extracellular domain causes a structural alteration that initiates rotations of the  $\alpha$ -helical rods lining the membrane-spanning pore. The amino acid sequences of these helices point to the presence of alternating ridges of small polar or neutral residues (serine, threonine, glycine) and large nonpolar ones (isoleucine,

**FIGURE 13.27** Structure of the acetylcholine receptor. A model for the structure of the acetylcholine receptor deduced from high-resolution electron microscopic studies reveals that each subunit consists of a large extracellular domain consisting primarily of  $\beta$  strands, four membrane-spanning  $\alpha$  helices, and a final  $\alpha$  helix inside the cell. (A) A side view shows the pentameric receptor with each subunit type in a different color. One copy of the  $\alpha$  subunit is shown in isolation. (B) A view down the channel from outside the cell. [Drawn from 2BG9.pdb.]

leucine, phenylalanine). In the closed state, the large residues may occlude the channel by forming a tight hydrophobic ring (Figure 13.28). Indeed, each subunit has a bulky leucine residue at a critical position. The binding of acetylcholine could allosterically rotate the membrane-spanning helices so that the pore would be lined by small polar residues rather than by large hydrophobic ones. The wider, more polar pore would then be open to the passage of  $\text{Na}^+$  and  $\text{K}^+$  ions.

### Action potentials integrate the activities of several ion channels working in concert

To see how ligand-gated and voltage-gated channels work together to generate a sophisticated physiological response, we now revisit the action potential introduced at the beginning of this section. First, we need to introduce the concept of *equilibrium potential*. Suppose that a membrane separates two solutions that contain different concentrations of some cation  $\text{X}^+$ , as well as an equivalent amount of anions to balance the charge in each solution (Figure 13.29). Let  $[\text{X}^+]_{\text{in}}$  be the concentration of  $\text{X}^+$  on one side of the membrane (corresponding to the inside of a cell) and  $[\text{X}^+]_{\text{out}}$  be the concentration of  $\text{X}^+$  on the other side (corresponding to the outside of a cell). Suppose that an ion channel opens that allows  $\text{X}^+$  to move across the membrane. What will happen? It seems clear that  $\text{X}^+$  will move through the channel from the side with the higher concentration to the side with the lower concentration. However, positive charges will start to accumulate on the side with the lower concentration, making it more difficult to move each additional positively charged ion. An equilibrium will be achieved when the driving force due to the concentration gradient is balanced by the electrostatic force resisting the motion of an additional charge. In these circumstances, the membrane potential is given by the *Nernst equation*:

$$V_{\text{eq}} = -(RT/zF) \ln([\text{X}]_{\text{in}}/[\text{X}]_{\text{out}})$$

where  $R$  is the gas constant and  $F$  is the Faraday constant ( $96.5 \text{ kJ V}^{-1} \text{ mol}^{-1}$ , or  $23.1 \text{ kcal V}^{-1} \text{ mol}^{-1}$ ) and  $z$  is the charge on the ion  $\text{X}$  (e.g.,  $+1$  for  $\text{X}^+$ ).

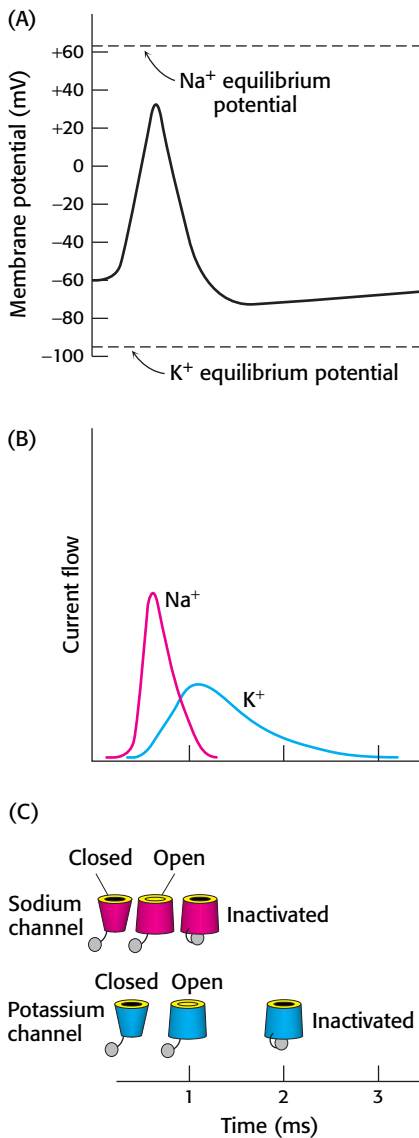

The membrane potential at equilibrium is called the equilibrium potential for a given ion at a given concentration ratio across a membrane. For sodium with  $[\text{Na}^+]_{\text{in}} = 14 \text{ mM}$  and  $[\text{Na}^+]_{\text{out}} = 143 \text{ mM}$ , the equilibrium potential is  $+62 \text{ mV}$  at  $37^\circ\text{C}$ . Similarly, for potassium with  $[\text{K}^+]_{\text{in}} = 157 \text{ mM}$  and  $[\text{K}^+]_{\text{out}} = 4 \text{ mM}$ , the equilibrium potential is  $-98 \text{ mV}$ . In the absence of

**FIGURE 13.28 Opening the acetylcholine receptor.** Cross sections from electron microscopic reconstructions of the acetylcholine receptor in (top) its closed form and (bottom) its open form. (The open form corresponds to the structure shown in Figure 13.27). The areas labeled M1, M2, M3, and M4 correspond to the four membrane-spanning  $\alpha$  helices of one subunit. The cross section of the open channel was generated by treating the receptor with acetylcholine and freezing the sample within 20 ms. Notice that the hole in the center of the channel is substantially larger in the open structure. The enlargement of the hole is due to the rotation of the M2 helices by approximately 15 degrees along their long axes. [Courtesy of Nigel Unwin.]

**FIGURE 13.29 Equilibrium potential.** The membrane potential reaches equilibrium when the driving force due to the concentration gradient is exactly balanced by the opposing force due to the repulsion of like charges.

**FIGURE 13.30 Action-potential mechanism.** (A) On the initiation of an action potential, the membrane potential moves from the resting potential upward toward the  $\text{Na}^+$  equilibrium potential and then downward toward the  $\text{K}^+$  equilibrium potential. (B) The currents through the  $\text{Na}^+$  and  $\text{K}^+$  channels underlying the action potential. (C) The states of the  $\text{Na}^+$  and  $\text{K}^+$  channels during the action potential.

stimulation, the resting potential for a typical neuron is  $-60$  mV. This value is close to the equilibrium potential for  $\text{K}^+$  owing to the fact that a small number of  $\text{K}^+$  channels are open.

We are now prepared to consider what happens in the generation of an action potential (Figure 13.30). Initially, a neurotransmitter such as acetylcholine is released into the synaptic cleft from a presynaptic membrane (Figure 13.26). The released acetylcholine binds to the acetylcholine receptor on the postsynaptic membrane, causing it to open within less than a millisecond. The acetylcholine receptor is a nonspecific cation channel. Sodium ions flow into the cell and potassium ions flow out of the cell. Without any further events, the membrane potential would move to a value corresponding to the average of the equilibrium potentials for  $\text{Na}^+$  and  $\text{K}^+$ , approximately  $-20$  mV. However, as the membrane potential approaches  $-40$  mV, the voltage-sensing paddles of  $\text{Na}^+$  channels are pulled into the membrane, opening the  $\text{Na}^+$  channels. With these channels open, sodium ions flow rapidly into the cell and the membrane potential rises rapidly toward the  $\text{Na}^+$  equilibrium potential (Figure 13.30B, red curve). The voltage-sensing paddles of  $\text{K}^+$  channels also are pulled into the membrane by the changed membrane potential, but more slowly than  $\text{Na}^+$  channel paddles. Nonetheless, after approximately 1 ms, many  $\text{K}^+$  channels start to open. At the same time, inactivation “ball” domains plug the open  $\text{Na}^+$  channels, decreasing the  $\text{Na}^+$  current. The acetylcholine receptors that initiated these events are also inactivated on this time scale. With the  $\text{Na}^+$  channels inactivated and only the  $\text{K}^+$  channels open, the membrane potential drops rapidly toward the  $\text{K}^+$  equilibrium potential (Figure 13.30B, blue curve). The open  $\text{K}^+$  channels are susceptible to inactivation by their “ball” domains, and these  $\text{K}^+$  currents, too, are blocked. With the membrane potential returned to close to its initial value, the inactivation domains are released and the channels return to their original closed states. These events propagate along the neuron as the depolarization of the membrane opens channels in nearby patches of membrane.

How much current actually flows across the membrane over the course of an action potential? This question can be addressed from two complementary directions. First, a typical nerve cell contains 100  $\text{Na}^+$  channels per square micrometer. At a membrane potential of  $+20$  mV, each channel conducts  $10^7$  ions per second. Thus, in a period of 1 millisecond, approximately  $10^5$  ions flow through each square micrometer of membrane surface. Assuming a cell volume of  $10^4 \mu\text{m}^3$  and a surface area of  $10^4 \mu\text{m}^2$ , this rate of ion flow corresponds to an increase in the  $\text{Na}^+$  concentration of less than 1%. How can this be? A robust action potential is generated because the membrane potential is very sensitive to even a slight change in the distribution of charge. This sensitivity makes the action potential a very efficient means of signaling over long distances and with rapid repetition rates.

### Disruption of ion channels by mutations or chemicals can be potentially life-threatening

 The generation of an action potential requires the precise coordination of gating events of a collection of ion channels. Perturbation of this timing can have devastating effects. For example, the rhythmic generation of action potentials by the heart is absolutely essential to maintain delivery of oxygenated blood to the peripheral tissues. *Long QT syndrome* (LQTS) is a genetic disorder in which the recovery of the action potential from its peak potential to the resting equilibrium potential is delayed. The term “QT” refers to a specific feature of the cardiac electrical activity pattern as measured by electrocardiography. LQTS can lead to brief losses of consciousness (syncope), disruption of normal cardiac rhythm

(arrhythmia), and sudden death. The most common mutations identified in LQTS patients inactivate  $K^+$  channels or prevent the proper trafficking of these channels to the plasma membrane. The resulting loss in potassium permeability slows the repolarization of the membrane and delays the induction of the subsequent cardiac contraction, rendering the cardiac tissue susceptible to arrhythmias.

Prolongation of the cardiac action potential in this manner can also be induced by a number of therapeutic drugs. In particular, the  $K^+$  channel hERG (for human *ether-a-go-go*-related gene, named for its ortholog in *Drosophila melanogaster*) is highly susceptible to interactions with certain drugs. The hydrophobic regions of these drugs can block hERG by binding to two nonconserved aromatic residues on the internal surface of the channel cavity. In addition, this cavity is predicted to be wider than other  $K^+$  channels because of the absence of a conserved Pro-X-Pro motif within the S6 hydrophobic segment. Inhibition of hERG by these drugs can lead to an increased risk of cardiac arrhythmias and sudden death. Accordingly, a number of these agents, such as the antihistamine terfenadine, have been withdrawn from the market. Screening for the inhibition of hERG is now a critical safety hurdle for the pharmaceutical advancement of a molecule to an approved drug.

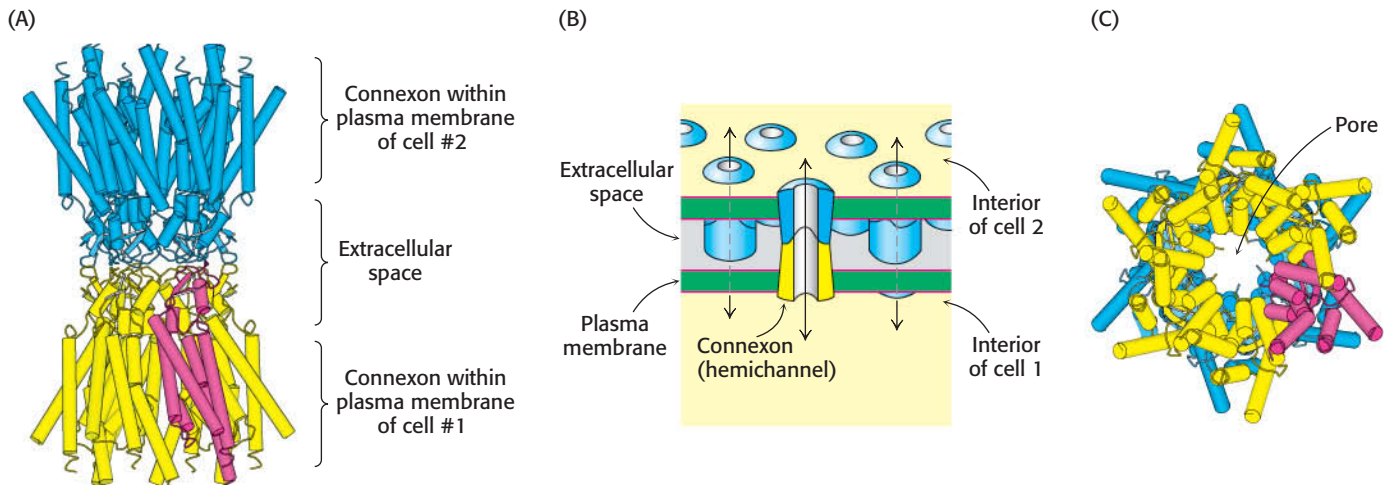

### 13.5 Gap Junctions Allow Ions and Small Molecules to Flow Between Communicating Cells

The ion channels that we have considered thus far have narrow pores and are moderately to highly selective in the ions that they allow to pass through them. They are closed in the resting state and have short lifetimes in the open state, typically a millisecond, that enable them to transmit frequent neural signals. We turn now to a channel with a very different role. *Gap junctions*, also known as *cell-to-cell channels*, serve as passageways between the interiors of contiguous cells. Gap junctions are clustered in discrete regions of the plasma membranes of apposed cells. Electron micrographs of sheets of gap junctions show them tightly packed in a regular hexagonal array (Figure 13.31). An approximately 20-Å central hole, the lumen of the channel, is prominent in each gap junction. These channels span the intervening space, or gap, between apposed cells (hence, the name “gap junction”). The width of the gap between the cytoplasm of the two cells is about 35 Å.

Small hydrophilic molecules as well as ions can pass through gap junctions. The pore size of the junctions was determined by microinjecting a series of fluorescent molecules into cells and observing their passage into adjoining cells. All polar molecules with a mass of less than about 1 kDa can readily pass through these cell-to-cell channels. Thus, *inorganic ions and most metabolites (e.g., sugars, amino acids, and nucleotides) can flow between the interiors of cells joined by gap junctions*. In contrast, proteins, nucleic acids, and polysaccharides are too large to traverse these channels. *Gap junctions are important for intercellular communication*. Cells in some excitable tissues, such as heart muscle, are coupled by the rapid flow of ions through these junctions, which ensures a rapid and synchronous response to stimuli. Gap junctions are also essential for the nourishment of cells that are distant from blood vessels, as in lens and bone. Moreover, communicating channels are important in development and differentiation. For example, the quiescent uterus transforms to a forcefully contracting organ at the onset of labor; the formation of functional gap junctions at that time creates a syncytium of muscle cells that contract in synchrony.

**FIGURE 13.31 Gap junctions.** This electron micrograph shows a sheet of isolated gap junctions. The cylindrical connexons form a hexagonal lattice having a unit-cell length of 85 Å. The densely stained central hole has a diameter of about 20 Å. [Don W. Fawcett/Photo Researchers.]

**FIGURE 13.32 Structure of a gap junction.** (A) Six connexins join to form a connexon, or hemichannel, within the plasma membrane (yellow). A single connexin monomer is highlighted in red. The extracellular region of one connexon binds to the same region of a connexon from another cell (blue), forming a complete gap junction. (B) Schematic view of the gap junction, oriented in the same direction as in (A). (C) A bottom-up view looking through the pore of a gap junction. This perspective is visualized in Figure 13.31. [(A) and (C) Drawn from 2ZW3.pdb; (B) Information from Dr. Werner Loewenstein.]

A cell-to-cell channel is made of 12 molecules of *connexin*, one of a family of transmembrane proteins with molecular masses ranging from 30 to 42 kDa. Each connexin molecule contains four membrane-spanning helices (Figure 13.32A). Six connexin molecules are hexagonally arrayed to form a half-channel, called a *connexon* or *hemichannel*. Two connexons join end to end in the intercellular space to form a functional channel between the communicating cells (Figure 13.32B). Each connexon adopts a funnel-shape: at the cytoplasmic face, the inner diameter of the channel is 35 Å, while at its innermost point, the pore narrows to a diameter of 14 Å (Figure 13.32C). Cell-to-cell channels differ from other membrane channels in three respects: (1) they traverse *two* membranes rather than one; (2) they connect cytoplasm to cytoplasm, rather than to the extracellular space or the lumen of an organelle; and (3) the connexons forming a channel are synthesized by different cells. Gap junctions form readily when cells are brought together. A cell-to-cell channel, once formed, tends to stay open for seconds to minutes. They are closed by high concentrations of calcium ion and by low pH. *The closing of gap junctions by  $Ca^{2+}$  and  $H^+$  serves to seal normal cells from injured or dying neighbors.* Gap junctions are also controlled by membrane potential and by hormone-induced phosphorylation.

The human genome encodes 21 distinct connexins. Different members of this family are expressed in different tissues. For example, connexin 26 is expressed in key tissues in the ear. Mutations in this connexin are associated with hereditary deafness. The mechanistic basis for this deafness appears to be insufficient transport of ions or second-messenger molecules, such as inositol trisphosphate, between sensory cells.

### 13.6 Specific Channels Increase the Permeability of Some Membranes to Water

One more important class of channels does not take part in ion transport at all. Instead, these channels increase the rate at which water flows through membranes. As noted in Section 12.3, membranes are reasonably

permeable to water. Why, then, are water-specific channels required? In certain tissues, in some circumstances, rapid water transport through membranes is necessary. In the kidney, for example, water must be rapidly reabsorbed into the bloodstream after filtration. Similarly, in the secretion of saliva and tears, water must flow quickly through membranes. These observations suggested the existence of specific water channels, but initially the channels could not be identified.

The channels (now called *aquaporins*) were discovered serendipitously. Peter Agre noticed a protein present at high levels in red-blood-cell membranes that had been missed because the protein does not stain well with Coomassie blue. In addition to red blood cells, this protein was found in large quantities in tissues such as the kidney and the cornea, precisely the tissues thought to contain water channels. On the basis of this observation, further studies were designed, revealing that this 24-kDa membrane protein is, indeed, a water channel.

The structure of aquaporin has been determined (Figure 13.33). The protein consists of six membrane-spanning  $\alpha$  helices. Two loops containing hydrophilic residues line the actual channel. Water molecules pass through in single file at a rate of  $10^6$  molecules per second. Importantly, specific positively charged residues toward the center of the channel prevent the transport of protons through aquaporin. Thus, aquaporin channels will not disrupt proton gradients, which play fundamental roles in energy transduction, as we will see in Chapter 18. Remarkably, the aquaporins are channels that have evolved specifically to conduct uncharged substrates.

**FIGURE 13.33 Structure of aquaporin.** The structure of aquaporin viewed from the side (left) and from the top (right). Notice the hydrophilic residues (shown as space-filling models) that line the water channel. [Drawn from 1J4N.pdb.]

## SUMMARY

### 13.1 The Transport of Molecules Across a Membrane May Be Active or Passive

For a net movement of molecules across a membrane, two features are required: (1) the molecule must be able to cross a hydrophobic barrier and (2) an energy source must power the movement. Lipophilic molecules can pass through a membrane's hydrophobic interior by simple diffusion. These molecules will move down their concentration gradients. Polar or charged molecules require proteins to form passages through the hydrophobic barrier. Passive transport or facilitated

diffusion takes place when an ion or polar molecule moves down its concentration gradient. If a molecule moves against a concentration gradient, an external energy source is required; this movement is referred to as active transport and results in the generation of concentration gradients. The electrochemical potential measures the combined ability of a concentration gradient and an uneven distribution of charge to drive species across a membrane.

### 13.2 Two Families of Membrane Proteins Use ATP Hydrolysis to Pump Ions and Molecules Across Membranes

Active transport is often carried out at the expense of ATP hydrolysis. P-type ATPases pump ions against a concentration gradient and become transiently phosphorylated on an aspartic acid residue in the process of transport. P-type ATPases, which include the sarcoplasmic reticulum  $\text{Ca}^{2+}$  ATPase and the  $\text{Na}^{+}$ - $\text{K}^{+}$  ATPase, are integral membrane proteins with conserved structures and catalytic mechanisms. Membrane proteins containing ATP-binding cassette domains are another family of ATP-dependent pumps. Each pump includes four major domains: two domains span the membrane and two others contain ABC P-loop ATPase structures. These pumps are not phosphorylated during pumping; rather, they use the energy of ATP binding and hydrolysis to drive conformational changes that result in the transport of specific substrates across membranes. The multidrug-resistance proteins confer resistance on cancer cells by pumping chemotherapeutic drugs out of a cancer cell before the drugs can exert their effects.

### 13.3 Lactose Permease is an Archetype of Secondary Transporters That Use One Concentration Gradient to Power the Formation of Another

Carriers are proteins that transport ions or molecules across the membrane without hydrolysis of ATP. They can be classified as uniporters, antiporters, and symporters. Uniporters transport a substrate in either direction, determined by the concentration gradient. Antiporters and symporters can mediate secondary active transport by coupling the uphill flow of one substrate to the downhill flow of another. Antiporters couple the downhill flow of one substrate in one direction to the uphill flow of another in the opposite direction. Symporters move both substrates in the same direction. Studies of the lactose permease from *E. coli* have been a source of insight into both the structures and the mechanisms of secondary transporters.

### 13.4 Specific Channels Can Rapidly Transport Ions Across Membranes

Ion channels allow the rapid movement of ions across the hydrophobic barrier of the membrane. The activity of individual ion-channel molecules can be observed by using patch-clamp techniques. Many ion channels have a common structural framework. In regard to  $\text{K}^{+}$  channels, hydrated potassium ions must transiently lose their coordinated water molecules as they move to the narrowest part of the channel, termed the selectivity filter. In the selectivity filter, peptide carbonyl groups coordinate the ions. Rapid ion flow through the selectivity filter is facilitated by ion-ion repulsion, with one ion pushing the next ion through the channel. Some ion channels are voltage gated: changes in membrane potential induce conformational changes that open these channels. Many channels spontaneously inactivate after having been open for a short period of time. In some cases, inactivation is due to the binding of a domain of the channel termed the “ball” in the mouth of the channel to block it. Other channels, typified by the acetylcholine

receptor, are opened or closed by the binding of ligands. Ligand-gated and voltage-gated channels work in concert to generate action potentials. Inherited mutations or drugs that interfere with the ion channels that produce the action potential can result in potentially life-threatening conditions.

### 13.5 Gap Junctions Allow Ions and Small Molecules to Flow Between Communicating Cells

In contrast with many channels, which connect the cell interior with the environment, gap junctions, or cell-to-cell channels, serve to connect the interiors of contiguous groups of cells. A cell-to-cell channel is composed of 12 molecules of connexin, which associate to form two 6-membered connexons.

### 13.6 Specific Channels Increase the Permeability of Some Membranes to Water

Some tissues contain proteins that increase the permeability of membranes to water. Each water-channel-forming protein, termed an aquaporin, consists of six membrane-spanning  $\alpha$  helices and a central channel lined with hydrophilic residues that allow water molecules to pass in single file. Aquaporins do not transport protons.

## PROBLEMS

1. *A helping hand.* Differentiate between simple diffusion and facilitated diffusion.
2. *Powering movement.* What are the two forms of energy that can power active transport?
3. *Carriers.* Name the three types of carrier proteins. Which of these can mediate secondary active transport?
4. *The price of extrusion.* What is the free-energy cost at 25°C of pumping  $\text{Ca}^{2+}$  out of a cell when the cytoplasmic concentration is 0.4  $\mu\text{M}$ , the extracellular concentration is 1.5 mM, and the membrane potential is  $-60$  mV?
5. *Equilibrium potentials.* For a typical mammalian cell, the intracellular and extracellular concentrations of the chloride ion ( $\text{Cl}^-$ ) are 4 mM and 150 mM, respectively.

For the calcium ion ( $\text{Ca}^{2+}$ ), the intracellular and extracellular concentrations are  $0.2 \mu\text{M}$  and  $1.8 \text{ mM}$ , respectively. Calculate the equilibrium potentials at  $37^\circ\text{C}$  for these two ions.

6. *How sweet it is.* Some animal cells take up glucose by a symporter powered by the simultaneous entry of  $\text{Na}^+$ . The entry of  $\text{Na}^+$  provides a free-energy input of  $10.8 \text{ kJ mol}^{-1}$  ( $2.6 \text{ kcal mol}^{-1}$ ) under typical cellular conditions (external  $[\text{Na}^+] = 143 \text{ mM}$ , internal  $[\text{Na}^+] = 14 \text{ mM}$ , and membrane potential =  $-50 \text{ mV}$ ). How large a concentration gradient of glucose at  $37^\circ\text{C}$  can be generated by this free-energy input?

7. *Variations on a theme.* Write a detailed mechanism for transport by the  $\text{Na}^+\text{-K}^+$  ATPase based on analogy with the mechanism of the  $\text{Ca}^{2+}$  ATPase shown in Figure 13.5.

8. *Pumping protons.* Design an experiment to show that the action of lactose permease can be reversed in vitro to pump protons.

9. *Opening channels.* Differentiate between ligand-gated and voltage-gated channels.

10. *Different directions.* The  $\text{K}^+$  channel and the  $\text{Na}^+$  channel have similar structures and are arranged in the same orientation in the cell membrane. Yet the  $\text{Na}^+$  channel allows sodium ions to flow into the cell and the  $\text{K}^+$  channel allows potassium ions to flow out of the cell. Explain.

11. *Differing mechanisms.* Distinguish the mechanisms by which uniporters and channels transport ions or molecules across the membrane.

12. *Short circuit.* Carbonyl cyanide 4-(trifluoromethoxy) phenylhydrazone (FCCP) is a proton ionophore: it enables protons to pass freely through membranes. Treatment of *E. coli* with FCCP prevents the accumulation of lactose in these cells. Explain.

13. *Working together.* The human genome contains more than 20 connexin-encoding genes. Several of these genes are expressed in high levels in the heart. Why are connexins so highly expressed in cardiac tissue?

14. *Structure–activity relations.* On the basis of the structure of tetrodotoxin, propose a mechanism by which the toxin inhibits  $\text{Na}^+$  flow through the  $\text{Na}^+$  channel.

15. *Hot stuff.* When SERCA is incubated with  $[\gamma\text{-}^{32}\text{P}]\text{ATP}$  (a form of ATP in which the terminal phosphate is labeled with radioactive  $^{32}\text{P}$ ) and calcium at  $0^\circ\text{C}$  for 20 seconds and analyzed by gel electrophoresis, a radioactive band is observed at the molecular weight corresponding to full-length SERCA. Why is a labeled band observed? Would you expect a similar band if you were

performing a similar assay, with a suitable substrate, for the MDR protein?

16. *A dangerous snail.* Cone snails are carnivores that inject a powerful set of toxins into their prey, leading to rapid paralysis. Many of these toxins are found to bind to specific ion-channel proteins. Why are such molecules so toxic? How might such toxins be useful for biochemical studies?

17. *Pause for effect.* Immediately after the repolarization phase of an action potential, the neuronal membrane is temporarily unable to respond to the stimulation of a second action potential, a phenomenon referred to as the *refractory period*. What is the mechanistic basis for the refractory period?

18. *Only a few.* Why do only a small number of sodium ions need to flow through the  $\text{Na}^+$  channel to change the membrane potential significantly?

19. *More than one mechanism.* How might a mutation in a cardiac voltage-dependent sodium channel cause long QT syndrome?

20. *Mechanosensitive channels.* Many species contain ion channels that respond to mechanical stimuli. On the basis of the properties of other ion channels, would you expect the flow of ions through a single open mechanosensitive channel to increase in response to an appropriate stimulus? Why or why not?

21. *Concerted opening.* Suppose that a channel obeys the concerted allosteric model (MWC model, Section 7.2). The binding of ligand to the R state (the open form) is 20 times as tight as that to the T state (the closed form). In the absence of ligand, the ratio of closed to open channels is  $10^5$ . If the channel is a tetramer, what is the fraction of open channels when 1, 2, 3, and 4 ligands are bound?

22. *Respiratory paralysis.* The neurotransmitter acetylcholine is degraded by a specific enzyme that is inactivated by Tabun, sarin, and parathion. On the basis of the structures below, propose a possible basis for their lethal actions.

23. *Ligand-induced channel opening.* The ratio of open to closed forms of the acetylcholine receptor channel containing zero, one, and two bound acetylcholine molecules is  $5 \times 10^{-6}$ ,  $1.2 \times 10^{-3}$ , and 14, respectively.

(a) By what factor is the open-to-closed ratio increased by the binding of the first acetylcholine molecule? The second acetylcholine molecule?

(b) What are the corresponding free-energy contributions to channel opening at 25°C?

(c) Can the allosteric transition be accounted for by the MWC concerted model (Section 7.2)?

24. *Frog poison.* Batrachotoxin (BTX) is a steroidal alkaloid from the skin of *Phylllobates terribilis*, a poisonous Colombian frog (the source of the poison used on blowgun darts). In the presence of BTX,  $\text{Na}^+$  channels in an excised patch stay persistently open when the membrane is depolarized. They close when the membrane is repolarized. Which transition is blocked by BTX?

25. *Valium target.*  $\gamma$ -Aminobutyric acid (GABA) opens channels that are specific for chloride ions. The  $\text{GABA}_A$  receptor channel is pharmacologically important because it is the target of Valium, which is used to diminish anxiety.

(a) The extracellular concentration of  $\text{Cl}^-$  is 123 mM and the intracellular concentration is 4 mM. In which direction does  $\text{Cl}^-$  flow through an open channel when the membrane potential is in the  $-60$  mV to  $+30$  mV range?

(b) What is the effect of  $\text{Cl}^-$ -channel opening on the excitability of a neuron?

(c) The hydropathy profile of the  $\text{GABA}_A$  receptor resembles that of the acetylcholine receptor. Predict the number of subunits in this  $\text{Cl}^-$  channel.

26. *Understanding SERCA.* To study the mechanism of SERCA, you prepare membrane vesicles containing this protein oriented such that its ATP binding site is on the outer surface of the vesicle. To measure pump activity, you use an assay that detects the formation of inorganic phosphate in the medium. When you add calcium and ATP to the medium, you observe phosphate production for only a short period of time. Only after the addition of calcimycin, a molecule that makes membranes selectively permeable to calcium, do you observe sustained phosphate production. Explain.

### Chapter Integration Problem

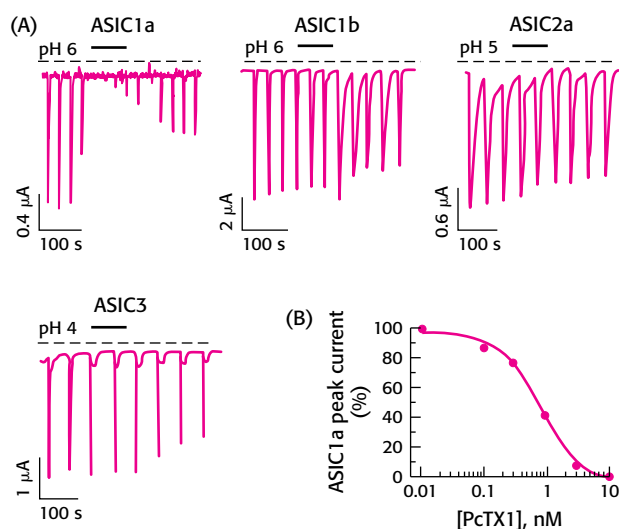

27. *Speed and efficiency matter.* Acetylcholine is rapidly destroyed by the enzyme acetylcholinesterase. This enzyme, which has a turnover number of 25,000 per second, has attained catalytic perfection with a  $k_{\text{cat}}/K_M$  of  $2 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$ . Why is the efficiency of this enzyme physiologically crucial?

### Mechanism Problem

28. *Remembrance of mechanisms past.* Acetylcholinesterase converts acetylcholine into acetate and choline. Like serine proteases, acetylcholinesterase is inhibited by DIPP. Propose a catalytic mechanism for acetylcholine digestion by acetylcholinesterase. Show the reaction as chemical structures.

### Data Interpretation Problems

29. *Tarantula toxin.* Acid sensing is associated with pain, tasting, and other biological activities (Chapter 33). Acid sensing is carried out by a ligand-gated channel that permits  $\text{Na}^+$  influx in response to  $\text{H}^+$ . This family of acid-sensitive ion channels (ASICs) includes a number of members. Psalmotoxin 1 (PcTX1), a venom from the tarantula, inhibits some members of this family. The following electrophysiological recordings of cells containing several members of the ASIC family were made in the presence of the toxin at a concentration of 10 nM. The channels were opened by changing the pH from 7.4 to the indicated values. The PcTX1 was present for a short time (indicated by the black bar above the recordings below), after which time it was rapidly washed from the system.

(A) Electrophysiological recordings of cells exposed to tarantula toxin. (B) Plot of peak current of a cell containing the ASIC1a protein versus the toxin concentration. [Data from P. Escoubas et al., *J. Biol. Chem.* 275:25116–25121, 2000.]

(a) Which member of the ASIC family—ASIC1a, ASIC1b, ASIC2a, or ASIC3—is most sensitive to the toxin?

(b) Is the effect of the toxin reversible? Explain.

(c) What concentration of PcTX1 yields 50% inhibition of the sensitive channel?

30. *Channel problems 1.* A number of pathological conditions result from mutations in the acetylcholine receptor

channel. One such mutation in the  $\beta$  subunit,  $\beta V266M$ , causes muscle weakness and rapid fatigue. An investigation of the acetylcholine-generated currents through the acetylcholine receptor channel for both a control and a patient yielded the following results.

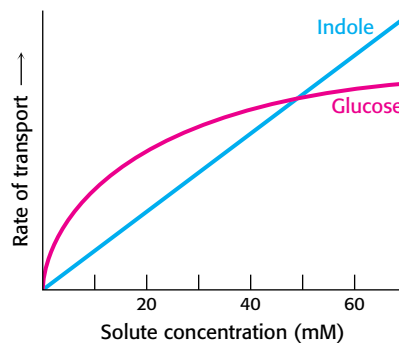

What is the effect of the mutation on channel function? Suggest some possible biochemical explanations for the effect.

31. *Channel problems 2.* The acetylcholine receptor channel can also undergo mutation leading to fast-channel syndrome (FCS), with clinical manifestations similar to those of slow-channel syndrome (Problem 30). What would the

recordings of ion movement look like in this syndrome? Suggest a biochemical explanation.

32. *Transport differences.* The rate of transport of two molecules, indole and glucose, across a cell membrane is shown below. What are the differences between the transport mechanisms of the two molecules? Suppose that ouabain inhibited the transport of glucose. What would this inhibition suggest about the mechanism of transport?

## Signal-Transduction Pathways

Signal-transduction circuits in biological systems have molecular on-off switches that, like those in a computer chip (above), transmit information when “on.” Common among these circuits are those including G proteins (right), which transmit a signal when bound to GTP and are silent when bound to GDP. [(Left) Astrid & Hanns-Frieder Michler/Science Source.]

A cell is highly responsive to specific chemicals in its environment: it may adjust its metabolism or alter gene-expression patterns on sensing the presence of these molecules. In multicellular organisms, these chemical signals are crucial to coordinating physiological responses (Figure 14.1). Three examples of molecular signals that stimulate a physiological response are epinephrine (sometimes called adrenaline), insulin, and epidermal growth factor (EGF). When a mammal is threatened, its adrenal glands release the hormone epinephrine, which stimulates the mobilization of energy stores and leads to improved cardiac function. After a full meal, the  $\beta$  cells in the pancreas release insulin, which stimulates a host of physiological responses, including the uptake of glucose from the bloodstream and its storage as glycogen. The release of EGF in response to a wound stimulates specific cells to grow and divide. In all these cases, the cell receives information that a certain molecule within its environment is present above some threshold concentration. The chain of events that converts the message “this molecule is present” into the ultimate physiological response is called *signal transduction*.

Signal-transduction pathways often comprise many components and branches. They can thus be immensely complicated and confusing. However, the logic of signal transduction can be simplified by examining the common strategies and classes of molecules that recur in these pathways.

- 14.5 Defects in Signal-Transduction Pathways Can Lead to Cancer and Other Diseases

**FIGURE 14.1 Three signal-transduction pathways.** The binding of signaling molecules to their receptors initiates pathways that lead to important physiological responses.

These principles are introduced here because signal-transduction pathways affect essentially all of the metabolic pathways that we will be exploring throughout the rest of the book.

### Signal transduction depends on molecular circuits

Signal-transduction pathways follow a broadly similar course that can be viewed as a molecular circuit (Figure 14.2). All such circuits contain certain key steps:

**FIGURE 14.2 Principles of signal transduction.** An environmental signal is first received by interaction with a cellular component, most often a cell-surface receptor. The information that the signal has arrived is then converted into other chemical forms, or *transduced*. Typically, the transduction process comprises many steps. The signal is often amplified before evoking a response. Feedback pathways regulate the entire signaling process.

1. *Release of the Primary Messenger.* A stimulus such as a wound or digested meal triggers the release of the signal molecule, also called the *primary messenger*.

2. *Reception of the Primary Messenger.* Most signal molecules do not enter cells. Instead, proteins in the cell membrane act as *receptors* that bind the signal molecules and transfer the information that the molecule has bound from the external environment to the cell's interior. Receptors span the cell membrane and thus have both extracellular and intracellular components. A binding site on the extracellular side specifically recognizes the signal molecule (often referred to as the *ligand*). Such binding sites are analogous to enzyme active sites except that no catalysis takes place within them. The interaction of the ligand and the receptor alters the tertiary or quaternary structure of the receptor so as to induce a structural change on the intracellular side.

3. *Delivery of the Message Inside the Cell by the Second Messenger.* Other small molecules, called *second messengers*, are used to relay information from receptor–ligand complexes. Second messengers are intracellular molecules that change in concentration in response to environmental signals and mediate the next step in the molecular information circuit. Some particularly important second messengers are cyclic AMP (cAMP) and cyclic GMP (cGMP), calcium ion, inositol 1,4,5-trisphosphate (IP<sub>3</sub>), and diacylglycerol (DAG; Figure 14.3).

The use of second messengers has several consequences. First, the signal may be amplified significantly: only a small number of receptor molecules may be activated by the direct binding of signal molecules, but each activated receptor molecule can lead to the generation of many second messengers. Thus, *a low concentration of signal in the environment, even as little as a single molecule, can yield a large intracellular signal and response*. Second, these messengers are often free to diffuse to other cellular compartments where they can influence processes throughout the cell. Third, the use of common second messengers in multiple signaling pathways creates both opportunities and potential problems. Input from several signaling pathways, often called *cross talk*, may alter the concentration of a common second messenger. Cross talk permits more finely tuned regulation of cell activity than

**FIGURE 14.3 Common second messengers.** Second messengers are intracellular molecules that change in concentration in response to environmental signals. That change in concentration conveys information inside the cell.

would the action of individual independent pathways. However, inappropriate cross talk can result in the misinterpretation of changes in second-messenger concentration.

4. *Activation of Effectors That Directly Alter the Physiological Response.* The ultimate effect of the signal pathway is to activate (or inhibit) the pumps, channels, enzymes, and transcription factors that directly control metabolic pathways, gene expression, and the permeability of membranes to specific ions.

5. *Termination of the Signal.* After a cell has completed its response to a signal, the signaling process must be terminated or the cell loses its responsiveness to new signals. Moreover, signaling processes that fail to terminate properly can have highly undesirable consequences. As we will see, many cancers are associated with signal-transduction processes that are not properly terminated, especially processes that control cell growth.

In this chapter, we will examine components of the three signal-transduction pathways shown in Figure 14.1. In doing so, we will see several classes of adaptor domains present in signal-transduction proteins. These domains usually recognize specific classes of molecules and help transfer information from one protein to another. The components described in the context of these three pathways recur in many other signal-transduction pathways; bear in mind that the specific examples are representative of many such pathways.

## 14.1 Heterotrimeric G Proteins Transmit Signals and Reset Themselves

Epinephrine is a hormone secreted by the adrenal glands of mammals in response to internal and external stressors. It exerts a wide range of effects—referred to as the *fight-or-flight response*—to help organisms anticipate the need for rapid muscular activity, including acceleration of heart rate, dilation of the smooth muscle of the airways, and initiation of the breakdown of glycogen (Section 21.3) and fatty acids (Section 22.2). Epinephrine signaling begins with ligand binding to a protein called the  $\beta$ -adrenergic receptor ( $\beta$ -AR). The  $\beta$ -AR is a member of the largest class of cell-surface receptors, called the *seven-transmembrane-helix (7TM) receptors*. Members of this family are responsible for transmitting information initiated by signals as

**FIGURE 14.4** The 7TM receptor. Schematic representation of a 7TM receptor showing its passage through the membrane seven times.

diverse as hormones, neurotransmitters, odorants, tastants, and even photons (Table 14.1). More than 20,000 such receptors are now known, including nearly 800 encoded in the human genome. Furthermore, about one-third of the marketed therapeutic drugs target receptors of this class. As the name indicates, these receptors contain seven helices that span the membrane bilayer (Figure 14.4).

The first member of the 7TM receptor family to have its three-dimensional structure determined was *rhodopsin* (Figure 14.5A), a protein in the retina of the eye that senses the presence of photons and initiates the signaling cascade responsible for visual sensation. A single lysine residue within rhodopsin is covalently modified by a form of vitamin A, 11-*cis*-retinal. This modification is located near the extracellular side of the receptor, within the region surrounded by the seven transmembrane helices. As will be considered in greater detail in Section 33.3, exposure to light induces the isomerization of 11-*cis*-retinal to its all-*trans* form, producing a structural change in the receptor that results in the initiation of an action potential that is ultimately interpreted by the brain as visual stimulus.

In 2007, the first three-dimensional structure of the  $\beta_2$  subtype of the human adrenergic receptor ( $\beta_2$ -AR) bound to an inhibitor was solved by x-ray crystallography. This inhibitor, carazolol, competes with epinephrine for binding to the  $\beta_2$ -AR, much in the same way that competitive inhibitors act at enzyme active sites (Section 8.5). The structure of the  $\beta_2$ -AR revealed considerable similarities with that of rhodopsin, particularly with respect to the locations of 11-*cis*-retinal in rhodopsin and the binding site for carazolol (Figure 14.5B).

### Ligand binding to 7TM receptors leads to the activation of heterotrimeric G proteins

What is the next step in the pathway? The conformational change in the receptor's cytoplasmic domain activates a protein called a *G protein*, named for the fact that it binds guanyl nucleotides. The activated G protein stimulates the activity of adenylyl cyclase, an enzyme that catalyzes the conversion of ATP into cAMP. The G protein and adenylyl cyclase remain attached to the membrane, whereas cAMP, a second messenger, can travel

**FIGURE 14.5** Structures of rhodopsin and the  $\beta_2$ -adrenergic receptor. Three-dimensional structure of rhodopsin (A) and the  $\beta_2$ -adrenergic receptor ( $\beta_2$ -AR). (B). **FIGURE 14.6 Activation of protein kinase A by a G-protein pathway.** Hormone binding to a 7TM receptor initiates a signal-transduction pathway that acts through a G protein and cAMP to activate protein kinase A.

throughout the cell carrying the signal originally brought by the binding of epinephrine. Figure 14.6 provides a broad overview of these steps.

Let us consider the role of the G protein in this signaling pathway in greater detail. In its unactivated state, the G protein is bound to GDP. In this form, the G protein exists as a heterotrimer consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits; the  $\alpha$  subunit (referred to as  $G_{\alpha}$ ) binds the nucleotide (Figure 14.7). The  $\alpha$  subunit is a member of the P-loop NTPase family (Section 9.4), and the P-loop participates in nucleotide binding. The  $\alpha$  and  $\gamma$  subunits are usually anchored to the membrane by covalently attached fatty acids. *The role of the hormone-bound receptor is to catalyze the exchange of GTP for bound GDP.* The interaction between the hormone- $\beta_2$ -AR complex and the heterotrimeric G protein was illustrated in molecular detail when the crystal structure of this complex was determined in 2011. In this structure, a synthetic *agonist*, or small molecule that activates a receptor, was used to induce the active conformation of the  $\beta_2$ -AR. Agonist binding results in the movement of two transmembrane helices, yielding an extensive interaction surface for the  $G_{\alpha}$  subunit of the

**FIGURE 14.7 A heterotrimeric G protein.** (A) A ribbon diagram shows the relation between the three subunits. In this complex, the  $\alpha$  subunit (gray and purple) is bound to GDP. Notice that GDP is bound in a pocket close to the surface at which the  $\alpha$  subunit interacts with the  $\beta\gamma$  dimer. (B) A schematic representation of the heterotrimeric G protein. [Drawn from 1GOT.pdb.]

**FIGURE 14.8 The complex between the activated  $\beta_2$ -AR and a heterotrimeric G protein.** (A) When the  $\beta_2$ -AR (green) binds a receptor agonist, the cytoplasmic face of the receptor forms an interaction surface with the  $G_\alpha$  subunit of a heterotrimeric G protein. (B) The interaction with the activated receptor leads to a substantial conformational change in the  $G_\alpha$  protein, in which the GTP binding site is opened, enabling nucleotide exchange. In this figure,  $G_\alpha$  in its GTP form is shown in red and in its receptor-bound form is shown in blue. [Drawn from 3SN6.pdb and 1AZT.pdb.]

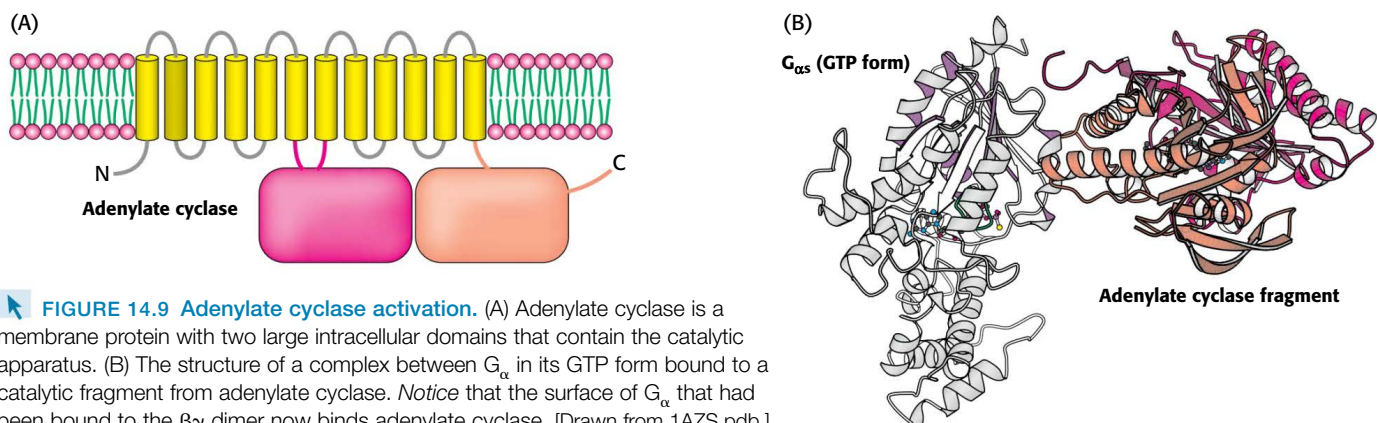

heterotrimer (Figure 14.8A). When bound to the receptor, the nucleotide-binding site of  $G_\alpha$  opens substantially, enabling the displacement of GDP by GTP (Figure 14.8B).

On GTP binding, the  $\alpha$  subunit simultaneously dissociates from the  $\beta\gamma$  dimer ( $G_{\beta\gamma}$ ), transmitting the signal that the receptor has bound its ligand. *A single hormone–receptor complex can stimulate nucleotide exchange in many G-protein heterotrimers.* Thus, hundreds of  $G_\alpha$  molecules are converted from their GDP form into their GTP form for each bound molecule of hormone, giving an amplified response. Because they signal through G proteins, 7TM receptors are often called *G-protein-coupled receptors* (GPCRs).

### Activated G proteins transmit signals by binding to other proteins

In the GTP form, the surface of  $G_\alpha$  that had been bound to  $G_{\beta\gamma}$  has changed its conformation from the GDP form so that it no longer has a high affinity for  $G_{\beta\gamma}$ . This surface is now exposed for binding to other proteins. In the  $\beta$ -AR pathway, the new binding partner is *adenylate cyclase*, the enzyme that converts ATP into cAMP. This enzyme is a membrane protein that contains 12 membrane-spanning helices; two large cytoplasmic domains form the catalytic part of the enzyme (Figure 14.9). The interaction of  $G_\alpha$  with adenylate cyclase favors a more catalytically active conformation of the enzyme, thus stimulating cAMP production. Indeed, the  $G_\alpha$  subunit that participates in the  $\beta$ -AR pathway is called  $G_{\alpha_s}$  (“s” stands for stimulatory). *The net result is that*

**FIGURE 14.9 Adenylate cyclase activation.** (A) Adenylate cyclase is a membrane protein with two large intracellular domains that contain the catalytic apparatus. (B) The structure of a complex between  $G_\alpha$  in its GTP form bound to a catalytic fragment from adenylate cyclase. *Notice that the surface of  $G_\alpha$  that had been bound to the  $\beta\gamma$  dimer now binds adenylate cyclase.* [Drawn from 1AZS.pdb.]

the binding of epinephrine to the receptor on the cell surface increases the rate of cAMP production inside the cell. The generation of cAMP by adenylate cyclase provides a second level of amplification because each activated adenylate cyclase can convert many molecules of ATP into cAMP.

### Cyclic AMP stimulates the phosphorylation of many target proteins by activating protein kinase A

The increased concentration of cAMP can affect a wide range of cellular processes. In the muscle, cAMP stimulates the production of ATP for muscle contraction. In other cell types, cAMP enhances the degradation of storage fuels, increases the secretion of acid by the gastric mucosa, leads to the dispersion of melanin pigment granules, diminishes the aggregation of blood platelets, and induces the opening of chloride channels. How does cAMP influence so many cellular processes? *Most effects of cAMP in eukaryotic cells are mediated by the activation of a single protein kinase.* This key enzyme is *protein kinase A (PKA)*.

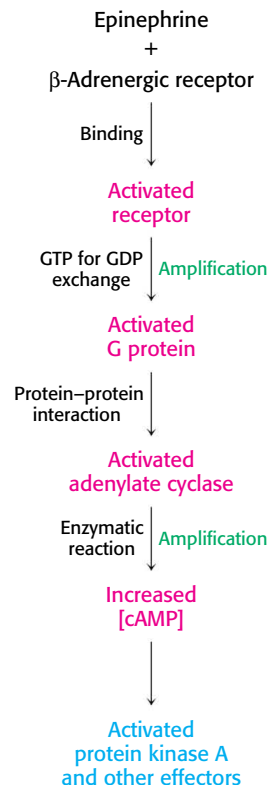

As described earlier, PKA consists of two regulatory (R) chains and two catalytic (C) chains ( $R_2C_2$ ; see Figure 10.16). In the absence of cAMP, the  $R_2C_2$  complex is catalytically inactive. The binding of cAMP to the regulatory chains releases the catalytic chains, which are catalytically active on their own. Activated PKA then phosphorylates specific serine and threonine residues in many targets to alter their activity. For instance, PKA phosphorylates two enzymes that lead to the breakdown of glycogen, the polymeric store of glucose, and the inhibition of further glycogen synthesis (Section 21.3). *PKA stimulates the expression of specific genes* by phosphorylating a transcriptional activator called the cAMP response element binding (CREB) protein. This activity of PKA illustrates that signal-transduction pathways can extend into the nucleus to alter gene expression.

The signal-transduction pathway initiated by epinephrine is summarized in Figure 14.10.

### G proteins spontaneously reset themselves through GTP hydrolysis

How is the signal initiated by epinephrine switched off?  $G_\alpha$  subunits have *intrinsic GTPase activity*, which is used to hydrolyze bound GTP to GDP and  $P_i$ . This hydrolysis reaction is slow, however, requiring from seconds to minutes. Thus, the GTP form of  $G_\alpha$  is able to activate downstream components of the signal-transduction pathway before it is deactivated by GTP hydrolysis. In essence, *the bound GTP acts as a built-in clock that spontaneously resets the  $G_\alpha$  subunit after a short time period.* After GTP hydrolysis and the release of  $P_i$ , the GDP-bound form of  $G_\alpha$  then reassociates with  $G_{\beta\gamma}$  to re-form the inactive heterotrimeric protein (Figure 14.11).

The hormone-bound activated receptor must be reset as well to prevent the continuous activation of G proteins. This resetting is accomplished by two processes (Figure 14.12). First, the hormone dissociates, returning the receptor to its initial, unactivated state. The likelihood that the receptor remains in

**FIGURE 14.10 Epinephrine signaling pathway.** The binding of epinephrine to the  $\beta$ -adrenergic receptor initiates the signal-transduction pathway. The process in each step is indicated (in black) at the left of each arrow. Steps that have the potential for signal amplification are indicated at the right in green.

**FIGURE 14.11 Resetting  $G_\alpha$ .** On hydrolysis of the bound GTP by the intrinsic GTPase activity of  $G_\alpha$ ,  $G_\alpha$  reassociates with the  $\beta\gamma$  dimer to form the heterotrimeric G protein, thereby terminating the activation of adenylate cyclase.

**FIGURE 14.12 Signal termination.** Signal transduction by the 7TM receptor is halted (1) by dissociation of the signal molecule from the receptor and (2) by phosphorylation of the cytoplasmic C-terminal tail of the receptor and the subsequent binding of  $\beta$ -arrestin.

its unbound state depends on the extracellular concentration of hormone. Second, the signaling cascade initiated by the hormone–receptor complex activates a kinase that phosphorylates serine and threonine residues in the carboxyl-terminal tail of the receptor. These phosphorylation events result in the deactivation of the receptor. In the example under consideration,  *$\beta$ -adrenergic-receptor kinase* (also called *G-protein receptor kinase 2*, or *GRK2*) phosphorylates the carboxyl-terminal tail of the hormone–receptor complex but not the unoccupied receptor. Finally, the molecule  *$\beta$ -arrestin* binds to the phosphorylated receptor and further diminishes its ability to activate G proteins.

### Some 7TM receptors activate the phosphoinositide cascade

We now turn to another common second-messenger cascade, also employing a 7TM receptor, that is used by many hormones to evoke a variety of responses. The *phosphoinositide cascade*, like the cAMP cascade, converts extracellular signals into intracellular ones. The intracellular second messengers formed by activation of this pathway arise from the cleavage of *phosphatidylinositol 4,5-bisphosphate* ( $\text{PIP}_2$ ), a phospholipid present in cell membranes. An example of a signaling pathway based on the phosphoinositide cascade is the one triggered by the receptor for angiotensin II, a peptide hormone that controls blood pressure.

Each type of 7TM receptor signals through a distinct G protein. Whereas the  $\beta$ -adrenergic receptor activates the G protein  $G_{\alpha_s}$ , the angiotensin II receptor activates a G protein called  $G_{\alpha_q}$ . In its GTP form,  $G_{\alpha_q}$  binds to and activates the  $\beta$  isoform of the enzyme *phospholipase C*. This enzyme catalyzes the cleavage of  $\text{PIP}_2$  into the two second messengers—inositol 1,4,5-trisphosphate ( $\text{IP}_3$ ) and diacylglycerol (DAG; Figure 14.13).

$\text{IP}_3$  is soluble and diffuses away from the membrane. This second messenger causes the rapid release of  $\text{Ca}^{2+}$  from the intracellular stores in the endoplasmic reticulum (ER), which accumulates a reservoir of  $\text{Ca}^{2+}$  through the action of transporters such as  $\text{Ca}^{2+}$  ATPase (Section 13.2). On binding  $\text{IP}_3$ , specific  $\text{IP}_3$ -gated  $\text{Ca}^{2+}$ -channel proteins in the ER membrane open to allow calcium ions to flow from the ER into the cytoplasm. Calcium ion is itself a signaling molecule: It can bind proteins, including a ubiquitous signaling protein called calmodulin and enzymes such as protein kinase C. By such means, the elevated level of cytoplasmic  $\text{Ca}^{2+}$  triggers processes such as smooth-muscle contraction, glycogen breakdown, and vesicle release.

**FIGURE 14.13 Phospholipase C reaction.** Phospholipase C cleaves the membrane lipid phosphatidylinositol 4,5-bisphosphate into two second messengers: diacylglycerol, which remains in the membrane, and inositol 1,4,5-trisphosphate, which diffuses away from the membrane.

DAG remains in the plasma membrane. There, it activates *protein kinase C* (PKC), a protein kinase that phosphorylates serine and threonine residues in many target proteins. To bind DAG, the specialized DAG-binding domains of this kinase require bound calcium. Note that DAG and IP<sub>3</sub> work in tandem: IP<sub>3</sub> increases the Ca<sup>2+</sup> concentration, and Ca<sup>2+</sup> facilitates the DAG-mediated activation of protein kinase C. The phosphoinositide cascade is summarized in Figure 14.14. Both IP<sub>3</sub> and DAG act transiently because they are converted into other species by phosphorylation or other processes.

### Calcium ion is a widely used second messenger

Calcium ion participates in many signaling processes in addition to the phosphoinositide cascade. Several properties of this ion account for its widespread use as an intracellular messenger. First, fleeting changes in Ca<sup>2+</sup> concentration are readily detected. At steady state, intracellular levels of Ca<sup>2+</sup> must be kept low to prevent the precipitation of carboxylated and phosphorylated compounds, which form poorly soluble salts with Ca<sup>2+</sup>. Transport systems extrude Ca<sup>2+</sup> from the cytoplasm, maintaining the cytoplasmic concentration of Ca<sup>2+</sup> at approximately 100 nM, several orders of magnitude lower than that of the extracellular medium (Section 13.2). Given this low steady-state level, transient increases in Ca<sup>2+</sup> concentration produced by signaling events can be readily sensed.

A second property of Ca<sup>2+</sup> that makes it a highly suitable intracellular messenger is that it can bind tightly to proteins and induce substantial structural rearrangements. Calcium ions bind well to negatively charged oxygen atoms (from the side chains of glutamate and aspartate) and uncharged oxygen atoms (main-chain carbonyl

**FIGURE 14.14 Phosphoinositide cascade.** The cleavage of phosphatidylinositol 4,5-bisphosphate (PIP<sub>2</sub>) into diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP<sub>3</sub>) results in the release of calcium ions (owing to the opening of the IP<sub>3</sub> receptor ion channels) and the activation of protein kinase C (owing to the binding of protein kinase C to free DAG in the membrane). Calcium ions bind to protein kinase C and help facilitate its activation.

**FIGURE 14.15 Calcium-binding site.** In one common mode of binding, calcium is coordinated to six oxygen atoms of a protein and one (top) of water.

groups and side-chain oxygen atoms from glutamine and asparagine; Figure 14.15). *The capacity of  $\text{Ca}^{2+}$  to be coordinated to multiple ligands—from six to eight oxygen atoms—enables it to cross-link different segments of a protein and induce significant conformational changes.*

Our understanding of the role of  $\text{Ca}^{2+}$  in cellular processes has been greatly enhanced by our ability to detect changes in  $\text{Ca}^{2+}$  concentrations inside cells and even monitor these changes in real time. This ability depends on the use of specially designed dyes such as Fura-2 that bind  $\text{Ca}^{2+}$  and change their fluorescent properties on  $\text{Ca}^{2+}$  binding. Fura-2 binds  $\text{Ca}^{2+}$  through appropriately positioned oxygen atoms (shown in red) within its structure.

**Fura-2**

When such a dye is introduced into cells, changes in available  $\text{Ca}^{2+}$  concentration can be monitored with microscopes capable of detecting changes in fluorescence (Figure 14.16). Probes for sensing other second messengers such as cAMP also have been developed. These *molecular-imaging agents* are greatly enhancing our understanding of signal-transduction processes.

**FIGURE 14.16 Calcium imaging.** (A) The fluorescence spectra of the calcium-binding dye Fura-2 can be used to measure available calcium ion concentrations in solution and in cells. (B) A series of images show  $\text{Ca}^{2+}$  spreading across an egg cell following fertilization by sperm. These images were obtained through the use of Fura-2. The images are false colored: orange represents high  $\text{Ca}^{2+}$  concentrations, and green represents low  $\text{Ca}^{2+}$  concentrations. [(A) Information from S. J. Lippard and J. M. Berg, *Principles of Bioinorganic Chemistry* (University Science Books, 1994), p. 193; (B) data from Carroll M. et al., *J. Cell Sci.* 116: 4997–5004, 2003.]

(B)

### Calcium ion often activates the regulatory protein calmodulin

*Calmodulin* (CaM), a 17-kDa protein with four  $\text{Ca}^{2+}$ -binding sites, serves as a calcium sensor in nearly all eukaryotic cells. At cytoplasmic concentrations above about 500 nM,  $\text{Ca}^{2+}$  binds to and activates calmodulin. Calmodulin is a member of the *EF-hand protein family*. The *EF hand* is a  $\text{Ca}^{2+}$ -binding motif that consists of a helix, a loop, and a second helix. This motif, originally discovered in the protein parvalbumin, was named the EF hand because the two key helices designated E and F in parvalbumin are positioned like the forefinger and thumb of the right hand (Figure 14.17). These two helices and the intervening loop form the  $\text{Ca}^{2+}$ -binding motif. Seven oxygen atoms are coordinated to each  $\text{Ca}^{2+}$ , six from the protein and one from a bound water molecule. Calmodulin is made up of four EF-hand motifs, each of which can bind a single  $\text{Ca}^{2+}$  ion.

The binding of  $\text{Ca}^{2+}$  to calmodulin induces substantial conformational changes in its EF hands, exposing hydrophobic surfaces that can be used to bind other proteins. Using its two sets of two EF hands, calmodulin clamps down around specific regions of target proteins, usually exposed  $\alpha$  helices with appropriately positioned hydrophobic and charged groups (Figure 14.18). The  $\text{Ca}^{2+}$ -calmodulin complex stimulates a wide variety of enzymes, pumps, and other target proteins by inducing structural rearrangements in these binding partners. An especially noteworthy set of targets are several *calmodulin-dependent protein kinases* (CaM kinases) that phosphorylate many different proteins and regulate fuel metabolism, ionic permeability, neurotransmitter synthesis, and neurotransmitter release. We see here a recurring theme in signal-transduction pathways: the concentration of a second messenger is increased (in this case,  $\text{Ca}^{2+}$ ); the signal is sensed by a second-messenger-binding protein (in this case, calmodulin); and the second-messenger-binding protein acts to generate changes in enzymes (in this case, calmodulin-dependent kinases) that control effectors.

**FIGURE 14.17 EF hand.** Formed by a helix-loop-helix unit, an EF hand is a binding site for  $\text{Ca}^{2+}$  in many calcium-sensing proteins. Here, the E helix is yellow, the F helix is blue, and calcium is represented by the green sphere. Note that the calcium ion is bound in a loop connecting two nearly perpendicular helices. [Drawn from 1CLL.pdb.]

**FIGURE 14.18 Calmodulin binds to  $\alpha$  helices.** (A) An  $\alpha$  helix (purple) in CaM kinase I is a target for calmodulin. (B) On  $\text{Ca}^{2+}$  binding to the apo, or calcium-free, form of calmodulin (1), the two halves of calmodulin clamp down around the target helix (2), binding it through hydrophobic and ionic interactions. In CaM kinase I, this interaction allows the enzyme to adopt an active conformation. [Drawn from 1A06, 1CFD, 1CLL, and 1CM1.pdb.]

## 14.2 Insulin Signaling: Phosphorylation Cascades Are Central to Many Signal-Transduction Processes

The signaling pathways that we have examined so far have activated a protein kinase as a downstream component of the pathway. We now turn to a class of signal-transduction pathways that are *initiated by receptors that*

**FIGURE 14.19 Insulin structure.**

Notice that insulin consists of two chains (shown in blue and yellow) linked by two interchain disulfide bonds. The  $\alpha$  chain (blue) also has an intrachain disulfide bond. [Drawn from 1B2F.pdb.]

**FIGURE 14.20 The insulin receptor.** The receptor consists of two units, each of which consists of an  $\alpha$  subunit and a  $\beta$  subunit linked by a disulfide bond. Two  $\alpha$  subunits, which lie outside the cell, come together to form a binding site for insulin. Each  $\beta$  subunit lies primarily inside the cell and includes a protein kinase domain.

include protein kinases as part of their structures. The activation of these protein kinases sets in motion other processes that ultimately modify the effectors of these pathways.

An example is the signal-transduction pathway initiated by *insulin*, the hormone released in response to increased blood-glucose levels after a meal. In all of its detail, this multifaceted pathway is quite complex. Hence, we will focus solely on the major branch, which leads to the mobilization of glucose transporters to the cell surface. These transporters allow the cell to take up the glucose that is plentiful in the blood stream after a meal.

### The insulin receptor is a dimer that closes around a bound insulin molecule

Insulin is a peptide hormone that consists of two chains that are linked by three disulfide bonds (Figure 14.19). Its receptor has a quite different structure from that of the  $\beta$ -AR. The *insulin receptor* is a dimer of two identical units. Each unit consists of one  $\alpha$  chain and one  $\beta$  chain linked to one another by a single disulfide bond (Figure 14.20). Each  $\alpha$  subunit lies completely outside the cell, whereas each  $\beta$  subunit lies primarily inside the cell, spanning the membrane with a single transmembrane segment. The two  $\alpha$  subunits move together to form a binding site for a single insulin molecule, a surprising occurrence because two different surfaces on the insulin molecule must interact with the two identical insulin-receptor chains. The moving together of the dimeric units in the presence of an insulin molecule sets the signaling pathway in motion. *The closing up of an oligomeric receptor or the oligomerization of monomeric receptors around a bound ligand is a strategy used by many receptors to initiate a signal, particularly by those containing a protein kinase.*

Each  $\beta$  subunit consists primarily of a protein kinase domain, homologous to protein kinase A. However, this kinase differs from protein kinase A in two important ways. First, the insulin-receptor kinase is a *tyrosine kinase*; that is, it catalyzes the transfer of a phosphoryl group from ATP to the hydroxyl group of tyrosine, rather than serine or threonine.

Because this tyrosine kinase is a component of the receptor itself, the insulin receptor is referred to as a *receptor tyrosine kinase*. Second, the insulin receptor kinase is in an inactive conformation when the domain is not covalently modified. The kinase is rendered inactive by the position of an unstructured loop (called the *activation loop*) that lies in the center of the structure.

### Insulin binding results in the cross-phosphorylation and activation of the insulin receptor

When the two  $\alpha$  subunits move together to surround an insulin molecule, the two protein kinase domains on the inside of the cell also are drawn together. It is important to note that as they come together, the flexible

**FIGURE 14.21 Activation of the insulin receptor by phosphorylation.** The activation loop is shown in red in this model of the protein kinase domain of the  $\beta$  subunit of the insulin receptor. The unphosphorylated structure on the left is not catalytically active. Notice that, when three tyrosine residues in the activation loop are phosphorylated, the activation loop swings across the structure and the kinase structure adopts a more compact conformation. This conformation is catalytically active. [Drawn from 1IRK.pdb and 1IR3.pdb.]

activation loop of one kinase subunit is able to fit into the active site of the other kinase subunit within the dimer. With the two  $\beta$  subunits forced together, the kinase domains catalyze the addition of phosphoryl groups from ATP to tyrosine residues in the activation loops. When these tyrosine residues are phosphorylated, a striking conformational change takes place (Figure 14.21). The rearrangement of the activation loop converts the kinase into an active conformation. Thus, *insulin binding on the outside of the cell results in the activation of a membrane-associated kinase within the cell.*

### The activated insulin-receptor kinase initiates a kinase cascade

On phosphorylation, the insulin-receptor tyrosine kinase is activated. Because the two units of the receptor are held in close proximity to one another, additional sites within the receptor also are phosphorylated. These phosphorylated sites act as docking sites for other substrates, including a class of molecules referred to as *insulin-receptor substrates* (IRS; Figure 14.22). IRS-1 and IRS-2 are two homologous

**FIGURE 14.22 Insulin signaling.** The binding of insulin results in the cross-phosphorylation and activation of the insulin receptor. Phosphorylated sites on the receptor act as binding sites for insulin-receptor substrates such as IRS-1. The lipid kinase phosphoinositide 3-kinase binds to phosphorylated sites on IRS-1 through its regulatory domain, then converts  $\text{PIP}_2$  into  $\text{PIP}_3$ . Binding to  $\text{PIP}_3$  activates  $\text{PIP}_3$ -dependent protein kinase (PDK1), which phosphorylates and activates kinases such as Akt1. Activated Akt1 can then diffuse throughout the cell to continue the signal-transduction pathway.

**FIGURE 14.23 The modular structure of insulin-receptor substrates IRS-1 and IRS-2.**

This schematic view represents the amino acid sequence common to IRS-1 and IRS-2. Each protein contains a pleckstrin homology domain (which binds phosphoinositide lipids), a phosphotyrosine-binding domain, and four sequences that approximate Tyr-X-X-Met (YXXM). The four sequences are phosphorylated by the insulin-receptor tyrosine kinase.

**FIGURE 14.24 Structure of the SH2 domain.** The domain is shown bound to a phosphotyrosine-containing peptide. Notice at the top that the negatively charged phosphotyrosine residue interacts with two arginine residues that are conserved in essentially all SH2 domains. [Drawn from 1SPS.pdb.]

proteins with a common modular structure (Figure 14.23). The amino-terminal part includes a *pleckstrin homology domain*, which binds phosphoinositide, and a phosphotyrosine-binding domain. These domains act together to anchor the IRS protein to the insulin receptor and the associated membrane. Each IRS protein contains four sequences that approximate the form Tyr-X-X-Met. These sequences are also substrates for the activated insulin-receptor kinase. When the tyrosine residues within these sequences are phosphorylated to become phosphotyrosine residues, IRS molecules can act as *adaptor proteins*: they are not enzymes but serve to tether the downstream components of this signaling pathway to the membrane.

Phosphotyrosine residues, such as those in the IRS proteins, are recognized most often by *Src homology 2* (SH2) domains (Figure 14.24). These domains, present in many signal-transduction proteins, bind to stretches of polypeptide that contain phosphotyrosine residues. Each specific SH2 domain shows a binding preference for phosphotyrosine in a particular sequence context. Which proteins contain SH2 domains that bind to phosphotyrosine-containing sequences in the IRS proteins? The most important of them are in a class of lipid kinases, called phosphoinositide 3-kinases (PI3Ks), that add a phosphoryl group to the 3-position of inositol in phosphatidylinositol 4,5-bisphosphate (PIP<sub>2</sub>; Figure 14.25). These enzymes are heterooligomers that consist of 110-kDa catalytic subunits and 85-kDa regulatory subunits. Through SH2 domains in the regulatory subunits, these enzymes bind to the IRS proteins and are drawn to the membrane where they can phosphorylate PIP<sub>2</sub> to form phosphatidylinositol 3,4,5-trisphosphate (PIP<sub>3</sub>). PIP<sub>3</sub>, in turn, activates a protein kinase, PDK1, by virtue of a pleckstrin homology domain present in this kinase that is specific for PIP<sub>3</sub> (Figure 14.22). The activated PDK1 phosphorylates and activates Akt, another protein kinase. Akt is not membrane anchored and moves through the cell to phosphorylate targets that include components that control the trafficking of the glucose receptor GLUT4 to the cell surface as well as enzymes that stimulate glycogen synthesis (Section 21.4).

**FIGURE 14.25 Action of a lipid kinase in insulin signaling.** Phosphorylated IRS-1 and IRS-2 activate the enzyme phosphatidylinositol 3-kinase, an enzyme that converts PIP<sub>2</sub> into PIP<sub>3</sub>.

The cascade initiated by the binding of insulin to the insulin receptor is summarized in Figure 14.26. The signal is amplified at several stages along this pathway. Because the activated insulin receptor itself is a protein kinase, each activated receptor can phosphorylate multiple IRS molecules. Activated enzymes further amplify the signal in at least two of the subsequent steps. Thus, a small increase in the concentration of circulating insulin can produce a robust intracellular response. Note that although the insulin pathway described here may seem complicated, it is substantially less elaborate than the full signaling network initiated by insulin.

### Insulin signaling is terminated by the action of phosphatases

We have seen that the activated G protein promotes its own inactivation by the release of a phosphoryl group from GTP. In contrast, proteins phosphorylated on serine, threonine, or tyrosine residues are extremely stable kinetically. Specific enzymes, called protein phosphatases, are required to hydrolyze these phosphorylated proteins and return them to their initial states. Similarly, lipid phosphatases are required to remove phosphoryl groups from inositol lipids that had been activated by lipid kinases. In insulin signaling, three classes of enzymes are of particular importance in shutting off the signaling pathway: (1) protein tyrosine phosphatases that remove phosphoryl groups from tyrosine residues on the insulin receptor and the IRS adaptor proteins, (2) lipid phosphatases that hydrolyze  $\text{PIP}_3$  to  $\text{PIP}_2$ , and (3) protein serine phosphatases that remove phosphoryl groups from activated protein kinases such as Akt. Many of these phosphatases are activated or recruited as part of the response to insulin. Thus, the binding of the initial signal sets the stage for the eventual termination of the response.

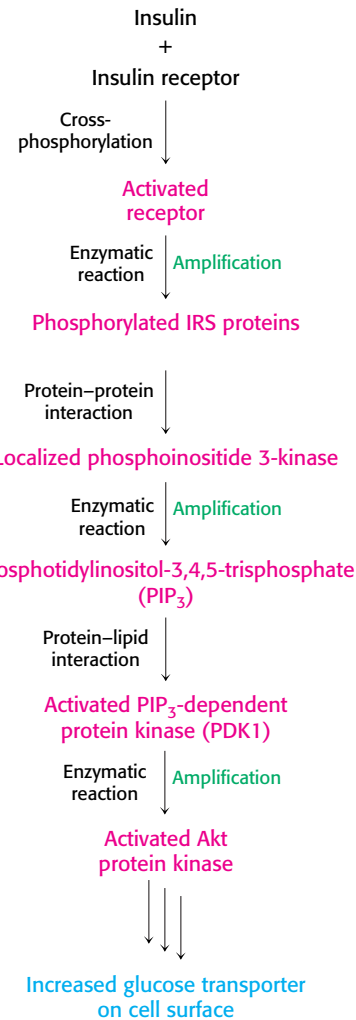

## 14.3 EGF Signaling: Signal-Transduction Pathways Are Poised to Respond

Our consideration of the signal-transduction cascades initiated by epinephrine and insulin included examples of how components of signal-transduction pathways are poised for action, ready to be activated by minor modifications. For example, G-protein subunits require only the binding of GTP in exchange for GDP to transmit a signal. This exchange reaction is thermodynamically favorable, but it is quite slow in the absence of an appropriate activated 7TM receptor. Similarly, the tyrosine kinase domains of the dimeric insulin receptor are ready for phosphorylation and activation but require insulin bound between two  $\alpha$  subunits to draw the activation loop of one tyrosine kinase into the active site of a partner tyrosine kinase to initiate the signaling cascade.

Next, we examine a signal-transduction pathway that reveals another clear example of how these signaling cascades are poised to respond. This pathway is activated by the signal molecule *epidermal growth factor* (EGF). Like that of the insulin receptor, the initiator of this pathway is a receptor tyrosine kinase. Both the extracellular and the intracellular domains of this receptor are ready for action, held in check only by a specific structure that prevents receptors from coming together. Furthermore, in the EGF pathway, we will encounter several additional classes of signaling components that participate in many other signaling networks.

### EGF binding results in the dimerization of the EGF receptor

Epidermal growth factor is a 6-kDa polypeptide that stimulates the growth of epidermal and epithelial cells (Figure 14.27). The *EGF receptor* (EGFR),

**FIGURE 14.26** Insulin signaling pathway. Key steps in the signal-transduction pathway initiated by the binding of insulin to the insulin receptor.

**FIGURE 14.27** Structure of epidermal growth factor. Notice that three intrachain disulfide bonds stabilize the compact three-dimensional structure of the growth factor. [Drawn from 1EGF.pdb.]

**FIGURE 14.28 Modular structure of the EGF receptor.** This schematic view of the amino acid sequence of the EGF receptor shows the EGF-binding domain that lies outside the cell, a single transmembrane helix-forming region, the intracellular tyrosine kinase domain, and the tyrosine-rich domain at the carboxyl terminus.

like the insulin receptor, is a dimer of two identical subunits. Each subunit contains an intracellular protein tyrosine kinase domain that participates in cross-phosphorylation reactions (Figure 14.28). Unlike those of the insulin receptor, however, these units exist as monomers until they bind EGF. Moreover, each EGF receptor monomer binds a single molecule of EGF in its extracellular domain (Figure 14.29). Thus the dimer binds two ligand molecules, in contrast with the insulin-receptor dimer, which binds only one ligand. Note that each EGF molecule lies far away from the dimer interface. This interface includes a so-called *dimerization arm* from each monomer that reaches out and inserts into a binding pocket on the other monomer.

**FIGURE 14.29 EGF receptor dimerization.** The structure of the extracellular region of the EGF receptor is shown bound to EGF. Notice that the structure is dimeric with one EGF molecule bound to each receptor molecule and that the dimerization is mediated by a dimerization arm that extends from each receptor molecule. [Drawn from 1IVO.pdb.]

Although this structure nicely reveals the interactions that support the formation of a receptor dimer favoring cross-phosphorylation, it raises another question: Why doesn't the receptor dimerize and signal in the absence of EGF? This question has been addressed by examining the structure of the EGF receptor in the absence of bound ligand (Figure 14.30). This structure is, indeed, monomeric, and each monomer is in a conformation that is quite different from that observed in the ligand-bound dimer. In particular, the dimerization arm binds to a domain *within the same monomer* that holds the receptor in a closed configuration. In essence, the

receptor is poised in a spring-loaded conformation held in position by the contact between the interaction loop and another part of the structure, ready to bind ligand and change into a conformation active for dimerization and signaling.

This observation suggests that a receptor that exists in the extended conformation even in the absence of bound ligand would be constitutively active. Remarkably, such a receptor exists. This receptor, HER2, is approximately 50% identical in amino acid sequence with the EGF receptor and has the same domain structure. HER2 does not bind any known ligand, yet crystallographic studies reveal that it adopts an extended structure very similar to that observed for the ligand-bound EGF receptor. Under normal conditions, HER2 forms heterodimers with the EGF receptor and other members of the EGF receptor family and participates in cross-phosphorylation reactions with these receptors. HER2 is overexpressed in some cancers, presumably contributing to tumor growth by forming homodimers that signal even in the absence of ligand. We will return to HER2 when we consider approaches to cancer treatment based on knowledge of signaling pathways (Section 14.5).

### The EGF receptor undergoes phosphorylation of its carboxyl-terminal tail

Like the insulin receptor, the EGF receptor undergoes cross-phosphorylation of one unit by another unit within a dimer. However, unlike that of the insulin receptor, the site of this phosphorylation is not within the activation loop of the kinase, but rather in a region that lies on the C-terminal side of the kinase domain. As many as five tyrosine residues in this region are phosphorylated. The dimerization of the EGF receptor brings the C-terminal region on one receptor into the active site of its partner's kinase. The kinase itself is in an active conformation without phosphorylation, revealing again how this signaling system is poised to respond.

### EGF signaling leads to the activation of Ras, a small G protein

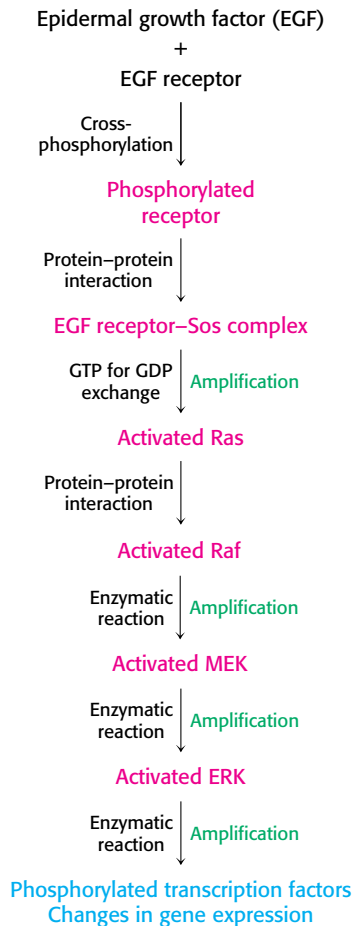

The phosphotyrosines on the EGF receptors act as docking sites for SH2 domains on other proteins. The intracellular signaling cascade begins with the binding of *Grb2*, a key adaptor protein that contains one SH2 domain and two *Src homology 3* (SH3) domains. On phosphorylation of the receptor, the SH2 domain of *Grb2* binds to the phosphotyrosine residues of the receptor tyrosine kinase. Through its two SH3 domains, *Grb2* then binds polyproline-rich polypeptides within a protein called *Sos*. *Sos*, in turn, binds to *Ras* and activates it. A very prominent signal-transduction component, *Ras* is a member of a class of proteins called the *small G proteins*. Like the G proteins described in Section 14.1, the small G proteins contain bound GDP in their unactivated forms. *Sos* opens up the nucleotide-binding pocket of *Ras*, allowing GDP to escape and GTP to enter in its place. Because of its effect on *Ras*, *Sos* is referred to as a *guanine-nucleotide-exchange factor* (GEF). Thus, the binding of EGF to its receptor leads to the conversion of *Ras* into its GTP form through the intermediacy of *Grb2* and *Sos* (Figure 14.31).

**FIGURE 14.30 Structure of the unactivated EGF receptor.** The extracellular domain of the EGF receptor is shown in the absence of bound EGF. Notice that the dimerization arm is bound to a part of the receptor that makes it unavailable for interaction with the other receptor. [Drawn from 1NQL.pdb.]

**FIGURE 14.31 Ras activation mechanism.** The dimerization of the EGF receptor due to EGF binding leads to: (1) the phosphorylation of the C-terminal tails of the receptor, (2) the subsequent recruitment of *Grb2* and *Sos*, and (3) the exchange of GTP for GDP in *Ras*. This signal-transduction pathway results in the conversion of *Ras* into its activated GTP-bound form.

**FIGURE 14.32 EGF signaling pathway.** The key steps in the pathway initiated by EGF binding to the EGF receptor. A kinase cascade leads to the phosphorylation of transcription factors and concomitant changes in gene expression.

### Activated Ras initiates a protein kinase cascade

Ras changes conformation when it is transformed from its GDP into its GTP form. In the GTP form, Ras binds other proteins, including a protein kinase termed *Raf*. When bound to Ras, *Raf* undergoes a conformational change that activates the *Raf* protein kinase domain. Both Ras and *Raf* are anchored to the membrane through covalently bound lipid modifications. Activated *Raf* then phosphorylates other proteins, including protein kinases termed MEKs. In turn, MEKs activate kinases called *extracellular signal-regulated kinases* (ERKs). ERKs then phosphorylate numerous substrates, including transcription factors in the nucleus as well as other protein kinases. The complete flow of information from the arrival of EGF at the cell surface to changes in gene expression is summarized in Figure 14.32.

 Small G proteins, or small GTPases, constitute a large superfamily of proteins—grouped into subfamilies called Ras, Rho, Arf, Rab, and Ran—that play a major role in a host of cell functions including growth, differentiation, cell motility, cytokinesis (the separation of two cells during division), and the transport of materials throughout the cell (Table 14.2). As with the heterotrimeric G proteins, the small G proteins cycle between an active GTP-bound form and an inactive GDP-bound form. They differ from the heterotrimeric G proteins in being smaller (20–25 kDa versus 30–35 kDa) and monomeric. Nonetheless, the two families are related by divergent evolution, and small G proteins have many key mechanistic and structural motifs in common with the  $G_{\alpha}$  subunit of the heterotrimeric G proteins.

### EGF signaling is terminated by protein phosphatases and the intrinsic GTPase activity of Ras

Because so many components of the EGF signal-transduction pathway are activated by phosphorylation, we can expect protein phosphatases to play key roles in the termination of EGF signaling. Indeed, crucial phosphatases remove phosphoryl groups from tyrosine residues on the EGF receptor and from serine, threonine, and tyrosine residues in the protein kinases that participate in the signaling cascade. The signaling process itself sets in motion the events that activate many of these phosphatases. Consequently, signal activation also initiates signal termination.

Like the G proteins activated by 7TM receptors, Ras possesses intrinsic GTPase activity. Thus, the activated GTP form of Ras spontaneously converts into the inactive GDP form. The rate of conversion can be accelerated in the presence of *GTPase-activating proteins* (GAPs), which interact with small G proteins in the GTP form and facilitate GTP hydrolysis. Thus, the lifetime of activated Ras is regulated by accessory proteins in the cell. The GTPase activity of Ras is crucial for shutting off signals leading to cell growth, and so it is not surprising that mutations in Ras are found in many types of cancer, as discussed in Section 14.5.

**TABLE 14.2 Ras superfamily of GTPases**

Subfamily	Function
Ras	Regulates cell growth through serine–threonine protein kinases
Rho	Reorganizes cytoskeleton through serine–threonine protein kinases
Arf	Activates the ADP-ribosyltransferase of the cholera toxin A subunit; regulates vesicular trafficking pathways; activates phospholipase D
Rab	Plays a key role in secretory and endocytotic pathways
Ran	Functions in the transport of RNA and protein into and out of the nucleus

## 14.4 Many Elements Recur with Variation in Different Signal-Transduction Pathways

We can begin to make sense of the complexity of signal-transduction pathways by taking note of several common themes that have appeared consistently in the pathways described in this chapter and underlie many additional signaling pathways not considered herein.

1. *Protein kinases are central to many signal-transduction pathways.* Protein kinases are central to all three signal-transduction pathways described in this chapter. In the epinephrine-initiated pathway, cAMP-dependent protein kinase (PKA) lies at the end of the pathway, transducing information represented by an increase in cAMP concentration into covalent modifications that alter the activity of key metabolic enzymes. In the insulin- and EGF-initiated pathways, the receptors themselves are protein kinases and several additional protein kinases participate downstream in the pathways. Signal amplification due to protein kinase cascades is a feature common to all three pathways. Although not presented in this chapter, protein kinases often phosphorylate multiple substrates and are thus able to generate a diversity of responses.

2. *Second messengers participate in many signal-transduction pathways.* We have encountered several second messengers, including cAMP,  $\text{Ca}^{2+}$ ,  $\text{IP}_3$ , and the lipid DAG. Because second messengers are generated by enzymes or by the opening of ion channels, their concentrations can be tremendously amplified compared with the signals that lead to their generation. Specialized proteins sense the concentrations of these second messengers and continue the flow of information along signal-transduction pathways.

The second messengers that we have seen recur in many additional signal-transduction pathways. For example, in a consideration of the sensory systems in Chapter 33, we will see how  $\text{Ca}^{2+}$ -based signaling and cyclic nucleotide-based signaling play key roles in vision and olfaction.

3. *Specialized domains that mediate specific interactions are present in many signaling proteins.* The “wiring” of many signal-transduction pathways is based on particular protein domains that mediate the interactions between protein components of a particular signaling cascade. We have encountered several of them, including pleckstrin homology domains, which facilitate protein interactions with the lipid  $\text{PIP}_3$ ; SH2 domains, which mediate interactions with polypeptides containing phosphorylated tyrosine residues; and SH3 domains, which interact with peptide sequences that contain multiple proline residues. Many other such domain families exist. In many cases, individual members of each domain family have unique features that allow them to bind to their targets only within a particular sequence context, making them specific for a given signaling pathway and avoiding unwanted cross-talk. *Signal-transduction pathways have evolved in large part by the incorporation of DNA fragments encoding these domains into genes encoding pathway components.*

The presence of these domains is tremendously helpful to scientists trying to unravel signal-transduction pathways. When a protein in a signal-transduction pathway is identified, its amino acid sequence can be analyzed for the presence of these specialized domains by the methods described in Chapter 6. If one or more domains of known function is found, it is often possible to develop clear hypotheses about potential binding partners and signal-transduction mechanisms.

## 14.5 Defects in Signal-Transduction Pathways Can Lead to Cancer and Other Diseases

 In light of their complexity, it comes as no surprise that signal-transduction pathways occasionally fail, leading to disease states. Cancer, a set of diseases characterized by uncontrolled or inappropriate cell growth, is strongly associated with defects in signal-transduction proteins. Indeed, the study of cancer, particularly cancers caused by certain viruses, has contributed greatly to our understanding of signal-transduction proteins and pathways.

For example, Rous sarcoma virus is a retrovirus that causes sarcoma (a cancer of tissues of mesodermal origin such as muscle or connective tissue) in chickens. In addition to the genes necessary for viral replication, this virus carries a gene termed *v-src*. The *v-src* gene is an *oncogene*; it leads to the generation of cancerlike characteristics in susceptible cell types. The protein encoded by the *v-src* gene, v-Src, is a protein tyrosine kinase that includes SH2 and SH3 domains. The v-Src protein is similar in amino acid sequence to a protein normally found in chicken-muscle cells referred to as c-Src (for cellular Src; Figure 14.33A). The *c-src* gene does not induce cell transformation and is termed a *proto-oncogene*, referring to the fact that this gene, when mutated, can be converted into an oncogene. The protein that it encodes is a signal-transduction protein that regulates cell growth.

Why is the biological activity of the v-Src protein so different from that of c-Src? c-Src contains a key tyrosine residue near its C-terminal end that, when phosphorylated, is bound intramolecularly by the upstream SH2 domain (Figure 14.33B). This interaction maintains the kinase domain in an inactive conformation. However, in v-Src, the C-terminal 19 amino acids of c-Src are replaced by a completely different stretch of 11 amino acids that lacks this critical tyrosine residue. Thus, v-Src is always active and can promote unregulated cell growth. Since the discovery of Src, many other mutated protein kinases have been identified as oncogenes.

The gene encoding Ras, a component of the EGF-initiated pathway, is one of the genes most commonly mutated in human tumors. Mammalian cells contain three 21-kDa Ras proteins (H-, K-, and N-Ras), each of which cycles between inactive GDP and active GTP forms. The most common mutations in tumors lead to a loss of the ability to hydrolyze GTP. Thus, the Ras protein is trapped in the “on” position and continues to stimulate cell growth, even in the absence of a continuing signal.

Other genes can contribute to cancer development only when both copies of the gene normally present in a cell are deleted or otherwise damaged. Such genes are called *tumor-suppressor genes*. For example, genes for some of the phosphatases that participate in the termination of EGF signaling are tumor suppressors. Without any functional phosphatase present, EGF signaling persists once initiated, stimulating inappropriate cell growth.

### Monoclonal antibodies can be used to inhibit signal-transduction pathways activated in tumors

 Mutated or overexpressed receptor tyrosine kinases are frequently observed in tumors. For instance, the epidermal-growth-factor receptor (EGFR) is overexpressed in some human epithelial cancers, including breast, ovarian, and colorectal cancer.

 **FIGURE 14.33 Src structure.** (A) Cellular Src includes an SH3 domain, an SH2 domain, a protein kinase domain, and a carboxyl-terminal tail that includes a key tyrosine residue. (B) Structure of c-Src in an inactivated form with the key tyrosine residue phosphorylated. Notice how the three domains work together to keep the enzyme in an inactive conformation: the phosphotyrosine residue is bound in the SH2 domain and the linker between the SH2 domain and the protein kinase domain is bound by the SH3 domain. [Drawn from 2PTK.pdb.]

Because some small amount of the receptor can dimerize and activate the signaling pathway even without binding to EGF, overexpression of the receptor increases the likelihood that a “grow and divide” signal will be inappropriately sent to the cell. This understanding of cancer-related signal-transduction pathways has led to a therapeutic approach that targets the EGFR. The strategy is to produce monoclonal antibodies to the extracellular domains of the offending receptors. One such antibody, cetuximab (Erbix), has effectively targeted the EGFR in colorectal cancers. Cetuximab inhibits the EGFR by competing with EGF for the binding site on the receptor. Because the antibody sterically blocks the change in conformation that exposes the dimerization arm, the antibody itself cannot induce dimerization. The result is that the EGFR-controlled pathway is not initiated.

Cetuximab is not the only monoclonal antibody that has been developed to target a receptor tyrosine kinase. Trastuzumab (Herceptin) inhibits another EGFR family member, HER2, that is overexpressed in approximately 30% of breast cancers. Recall that this protein can signal even in the absence of ligand, so it is especially likely that overexpression will stimulate cell proliferation. Breast-cancer patients are now being screened for HER2 overexpression and treated with Herceptin as appropriate. Thus, this cancer treatment is tailored to the genetic characteristics of the tumor.

### Protein kinase inhibitors can be effective anticancer drugs

 The widespread occurrence of overactive protein kinases in cancer cells suggests that molecules that inhibit these enzymes might act as antitumor agents. For example, more than 90% of patients with chronic myelogenous leukemia (CML) show a specific chromosomal defect in cancer cells (Figure 14.34). The translocation of genetic material between chromosomes 9 and 22 causes the *c-abl* gene, which encodes a tyrosine kinase of the Src family, to be inserted into the *bcr* gene on chromosome 22. The result is the production of a fusion protein called Bcr-Abl that consists primarily of sequences for the c-Abl kinase. However, the *bcr-abl* gene is not regulated appropriately; it is expressed at higher levels than that of the gene encoding the normal c-Abl kinase, stimulating a growth-promoting pathway. Because of this overexpression, leukemia cells express a unique target for chemotherapy. A specific inhibitor of the Bcr-Abl kinase, Gleevec (STI-571, imatinib mesylate), has proved to be a highly effective treatment for patients suffering from CML. This approach to cancer chemotherapy is fundamentally distinct from most approaches, which target all rapidly growing cells, including normal ones. Because Gleevec targets tumor cells specifically, side effects caused by the impairment of normal dividing cells can be minimized. Thus, our understanding of signal-transduction pathways is leading to conceptually new disease treatment strategies.

### Cholera and whooping cough are the result of altered G-protein activity

 Although defects in signal-transduction pathways have been most extensively studied in the context of cancer, such defects are important in many other diseases. Cholera and whooping cough are two pathologies of the G-protein-dependent signal pathways. Let us first consider the mechanism of action of the cholera toxin, secreted by the intestinal bacterium *Vibrio cholerae*. Cholera is a potentially life-threatening, acute diarrheal disease transmitted through contaminated water and food. It causes the voluminous secretion of electrolytes and fluids from the intestines of infected persons. The cholera toxin, also called *cholera*gen, is a protein composed of two functional units—a  $\beta$  subunit that binds to  $G_{M1}$  gangliosides (Section 26.1) of the intestinal epithelium and a catalytic A subunit that enters the cell.

**FIGURE 14.34 Formation of the *bcr-abl* gene by translocation.** In chronic myelogenous leukemia, parts of chromosomes 9 and 22 are reciprocally exchanged, causing the *bcr* and *abl* genes to fuse. The protein kinase encoded by the *bcr-abl* gene is expressed at higher levels in tumor cells than is the *c-abl* gene in normal cells.

The A subunit catalyzes the covalent modification of a  $G_{\alpha s}$  protein: the  $\alpha$  subunit is modified by the attachment of an ADP-ribose to an arginine residue. This modification stabilizes the GTP-bound form of  $G_{\alpha s}$ , trapping the molecule in its active conformation. The active G protein, in turn, continuously activates protein kinase A. PKA opens a chloride channel and inhibits sodium absorption by the  $\text{Na}^+ - \text{H}^+$  exchanger by phosphorylating both the channel and the exchanger. The net result of the phosphorylation is an excessive loss of NaCl and the loss of large amounts of water into the intestine. Patients suffering from cholera may pass as much as twice their body weight in fluid in 4 to 6 days. Treatment consists of rehydration with a glucose–electrolyte solution.

Whereas cholera is a result of a G protein trapped in the active conformation, causing the signal-transduction pathway to be persistently stimulated, pertussis is a result of the opposite situation. Pertussis toxin is secreted by *Bordetella pertussis*, the bacterium responsible for whooping cough. Like cholera, pertussis toxin adds an ADP-ribose moiety to a  $G_{\alpha}$  subunit. However, in this case, the ADP-ribose group is added to a  $G_{\alpha i}$  protein, a  $G_{\alpha}$  subunit that inhibits adenylate cyclase, closes  $\text{Ca}^{2+}$  channels, and opens  $\text{K}^+$  channels. The effect of this modification is to prevent binding of the heterotrimeric  $G_i$  protein to its receptor, trapping it in the “off” conformation. The pulmonary symptoms have not yet been traced to a particular target of the  $G_{\alpha i}$  protein.

## SUMMARY

In humans and other multicellular organisms, specific signal molecules are released from cells in one organ and are sensed by cells in other organs throughout the body. The message initiated by an extracellular ligand is converted into specific changes in metabolism or gene expression by means of often complex networks referred to as signal-transduction pathways. These pathways amplify the initial signal and lead to changes in the properties of specific effector molecules.

### 14.1 Heterotrimeric G Proteins Transmit Signals and Reset Themselves

Epinephrine binds to a cell-surface protein called the  $\beta$ -adrenergic receptor. This receptor is a member of the seven-transmembrane-helix receptor family, so named because each receptor has seven  $\alpha$  helices that span the cell membrane. When epinephrine binds to the  $\beta$ -adrenergic receptor on the outside of the cell, the receptor undergoes a conformational change that is sensed inside the cell by a signaling protein termed a heterotrimeric G protein. The  $\alpha$  subunit of the G protein exchanges a bound GDP molecule for GTP and concomitantly releases the heterodimer consisting of the  $\beta$  and  $\gamma$  subunits. The  $\alpha$  subunit in the GTP form then binds to adenylate cyclase and activates it, leading to an increase in the concentration of the second messenger cyclic AMP. This increase in cyclic AMP concentration, in turn, activates protein kinase A. Other 7TM receptors also signal through heterotrimeric G proteins, although these pathways often include enzymes other than adenylate cyclase. One prominent pathway, the phosphoinositide pathway, leads to the activation of phospholipase C, which cleaves a membrane lipid to produce two secondary messengers, diacylglycerol and inositol 1,4,5-trisphosphate. An increased  $\text{IP}_3$  concentration leads to the release of calcium ion, another important second messenger, into the cell. G-protein signaling is terminated by the hydrolysis of the bound GTP to GDP.

#### 14.2 Insulin Signaling: Phosphorylation Cascades Are Central to Many Signal-Transduction Processes

Protein kinases are key components in many signal-transduction pathways, including some for which the protein kinase is an integral component of the initial receptor. An example of such a receptor is the membrane tyrosine kinase bound by insulin. Insulin binding causes one subunit within the dimeric receptor to phosphorylate specific tyrosine residues in the other subunit. The resulting conformational changes dramatically increase the kinase activity of the receptor. The activated receptor kinase initiates a signaling cascade that includes both lipid kinases and protein kinases. This cascade eventually leads to the mobilization of glucose transporters to the cell surface, increasing glucose uptake. Insulin signaling is terminated through the action of phosphatases.

#### 14.3 EGF Signaling: Signal-Transduction Systems Are Poised to Respond

Only minor modifications are necessary to transform many signal-transduction proteins from their inactive into their active forms. Epidermal growth factor also signals through a receptor tyrosine kinase. EGF binding induces a conformational change that allows receptor dimerization and cross-phosphorylation. The phosphorylated receptor binds adaptor proteins that mediate the activation of Ras, a small G protein. Activated Ras initiates a protein kinase cascade that eventually leads to the phosphorylation of transcription factors and changes in gene expression. EGF signaling is terminated by the action of phosphatases and the hydrolysis of GTP by Ras.

#### 14.4 Many Elements Recur with Variation in Different Signal-Transduction Pathways

Protein kinases are components of many signal-transduction pathways, both as components of receptors and in other roles. Second messengers, including cyclic nucleotides, calcium, and lipid derivatives, are common in many signaling pathways. The changes in the concentrations of second messengers are often much larger than the changes associated with the initial signal owing to amplification along the pathway. Small domains that recognize phosphotyrosine residues or specific lipids are present in many signaling proteins and are essential to determining the specificity of interactions.

#### 14.5 Defects in Signal-Transduction Pathways Can Lead to Cancer and Other Diseases

Genes encoding components of signal-transduction pathways that control cell growth are often mutated in cancer. Some genes can be mutated to forms called oncogenes that are active regardless of appropriate signals. Monoclonal antibodies directed against cell-surface receptors that participate in signaling have been developed for use in cancer treatment. Our understanding of the molecular basis of cancer is leading to the development of anticancer drugs directed against specific targets, such as the specific kinase inhibitor Gleevec.

## PROBLEMS

- Active mutants.* Some protein kinases are inactive unless they are phosphorylated on key serine or threonine residues. In some cases, active enzymes can be generated by mutating these serine or threonine residues to aspartate. Explain.
- In the pocket.* SH2 domains bind phosphotyrosine residues in deep pockets on their surfaces. Would you expect SH2 domains to bind phosphoserine and phosphothreonine with high affinity? Why or why not?
- On-off.* Why is the GTPase activity of G proteins crucial to the proper functioning of a cell? Why have G proteins not evolved to catalyze GTP hydrolysis more efficiently?
- Viva la différence.* Why is the fact that a monomeric hormone binds simultaneously to two identical receptor molecules, thus promoting the formation of a dimer of the receptor, considered remarkable?
- Antibodies mimicking hormones.* Antibodies have two identical antigen-binding sites. Remarkably, antibodies to the extracellular parts of growth-factor receptors often lead to the same cellular effects as does exposure to growth factors. Explain this observation.
- Facile exchange.* A mutated form of the  $\alpha$  subunit of the heterotrimeric G protein has been identified; this form readily exchanges nucleotides even in the absence of an activated receptor. What would be the effect on a signaling pathway containing the mutated  $\alpha$  subunit?
- Making connections.* Suppose that you were investigating a newly discovered growth-factor signal-transduction pathway. You found that, if you added GTP $\gamma$ S, a nonhydrolyzable analog of GTP, the duration of the hormonal response increased. What can you conclude?
- Diffusion rates.* Usually, rates of diffusion vary inversely with molecular weights; so smaller molecules diffuse faster than do larger ones. In cells, however, calcium ion diffuses more slowly than does cAMP. Propose a possible explanation.
- Negativity abounds.* Fura-2 is not effective for the study of calcium levels in intact, living cells. On the basis of how Fura-2 is depicted on p. 406, why is it ineffective?
- Awash with glucose.* Glucose is mobilized for ATP generation in muscle in response to epinephrine, which activates G<sub>as</sub>. Cyclic AMP phosphodiesterase is an enzyme that converts cAMP into AMP. How would inhibitors of cAMP phosphodiesterase affect glucose mobilization in muscle?
- Getting it started.* The insulin receptor, on dimerization, cross-phosphorylates the activation loop of the other receptor molecule, leading to activation of the kinase. Propose how this phosphorylation event can take place if the kinase starts in an inactive conformation.
- Many defects.* Considerable effort has been directed toward determining the genes in which sequence variation contributes to the development of type 2 diabetes. Approximately 800 genes have been implicated. Propose an explanation for this observation.
- Growth-factor signaling.* Human growth hormone binds to a cell-surface membrane protein that is not a receptor tyrosine kinase. The intracellular domain of the receptor can bind other proteins inside the cell. Furthermore, studies indicate that the receptor is monomeric in the absence of hormone but dimerizes on hormone binding. Propose a possible mechanism for growth-hormone signaling.
- Receptor truncation.* You prepare a cell line that overexpresses a mutant form of EGFR in which the entire intracellular region of the receptor has been deleted. Predict the effect of overexpression of this construct on EGF signaling in this cell line.

15. *Hybrid.* Suppose that, through genetic manipulations, a chimeric receptor is produced that consists of the extracellular domain of the insulin receptor and the transmembrane and intracellular domains of the EGF receptor. Cells expressing this receptor are exposed to insulin, and the level of phosphorylation of the chimeric receptor is examined. What would you expect to observe and why? What would you expect to observe if these cells were exposed to EGF?

16. *Total amplification.* Suppose that each  $\beta$ -adrenergic receptor bound to epinephrine converts 100 molecules of  $G_{\alpha s}$  into their GTP forms and that each molecule of activated adenylate cyclase produces 1000 molecules of cAMP per second. With the assumption of a full response, how many molecules of cAMP will be produced in 1 s after the formation of a single complex between epinephrine and the  $\beta$ -adrenergic receptor?

### Chapter Integration Problems

17. *Nerve-growth-factor pathway.* Nerve-growth factor (NGF) binds to a protein tyrosine kinase receptor. The amount of diacylglycerol in the plasma membrane increases in cells expressing this receptor when treated with NGF. Propose a simple signaling pathway and identify the isoform of any participating enzymes. Would you expect the concentrations of any other common second messengers to increase on NGF treatment?

18. *Redundancy.* Because of the high degree of genetic variability in tumors, typically no single anticancer therapy is universally effective for all patients, even within a given tumor type. Hence, it is often desirable to inhibit a particular pathway at more than one point in the signaling cascade. In addition to the EGFR-directed monoclonal antibody cetuximab, propose alternative strategies for targeting the EGF signaling pathway for antitumor drug development.

### Mechanism Problems

19. *Distant relatives.* The structure of adenylate cyclase is similar to the structures of some types of DNA polymerases, suggesting that these enzymes derived from a common ancestor. Compare the reactions catalyzed by these two enzymes. In what ways are they similar?

20. *Kinase inhibitors as drugs.* Functional and structural analysis indicates that Gleevec is an ATP-competitive inhibitor of the Bcr-Abl kinase. In fact, many kinase inhibitors under investigation or currently marketed as drugs are ATP competitive. Can you suggest a potential drawback of drugs that utilize this particular mechanism of action?

### Data Interpretation Problems

21. *Establishing specificity.* You wish to determine the hormone-binding specificity of a newly identified mem-

brane receptor. Three different hormones, X, Y, and Z, were mixed with the receptor in separate experiments, and the percentage of binding capacity of the receptor was determined as a function of hormone concentration, as shown in graph A.

(a) What concentrations of each hormone yield 50% maximal binding?

(b) Which hormone shows the highest binding affinity for the receptor?

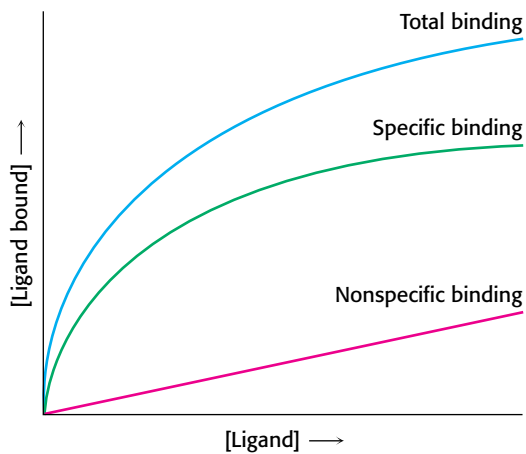

You next wish to determine whether the hormone–receptor complex stimulates the adenylate cyclase cascade. To do so, you measure adenylate cyclase activity as a function of hormone concentration, as shown in graph B.

(c) What is the relation between the binding affinity of the hormone–receptor complex and the ability of the hormone to enhance adenylate cyclase activity? What can you conclude about the mechanism of action of the hormone–receptor complex?

(d) Suggest experiments that would determine whether a  $G_{\alpha s}$  protein is a component of the signal-transduction pathway.

22. *Binding issues.* A scientist wishes to determine the number of receptors specific for a ligand X, which he has in both radioactive and nonradioactive form. In one experiment, he adds increasing amounts of radioactive X and measures how much of it is bound to the cells. The result is shown as total activity in the following graph. Next, he performs the same experiment, except that he includes a several hundredfold excess of nonradioactive X. This result is shown as nonspecific binding. The difference between the two curves is the specific binding.

- (a) Why is the total binding not an accurate representation of the number of receptors on the cell surface?
- (b) What is the purpose of performing the experiment in the presence of excess nonradioactive ligand?
- (c) What is the significance of the fact that specific binding attains a plateau?

23. *Counting receptors.* With the use of experiments such as those described in Problems 21 and 22, the number of receptors in the cell membrane can be calculated. Suppose that the specific activity of the ligand is  $10^{12}$  cpm per millimole and that the maximal specific binding is  $10^4$  cpm per milligram of membrane protein. There are  $10^{10}$  cells per milligram of membrane protein. Assume that one ligand binds per receptor. Calculate the number of receptor molecules present per cell.

# Metabolism: Basic Concepts and Design

An infinite number of books can be written with only a limited number of letters, 26 in the case of English. Likewise, the complex biochemistry of a cell—intermediary metabolism—is constructed from a limited number of recurring motifs, reactions, and molecules. One role of intermediary metabolism is the conversion of environmental energy into the cellular energy currency, ATP, represented by the model at the right. [(Left) MARKA/Alamy.]

The concepts of conformation and dynamics developed in Part I—especially those dealing with the specificity and catalytic power of enzymes, the regulation of their catalytic activity, and the transport of molecules and ions across membranes—enable us to now ask questions fundamental to biochemistry:

1. How does a cell extract energy and reducing power from its environment?
2. How does a cell synthesize the building blocks of its macromolecules and then the macromolecules themselves?

These processes are carried out by a highly integrated network of chemical reactions collectively known as *metabolism* or *intermediary metabolism*.

More than a thousand chemical reactions take place in even as simple an organism as *Escherichia coli*. The array of reactions may seem overwhelming at first glance. However, closer scrutiny reveals that metabolism has a *coherent design containing many common motifs*. These motifs include the use of an energy currency and the repeated appearance of a limited number of activated intermediates. In fact, a group of about 100 molecules play central

## OUTLINE

- 15.1 Metabolism Is Composed of Many Coupled, Interconnecting Reactions
- 15.2 ATP Is the Universal Currency of Free Energy in Biological Systems
- 15.3 The Oxidation of Carbon Fuels Is an Important Source of Cellular Energy
- 15.4 Metabolic Pathways Contain Many Recurring Motifs

roles in all forms of life. Furthermore, although the number of reactions in metabolism is large, the number of *kinds* of reactions is small and the mechanisms of these reactions are usually quite simple. Metabolic pathways are also regulated in common ways. The purpose of this chapter is to introduce some general principles of metabolism to provide a foundation for the more detailed studies to follow. These principles are:

1. Fuels are degraded and large molecules are constructed step by step in a series of linked reactions called *metabolic pathways*.
2. An energy currency common to all life forms, *adenosine triphosphate (ATP)*, links energy-releasing pathways with energy-requiring pathways.
3. The oxidation of carbon fuels powers the formation of ATP.
4. Although there are many metabolic pathways, a limited number of types of reactions and particular intermediates are common to many pathways.
5. Metabolic pathways are highly regulated.

## 15.1 Metabolism Is Composed of Many Coupled, Interconnecting Reactions

Living organisms require a continual input of free energy for three major purposes: (1) the performance of mechanical work in muscle contraction and cellular movements, (2) the active transport of molecules and ions, and (3) the synthesis of macromolecules and other biomolecules from simple precursors. The free energy used in these processes, which maintain an organism in a state that is far from equilibrium, is derived from the environment. Photosynthetic organisms, or *phototrophs*, obtain this energy by trapping sunlight, whereas *chemotrophs*, which include animals, obtain energy through the oxidation of foodstuffs generated by phototrophs.

### Metabolism consists of energy-yielding and energy-requiring reactions

*Metabolism* is essentially a sequence of chemical reactions that begins with a particular molecule and results in the formation of some other molecule or molecules in a carefully defined fashion (Figure 15.1). There are many such defined pathways in the cell (Figure 15.2), and we will examine a few of them in some detail later. These pathways are interdependent, and their activity is coordinated by exquisitely sensitive means of communication in which allosteric enzymes are predominant (Section 10.1). We considered the principles of this communication in Chapter 14.

We can divide metabolic pathways into two broad classes: (1) those that convert energy from fuels into biologically useful forms, and (2) those that require inputs of energy to proceed. Although this division is often imprecise, it is nonetheless a useful distinction in an examination of metabolism. Those reactions that transform fuels into cellular energy are called *catabolic reactions* or, more generally, *catabolism*.

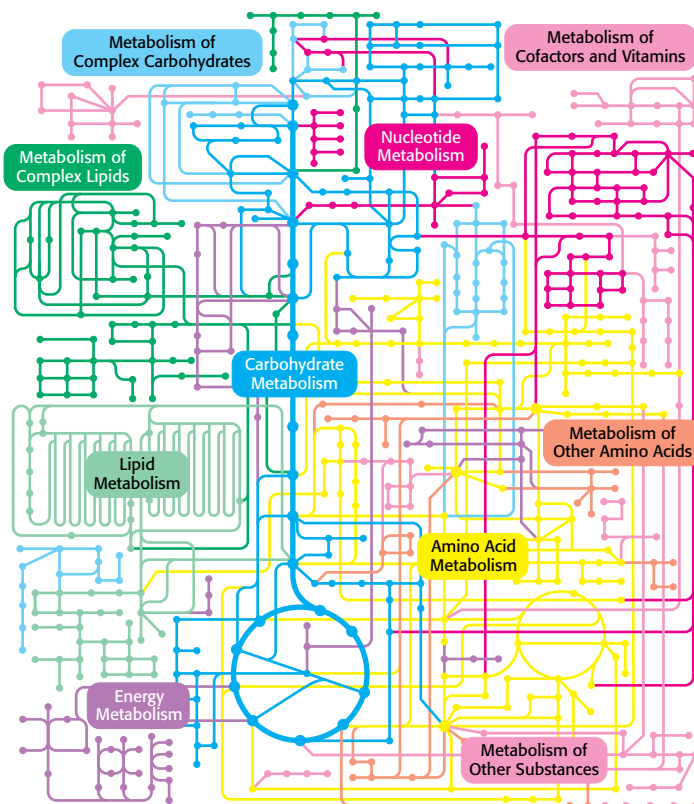

Those reactions that require energy—such as the synthesis of glucose, fats, or DNA—are called *anabolic reactions* or *anabolism*. The useful forms of energy that are produced in catabolism are employed in anabolism to generate complex structures from simple ones, or energy-rich states from energy-poor ones.

**FIGURE 15.1** Glucose metabolism.

Glucose is metabolized to pyruvate in 10 linked reactions. Under anaerobic conditions, pyruvate is metabolized to lactate and, under aerobic conditions, to acetyl CoA. The glucose-derived carbons of acetyl CoA are subsequently oxidized to  $\text{CO}_2$ .

**FIGURE 15.2 Metabolic pathways.** Each node represents a specific metabolite. [From the Kyoto Encyclopedia of Genes and Genomes ([www.genome.ad.jp/kegg](http://www.genome.ad.jp/kegg)).]

Some pathways can be either anabolic or catabolic, depending on the energy conditions in the cell. These pathways are referred to as *amphibolic pathways*.

An important general principle of metabolism is that *biosynthetic and degradative pathways are almost always distinct*. This separation is necessary for energetic reasons, as will be evident in subsequent chapters. It also facilitates the control of metabolism.

### A thermodynamically unfavorable reaction can be driven by a favorable reaction

How are specific pathways constructed from individual reactions? A pathway must satisfy minimally two criteria: (1) the individual reactions must be *specific*, and (2) the entire set of reactions that constitute the pathway must be *thermodynamically favored*. A reaction that is specific will yield only one particular product or set of products from its reactants. As discussed in Chapter 8, enzymes provide this specificity. The thermodynamics of metabolism is most readily approached in relation to free energy, which was discussed in chapters 1 and 8. A reaction can occur spontaneously only if  $\Delta G$ , the change in free energy, is negative. Recall that  $\Delta G$  for the formation of products C and D from substrates A and B is given by

$$\Delta G = \Delta G^{\circ'} + RT \ln \frac{[C][D]}{[A][B]}$$

Thus, the  $\Delta G$  of a reaction depends on the *nature* of the reactants and products (expressed by the  $\Delta G^{\circ'}$  term, the standard free-energy change) and on their *concentrations* (expressed by the second term).

An important thermodynamic fact is that *the overall free-energy change for a chemically coupled series of reactions is equal to the sum of the free-energy changes of the individual steps*. Consider the following reactions:

Under standard conditions, A cannot be spontaneously converted into B and C, because  $\Delta G^{\circ'}$  is positive. However, the conversion of B into D under standard conditions is thermodynamically feasible. Because free-energy changes are additive, the conversion of A into C and D has a  $\Delta G^{\circ'}$  of  $-13 \text{ kJ mol}^{-1}$  ( $-3 \text{ kcal mol}^{-1}$ ), which means that it can occur spontaneously under standard conditions. Thus, *a thermodynamically unfavorable reaction can be driven by a thermodynamically favorable reaction to which it is coupled*. In this example, the reactions are coupled by the shared chemical intermediate B. Metabolic pathways are formed by the coupling of enzyme-catalyzed reactions such that the overall free energy of the pathway is negative.

## 15.2 ATP Is the Universal Currency of Free Energy in Biological Systems

Just as commerce is facilitated by the use of a common currency, the commerce of the cell—metabolism—is facilitated by the use of a common energy currency, *adenosine triphosphate* (ATP). Part of the free energy derived from the oxidation of foodstuffs and from light is transformed into this highly accessible molecule, which acts as the free-energy donor in most energy-requiring processes such as motion, active transport, and biosynthesis. Indeed, most of catabolism consists of reactions that extract energy from fuels such as carbohydrates and fats and convert it into ATP.

### ATP hydrolysis is exergonic

ATP is a nucleotide consisting of adenine, a ribose, and a triphosphate unit (Figure 15.3). The active form of ATP is usually a complex of ATP with  $\text{Mg}^{2+}$  or  $\text{Mn}^{2+}$ . In considering the role of ATP as an energy carrier, we can focus on its triphosphate moiety. *ATP is an energy-rich molecule because its triphosphate unit contains two phosphoanhydride bonds*. A large amount of free energy is liberated when ATP is hydrolyzed to adenosine diphosphate (ADP) and orthophosphate ( $\text{P}_i$ ) or when ATP is hydrolyzed to adenosine monophosphate (AMP) and pyrophosphate ( $\text{PP}_i$ ).

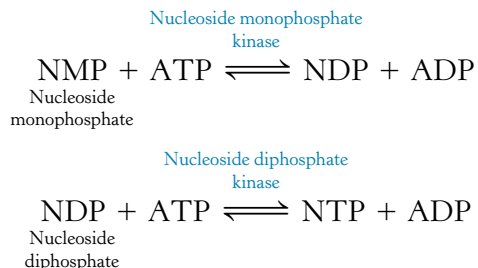

The precise  $\Delta G$  for these reactions depends on the ionic strength of the medium and on the concentrations of  $\text{Mg}^{2+}$  and other metal ions (problems 23 and 34). Under typical cellular concentrations, the  $\Delta G$  for these hydrolyses is approximately  $-50 \text{ kJ mol}^{-1}$  ( $-12 \text{ kcal mol}^{-1}$ ).

**FIGURE 15.3 Structures of ATP, ADP, and AMP.** These adenylates consist of adenine (blue), a ribose (black), and a tri-, di-, or monophosphate unit (red). The innermost phosphorus atom of ATP is designated  $P_{\alpha}$ , the middle one  $P_{\beta}$ , and the outermost one  $P_{\gamma}$ .

The free energy liberated in the hydrolysis of ATP is harnessed to drive reactions that require an input of free energy, such as muscle contraction. In turn, ATP is formed from ADP and  $P_i$  when fuel molecules are oxidized in chemotrophs or when light is trapped by phototrophs. *This ATP–ADP cycle is the fundamental mode of energy exchange in biological systems.*

Some biosynthetic reactions are driven by the hydrolysis of other nucleoside triphosphates—namely, guanosine triphosphate (GTP), uridine triphosphate (UTP), and cytidine triphosphate (CTP). The diphosphate forms of these nucleotides are denoted by GDP, UDP, and CDP, and the monophosphate forms are denoted by GMP, UMP, and CMP. Enzymes catalyze the transfer of the terminal phosphoryl group from one nucleotide to another. The phosphorylation of nucleoside monophosphates is catalyzed by a family of *nucleoside monophosphate kinases*, as discussed in Section 9.4. The phosphorylation of nucleoside diphosphates is catalyzed by *nucleoside diphosphate kinase*, an enzyme with broad specificity.

It is intriguing to note that although all of the nucleotide triphosphates are energetically equivalent, ATP is nonetheless the primary cellular energy carrier. In addition, two important electron carriers,  $\text{NAD}^+$  and FAD, as well as the acyl group carrier, coenzyme A, are derivatives of ATP. *The role of ATP in energy metabolism is paramount.*

### ATP hydrolysis drives metabolism by shifting the equilibrium of coupled reactions

An otherwise unfavorable reaction can be made possible by coupling to ATP hydrolysis. Consider a reaction that is thermodynamically unfavorable

without an input of free energy, a situation common to most biosynthetic reactions. Suppose that the standard free energy of the conversion of compound A into compound B is  $+16.7 \text{ kJ mol}^{-1}$  ( $+4.0 \text{ kcal mol}^{-1}$ ):

The equilibrium constant  $K'_{\text{eq}}$  of this reaction at  $25^{\circ}\text{C}$  is related to  $\Delta G^{\circ'}$  (in units of kilojoules per mole) by

$$K'_{\text{eq}} = [\text{B}]_{\text{eq}}/[\text{A}]_{\text{eq}} = e^{-\Delta G^{\circ'}/2.47} = 1.15 \times 10^{-3}$$

Thus, net conversion of A into B cannot take place when the molar ratio of B to A is equal to or greater than  $1.15 \times 10^{-3}$ . However, A can be converted into B under these conditions if the reaction is coupled to the hydrolysis of ATP. Under standard conditions, the  $\Delta G^{\circ'}$  of hydrolysis is approximately  $-30.5 \text{ kJ mol}^{-1}$  ( $-7.3 \text{ kcal mol}^{-1}$ ). The new overall reaction is

Its free-energy change of  $-13.8 \text{ kJ mol}^{-1}$  ( $-3.3 \text{ kcal mol}^{-1}$ ) is the sum of the value of  $\Delta G^{\circ'}$  for the conversion of A into B [ $+16.7 \text{ kJ mol}^{-1}$  ( $+4.0 \text{ kcal mol}^{-1}$ )] and the value of  $\Delta G^{\circ'}$  for the hydrolysis of ATP [ $-30.5 \text{ kJ mol}^{-1}$  ( $-7.3 \text{ kcal mol}^{-1}$ )]. At pH 7, the equilibrium constant of this coupled reaction is

$$K'_{\text{eq}} = \frac{[\text{B}]_{\text{eq}}}{[\text{A}]_{\text{eq}}} \times \frac{[\text{ADP}]_{\text{eq}}[\text{P}_i]_{\text{eq}}}{[\text{ATP}]_{\text{eq}}} = e^{13.8/2.47} = 2.67 \times 10^2$$

At equilibrium, the ratio of [B] to [A] is given by

$$\frac{[\text{B}]_{\text{eq}}}{[\text{A}]_{\text{eq}}} = K'_{\text{eq}} \frac{[\text{ATP}]_{\text{eq}}}{[\text{ADP}]_{\text{eq}}[\text{P}_i]_{\text{eq}}}$$

which means that the hydrolysis of ATP enables A to be converted into B until the [B]/[A] ratio reaches a value of  $2.67 \times 10^2$ . This equilibrium ratio is strikingly different from the value of  $1.15 \times 10^{-3}$  for the reaction  $A \rightarrow B$  in the absence of ATP hydrolysis. In other words, coupling the hydrolysis of ATP with the conversion of A into B under standard conditions has changed the equilibrium ratio of B to A by a factor of about  $10^5$ . If we were to use the  $\Delta G$  of hydrolysis of ATP under cellular conditions [ $-50.2 \text{ kJ mol}^{-1}$  ( $-12 \text{ kcal mol}^{-1}$ )] in our calculations instead of  $\Delta G^{\circ'}$ , the change in the equilibrium ratio would be even more dramatic, on the order of  $10^8$ .

We see here the thermodynamic essence of ATP's action as an *energy-coupling agent*. Cells maintain ATP levels by using oxidizable substrates or light as sources of free energy for synthesizing the molecule. In the cell, the hydrolysis of an ATP molecule in a coupled reaction then changes the equilibrium ratio of products to reactants by a very large factor, of the order of  $10^8$ . More generally, the hydrolysis of  $n$  ATP molecules changes the equilibrium ratio of a coupled reaction (or sequence of reactions) by a factor of  $10^{8n}$ . For example, the hydrolysis of three ATP molecules in a coupled reaction changes the equilibrium ratio by a factor of  $10^{24}$ . Thus, a *thermodynamically unfavorable reaction sequence can be converted into a favorable one by coupling it to the hydrolysis of a sufficient number of ATP molecules in a new reaction*. It should also be emphasized that A and B in the preceding coupled reaction may be interpreted very generally, not only as different chemical species. For example, A and B may represent activated and unactivated conformations of a protein that is activated by phosphorylation with ATP.

Through such changes in protein conformation, molecular motors such as myosin, kinesin, and dynein convert the chemical energy of ATP into mechanical energy (Chapter 34). Indeed, this conversion is the basis of muscle contraction.

Alternatively, A and B may refer to the concentrations of an ion or molecule on the outside and inside of a cell, as in the active transport of a nutrient. The active transport of  $\text{Na}^+$  and  $\text{K}^+$  across membranes is driven by the phosphorylation of the sodium–potassium pump by ATP and its subsequent dephosphorylation (Section 13.2).

### The high phosphoryl potential of ATP results from structural differences between ATP and its hydrolysis products

What makes ATP an efficient phosphoryl-group donor? Let us compare the standard free energy of hydrolysis of ATP with that of a phosphate ester, such as glycerol 3-phosphate:

The magnitude of  $\Delta G^{\circ'}$  for the hydrolysis of glycerol 3-phosphate is much smaller than that of ATP, which means that ATP has a stronger tendency to transfer its terminal phosphoryl group to water than does glycerol 3-phosphate. In other words, ATP has a higher *phosphoryl-transfer potential* (*phosphoryl-group-transfer potential*) than does glycerol 3-phosphate.

The high phosphoryl-transfer potential of ATP can be explained by features of the ATP structure. Because  $\Delta G^{\circ'}$  depends on the *difference* in free energies of the products and reactants, we need to examine the structures of both ATP and its hydrolysis products, ADP and  $\text{P}_i$ , to answer this question. Four factors are important: *resonance stabilization*, *electrostatic repulsion*, *increase in entropy*, and *stabilization due to hydration*.

1. *Resonance Stabilization*. Orthophosphate ( $\text{P}_i$ ), one of the products of ATP hydrolysis, has greater resonance stabilization than do any of the phosphoryl groups of ATP. Orthophosphate has a number of resonance forms of similar energy (Figure 15.4), whereas the  $\gamma$  phosphoryl group of ATP has a smaller number. Forms like that shown in Figure 15.5 are unfavorable because a positively charged oxygen atom is adjacent to a positively charged phosphorus atom, an electrostatically unfavorable juxtaposition.

FIGURE 15.4 Resonance structures of orthophosphate.

2. *Electrostatic Repulsion*. At pH 7, the triphosphate unit of ATP carries about four negative charges. These charges repel one another because they are in close proximity. The repulsion between them is reduced when ATP is hydrolyzed.

Glycerol 3-phosphate

FIGURE 15.5 Improbable resonance structure. The structure contributes little to the terminal part of ATP, because two positive charges are placed adjacent to each other.

3. *Increase in Entropy.* The entropy of the products of ATP hydrolysis is greater, in that there are now two molecules instead of a single ATP molecule. We disregard the molecule of water used to hydrolyze the ATP; given the high concentration (55.5 M), there is effectively no change in the concentration of water during the reaction.

4. *Stabilization Due to Hydration.* Water binds to ADP and  $P_i$ , stabilizing these molecules, and rendering the reverse reaction, the synthesis of ATP, more unfavorable.

ATP is often called a high-energy phosphate compound, and its phosphoanhydride bonds are referred to as high-energy bonds. Indeed, a “squiggle” ( $\sim P$ ) is often used to indicate such a bond. Nonetheless, there is nothing special about the bonds themselves. *They are high-energy bonds in the sense that much free energy is released when they are hydrolyzed,* for the reasons listed above.

### Phosphoryl-transfer potential is an important form of cellular energy transformation

The standard free energies of hydrolysis provide a convenient means of comparing the phosphoryl-transfer potential of phosphorylated compounds. Such comparisons reveal that ATP is not the only compound with a high phosphoryl-transfer potential. In fact, some compounds in biological systems have a higher phosphoryl-transfer potential than that of ATP. These compounds include phosphoenolpyruvate (PEP), 1,3-bisphosphoglycerate (1,3-BPG), and creatine phosphate (Figure 15.6). Thus, PEP can transfer its phosphoryl group to ADP to form ATP. Indeed, this transfer is one of the ways in which ATP is generated in the breakdown of sugars (Chapter 16). It is significant that ATP has a phosphoryl-transfer potential that is intermediate among the biologically important phosphorylated molecules (Table 15.1). *This intermediate position enables ATP to function efficiently as a carrier of phosphoryl groups.*

**FIGURE 15.6 Compounds with high phosphoryl-transfer potential.** The role of ATP as the cellular energy currency is illustrated by its relation to other phosphorylated compounds. ATP has a phosphoryl-transfer potential that is intermediate among the biologically important phosphorylated molecules. High-phosphoryl-transfer-potential compounds (1,3-BPG, PEP, and creatine phosphate) derived from the metabolism of fuel molecules are used to power ATP synthesis. In turn, ATP donates a phosphoryl group to other biomolecules to facilitate their metabolism. [Data from D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry*, 5th ed. (W. H. Freeman and Company, 2009), Fig. 13-19.]

**TABLE 15.1** Standard free energies of hydrolysis of some phosphorylated compounds

Compound	$\text{kJ mol}^{-1}$	$\text{kcal mol}^{-1}$
Phosphoenolpyruvate	-61.9	-14.8
1,3-Bisphosphoglycerate	-49.4	-11.8
Creatine phosphate	-43.1	-10.3
ATP (to ADP)	-30.5	-7.3
Glucose 1-phosphate	-20.9	-5.0
Pyrophosphate	-19.3	-4.6
Glucose 6-phosphate	-13.8	-3.3
Glycerol 3-phosphate	-9.2	-2.2

The amount of ATP in muscle suffices to sustain contractile activity for less than a second. Creatine phosphate in vertebrate muscle serves as a reservoir of high-potential phosphoryl groups that can be readily transferred to ADP. Indeed, we use creatine phosphate to regenerate ATP from ADP every time that we exercise strenuously. This reaction is catalyzed by *creatine kinase*.

At pH 7, the standard free energy of hydrolysis of creatine phosphate is  $-43.1 \text{ kJ mol}^{-1}$  ( $-10.3 \text{ kcal mol}^{-1}$ ), compared with  $-30.5 \text{ kJ mol}^{-1}$  ( $-7.3 \text{ kcal mol}^{-1}$ ) for ATP. Hence, the standard free-energy change in forming ATP from creatine phosphate is  $-12.6 \text{ kJ mol}^{-1}$  ( $-3.0 \text{ kcal mol}^{-1}$ ), which corresponds to an equilibrium constant of 162.

$$K_{\text{eq}} = \frac{[\text{ATP}][\text{creatine}]}{[\text{ADP}][\text{creatine phosphate}]} = e^{-\Delta G^\circ/2.47} = e^{12.6/2.47} = 162$$

In resting muscle, typical concentrations of these metabolites are  $[\text{ATP}] = 4 \text{ mM}$ ,  $[\text{ADP}] = 0.013 \text{ mM}$ ,  $[\text{creatine phosphate}] = 25 \text{ mM}$ , and  $[\text{creatine}] = 13 \text{ mM}$ . Because of its abundance and high phosphoryl-transfer potential relative to that of ATP, creatine phosphate is a highly effective phosphoryl buffer. Indeed, creatine phosphate is the major source of phosphoryl groups for ATP regeneration for a runner during the first 4 seconds of a 100-meter sprint. The fact that creatine phosphate can replenish ATP pools is the basis of the use of creatine as a dietary supplement by athletes in sports requiring short bursts of intense activity. After the creatine phosphate pool is depleted, ATP must be generated through metabolism (Figure 15.7).

**FIGURE 15.7** Sources of ATP during exercise. In the initial seconds, exercise is powered by existing high-phosphoryl-transfer compounds (ATP and creatine phosphate). Subsequently, the ATP must be regenerated by metabolic pathways.

## 15.3 The Oxidation of Carbon Fuels Is an Important Source of Cellular Energy

**FIGURE 15.8 ATP-ADP cycle.** This cycle is the fundamental mode of energy exchange in biological systems.

ATP serves as the principal *immediate donor of free energy* in biological systems rather than as a long-term storage form of free energy. In a typical cell, an ATP molecule is consumed within a minute of its formation. Although the total quantity of ATP in the body is limited to approximately 100 g, *the turnover of this small quantity of ATP is very high*. For example, a resting human being consumes about 40 kg (88 pounds) of ATP in 24 hours. During strenuous exertion, the rate of utilization of ATP may be as high as 0.5 kg/minute. For a 2-hour run, 60 kg (132 pounds) of ATP is utilized. Clearly, having mechanisms for regenerating ATP is vital. Motion, active transport, signal amplification, and biosynthesis can take place only if ATP is continually regenerated from ADP (Figure 15.8). *The generation of ATP is one of the primary roles of catabolism*. The carbon in fuel molecules—such as glucose and fats—is oxidized to  $\text{CO}_2$ . The resulting electrons are captured and used to regenerate ATP from ADP and  $\text{P}_i$ .

In aerobic organisms, the ultimate electron acceptor in the oxidation of carbon is  $\text{O}_2$  and the oxidation product is  $\text{CO}_2$ . Consequently, the more reduced a carbon is to begin with, the more free energy is released by its oxidation. Figure 15.9 shows the  $\Delta G^{\circ}$  of oxidation for one-carbon compounds.

	Most energy	→ Least energy			
	<b>Methane</b>	<b>Methanol</b>	<b>Formaldehyde</b>	<b>Formic acid</b>	<b>Carbon dioxide</b>
$\Delta G^{\circ}$ oxidation ( $\text{kJ mol}^{-1}$ )	-820	-703	-523	-285	0
$\Delta G^{\circ}$ oxidation ( $\text{kcal mol}^{-1}$ )	-196	-168	-125	-68	0

**FIGURE 15.9 Free energy of oxidation of single-carbon compounds.**

Fuel molecules are more complex (Figure 15.10) than the single-carbon compounds depicted in Figure 15.9. Nevertheless, oxidation of these fuels takes place one carbon at a time. The carbon-oxidation energy is used in some cases to create a compound with high phosphoryl-transfer potential and in other cases to create an ion gradient. In either case, the end point is the formation of ATP.

**FIGURE 15.10 Prominent fuels.** Fats are a more efficient fuel source than carbohydrates such as glucose because the carbon in fats is more reduced.

### Compounds with high phosphoryl-transfer potential can couple carbon oxidation to ATP synthesis

How is the energy released from the oxidation of a carbon compound converted into ATP? As an example, consider glyceraldehyde 3-phosphate (shown in the margin), which is a metabolite of glucose formed in the

oxidation of that sugar. The C-1 carbon (shown in red) is at the aldehyde-oxidation level and is not in its most oxidized state. Oxidation of the aldehyde to an acid will release energy.

However, the oxidation does not take place directly. Instead, the carbon oxidation generates an acyl phosphate, 1,3-bisphosphoglycerate. The electrons released are captured by  $\text{NAD}^+$ , which we will consider shortly.

For reasons similar to those discussed for ATP, 1,3-bisphosphoglycerate has a high phosphoryl-transfer potential that is, in fact, greater than that of ATP. Thus, the hydrolysis of 1,3-BPG can be coupled to the synthesis of ATP.

The energy of oxidation is initially trapped as a high-phosphoryl-transfer-potential compound and then used to form ATP. The oxidation energy of a carbon atom is transformed into phosphoryl-transfer potential, first as 1,3-bisphosphoglycerate and ultimately as ATP. We will consider these reactions in mechanistic detail in Chapter 16.

### Ion gradients across membranes provide an important form of cellular energy that can be coupled to ATP synthesis

As described in Chapter 13, electrochemical potential is an effective means of storing free energy. Indeed, the electrochemical potential of *ion gradients across membranes*, produced by the oxidation of fuel molecules or by photosynthesis, ultimately powers the synthesis of most of the ATP in cells. In general, ion gradients are versatile means of coupling thermodynamically unfavorable reactions to favorable ones. Indeed, in animals, *proton gradients* generated by the oxidation of carbon fuels account for more than 90% of ATP generation (Figure 15.11). This process is called *oxidative phosphorylation* (Chapter 18). ATP hydrolysis can then be used to form ion gradients of different types and functions. The electrochemical potential of a

**FIGURE 15.11 Proton gradients.** The oxidation of fuels can power the formation of proton gradients by the action of specific proton pumps (yellow cylinders). These proton gradients can in turn drive the synthesis of ATP when the protons flow through an ATP-synthesizing enzyme (red complex).

$\text{Na}^+$  gradient, for example, can be tapped to pump  $\text{Ca}^{2+}$  out of cells or to transport nutrients such as sugars and amino acids into cells.

### Phosphates play a prominent role in biochemical processes

We have seen in Section 10.3, Chapter 14, and in this chapter the prominence of phosphoryl group transfer from ATP to acceptor molecules. How is it that phosphate came to play such a prominent role in biology? Phosphate and its esters have several characteristics that render it useful for biochemical systems. First, phosphate esters have the important property of being *thermodynamically unstable* while being *kinetically stable*. Phosphate esters are thus molecules whose energy release can be manipulated by enzymes. The stability of phosphate esters is due to the negative charges that make them resistant to hydrolysis in the absence of enzymes. This accounts for the presence of phosphate in the backbone of DNA. Furthermore, because phosphate esters are so kinetically stable, they make ideal regulatory molecules, added to proteins by kinases and removed only by phosphatases. Phosphates are also frequently added to metabolites that might otherwise diffuse through the cell membrane. Furthermore, even when transporters exist for unphosphorylated forms of a metabolite, the addition of a phosphate changes the geometry and polarity of the molecules so that they no longer fit in the binding sites of the transporters.

No other ions have the chemical characteristics of phosphate. Citrate is not sufficiently charged to prevent hydrolysis. Arsenate forms esters that are unstable and susceptible to spontaneous hydrolysis. Indeed, arsenate is poisonous to cells because it can replace phosphate in reactions required for ATP synthesis, generating unstable compounds and preventing ATP synthesis. Silicate is more abundant than phosphate, but silicate salts are virtually insoluble, and in fact, are used for biomineralization. Only phosphate has the chemical properties to meet the needs of living systems.

### Energy from foodstuffs is extracted in three stages

Let us take an overall view of the processes of energy conversion in higher organisms before considering them in detail in subsequent chapters. Hans Krebs described three stages in the generation of energy from the oxidation of foodstuffs (Figure 15.12).

*In the first stage, large molecules in food are broken down into smaller units in the process of digestion.* Proteins are hydrolyzed to their 20 different amino acids, polysaccharides are hydrolyzed to simple sugars such as glucose, and lipids are hydrolyzed to glycerol and fatty acids. The degradation products are then absorbed by the cells of the intestine and distributed throughout the body. This stage is strictly a preparation stage; no useful energy is captured in this phase.

*In the second stage, these numerous small molecules are degraded to a few simple units that play a central role in metabolism.* In fact, most of them—sugars, fatty acids, glycerol, and several amino acids—are converted into the acetyl unit of acetyl CoA. Some ATP is generated in this stage, but the amount is small compared with that obtained in the third stage.

*In the third stage, ATP is produced from the complete oxidation of the acetyl unit of acetyl CoA.* The third stage consists of the citric acid cycle and oxidative phosphorylation, which are the final common pathways in the oxidation of fuel molecules. Acetyl CoA brings acetyl units into the citric acid cycle [also called the tricarboxylic acid (TCA) cycle or Krebs cycle], where they are

**FIGURE 15.12 Stages of catabolism.** The extraction of energy from fuels can be divided into three stages.

completely oxidized to  $\text{CO}_2$ . Four pairs of electrons are transferred (three to  $\text{NAD}^+$  and one to  $\text{FAD}$ ) for each acetyl group that is oxidized. Then, a proton gradient is generated as electrons flow from the reduced forms of these carriers to  $\text{O}_2$ , and this gradient is used to synthesize ATP (Chapters 17 and 18).

## 15.4 Metabolic Pathways Contain Many Recurring Motifs

At first glance, metabolism appears intimidating because of the sheer number of reactants and reactions. Nevertheless, there are unifying themes that make the comprehension of this complexity more manageable. These unifying themes include common metabolites, reactions, and regulatory schemes that stem from a common evolutionary heritage.

### Activated carriers exemplify the modular design and economy of metabolism

We have seen that phosphoryl transfer can be used to drive otherwise endergonic reactions, alter the energy of conformation of a protein, or serve as a signal to alter the activity of a protein. The phosphoryl-group donor in all of these reactions is ATP. In other words, *ATP is an activated carrier of phosphoryl groups because phosphoryl transfer from ATP is an exergonic process.* The use of activated carriers is a recurring motif in biochemistry, and we will consider several such carriers here. Many such activated carriers function as coenzymes (Section 8.1):

1. *Activated Carriers of Electrons for Fuel Oxidation.* In aerobic organisms, the ultimate electron acceptor in the oxidation of fuel molecules is  $\text{O}_2$ . However, electrons are not transferred directly to  $\text{O}_2$ . Instead, fuel molecules transfer electrons to special carriers, which are either *pyridine nucleotides* or *flavins*. The reduced forms of these carriers then transfer their high-potential electrons to  $\text{O}_2$ .

Nicotinamide adenine dinucleotide is a major electron carrier in the oxidation of fuel molecules (Figure 15.13). The reactive part of  $\text{NAD}^+$  is its nicotinamide ring, a pyridine derivative synthesized from the vitamin niacin. *In the oxidation of a substrate, the nicotinamide ring of  $\text{NAD}^+$  accepts a hydrogen ion and two electrons, which are equivalent to a hydride ion ( $\text{H}^-$ ).* The reduced form of this carrier is called *NADH*. In the oxidized form, the nitrogen atom carries a positive charge, as indicated by  $\text{NAD}^+$ .  $\text{NAD}^+$  is the electron acceptor in many reactions of the type

In this dehydrogenation, one hydrogen atom of the substrate is directly transferred to  $\text{NAD}^+$ , whereas the other appears in the solvent as a proton. Both electrons lost by the substrate are transferred to the nicotinamide ring.

The other major electron carrier in the oxidation of fuel molecules is the coenzyme *flavin adenine dinucleotide* (Figure 15.14). The abbreviations for the oxidized and reduced forms of this carrier are  $\text{FAD}$  and  $\text{FADH}_2$ , respectively.  $\text{FAD}$  is the electron acceptor in reactions of the type

**FIGURE 15.13 Structures of the oxidized forms of nicotinamide-derived electron carriers.** Nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ) and nicotinamide adenine dinucleotide phosphate ( $\text{NADP}^+$ ) are prominent carriers of high-energy electrons. In  $\text{NAD}^+$ ,  $\text{R} = \text{H}$ ; in  $\text{NADP}^+$ ,  $\text{R} = \text{PO}_3^{2-}$ .

**FIGURE 15.14** Structure of the oxidized form of flavin adenine dinucleotide (FAD). This electron carrier consists of a flavin mononucleotide (FMN) unit (shown in blue) and an AMP unit (shown in black).

The reactive part of FAD is its isoalloxazine ring, a derivative of the vitamin riboflavin (Figure 15.15). FAD, like  $\text{NAD}^+$ , can accept two electrons. In doing so, FAD, unlike  $\text{NAD}^+$ , takes up two protons. These carriers of high-potential electrons as well as flavin mononucleotide (FMN), an electron carrier similar to FAD but lacking the adenine nucleotide, will be considered further in Chapter 18.

**FIGURE 15.15** Structures of the reactive components of FAD and  $\text{FADH}_2$ . The electrons and protons are carried by the isoalloxazine ring component of FAD and  $\text{FADH}_2$ .

2. *An Activated Carrier of Electrons for Reductive Biosynthesis.* High-potential electrons are required in most biosyntheses because the precursors are more oxidized than the products. Hence, reducing power is needed in addition to ATP. For example, in the biosynthesis of fatty acids, a keto group is reduced to a methylene group in several steps. This sequence of reactions requires an input of four electrons.

The electron donor in most reductive biosyntheses is NADPH, the reduced form of nicotinamide adenine dinucleotide phosphate ( $\text{NADP}^+$ ; Figure 15.13). NADPH differs from NADH in that the 2'-hydroxyl group of its adenosine moiety is esterified with phosphate. NADPH carries electrons in the same way as NADH. However, *NADPH is used almost exclusively for reductive biosyntheses, whereas NADH is used primarily for the generation of ATP.* The extra phosphoryl group on NADPH is a tag that enables enzymes to distinguish between high-potential electrons to be used in anabolism and those to be used in catabolism.

FIGURE 15.16 Structure of coenzyme A (CoA-SH).

3. *An Activated Carrier of Two-Carbon Fragments.* Coenzyme A, another central molecule in metabolism, is a carrier of acyl groups derived from the vitamin pantothenate (Figure 15.16). Acyl groups are important constituents both in catabolism, as in the oxidation of fatty acids, and in anabolism, as in the synthesis of membrane lipids. The terminal sulfhydryl group in CoA is the reactive site. Acyl groups are linked to CoA by thioester bonds. The resulting derivative is called an *acyl CoA*. An acyl group often linked to CoA is the acetyl unit; this derivative is called *acetyl CoA*. The  $\Delta G^{\circ'}$  for the hydrolysis of acetyl CoA has a large negative value:

A thioester is thermodynamically more unstable than an oxygen ester because the electrons of the  $\text{C}=\text{O}$  bond cannot form resonance structures with the  $\text{C}-\text{S}$  bond that are as stable as those that they can form with the  $\text{C}-\text{O}$  bond. Consequently, *acetyl CoA has a high acetyl-group-transfer potential because transfer of the acetyl group is exergonic.* Acetyl CoA carries an activated acetyl group, just as ATP carries an activated phosphoryl group.

The use of activated carriers illustrates two key aspects of metabolism. First, NADH, NADPH, and  $\text{FADH}_2$  react slowly with  $\text{O}_2$  in the absence of a catalyst. Likewise, ATP and acetyl CoA are hydrolyzed slowly (over many hours or even days) in the absence of a catalyst. These molecules are kinetically quite stable in the face of a large thermodynamic driving force for reaction with  $\text{O}_2$  (in regard to the electron carriers) and  $\text{H}_2\text{O}$  (for ATP and acetyl CoA). *The kinetic stability of these molecules in the absence of specific catalysts is essential for their biological function because it enables enzymes to control the flow of free energy and reducing power.*

Second, *most interchanges of activated groups in metabolism are accomplished by a rather small set of carriers* (Table 15.2). The existence of a recurring set of

TABLE 15.2 Some activated carriers in metabolism

Carrier molecule in activated form	Group carried	Vitamin precursor
ATP	Phosphoryl	
NADH and NADPH	Electrons	Nicotinate (niacin) (vitamin B <sub>3</sub> )
$\text{FADH}_2$	Electrons	Riboflavin (vitamin B <sub>2</sub> )
$\text{FMNH}_2$	Electrons	Riboflavin (vitamin B <sub>2</sub> )
Coenzyme A	Acyl	Pantothenate (vitamin B <sub>5</sub> )
Lipoamide	Acyl	
Thiamine pyrophosphate	Aldehyde	Thiamine (vitamin B <sub>1</sub> )
Biotin	$\text{CO}_2$	Biotin (vitamin B <sub>7</sub> )
Tetrahydrofolate	One-carbon units	Folate (vitamin B <sub>9</sub> )
S-Adenosylmethionine	Methyl	
Uridine diphosphate glucose	Glucose	
Cytidine diphosphate diacylglycerol	Phosphatidate	
Nucleoside triphosphates	Nucleotides	

Note: Many of the activated carriers are coenzymes that are derived from water-soluble vitamins.

TABLE 15.3 The B vitamins

Vitamin	Coenzyme	Typical reaction type	Consequences of deficiency
Thiamine (B <sub>1</sub> )	Thiamine pyrophosphate	Aldehyde transfer	Beriberi (weight loss, heart problems, neurological dysfunction)
Riboflavin (B <sub>2</sub> )	Flavin adenine dinucleotide (FAD)	Oxidation–reduction	Cheliosis and angular stomatitis (lesions of the mouth), dermatitis
Pyridoxine (B <sub>6</sub> )	Pyridoxal phosphate	Group transfer to or from amino acids	Depression, confusion, convulsions
Nicotinic acid (niacin) (B <sub>3</sub> )	Nicotinamide adenine dinucleotide (NAD <sup>+</sup> )	Oxidation–reduction	Pellagra (dermatitis, depression, diarrhea)
Pantothenic acid (B <sub>5</sub> )	Coenzyme A	Acyl-group transfer	Hypertension
Biotin (B <sub>7</sub> )	Biotin–lysine adducts (biocytin)	ATP-dependent carboxylation and carboxyl-group transfer	Rash about the eyebrows, muscle pain, fatigue (rare)
Folic acid (B <sub>9</sub> )	Tetrahydrofolate	Transfer of one-carbon components; thymine synthesis	Anemia, neural-tube defects in development
B <sub>12</sub>	5'-Deoxyadenosyl cobalamin	Transfer of methyl groups; intramolecular rearrangements	Anemia, pernicious anemia, methylmalonic acidosis

activated carriers in all organisms is one of the unifying motifs of biochemistry. Furthermore, it illustrates the modular design of metabolism. A small set of molecules carries out a very wide range of tasks. Metabolism is readily comprehended because of the economy and elegance of its underlying design.

### Many activated carriers are derived from vitamins

Almost all the activated carriers that act as coenzymes are derived from *vitamins*. Vitamins are organic molecules that are needed in small amounts in the diets of some higher animals. Table 15.3 lists the vitamins that act as coenzymes and Figure 15.17 shows the structures of some of them. This series of vitamins is known as the vitamin B group. In all cases, the vitamin must be modified before it can serve its function. We have already touched on the roles of niacin, riboflavin, and pantothenate. We will see these three and the other B vitamins many times in our study of biochemistry.

 Vitamins serve the same roles in nearly all forms of life, but higher animals lost the capacity to synthesize them in the course of evolution. For instance, whereas *E. coli* can thrive on glucose and organic salts, human beings require at least 12 vitamins in their diet. The biosynthetic pathways for

FIGURE 15.17 Structures of some of the B vitamins. These vitamins are often referred to as water-soluble vitamins because of the ease with which they dissolve in water.

**TABLE 15.4** Noncoenzyme vitamins

Vitamin	Function	Deficiency
A	Roles in vision, growth, reproduction	Night blindness, cornea damage, damage to respiratory and gastrointestinal tract
C (ascorbic acid)	Antioxidant	Scurvy (swollen and bleeding gums, subdermal hemorrhaging)
D	Regulation of calcium and phosphate metabolism	Rickets (children): skeletal deformities, impaired growth Osteomalacia (adults): soft, bending bones
E	Antioxidant	Lesions in muscles and nerves (rare)
K	Blood coagulation	Subdermal hemorrhaging

vitamins can be complex; thus, it is biologically more efficient to ingest vitamins than to synthesize the enzymes required to construct them from simple molecules. This efficiency comes at the cost of dependence on other organisms for chemicals essential for life. Indeed, vitamin deficiency can generate diseases in all organisms requiring these molecules (Tables 15.3 and 15.4).

Not all vitamins function as coenzymes. Vitamins designated by the letters A, C, D, E, and K (Figure 15.18 and Table 15.4) have a diverse array of functions. Vitamin A (retinol) is the precursor of retinal, the light-sensitive group in rhodopsin and other visual pigments (Section 32.3), and retinoic acid, an important signaling molecule. A deficiency of this vitamin leads to night blindness. In addition, young animals require vitamin A for growth. Vitamin C, or ascorbate, acts as an antioxidant. A deficiency in vitamin C results in the formation of unstable collagen molecules and is the cause of scurvy, a disease characterized by skin lesions and blood-vessel fragility (Section 27.6). A metabolite of vitamin D is a hormone that regulates the metabolism of calcium and phosphorus. A deficiency in vitamin D impairs bone formation in growing animals. Vitamin E ( $\alpha$ -tocopherol) deficiency causes a variety of neuromuscular pathologies. This vitamin inactivates reactive oxygen species such as hydroxyl

**FIGURE 15.18** Structures of some vitamins that do not function as coenzymes. These vitamins are often called the fat-soluble vitamins because of their hydrophobic nature.

**TABLE 15.5** Types of chemical reactions in metabolism

Type of reaction	Description
Oxidation–reduction	Electron transfer
Ligation requiring ATP cleavage	Formation of covalent bonds (i.e., carbon–carbon bonds)
Isomerization	Rearrangement of atoms to form isomers
Group transfer	Transfer of a functional group from one molecule to another
Hydrolytic	Cleavage of bonds by the addition of water
Carbon bond cleavage by means other than hydrolysis or oxidation	Two substrates yielding one product or vice versa. When H <sub>2</sub> O or CO <sub>2</sub> are a product, a double bond is formed.

radicals before they can oxidize unsaturated membrane lipids, damaging cell structures. Vitamin K is required for normal blood clotting (Section 10.4).

### Key reactions are reiterated throughout metabolism

Just as there is an economy of design in the use of activated carriers, so is there an economy of design in biochemical reactions. The thousands of metabolic reactions, bewildering at first in their variety, can be subdivided into just six types (Table 15.5). Specific reactions of each type appear repeatedly, reducing the number of reactions that a student needs to learn.

1. *Oxidation–reduction reactions* are essential components of many pathways. Useful energy is often derived from the oxidation of carbon compounds. Consider the following two reactions:

These two oxidation–reduction reactions are components of the citric acid cycle (Chapter 17), which completely oxidizes the activated two-carbon fragment of acetyl CoA to two molecules of CO<sub>2</sub>. In reaction 1, FADH<sub>2</sub> carries the electrons, whereas, in reaction 2, electrons are carried by NADH.

2. *Ligation reactions* form bonds by using free energy from ATP cleavage. Reaction 3 illustrates the ATP-dependent formation of a carbon–carbon bond, necessary to combine smaller molecules to form larger ones. Oxaloacetate is formed from pyruvate and CO<sub>2</sub>.

The oxaloacetate can be used in the citric acid cycle, or converted into glucose or amino acids such as aspartic acid.

3. *Isomerization reactions* rearrange particular atoms within a molecule. Their role is often to prepare the molecule for subsequent reactions such as the oxidation–reduction reactions described in point 1.

Reaction 4 is, again, a component of the citric acid cycle. This isomerization prepares the molecule for subsequent oxidation and decarboxylation reactions by moving the hydroxyl group of citrate from a tertiary to a secondary position.

4. *Group-transfer reactions* play a variety of roles. Reaction 5 is representative of such a reaction. A phosphoryl group is transferred from the activated phosphoryl-group carrier, ATP, to glucose, the initial step in glycolysis, a key pathway for extracting energy from glucose (Chapter 16). This reaction traps glucose in the cell so that further catabolism can take place.

As stated earlier, group-transfer reactions are used to synthesize ATP. We also saw examples of their use in signaling pathways (Chapter 14).

5. *Hydrolytic reactions* cleave bonds by the addition of water. Hydrolysis is a common means of degrading large molecules, either to facilitate further metabolism or to reuse some of the components for biosynthetic purposes. Proteins are digested by hydrolytic cleavage (chapters 9 and 10). Reaction 6 illustrates the hydrolysis of a peptide to yield two smaller peptides.

6. Carbon bonds can be cleaved by means other than hydrolysis or oxidation, with two substrates yielding one product or vice versa. When  $\text{CO}_2$  or  $\text{H}_2\text{O}$  is released, a double bond is formed. The enzymes that catalyze these types of reaction are classified as *lyases*. An important example, illustrated in reaction 7, is the conversion of the six-carbon molecule fructose 1,6-bisphosphate into two three-carbon fragments: dihydroxyacetone phosphate and glyceraldehyde 3-phosphate.

This reaction is a critical step in glycolysis (Chapter 16). Dehydrations to form double bonds, such as the formation of phosphoenolpyruvate (Figure 15.6) from 2-phosphoglycerate (reaction 8), are important reactions of this type.

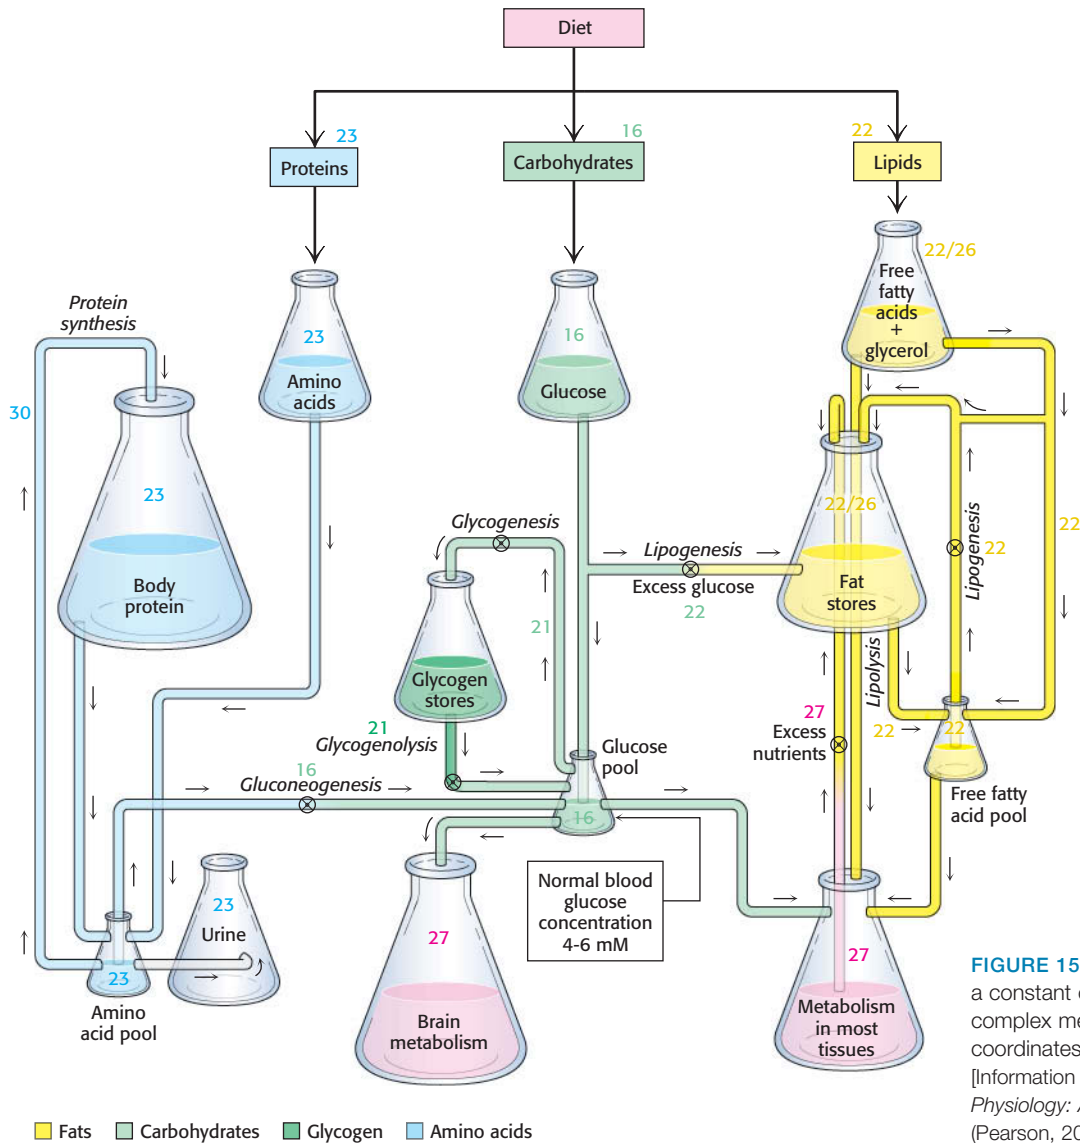

The dehydration sets up the next step in the pathway, a group-transfer reaction that uses the high phosphoryl-transfer potential of the product PEP to form ATP from ADP.

These six fundamental reaction types are the basis of metabolism. Remember that all six types can proceed in either direction, depending on the standard free energy for the specific reaction and the concentrations of the reactants and products inside the cell. An effective way to learn is to look for commonalities in the diverse metabolic pathways that we will be examining. There is a chemical logic that, when exposed, renders the complexity of the chemistry of living systems more manageable and reveals its elegance.

### Metabolic processes are regulated in three principal ways

It is evident that the complex network of metabolic reactions must be rigorously regulated. The levels of available nutrients must be monitored and the activity of metabolic pathways must be altered and integrated to create *homeostasis*, a stable biochemical environment. At the same time, metabolic control must be flexible, able to adjust metabolic activity to the constantly changing external environments of cells. Figure 15.19 illustrates the nutrient

**FIGURE 15.19 Homeostasis.** Maintaining a constant cellular environment requires complex metabolic regulation that coordinates the use of nutrient pools. [Information from D. U. Silverthorn, *Human Physiology: An Integrated Approach*, 3rd ed. (Pearson, 2004), Figure 22-2.]

pools and their connections that must be monitored and regulated. Metabolism is regulated through control of (1) *the amounts of enzymes*, (2) *their catalytic activities*, and (3) *the accessibility of substrates*.

**Controlling the amounts of enzymes.** The amount of a particular enzyme depends on both its rate of synthesis and its rate of degradation. The level of many enzymes is adjusted by a change in the *rate of transcription* of the genes encoding them (chapters 29 and 31). In *E. coli*, for example, the presence of lactose induces within minutes a more than 50-fold increase in the rate of synthesis of  $\beta$ -galactosidase, the enzyme required for the breakdown of this disaccharide.

**Controlling catalytic activity.** The catalytic activity of enzymes is controlled in several ways. *Allosteric control* is especially important. For example, the first reaction in many biosynthetic pathways is allosterically inhibited by the ultimate product of the pathway. The inhibition of aspartate transcarbamoylase by cytidine triphosphate (Section 10.1) is a well-understood example of *feedback inhibition*. This type of control can be almost instantaneous. Another recurring mechanism is *reversible covalent modification* (Section 10.3). For example, glycogen phosphorylase, the enzyme catalyzing the breakdown of glycogen, a storage form of sugar, is activated by the phosphorylation of a particular serine residue when glucose is scarce (Section 21.1).

**FIGURE 15.20 Energy charge regulates metabolism.** When the energy charge is high, ATP inhibits the relative rates of a typical ATP-generating (catabolic) pathway and stimulates the typical ATP-utilizing (anabolic) pathway.

*Hormones coordinate metabolic relations* between different tissues, often by regulating the reversible modification of key enzymes. For instance, the hormone epinephrine triggers a signal-transduction cascade in muscle, resulting in the phosphorylation and activation of key enzymes and leading to the rapid degradation of glycogen to glucose, which is then used to supply ATP for muscle contraction. As described in Chapter 14, many hormones act through intracellular messengers, such as cyclic AMP and calcium ion, that coordinate the activities of many target proteins.

Many reactions in metabolism are controlled by the *energy status* of the cell. One index of the energy status is the *energy charge*, which is proportional to the mole fraction of ATP plus half the mole fraction of ADP, given that ATP contains two anhydride bonds, whereas ADP contains one. Hence, the energy charge is defined as

$$\text{Energy charge} = \frac{[\text{ATP}] + \frac{1}{2}[\text{ADP}]}{[\text{ATP}] + [\text{ADP}] + [\text{AMP}]}$$

The energy charge can have a value ranging from 0 (all AMP) to 1 (all ATP). *ATP-generating (catabolic) pathways are inhibited by a high energy charge, whereas ATP-utilizing (anabolic) pathways are stimulated by a high energy charge.* In plots of the reaction rates of such pathways versus the energy charge, the curves are steep near an energy charge of 0.9, where they usually intersect (Figure 15.20). It is evident that the control of these pathways has evolved to maintain the energy charge within rather narrow limits. In other words, *the energy charge, like the pH of a cell, is buffered.* The energy charge of most cells ranges from 0.90 to 0.95, but can fall to less than 0.7 in muscle during high-intensity exercise. An alternative index of the energy status is the *phosphorylation potential*, which is defined as

$$\text{Phosphorylation potential} = \frac{[\text{ATP}]}{[\text{ADP}] + [\text{P}_i]}$$

The phosphorylation potential, in contrast with the energy charge, depends on the concentration of  $\text{P}_i$  and is directly related to the free-energy storage available from ATP.

**Controlling the accessibility of substrates.** Controlling the *availability of substrates* is another means of regulating metabolism in all organisms. For instance, glucose breakdown can take place in many cells only if insulin is present to promote the entry of glucose into the cell. In eukaryotes, metabolic regulation and flexibility are enhanced by compartmentalization. The transfer of substrates from one compartment of a cell to another can serve as a control point. For example, fatty acid oxidation takes place in mitochondria, whereas fatty acid synthesis takes place in the cytoplasm. *Compartmentalization segregates opposed reactions.*

### Aspects of metabolism may have evolved from an RNA world

How did the complex pathways that constitute metabolism evolve? The current thinking is that RNA was an early biomolecule that dominated metabolism, serving both as a catalyst and an information storage molecule. This hypothetical time is called the RNA world.

Why do activated carriers such as ATP, NADH,  $\text{FADH}_2$ , and coenzyme A contain adenosine diphosphate units? A possible explanation is that these molecules evolved from the early RNA catalysts. Non-RNA units such as the isoalloxazine ring may have been recruited to serve as efficient carriers of activated electrons and chemical units, a function not readily performed by RNA itself. We can picture the adenine ring of  $\text{FADH}_2$  binding to a uracil unit in a

niche of an RNA enzyme (ribozyme) by base-pairing, whereas the isoalloxazine ring protrudes and functions as an electron carrier. When the more versatile proteins replaced RNA as the major catalysts, the ribonucleotide coenzymes stayed essentially unchanged because they were already well suited to their metabolic roles. The nicotinamide unit of NADH, for example, can readily transfer electrons irrespective of whether the adenine unit interacts with a base in an RNA enzyme or with amino acid residues in a protein enzyme. With the advent of protein enzymes, these important cofactors evolved as free molecules without losing the adenosine diphosphate vestige of their RNA-world ancestry. That molecules and motifs of metabolism are common to all forms of life testifies to their common origin and to the retention of functioning modules through billions of years of evolution. Our understanding of metabolism, like that of other biological processes, is enriched by inquiry into how these beautifully integrated patterns of reactions came into being.

## SUMMARY

All cells transform energy. They extract energy from their environment and use this energy to convert simple molecules into cellular components.

### 15.1 Metabolism Is Composed of Many Coupled, Interconnecting Reactions

The process of energy transduction takes place through metabolism, a highly integrated network of chemical reactions. Metabolism can be subdivided into catabolism (reactions employed to extract energy from fuels) and anabolism (reactions that use this energy for biosynthesis). The most valuable thermodynamic concept for understanding bioenergetics is free energy. A reaction can occur spontaneously only if the change in free energy ( $\Delta G$ ) is negative. A thermodynamically unfavorable reaction can be driven by a thermodynamically favorable one, which is the hydrolysis of ATP in many cases.

### 15.2 ATP Is the Universal Currency of Free Energy in Biological Systems

The energy derived from catabolism is transformed into adenosine triphosphate. ATP hydrolysis is exergonic and the energy released can be used to power cellular processes, including motion, active transport, and biosynthesis. Under cellular conditions, the hydrolysis of ATP shifts the equilibrium of a coupled reaction by a factor of  $10^8$ . ATP, the universal currency of energy in biological systems, is an energy-rich molecule because it contains two phosphoanhydride bonds.

### 15.3 The Oxidation of Carbon Fuels Is an Important Source of Cellular Energy

ATP formation is coupled to the oxidation of carbon fuels, either directly or through the formation of ion gradients. Photosynthetic organisms can use light to generate such gradients. ATP is consumed to drive endergonic reactions and in signal-transduction processes. The extraction of energy from foodstuffs by aerobic organisms comprises three stages. In the first stage, large molecules are broken down into smaller ones, such as amino acids, sugars, and fatty acids. In the second stage, these small molecules are degraded to a few simple units, such as acetyl CoA, that have widespread roles in metabolism. The third stage of metabolism is the citric acid cycle and oxidative phosphorylation, in which ATP is generated as electrons flow to  $O_2$ , the ultimate electron acceptor, and fuels are completely oxidized to  $CO_2$ .

### 15.4 Metabolic Pathways Contain Many Recurring Motifs

Metabolism is characterized by common motifs. A small number of recurring activated carriers, such as ATP, NADH, and acetyl CoA,

transfer activated groups in many metabolic pathways. NADPH, which carries two electrons at a high potential, provides reducing power for reductive biosynthesis of cell components. Many activated carriers are derived from vitamins, small organic molecules required in the diets of many higher organisms. Moreover, key reaction types are used repeatedly in metabolic pathways.

Metabolism is regulated in a variety of ways. The amounts of some critical enzymes are controlled by regulation of the rate of synthesis and degradation. In addition, the catalytic activities of many enzymes are regulated by allosteric interactions and by covalent modification. The movement of many substrates into cells and subcellular compartments also is controlled. The energy charge, which depends on the relative amounts of ATP, ADP, and AMP, plays a role in metabolic regulation. A high energy charge inhibits ATP-generating (catabolic) pathways, whereas it stimulates ATP-utilizing (anabolic) pathways.

## KEY TERMS

metabolism or intermediary metabolism (p. 423)	adenosine triphosphate (ATP) (p. 426)	group-transfer reaction (p. 441)
phototroph (p. 424)	phosphoryl-transfer potential (p. 429)	hydrolytic reaction (p. 441)
chemotroph (p. 424)	activated carrier (p. 435)	cleavage of carbon bonds by means other than hydrolysis or oxidation (p. 442)
catabolism (p. 424)	vitamin (p. 438)	lyase (p. 442)
anabolism (p. 424)	oxidation–reduction reaction (p. 440)	energy charge (p. 444)
amphibolic pathway (p. 425)	ligation reaction (p. 440)	phosphorylation potential (p. 444)
	isomerization reaction (p. 441)	

## PROBLEMS

- Complex patterns.* What is meant by *intermediary metabolism*?
- Opposites.* Differentiate between anabolism and catabolism.
- Graffiti.* While walking to biochemistry class with a friend, you see the following graffiti spray painted on the wall of the science building: “When a system is in equilibrium, the Gibbs free energy is maximum.” You are disgusted, not only at the vandalism, but at the ignorance of the vandal. Your friend asks you to explain.
- Why bother to eat?* What are the three primary uses for cellular energy?
- Match 'em.*
  - Cellular energy currency \_\_\_\_\_ a. NAD<sup>+</sup>
  - Anabolic electron carrier \_\_\_\_\_ b. Coenzyme A
  - Phototroph \_\_\_\_\_ c. Precursor to coenzymes
  - Catabolic electron carrier reaction \_\_\_\_\_ d. Yields energy
  - Oxidation-reduction reaction \_\_\_\_\_ e. Requires energy
  - Activated carrier of two carbon fragments \_\_\_\_\_ f. ATP
  - Vitamin \_\_\_\_\_ g. Transfers electrons
- Anabolism \_\_\_\_\_
- Amphibolic reaction \_\_\_\_\_
- Catabolism \_\_\_\_\_
- Charges.* In vivo, ATP is usually bound to magnesium or manganese ions. Why is this the case?
- Energy to burn.* What factors account for the high phosphoryl-transfer potential of nucleoside triphosphates?
- Back in time.* Account for the fact that ATP, and not another nucleoside triphosphate, is the cellular energy currency.
- Currency issues.* Why does it make good sense to have a single nucleotide, ATP, function as the cellular energy currency?
- Environmental conditions.* The standard free energy of hydrolysis for ATP is  $-30.5 \text{ kJ mol}^{-1}$  ( $-7.3 \text{ kcal mol}^{-1}$ ).
 
$$\text{ATP} + \text{H}_2\text{O} \rightleftharpoons \text{ADP} + \text{P}_i$$
 What conditions might be changed to alter the free energy of hydrolysis?
- Brute force?* Metabolic pathways frequently contain reactions with positive standard free energy values, yet the reactions still take place. How is this possible?
- h. NADP<sup>+</sup>
- i. Converts light energy to chemical energy
- j. Used in anabolism and catabolism

12. *Energy flow.* What is the direction of each of the following reactions when the reactants are initially present in equimolar amounts? Use the data given in Table 15.1.

- (a)  $\text{ATP} + \text{creatine} \rightleftharpoons \text{creatine phosphate} + \text{ADP}$   
 (b)  $\text{ATP} + \text{glycerol} \rightleftharpoons \text{glycerol 3-phosphate} + \text{ADP}$   
 (c)  $\text{ATP} + \text{pyruvate} \rightleftharpoons \text{phosphoenolpyruvate} + \text{ADP}$   
 (d)  $\text{ATP} + \text{glucose} \rightleftharpoons \text{glucose 6-phosphate} + \text{ADP}$

13. *A proper inference.* What information do the  $\Delta G^{\circ}$  data given in Table 15.1 provide about the relative rates of hydrolysis of pyrophosphate and acetyl phosphate?

14. *A potent donor.* Consider the following reaction:

- (a) Calculate  $\Delta G^{\circ}$  and  $K'_{\text{eq}}$  at 25°C for this reaction by using the data given in Table 15.1.  
 (b) What is the equilibrium ratio of pyruvate to phosphoenolpyruvate if the ratio of ATP to ADP is 10?

15. *Isomeric equilibrium.* Using the information in Table 15.1, calculate  $\Delta G^{\circ}$  for the isomerization of glucose 6-phosphate to glucose 1-phosphate. What is the equilibrium ratio of glucose 6-phosphate to glucose 1-phosphate at 25°C?

16. *Activated acetate.* The formation of acetyl CoA from acetate is an ATP-driven reaction:

- (a) Calculate  $\Delta G^{\circ}$  for this reaction by using data given in this chapter.  
 (b) The  $\text{PP}_i$  formed in the preceding reaction is rapidly hydrolyzed in vivo because of the ubiquity of inorganic pyrophosphatase. The  $\Delta G^{\circ}$  for the hydrolysis of  $\text{PP}_i$  is  $-19.2 \text{ kJ mol}^{-1}$  ( $-4.6 \text{ kcal mol}^{-1}$ ). Calculate the  $\Delta G^{\circ}$  for the overall reaction, including pyrophosphate hydrolysis. What effect does the hydrolysis of  $\text{PP}_i$  have on the formation of acetyl CoA?

17. *Acid strength.* The  $\text{pK}$  of an acid is a measure of its proton-group-transfer potential.

- (a) Derive a relation between  $\Delta G^{\circ}$  and  $\text{pK}$ .  
 (b) What is the  $\Delta G^{\circ}$  for the ionization of acetic acid, which has a  $\text{pK}$  of 4.8?

18. *Raison d'être.* The muscles of some invertebrates are rich in arginine phosphate (phosphoarginine). Propose a function for this amino acid derivative.

19. *Recurring motif.* What is the structural feature common to ATP, FAD,  $\text{NAD}^+$ , and CoA?

20. *Ergogenic help or hindrance?* Creatine is a popular, but untested, dietary supplement.

- (a) What is the biochemical rationale for the use of creatine?  
 (b) What type of exercise would most benefit from creatine supplementation?

21. *Standard conditions versus real life 1.* The enzyme aldolase catalyzes the following reaction in the glycolytic pathway:

The  $\Delta G^{\circ}$  for the reaction is  $+23.8 \text{ kJ mol}^{-1}$  ( $+5.7 \text{ kcal mol}^{-1}$ ), whereas the  $\Delta G$  in the cell is  $-1.3 \text{ kJ mol}^{-1}$  ( $-0.3 \text{ kcal mol}^{-1}$ ). Calculate the ratio of reactants to products under equilibrium and intracellular conditions. Using your results, explain how the reaction can be endergonic under standard conditions and exergonic under intracellular conditions.

22. *Standard conditions versus real life 2.* On page 428, we showed that a reaction,  $\text{A} \rightleftharpoons \text{B}$ , with a  $\Delta G^{\circ} = +16.7 \text{ kJ mol}^{-1}$  ( $+4.0 \text{ kcal mol}^{-1}$ ) has an  $K'_{\text{eq}}$  of  $1.15 \times 10^{-3}$ . The  $K'_{\text{eq}}$  is increased to  $2.67 \times 10^2$  if the reaction is coupled to ATP hydrolysis under standard conditions. The ATP-generating system of cells maintains the  $[\text{ATP}]/[\text{ADP}][\text{P}_i]$  ratio at a high level, typically of the order of  $500 \text{ M}^{-1}$ . Calculate the ratio of B/A under cellular conditions.

23. *Not all alike.* The concentrations of ATP, ADP, and  $\text{P}_i$  differ with cell type. Consequently, the release of free energy with the hydrolysis of ATP will vary with cell type. Using the following table, calculate the  $\Delta G$  for the hydrolysis of ATP in liver, muscle, and brain cells. In which cell type is the free energy of ATP hydrolysis most negative?

	ATP (mM)	ADP (mM)	$\text{P}_i$ (mM)
Liver	3.5	1.8	5.0
Muscle	8.0	0.9	8.0
Brain	2.6	0.7	2.7

24. *Oxidation issues.* Examine the pairs of molecules and identify the more-reduced molecule in each pair.

25. *Running downhill.* Glycolysis is a series of 10 linked reactions that convert one molecule of glucose into two molecules of pyruvate with the concomitant synthesis of two molecules of ATP (Chapter 16). The  $\Delta G^{\circ'}$  for this set of reactions is  $-35.6 \text{ kJ mol}^{-1}$  ( $-8.5 \text{ kcal mol}^{-1}$ ), whereas the  $\Delta G$  is  $-90 \text{ kJ mol}^{-1}$  ( $-22 \text{ kcal mol}^{-1}$ ). Explain why the free-energy release is so much greater under intracellular conditions than under standard conditions.

26. *Outsourcing.* Outsourcing, a common business practice, is contracting with another business to perform a particular function. Higher organisms were the original outsourcers, frequently depending on lower organisms to perform key biochemical functions. Give an example from this chapter of biochemical outsourcing.

27. *Breakdown products.* Digestion is the first stage in the extraction of energy from food, but no useful energy is

acquired during this stage. Why is digestion considered a stage in energy extraction?

28. *High-energy electrons.* What are the activated electron carriers for catabolism? For anabolism?

29. *Less reverberation.* Thioesters, common in biochemistry, are more unstable (energy-rich) than oxygen esters. Explain why this is the case.

30. *Classifying reactions.* What are the six common types of reactions seen in biochemistry?

31. *Staying in control.* What are the three principal means of controlling metabolic reactions?

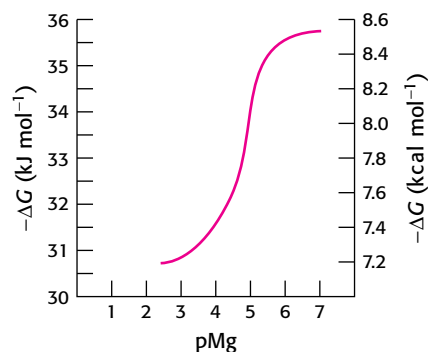

### Chapter Integration Problems

32. *Kinetic versus thermodynamic.* The reaction of NADH with oxygen to produce  $\text{NAD}^+$  and  $\text{H}_2\text{O}$  is very exergonic, yet the reaction of NADH and oxygen takes place very slowly. Why does a thermodynamically favorable reaction not occur rapidly?

33. *Activated sulfate.* Fibrinogen contains tyrosine-*O*-sulfate. Propose an activated form of sulfate that could react in vivo with the aromatic hydroxyl group of a tyrosine residue in a protein to form tyrosine-*O*-sulfate.

### Data Interpretation Problem

34. *Opposites attract.* The following graph shows how the  $\Delta G$  for the hydrolysis of ATP varies as a function of the  $\text{Mg}^{2+}$  concentration ( $\text{pMg} = -\log[\text{Mg}^{2+}]$ ).

(a) How does decreasing  $[\text{Mg}^{2+}]$  affect the  $\Delta G$  of hydrolysis for ATP?

(b) Explain this effect.

## Glycolysis and Gluconeogenesis

Usain Bolt sprints to a win in the 200-meter final at the Olympics in London in 2012. Glucose metabolism can generate the ATP to power muscle contraction. During a sprint, when the ATP needs outpace oxygen delivery, as would be the case for Bolt, glucose is metabolized to lactate. When oxygen delivery is adequate, glucose is metabolized more efficiently to carbon dioxide and water. [Christophe Karaba/epa/Corbis.]

The first metabolic pathway that we encounter is *glycolysis*, an ancient pathway employed by a host of organisms. *Glycolysis is the sequence of reactions that metabolizes one molecule of glucose to two molecules of pyruvate with the concomitant net production of two molecules of ATP.* This process is anaerobic (i.e., it does not require  $O_2$ ) because it evolved before substantial amounts of oxygen accumulated in the atmosphere. Pyruvate can be further processed anaerobically to lactate (*lactic acid fermentation*) or ethanol (*alcoholic fermentation*). Under aerobic conditions, pyruvate can be completely oxidized to  $CO_2$ , generating much more ATP, as will be described in chapters 17 and 18. Figure 16.1 shows some possible fates of pyruvate produced by glycolysis.

Because glucose is such a precious fuel, metabolic products, such as pyruvate and lactate, are salvaged to synthesize glucose in the process of *gluconeogenesis*. Although glycolysis and gluconeogenesis have some enzymes in common, the two pathways are not simply the reverse of each other. In particular, the highly exergonic, irreversible steps of glycolysis are bypassed in gluconeogenesis. The two pathways are reciprocally regulated so that glycolysis and gluconeogenesis do not take place simultaneously in the same cell to a significant extent.

## OUTLINE

- 16.1 Glycolysis Is an Energy-Conversion Pathway in Many Organisms
- 16.2 The Glycolytic Pathway Is Tightly Controlled
- 16.3 Glucose Can Be Synthesized from Noncarbohydrate Precursors
- 16.4 Gluconeogenesis and Glycolysis Are Reciprocally Regulated

**Glycolysis**

Derived from the Greek stem *glyk-*, “sweet,” and the word *lysis*, “dissolution.”

FIGURE 16.1 Some fates of glucose.

Our understanding of glucose metabolism, especially glycolysis, has a rich history. Indeed, the development of biochemistry and the delineation of glycolysis went hand in hand. A key discovery was made by Hans and Eduard Buchner in 1897, quite by accident. The Buchners were interested in manufacturing cell-free extracts of yeast for possible therapeutic use. These extracts had to be preserved without the use of antiseptics such as phenol, and so they decided to try sucrose, a commonly used preservative in kitchen chemistry. They obtained a startling result: sucrose was rapidly fermented into alcohol by the yeast juice. The significance of this finding was immense. *The Buchners demonstrated for the first time that fermentation could take place outside living cells.* The accepted view of their day, asserted by Louis Pasteur in 1860, was that fermentation is inextricably tied to living cells. The chance discovery by the Buchners refuted this dogma and opened the door to modern biochemistry. The Buchners' discovery inspired the search for the biochemicals that catalyze the conversion of sucrose into alcohol. *The study of metabolism became the study of chemistry.*

Studies of muscle extracts then showed that many of the reactions of lactic acid fermentation were the same as those of alcoholic fermentation. *This exciting discovery revealed an underlying unity in biochemistry.* The complete glycolytic pathway was elucidated by 1940. Glycolysis is also known as the *Embden–Meyerhof pathway*, after two pioneers of research on glycolysis.

### Glucose is generated from dietary carbohydrates

We typically consume in our diets a generous amount of starch and a smaller amount of glycogen. These complex carbohydrates must be converted into simpler carbohydrates for absorption by the intestine and transport in the blood. Starch and glycogen are digested primarily by the pancreatic enzyme  $\alpha$ -amylase and to a lesser extent by salivary  $\alpha$ -amylase. Amylase cleaves the  $\alpha$ -1,4 bonds of starch and glycogen, but not the  $\alpha$ -1,6 bonds. The products are the di- and trisaccharides maltose and maltotriose. The material not digestible because of the  $\alpha$ -1,6 bonds is called the *limit dextrin*.

*Maltase* cleaves maltose into two glucose molecules, whereas  $\alpha$ -glucosidase digests maltotriose and any other oligosaccharides that may have escaped digestion by the amylase.  $\alpha$ -Dextrinase further digests the limit dextrin. Maltase and  $\alpha$ -glucosidase are located on the surface of the intestinal cells, as is *sucrase*, an enzyme that degrades the sucrose contributed by vegetables to fructose and glucose. The enzyme *lactase* is responsible for degrading the milk sugar lactose into glucose and galactose. The monosaccharides are transported into the cells lining the intestine and then into the bloodstream.

#### Enzyme

A term coined by Friedrich Wilhelm Kühne in 1878 to designate catalytically active substances that had formerly been called ferments. Derived from the Greek words *en*, "in," and *zyme*, "leaven."

## Glucose is an important fuel for most organisms

 Glucose is a common and important fuel. In mammals, glucose is the only fuel that the brain uses under nonstarvation conditions and the only fuel that red blood cells can use at all. Indeed, almost all organisms use glucose, and most that do process it in a similar fashion. Recall from Chapter 11 that there are many carbohydrates. Why is glucose instead of some other monosaccharide such a prominent fuel? We can speculate on the reasons. First, glucose is one of several monosaccharides formed from formaldehyde under prebiotic conditions, and so it may have been available as a fuel source for primitive biochemical systems. Second, glucose has a low tendency, relative to other monosaccharides, to nonenzymatically glycosylate proteins. In their open-chain forms, monosaccharides contain carbonyl groups that can react with the amino groups of proteins to form Schiff bases, which rearrange to form a more stable amino–ketone linkage (p. 321). Such nonspecifically modified proteins often do not function effectively. Glucose has a strong tendency to exist in the ring conformation and, consequently, relatively little tendency to modify proteins. Recall that all the hydroxyl groups in the ring conformation of  $\beta$ -glucose are equatorial, contributing to the sugar's high relative stability (p. 320).

### 16.1 Glycolysis Is an Energy-Conversion Pathway in Many Organisms

We now begin our consideration of the glycolytic pathway. This pathway is common to virtually all cells, both prokaryotic and eukaryotic. In eukaryotic cells, glycolysis takes place in the cytoplasm. This pathway can be thought of as comprising two stages (Figure 16.2). Stage 1 is the trapping and preparation phase. No ATP is generated in this stage. In stage 1, glucose is converted into fructose 1,6-bisphosphate in three steps: a phosphorylation, an isomerization, and a second phosphorylation reaction. *The strategy of these initial steps in glycolysis is to trap the glucose in the cell and form a compound that can be readily cleaved into phosphorylated three-carbon units.* Stage 1 is completed with the cleavage of the fructose 1,6-bisphosphate into two three-carbon fragments. These resulting three-carbon units are readily interconvertible. In stage 2, ATP is harvested when the three-carbon fragments are oxidized to pyruvate.

#### Hexokinase traps glucose in the cell and begins glycolysis

Glucose enters cells through specific transport proteins (p. 473) and has one principal fate: *it is phosphorylated by ATP to form glucose 6-phosphate.* This step is notable for several reasons. Glucose 6-phosphate cannot pass through the membrane because of the negative charges on the phosphoryl groups, and it is not a substrate for glucose transporters. Also, the addition of the phosphoryl group facilitates the eventual metabolism of glucose into three-carbon molecules with high-phosphoryl-transfer-potential. The transfer of the phosphoryl group from ATP to the hydroxyl group on carbon 6 of glucose is catalyzed by *hexokinase*.

**First stage of glycolysis.** The first stage of glycolysis begins with the phosphorylation of glucose by hexokinase and ends with the isomerization of dihydroxyacetone phosphate to glyceraldehyde 3-phosphate.

**FIGURE 16.2 Stages of glycolysis.** The glycolytic pathway can be divided into two stages: (1) glucose is trapped, destabilized, and cleaved into two interconvertible three-carbon molecules generated by cleavage of six-carbon fructose; and (2) ATP is generated.

**FIGURE 16.3 Induced fit in hexokinase.**

The two lobes of hexokinase are separated in the absence of glucose (left). The conformation of hexokinase changes markedly on binding glucose (right). Notice that two lobes of the enzyme come together, creating the necessary environment for catalysis. [After RSCB Protein Data Bank; drawn from yhx and 1hkg by Adam Steinberg.]

Phosphoryl transfer is a fundamental reaction in biochemistry. *Kinases* are enzymes that catalyze the transfer of a phosphoryl group from ATP to an acceptor. Hexokinase, then, catalyzes the transfer of a phosphoryl group from ATP to a variety of six-carbon sugars (*hexoses*), such as glucose and mannose. *Hexokinase, like adenylate kinase (Section 9.4) and all other kinases, requires  $Mg^{2+}$  (or another divalent metal ion such as  $Mn^{2+}$ ) for activity.* The divalent metal ion forms a complex with ATP.

X-ray crystallographic studies of yeast hexokinase revealed that the binding of glucose induces a large conformational change in the enzyme. Hexokinase consists of two lobes, which move toward each other when glucose is bound (Figure 16.3). On glucose binding, one lobe rotates 12 degrees with respect to the other, resulting in movements of the polypeptide backbone of as much as 8 Å. The cleft between the lobes closes, and the bound glucose becomes surrounded by protein, except for the hydroxyl group of carbon 6, which will accept the phosphoryl group from ATP. The closing of the cleft in hexokinase is a striking example of the role of *induced fit* in enzyme action (Section 8.3).

The glucose-induced structural changes are significant in two respects. First, the environment around the glucose becomes more nonpolar, which favors reaction between the hydrophilic hydroxyl group of glucose and the terminal phosphoryl group of ATP. Second, the conformational changes enable the kinase to discriminate against  $H_2O$  as a substrate. The closing of the cleft keeps water molecules away from the active site. If hexokinase were rigid, a molecule of  $H_2O$  occupying the binding site for the  $-CH_2OH$  of glucose could attack the  $\gamma$  phosphoryl group of ATP, forming ADP and  $P_i$ . In other words, a rigid kinase would likely also be an ATPase. It is interesting to note that other kinases taking part in glycolysis—phosphofructokinase, phosphoglycerate kinase, and pyruvate kinase—also contain clefts between lobes that close when substrate is bound, although the structures of these enzymes are different in other regards. *Substrate-induced cleft closing is a general feature of kinases.* Recall that protein kinase A also undergoes similar structural changes (p. 298).

### Fructose 1,6-bisphosphate is generated from glucose 6-phosphate

The next step in glycolysis is the *isomerization of glucose 6-phosphate to fructose 6-phosphate*. Recall that the open-chain form of glucose has an

aldehyde group at carbon 1, whereas the open-chain form of fructose has a keto group at carbon 2. Thus, the isomerization of glucose 6-phosphate to fructose 6-phosphate is a *conversion of an aldose into a ketose*. The reaction catalyzed by *phosphoglucose isomerase* takes several steps because both glucose 6-phosphate and fructose 6-phosphate are present primarily in the cyclic forms. The enzyme must first open the six-membered ring of glucose 6-phosphate, catalyze the isomerization, and then promote the formation of the five-membered ring of fructose 6-phosphate.

A second phosphorylation reaction follows the isomerization step. *Fructose 6-phosphate is phosphorylated at the expense of ATP to fructose 1,6-bisphosphate (F-1,6-BP)*. The prefix *bis-* in bisphosphate means that two separate monophosphoryl groups are present, whereas the prefix *di-* in diphosphate (as in adenosine diphosphate) means that two phosphoryl groups are present and are connected by an anhydride bond.

This reaction is catalyzed by *phosphofruktokinase* (PFK), an allosteric enzyme that sets the pace of glycolysis. As we will learn, this enzyme plays a central role in the metabolism of many molecules in all parts of the body.

What is the biochemical rationale for the isomerization of glucose 6-phosphate to fructose 6-phosphate and its subsequent phosphorylation to form fructose 1,6-bisphosphate? Had the aldol cleavage taken place in the aldose glucose, a two-carbon and a four-carbon fragment would have resulted. Two different metabolic pathways, one to process the two-carbon fragment and one for the four-carbon fragment, would have been required to extract energy. Phosphorylation of the fructose 6-phosphate to fructose 1,6-bisphosphate prevents the reformation of glucose 6-phosphate. As shown below, aldol cleavage of fructose 1,6-bisphosphate yields two phosphorylated interconvertible three-carbon fragments that will be oxidized in the later steps of glycolysis to capture energy in the form of ATP.

### The six-carbon sugar is cleaved into two three-carbon fragments

The newly formed fructose 1,6-bisphosphate is cleaved into *glyceraldehyde 3-phosphate* (GAP) and *dihydroxyacetone phosphate* (DHAP), completing stage 1 of glycolysis. The products of the remaining steps in glycolysis consist of three-carbon units rather than six-carbon units.

This reaction, which is readily reversible, is catalyzed by *aldolase*. This enzyme derives its name from the nature of the reverse reaction, an aldol condensation.

Glyceraldehyde 3-phosphate is on the direct pathway of glycolysis, whereas dihydroxyacetone phosphate is not. Unless a means exists to convert dihydroxyacetone phosphate into glyceraldehyde 3-phosphate, a three-carbon fragment useful for generating ATP will be lost. These compounds are isomers that can be readily interconverted: dihydroxyacetone phosphate is a ketose, whereas glyceraldehyde 3-phosphate is an aldose. The isomerization of these three-carbon phosphorylated sugars is catalyzed by *triose phosphate isomerase* (TPI, sometimes abbreviated TIM; Figure 16.4).

This reaction is rapid and reversible. At equilibrium, 96% of the triose phosphate is dihydroxyacetone phosphate. However, the reaction proceeds readily from dihydroxyacetone phosphate to glyceraldehyde 3-phosphate because the subsequent reactions of glycolysis remove this product. Triose phosphate isomerase deficiency, a rare condition, is the only glycolytic enzymopathy that is lethal. This deficiency is characterized by severe hemolytic anemia and neurodegeneration.

### Mechanism: Triose phosphate isomerase salvages a three-carbon fragment

Much is known about the catalytic mechanism of triose phosphate isomerase. TPI catalyzes the transfer of a hydrogen atom from carbon 1 to carbon 2, an intramolecular oxidation–reduction. This isomerization of a ketose into an aldose proceeds through an *enediol intermediate* (Figure 16.5).

X-ray crystallographic and other studies showed that glutamate 165 plays the role of a general acid–base catalyst: it abstracts a proton ( $\text{H}^+$ ) from carbon 1 and then donates it to carbon 2. However, the carboxylate group of glutamate 165 by itself is not basic enough to pull a proton away from a carbon atom adjacent to a carbonyl group. Histidine 95 assists catalysis by donating a proton to stabilize the negative charge that develops on the C-2 carbonyl group.

Two features of this enzyme are noteworthy. First, TPI displays great catalytic prowess. It accelerates isomerization by a

**FIGURE 16.4 Structure of triose phosphate isomerase.** This enzyme consists of a central core of eight parallel  $\beta$  strands (orange) surrounded by eight  $\alpha$  helices (blue). This structural motif, called an  $\alpha\beta$  barrel, is also found in the glycolytic enzymes aldolase, enolase, and pyruvate kinase. Notice that histidine 95 and glutamate 165, essential components of the active site of triose phosphate isomerase, are located in the barrel. A loop (red) closes off the active site on substrate binding. [Drawn from 2YPI.pdb.]

**FIGURE 16.5 Catalytic mechanism of triose phosphate isomerase.** (1)

Glutamate 165 acts as a general base by abstracting a proton ( $\text{H}^+$ ) from carbon 1. Histidine 95, acting as a general acid, donates a proton to the oxygen atom bonded to carbon 2, forming the enediol intermediate. (2) Glutamic acid, now acting as a general acid, donates a proton to C-2 while histidine removes a proton from the OH group of C-1. (3) The product is formed, and glutamate and histidine are returned to their ionized and neutral forms, respectively.

factor of  $10^{10}$  compared with the rate obtained with a simple base catalyst such as acetate ion. Indeed, the  $k_{\text{cat}}/K_M$  ratio for the isomerization of glyceraldehyde 3-phosphate is  $2 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ , which is close to the diffusion-controlled limit. In other words, catalysis takes place every time that enzyme and substrate meet. The diffusion-controlled encounter of substrate and enzyme is thus the rate-limiting step in catalysis. TPI is an example of a *kinetically perfect enzyme* (Section 8.4). Second, TPI suppresses an undesired side reaction, the decomposition of the enediol intermediate into methyl glyoxal and orthophosphate.

In solution, this physiologically useless reaction is 100 times as fast as isomerization. Moreover, methyl glyoxal is a highly reactive compound that can modify the structure and function of a variety of biomolecules, including proteins and DNA. The reaction of methyl glyoxal with a biomolecule is an example of deleterious reactions called advanced glycation end products, discussed earlier (AGEs, Section 11.1). Hence, TPI must prevent the enediol from leaving the enzyme. This labile intermediate is trapped in the active site by the movement of a loop of 10 residues (Figure 16.4). This loop serves as a lid on the active site, shutting it when the enediol is present and reopening it when isomerization is completed. *We see here a striking example of one means of preventing an undesirable alternative reaction: the active site is kept closed until the desirable reaction takes place.*

Thus, two molecules of glyceraldehyde 3-phosphate are formed from one molecule of fructose 1,6-bisphosphate by the sequential action of aldolase and triose phosphate isomerase. The economy of metabolism is evident in this reaction sequence. The isomerase funnels dihydroxyacetone phosphate into the main glycolytic pathway; a separate set of reactions is not needed.

## The oxidation of an aldehyde to an acid powers the formation of a compound with high phosphoryl-transfer potential

The preceding steps in glycolysis have transformed one molecule of glucose into two molecules of glyceraldehyde 3-phosphate, but no energy has yet been extracted. On the contrary, thus far, two molecules of ATP have been invested. We come now to the second stage of glycolysis, a series of steps that harvest some of the energy contained in glyceraldehyde 3-phosphate as ATP. The initial reaction in this sequence is the *conversion of glyceraldehyde 3-phosphate into 1,3-bisphosphoglycerate* (1,3-BPG), a reaction catalyzed by *glyceraldehyde 3-phosphate dehydrogenase*.

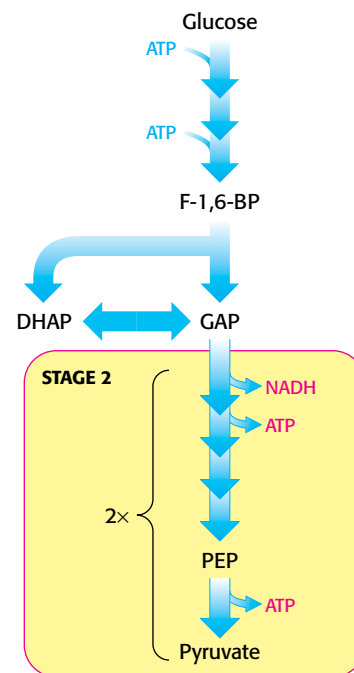

1,3-Bisphosphoglycerate is an acyl phosphate, which is a mixed anhydride of phosphoric acid and a carboxylic acid. Such compounds have a high phosphoryl-transfer potential; one of its phosphoryl groups is transferred to ADP in the next step in glycolysis.

The reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase can be viewed as the sum of two processes: the *oxidation* of the aldehyde to a carboxylic acid by  $\text{NAD}^+$  and the *joining* of the carboxylic acid and orthophosphate to form the acyl-phosphate product.

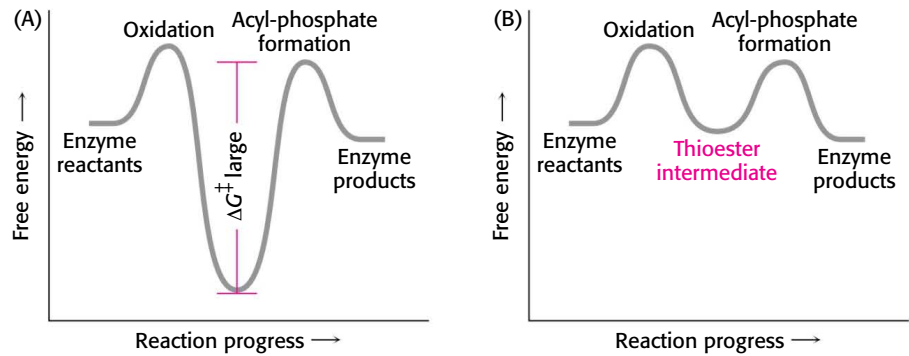

The first reaction is thermodynamically quite favorable, with a standard free-energy change,  $\Delta G^{\circ'}$ , of approximately  $-50 \text{ kJ mol}^{-1}$  ( $-12 \text{ kcal mol}^{-1}$ ), whereas the second reaction is quite unfavorable, with a standard free-energy change of the same magnitude but the opposite sign. If these two reactions simply took place in succession, the second reaction would have a very large activation energy and thus not take place at a biologically significant rate. These two processes *must be coupled* so that the favorable aldehyde oxidation can be used to drive the formation of the acyl phosphate. How are these reactions coupled? *The key is an intermediate, formed as a result of the aldehyde oxidation, that is linked to the enzyme by a thioester bond.* Thioesters are high-energy compounds found in many biochemical pathways (Section 15.4). This intermediate reacts with orthophosphate to form the high-energy compound 1,3-bisphosphoglycerate.

*The thioester intermediate is higher in free energy than the free carboxylic acid is.* The favorable oxidation and unfavorable phosphorylation reactions are coupled by the thioester intermediate, which preserves much of the free

**Second stage of glycolysis.** The oxidation of three-carbon fragments yields ATP.

**FIGURE 16.6 Free-energy profiles for glycer aldehyde oxidation followed by acyl-phosphate formation.** (A) A hypothetical case with no coupling between the two processes. The second step must have a large activation barrier, making the reaction very slow. (B) The actual case with the two reactions coupled through a thioester intermediate.

energy released in the oxidation reaction. We see here the use of a covalent enzyme-bound intermediate as a mechanism of energy coupling. A free-energy profile of the glycer aldehyde 3-phosphate dehydrogenase reaction, compared with a hypothetical process in which the reaction proceeds without this intermediate, reveals how this intermediate allows a favorable process to drive an unfavorable one (Figure 16.6).

### Mechanism: Phosphorylation is coupled to the oxidation of glycer aldehyde 3-phosphate by a thioester intermediate

The active site of glycer aldehyde 3-phosphate dehydrogenase includes a reactive cysteine residue, as well as  $\text{NAD}^+$  and a crucial histidine (Figure 16.7). Let us consider in detail how these components cooperate in the reaction mechanism (Figure 16.8). In step 1, the aldehyde substrate reacts with the sulfhydryl group of cysteine 149 on the enzyme to form a hemithioacetal. Step 2 is the transfer of a hydride ion to a molecule of  $\text{NAD}^+$  that is tightly bound to the enzyme and is adjacent to the cysteine residue. This reaction is favored by the deprotonation of the hemithioacetal by histidine 176. The products of this reaction are the reduced coenzyme  $\text{NADH}$  and a thioester intermediate. This thioester intermediate has a free energy close to that of the reactants (Figure 16.6). In step 3, the  $\text{NADH}$  formed from the aldehyde oxidation leaves the enzyme and is replaced by a second molecule of  $\text{NAD}^+$ . This step is important because the positive charge on  $\text{NAD}^+$  polarizes the thioester intermediate to facilitate the

**FIGURE 16.7 Structure of glycer aldehyde 3-phosphate dehydrogenase.** Notice that the active site includes a cysteine residue and a histidine residue adjacent to a bound  $\text{NAD}^+$  molecule. The sulfur atom of cysteine will link with the substrate to form a transitory thioester intermediate. [Drawn from 1GAD.pdb.]

**FIGURE 16.8 Catalytic mechanism of glyceraldehyde 3-phosphate dehydrogenase.** The reaction proceeds through a thioester intermediate, which allows the oxidation of glyceraldehyde to be coupled to the phosphorylation of 3-phosphoglycerate. (1) Cysteine reacts with the aldehyde group of the substrate, forming a hemithioacetal. (2) An oxidation takes place with the transfer of a hydride ion to NAD<sup>+</sup>, forming a thioester. This reaction is facilitated by the transfer of a proton to histidine. (3) The reduced NADH is exchanged for an NAD<sup>+</sup> molecule. (4) Orthophosphate attacks the thioester, forming the product 1,3-BPG.

attack by orthophosphate. In step 4, orthophosphate attacks the thioester to form 1,3-BPG and free the cysteine residue. This example illustrates the essence of energy transformations and of metabolism itself: energy released by carbon oxidation is converted into high phosphoryl-transfer potential.

### ATP is formed by phosphoryl transfer from 1,3-bisphosphoglycerate

1,3-Bisphosphoglycerate is an energy-rich molecule with a greater phosphoryl-transfer potential than that of ATP (Section 15.2). Thus, 1,3-BPG can be used to power the synthesis of ATP from ADP. *Phosphoglycerate kinase* catalyzes the transfer of the phosphoryl group from the acyl phosphate of 1,3-bisphosphoglycerate to ADP. ATP and 3-phosphoglycerate are the products.

The formation of ATP in this manner is referred to as *substrate-level phosphorylation* because the phosphate donor, 1,3-BPG, is a substrate with high phosphoryl-transfer potential. We will contrast this manner of ATP formation with the formation of ATP from ionic gradients in chapters 18 and 19.

Thus, the outcomes of the reactions catalyzed by glyceraldehyde 3-phosphate dehydrogenase and phosphoglycerate kinase are as follows:

1. Glyceraldehyde 3-phosphate, an aldehyde, is oxidized to 3-phosphoglycerate, a carboxylic acid.
2.  $\text{NAD}^+$  is concomitantly reduced to NADH.
3. ATP is formed from  $\text{P}_i$  and ADP at the expense of carbon-oxidation energy.

In essence, the energy released during the oxidation of glyceraldehyde 3-phosphate to 3-phosphoglycerate is temporarily trapped as 1,3-bisphosphoglycerate. This energy powers the transfer of a phosphoryl group from 1,3-bisphosphoglycerate to ADP to yield ATP. Keep in mind that, because of the actions of aldolase and triose phosphate isomerase, two molecules of glyceraldehyde 3-phosphate were formed and hence two molecules of ATP were generated. These ATP molecules make up for the two molecules of ATP consumed in the first stage of glycolysis.

#### Additional ATP is generated with the formation of pyruvate

In the remaining steps of glycolysis, 3-phosphoglycerate is converted into pyruvate, and a second molecule of ATP is formed from ADP.

The first reaction is a rearrangement. The position of the phosphoryl group shifts in the *conversion of 3-phosphoglycerate into 2-phosphoglycerate*, a reaction catalyzed by *phosphoglycerate mutase*. In general, a *mutase* is an enzyme that catalyzes the intramolecular shift of a chemical group, such as a phosphoryl group. The phosphoglycerate mutase reaction has an interesting mechanism: the phosphoryl group is not simply moved from one carbon atom to another. This enzyme requires catalytic amounts of 2,3-bisphosphoglycerate (2,3-BPG) to maintain an active-site histidine residue in a phosphorylated form. This phosphoryl group is transferred to 3-phosphoglycerate to reform 2,3-bisphosphoglycerate.

The mutase then functions as a phosphatase: it converts 2,3-bisphosphoglycerate into 2-phosphoglycerate. The mutase retains the phosphoryl group to regenerate the modified histidine.

The sum of these reactions yields the mutase reaction:

In the next reaction, the dehydration of 2-phosphoglycerate introduces a double bond, creating an *enol*. *Enolase* catalyzes this formation of the enol phosphate *phosphoenolpyruvate* (PEP). This dehydration markedly elevates the transfer potential of the phosphoryl group. An *enol phosphate* has a high phosphoryl-transfer potential, whereas the phosphate ester of an ordinary alcohol, such as 2-phosphoglycerate, has a low one. The  $\Delta G^{\circ}$  of the hydrolysis of a phosphate ester of an ordinary alcohol is  $-13 \text{ kJ mol}^{-1}$  ( $-3 \text{ kcal mol}^{-1}$ ), whereas that of phosphoenolpyruvate is  $-62 \text{ kJ mol}^{-1}$  ( $-15 \text{ kcal mol}^{-1}$ ).

Why does phosphoenolpyruvate have such a high phosphoryl-transfer potential? The phosphoryl group traps the molecule in its unstable enol form. When the phosphoryl group has been donated to ATP, the enol undergoes a conversion into the more stable ketone—namely, pyruvate.

Thus, *the high phosphoryl-transfer potential of phosphoenolpyruvate arises primarily from the large driving force of the subsequent enol–ketone conversion.* Hence, pyruvate is formed, and ATP is generated concomitantly. The virtually irreversible transfer of a phosphoryl group from phosphoenolpyruvate to ADP is catalyzed by *pyruvate kinase*. What is the energy source for the formation of phosphoenolpyruvate? The answer to this question becomes clear when we compare the structures of 2-phosphoglycerate and pyruvate. The formation of pyruvate from 2-phosphoglycerate is, in essence, an internal oxidation–reduction reaction; carbon 3 takes electrons from carbon 2 in the conversion of 2-phosphoglycerate into pyruvate. Compared with 2-phosphoglycerate, C-3 is more reduced in pyruvate, whereas C-2 is more oxidized. Once again, carbon oxidation powers the synthesis of a compound with high phosphoryl-transfer potential, phosphoenolpyruvate here and 1,3-bisphosphoglycerate earlier, which allows the synthesis of ATP.

Because the molecules of ATP used in forming fructose 1,6-bisphosphate have already been regenerated, the two molecules of ATP generated from phosphoenolpyruvate are “profit.”

### Two ATP molecules are formed in the conversion of glucose into pyruvate

The net reaction in the transformation of glucose into pyruvate is

Thus, *two molecules of ATP are generated in the conversion of glucose into two molecules of pyruvate.* The reactions of glycolysis are summarized in Table 16.1.

The energy released in the anaerobic conversion of glucose into two molecules of pyruvate is about  $-90 \text{ kJ mol}^{-1}$  ( $-22 \text{ kcal mol}^{-1}$ ). We shall

TABLE 16.1 Reactions of glycolysis

Step	Reaction
1	Glucose + ATP $\rightarrow$ glucose 6-phosphate + ADP + H <sup>+</sup>
2	Glucose 6-phosphate $\rightleftharpoons$ fructose 6-phosphate
3	Fructose 6-phosphate + ATP $\rightarrow$ fructose 1,6-bisphosphate + ADP + H <sup>+</sup>
4	Fructose 1,6-bisphosphate $\rightleftharpoons$ dihydroxyacetone phosphate + glyceraldehyde 3-phosphate
5	Dihydroxyacetone phosphate $\rightleftharpoons$ glyceraldehyde 3-phosphate
6	Glyceraldehyde 3-phosphate + P <sub>i</sub> + NAD <sup>+</sup> $\rightleftharpoons$ 1,3-bisphosphoglycerate + NADH + H <sup>+</sup>
7	1,3-Bisphosphoglycerate + ADP $\rightleftharpoons$ 3-phosphoglycerate + ATP
8	3-Phosphoglycerate $\rightleftharpoons$ 2-phosphoglycerate
9	2-Phosphoglycerate $\rightleftharpoons$ phosphoenolpyruvate + H <sub>2</sub> O
10	Phosphoenolpyruvate + ADP + H <sup>+</sup> $\rightarrow$ pyruvate + ATP

Note:  $\Delta G$ , the actual free-energy change, has been calculated from  $\Delta G^{\circ}$  and known concentrations of reactants under typical physiological conditions. Glycolysis can proceed only if the  $\Delta G$  values of all reactions are negative. The small positive  $\Delta G$  values of three of the above reactions indicate that the concentrations of metabolites in vivo in cells undergoing glycolysis are not precisely known.

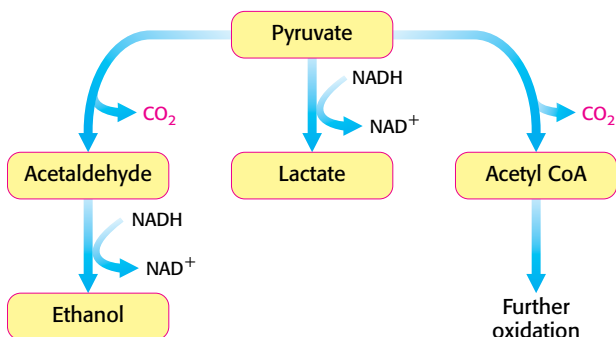

see in chapters 17 and 18 that much more energy can be released from glucose in the presence of oxygen.

### NAD<sup>+</sup> is regenerated from the metabolism of pyruvate

The conversion of glucose into two molecules of pyruvate has resulted in the net synthesis of ATP. However, an energy-converting pathway that stops at pyruvate will not proceed for long, because redox balance has not been maintained. As we have seen, the activity of glyceraldehyde 3-phosphate dehydrogenase, in addition to generating a compound with high phosphoryl-transfer potential, reduces NAD<sup>+</sup> to NADH. In the cell, there are limited amounts of NAD<sup>+</sup>, which is derived from the vitamin niacin (B<sub>3</sub>), a dietary requirement for human beings. Consequently, NAD<sup>+</sup> must be regenerated for glycolysis to proceed. Thus, the final process in the pathway is the regeneration of NAD<sup>+</sup> through the metabolism of pyruvate.

The sequence of reactions from glucose to pyruvate is similar in most organisms and most types of cells. In contrast, the fate of pyruvate is variable. Three reactions of pyruvate are of primary importance: conversion into ethanol, lactate, or carbon dioxide (Figure 16.9). The first two reactions are fermentations that take place in the absence of oxygen.

A *fermentation* is an ATP-generating process in which organic compounds act both as the donor and as the acceptor of electrons. In the presence of oxygen, the most common situation in multicellular organisms and in many unicellular ones, pyruvate is metabolized to carbon dioxide and water through the citric acid cycle and the electron-transport chain with oxygen serving as the final electron acceptor. We now take a closer look at these three possible fates of pyruvate.

**FIGURE 16.9 Diverse fates of pyruvate.** Ethanol and lactate can be formed by reactions that include NADH. Alternatively, a two-carbon unit from pyruvate can be coupled to coenzyme A (Chapter 17) to form acetyl CoA.

1. *Ethanol* is formed from pyruvate in yeast and several other microorganisms. The first step is the decarboxylation of pyruvate. This reaction is catalyzed by *pyruvate decarboxylase*, which requires the coenzyme thiamine pyrophosphate, a coenzyme, derived from the vitamin thiamine (B<sub>1</sub>). The second step is the reduction of acetaldehyde to ethanol

Enzyme	Reaction type	$\Delta G^{\circ}$ in kJ mol <sup>-1</sup> (kcal mol <sup>-1</sup> )	$\Delta G$ in kJ mol <sup>-1</sup> (kcal mol <sup>-1</sup> )
Hexokinase	Phosphoryl transfer	-16.7 (-4.0)	-33.5 (-8.0)
Phosphoglucose isomerase	Isomerization	+1.7 (+0.4)	-2.5 (-0.6)
Phosphofructokinase	Phosphoryl transfer	-14.2 (-3.4)	-22.2 (-5.3)
Aldolase	Aldol cleavage	+23.8 (+5.7)	-1.3 (-0.3)
Triose phosphate isomerase	Isomerization	+7.5 (+1.8)	+2.5 (+0.6)
Glyceraldehyde 3-phosphate dehydrogenase	Phosphorylation coupled to oxidation	+6.3 (+1.5)	-1.7 (-0.4)

Enolase	Dehydration	+1.7 (+0.4)	-3.3 (-0.8)
Pyruvate kinase	Phosphoryl transfer	-31.4 (-7.5)	-16.7 (-4.0)

by NADH, in a reaction catalyzed by *alcohol dehydrogenase*. This reaction regenerates NAD<sup>+</sup>.

The active site of alcohol dehydrogenase contains a zinc ion that is coordinated to the sulfur atoms of two cysteine residues and a nitrogen atom of histidine (Figure 16.10). This zinc ion polarizes the carbonyl group of the substrate to favor the transfer of a hydride from NADH.

The conversion of glucose into ethanol is an example of *alcoholic fermentation*. The net result of this anaerobic process is

Note that NAD<sup>+</sup> and NADH do not appear in this equation, even though they are crucial for the overall process. NADH generated by the oxidation of glyceraldehyde 3-phosphate is consumed in the reduction of acetaldehyde to ethanol. Thus, *there is no net oxidation–reduction in the conversion of glucose into ethanol* (Figure 16.11). The ethanol formed in alcoholic fermentation provides a key ingredient for brewing and winemaking.

2. *Lactate* is formed from pyruvate in a variety of microorganisms in a process called *lactic acid fermentation*. Certain types of skeletal muscles

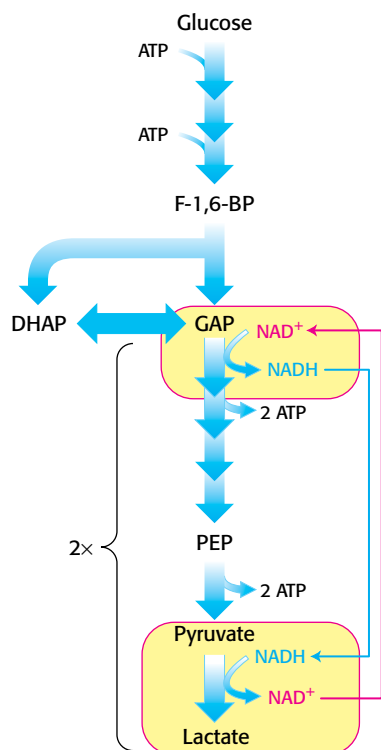

**FIGURE 16.10 Active site of alcohol dehydrogenase.** The active site contains a zinc ion bound to two cysteine residues and one histidine residue. Notice that the zinc ion binds the acetaldehyde substrate through its oxygen atom, polarizing the substrate so that it more easily accepts a hydride from NADH. Only the nicotinamide ring of NADH is shown.

**FIGURE 16.11 Maintaining redox balance.** The NADH produced by the glyceraldehyde 3-phosphate dehydrogenase reaction must be reoxidized to NAD<sup>+</sup> for the glycolytic pathway to continue. In alcoholic fermentation, alcohol dehydrogenase oxidizes NADH and generates ethanol. In lactic acid fermentation (not shown), lactate dehydrogenase oxidizes NADH while generating lactic acid.

Regeneration of NAD<sup>+</sup>.

in most animals can also function anaerobically for short periods. For example, a specific type of muscle fiber, called fast twitch or type IIb fibers, performs short bursts of intense exercise. The ATP needs rise faster than the ability of the body to provide oxygen to the muscle. The muscle functions anaerobically until fatigue sets in, which is caused, in part, by lactate buildup. Indeed, the pH of resting type IIb muscle fibers, which is about 7.0, may fall to as low as 6.3 during the bout of exercise. The drop in pH inhibits phosphofructokinase (p. 469). A lactate/H<sup>+</sup> symporter allows the exit of lactate from the muscle cell. The reduction of pyruvate by NADH to form lactate is catalyzed by *lactate dehydrogenase*.

The overall reaction in the conversion of glucose into lactate is

As in alcoholic fermentation, there is no net oxidation–reduction. The NADH formed in the oxidation of glyceraldehyde 3-phosphate is consumed in the reduction of pyruvate. *The regeneration of NAD<sup>+</sup> in the reduction of pyruvate to lactate or ethanol sustains the continued process of glycolysis under anaerobic conditions.*

3. Only a fraction of the energy of glucose is released in its anaerobic conversion into ethanol or lactate. Much more energy can be extracted aerobically by means of the citric acid cycle and the electron-transport chain. The entry point to this oxidative pathway is *acetyl coenzyme A* (acetyl CoA), which is formed inside mitochondria by the oxidative decarboxylation of pyruvate.

This reaction, which is catalyzed by the pyruvate dehydrogenase complex, will be considered in detail in Chapter 17. The NAD<sup>+</sup> required for this reaction and for the oxidation of glyceraldehyde 3-phosphate is regenerated when NADH ultimately transfers its electrons to O<sub>2</sub> through the electron-transport chain in mitochondria.

### Fermentations provide usable energy in the absence of oxygen

Fermentations yield only a fraction of the energy available from the complete combustion of glucose. Why is a relatively inefficient metabolic pathway so extensively used? The fundamental reason is that oxygen is not required. The ability to survive without oxygen affords a host of living accommodations such as soils, deep water, and skin pores. Some organisms, called *obligate anaerobes*, cannot survive in the presence of O<sub>2</sub>, a highly reactive compound. The bacterium *Clostridium perfringens*, the cause of gangrene, is an example of an obligate anaerobe. Other pathogenic obligate anaerobes are listed in Table 16.2. Some organisms, such as yeast, are *facultative anaerobes* that metabolize glucose aerobically when oxygen is present and perform fermentation when oxygen is absent.

Although we have considered only lactic acid and alcoholic fermentation, microorganisms are capable of generating a wide array of molecules as

**TABLE 16.2** Examples of pathogenic obligate anaerobes

Bacterium	Result of infection
<i>Clostridium tetani</i>	Tetanus (lockjaw)
<i>Clostridium botulinum</i>	Botulism (an especially severe type of food poisoning)
<i>Clostridium perfringens</i>	Gas gangrene (gas is produced as an end point of the fermentation, distorting and destroying the tissue)
<i>Bartonella hensela</i>	Cat scratch fever (flu-like symptoms)
<i>Bacteroides fragilis</i>	Abdominal, pelvic, pulmonary, and blood infections

end points of fermentation (Table 16.3). Indeed, many food products, including sour cream, yogurt, various cheeses, beer, wine, and sauerkraut, result from fermentation.

### The binding site for NAD<sup>+</sup> is similar in many dehydrogenases

 The three dehydrogenases—glyceraldehyde 3-phosphate dehydrogenase, alcohol dehydrogenase, and lactate dehydrogenase—have quite different three-dimensional structures. However, their NAD<sup>+</sup>-binding domains are strikingly similar (Figure 16.12). This nucleotide-binding region is made up of four  $\alpha$  helices and a sheet of six parallel  $\beta$  strands. Moreover, in all cases, the bound NAD<sup>+</sup> displays nearly the same conformation. This common structural domain is often called a *Rossmann fold* after Michael Rossmann, who first recognized it. This fold likely represents a primordial dinucleotide-binding domain that recurs in the dehydrogenases of glycolysis and other enzymes because of their descent from a common ancestor.

**TABLE 16.3** Starting and ending points of various fermentations

Glucose	→	lactate
Lactate	→	acetate
Glucose	→	ethanol
Ethanol	→	acetate
Arginine	→	carbon dioxide

The two domains together form a structural motif called a Rossmann fold. The NAD<sup>+</sup> molecule binds in an extended conformation. [Drawn from 3LDH.pdb.]

### Fructose is converted into glycolytic intermediates by fructokinase

Although glucose is the most widely used monosaccharide, others also are important fuels. Let us consider how fructose is funneled into the glycolytic pathway (Figure 16.13). There are no catabolic pathways for metabolizing fructose, and so the strategy is to convert this sugar into a metabolite of glucose.

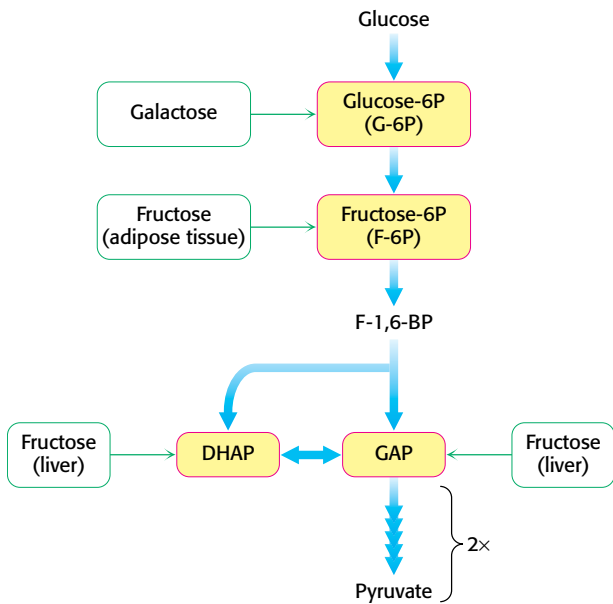

FIGURE 16.13 Entry points in glycolysis for fructose and galactose.

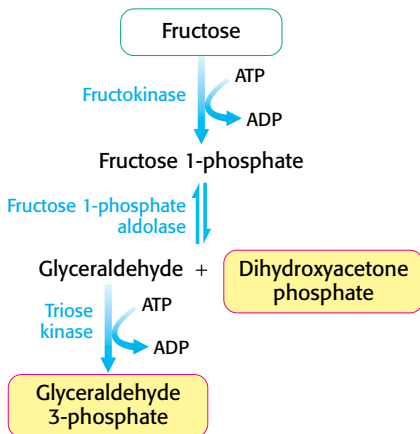

FIGURE 16.14 Fructose metabolism. Fructose enters the glycolytic pathway in the liver through the fructose 1-phosphate pathway.

The main site of fructose metabolism is the liver, using the *fructose 1-phosphate pathway* (Figure 16.14). The first step is the phosphorylation of *fructose* to *fructose 1-phosphate* by *fructokinase*. Fructose 1-phosphate is then split into *glyceraldehyde* and *dihydroxyacetone phosphate*, an intermediate in glycolysis. This aldol cleavage is catalyzed by a specific *fructose 1-phosphate aldolase*. Glyceraldehyde is then phosphorylated to *glyceraldehyde 3-phosphate*, a glycolytic intermediate, by *triose kinase*. In other tissues, such as adipose tissue, *fructose can be phosphorylated to fructose 6-phosphate* by *hexokinase*.

### Excessive fructose consumption can lead to pathological conditions

Fructose, a commonly used sweetener, is a component of sucrose and high fructose corn syrup (which contains approximately 55% fructose and 45% glucose). Epidemiological as well as clinical studies have linked excessive fructose consumption to fatty liver, insulin insensitivity, and obesity. These conditions may eventually result in type

2 diabetes (Chapter 27). Studies have shown that these disorders are not necessarily the result of simple excess energy consumption, but rather how fructose is processed by the liver. What aspects of liver fructose metabolism are the contributing factors then? Note that, as shown in Figure 16.14, the actions of fructokinase and triose kinase bypass the most important regulatory step in glycolysis, the phosphofructokinase-catalyzed reaction. The fructose-derived glyceraldehyde 3-phosphate and dihydroxyacetone phosphate are processed by glycolysis to pyruvate and subsequently to acetyl CoA in an unregulated fashion. As we will see in Chapter 22, this excess acetyl CoA is converted to fatty acids, which can be transported to adipose tissue, resulting in obesity. The liver also begins to accumulate fatty acids, resulting in fatty liver. The activity of the fructokinase and triose kinase can deplete the liver of ATP and inorganic phosphate, compromising liver function. We will return to the topic of obesity and caloric homeostasis in Chapter 27.

### Galactose is converted into glucose 6-phosphate

Like fructose, *galactose* is an abundant sugar that must be converted into metabolites of glucose (Figure 16.13). Galactose is converted into *glucose 6-phosphate* in four steps. The first reaction in the *galactose–glucose interconversion pathway* is the phosphorylation of galactose to galactose 1-phosphate by *galactokinase*.

Galactose 1-phosphate then acquires a uridyl group from uridine diphosphate glucose (UDP-glucose), an activated intermediate in the synthesis of carbohydrates (p. 331 and Section 21.4).

The products of this reaction, which is catalyzed by *galactose 1-phosphate uridyl transferase*, are UDP-galactose and glucose 1-phosphate. The galactose moiety of UDP-galactose is then epimerized to glucose. The configuration of the hydroxyl group at carbon 4 is inverted by *UDP-galactose 4-epimerase*.

The sum of the reactions catalyzed by galactokinase, the transferase, and the epimerase is

Note that UDP-glucose is not consumed in the conversion of galactose into glucose, because it is regenerated from UDP-galactose by the epimerase. This reaction is reversible, and the product of the reverse direction also is important. *The conversion of UDP-glucose into UDP-galactose is essential for the synthesis of galactosyl residues in complex polysaccharides and glycoproteins if the amount of galactose in the diet is inadequate to meet these needs.*

Finally, glucose 1-phosphate, formed from galactose, is isomerized to glucose 6-phosphate by *phosphoglucomutase*.

We shall return to this reaction when we consider the synthesis and degradation of glycogen, which proceeds through glucose 1-phosphate, in Chapter 21.

### Many adults are intolerant of milk because they are deficient in lactase

Many adults are unable to metabolize the milk sugar lactose and experience gastrointestinal disturbances if they drink milk. *Lactose*

*intolerance*, or hypolactasia, is most commonly caused by a deficiency of the enzyme lactase, which cleaves lactose into glucose and galactose.

“Deficiency” is not quite the appropriate term, because a decrease in lactase is normal in the course of development in all mammals. As children are weaned and milk becomes less prominent in their diets, lactase activity normally declines to about 5% to 10% of the level at birth. This decrease is not as pronounced with some groups of people, most notably Northern Europeans, and people from these groups can continue to ingest milk without gastrointestinal difficulties. With the development of dairy farming, an adult with active lactase would have a selective advantage in being able to consume calories from the readily available milk. Indeed, estimates suggest that people with the mutation would produce almost 20% more fertile offspring. Because dairy farming appeared in northern Europe about 10,000 years ago, the evolutionary selective pressure on lactase persistence must have been substantial, attesting to the biochemical value of being able to use milk as an energy source into adulthood.

What happens to the lactose in the intestine of a lactase-deficient person? The lactose is a good energy source for microorganisms in the colon, and they ferment it to lactic acid while generating methane ( $\text{CH}_4$ ) and hydrogen gas ( $\text{H}_2$ ). The gas produced creates the uncomfortable feeling of gut distension and the annoying problem of flatulence. The lactate produced by the microorganisms is osmotically active and draws water into the intestine, as does any undigested lactose, resulting in diarrhea. If severe enough, the gas and diarrhea hinder the absorption of other nutrients such as fats and proteins. The simplest treatment is to avoid the consumption of products containing much lactose. Alternatively, the enzyme lactase can be ingested with milk products.

### Galactose is highly toxic if the transferase is missing

 Less common than lactose intolerance are disorders that interfere with the metabolism of galactose. The disruption of galactose metabolism is referred to as *galactosemia*. The most common form, called classic galactosemia, is an inherited deficiency in galactose 1-phosphate uridylyl transferase activity. Afflicted infants fail to thrive. They vomit or have diarrhea after consuming milk, and enlargement of the liver and jaundice are common, sometimes progressing to cirrhosis. Cataracts will form, and lethargy and retarded mental development also are common. The blood-galactose level is markedly elevated, and galactose is found in the urine. The absence of the transferase in red blood cells is a definitive diagnostic criterion.

The most common treatment is to remove galactose (and lactose) from the diet. An enigma of galactosemia is that, although elimination of galactose from the diet prevents liver disease and cataract development, the majority of patients still suffer from central nervous system malfunction, most commonly a delayed acquisition of language skills. Female patients also display ovarian failure.

**Scanning electron micrograph of *Lactobacillus*.** The anaerobic bacterium *Lactobacillus* is shown here. As suggested by its name, this genus of bacteria ferments glucose into lactic acid and is widely used in the food industry. *Lactobacillus* is also a component of the normal human bacterial flora of the urogenital tract where, because of its ability to generate an acidic environment, it prevents the growth of harmful bacteria. [Power and Syred/ Science Photo Library.]

Cataract formation is better understood. A cataract is the clouding of the normally clear lens of the eye (Figure 16.15). If the transferase is not active in the lens of the eye, the presence of aldose reductase causes the accumulating galactose to be reduced to galactitol.

Galactitol is poorly metabolized and accumulates in the lens. Water will diffuse into the lens to maintain osmotic balance, triggering the formation of cataracts. In fact, there is a high incidence of cataract formation with age in populations that consume substantial amounts of milk into adulthood.

## 16.2 The Glycolytic Pathway Is Tightly Controlled

The glycolytic pathway has a dual role: it degrades glucose to generate ATP and it provides building blocks for biosynthetic reactions. The rate of conversion of glucose into pyruvate is regulated to meet these two major cellular needs. *In metabolic pathways, enzymes catalyzing essentially irreversible reactions are potential sites of control.* In glycolysis, the reactions catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase are virtually irreversible, and each of them serves as a control site. These enzymes become more active or less so in response to the reversible binding of allosteric effectors or to covalent modification. In addition, the amounts of these important enzymes are varied by the regulation of transcription to meet changing metabolic needs. The time required for allosteric control, regulation by phosphorylation, and transcriptional control is measured typically in milliseconds, seconds, and hours, respectively. We will consider the control of glycolysis in two different tissues—skeletal muscle and liver.

### Glycolysis in muscle is regulated to meet the need for ATP

Glycolysis in skeletal muscle provides ATP primarily to power contraction. Consequently, *the primary control of muscle glycolysis is the energy charge of the cell*—the ratio of ATP to AMP. Let us examine how each of the key regulatory enzymes responds to changes in the amounts of ATP and AMP present in the cell.

**Phosphofructokinase.** *Phosphofructokinase is the most important control site in the mammalian glycolytic pathway* (Figure 16.16). High levels of ATP allosterically inhibit the enzyme (a 340-kDa tetramer). ATP binds to a specific regulatory site that is distinct from the catalytic site. The binding of ATP lowers the enzyme's affinity for fructose 6-phosphate. Thus, a high concentration of ATP converts the hyperbolic binding curve of fructose 6-phosphate into a sigmoidal one (Figure 16.17). AMP reverses the inhibitory action of ATP, and so *the activity of the enzyme increases when the ATP/AMP ratio is lowered.* In other words, *glycolysis is stimulated as the energy charge falls.* A decrease in pH also inhibits phosphofructokinase

**FIGURE 16.15** Cataracts are evident as the clouding of the lens. (A) A healthy eye. (B) An eye with a cataract. [(A) © Imageafter; (B) SPL/Photo Researchers.]

**FIGURE 16.17 Allosteric regulation of phosphofructokinase.** A high level of ATP inhibits the enzyme by decreasing its affinity for fructose 6-phosphate.

**FIGURE 16.16 Structure of phosphofructokinase.** The structure of phosphofructokinase from *E. coli* comprises a tetramer of four identical subunits. Notice the separation of the catalytic and allosteric sites. Each subunit of the human liver enzyme consists of two domains that are similar to the *E. coli* enzyme. [Drawn from 1PFK.pdb.]

activity by augmenting the inhibitory effect of ATP. The pH might fall when fast twitch muscle is functioning anaerobically, producing excessive quantities of lactic acid. The inhibitory effect protects the muscle from damage that would result from the accumulation of too much acid.

Why is AMP and not ADP the positive regulator of phosphofructokinase? When ATP is being utilized rapidly, the enzyme *adenylate kinase* (Section 9.4) can form ATP from ADP by the following reaction:

Thus, some ATP is salvaged from ADP, and AMP becomes the signal for the low-energy state. Moreover, the use of AMP as an allosteric regulator provides an especially sensitive control. We can understand why by considering, first, that the total adenylate pool ( $[\text{ATP}]$ ,  $[\text{ADP}]$ ,  $[\text{AMP}]$ ) in a cell is constant over the short term and, second, that the concentration of ATP is greater than that of ADP and the concentration of ADP is, in turn, greater than that of AMP. Consequently, small-percentage changes in  $[\text{ATP}]$  result in larger-percentage changes in the concentrations of the other adenylate nucleotides. This magnification of small changes in  $[\text{ATP}]$  to larger changes in  $[\text{AMP}]$  leads to tighter control by increasing the range of sensitivity of phosphofructokinase (Problem 46).

**Hexokinase.** Phosphofructokinase is the most prominent regulatory enzyme in glycolysis, but it is not the only one. Hexokinase, the enzyme catalyzing the first step of glycolysis, is inhibited by its product, glucose 6-phosphate. High concentrations of this molecule signal that the cell no longer requires glucose for energy or for the synthesis of glycogen, a storage form of glucose

(Chapter 21), and the glucose will be left in the blood. A rise in glucose 6-phosphate concentration is a means by which phosphofructokinase communicates with hexokinase. When phosphofructokinase is inactive, the concentration of fructose 6-phosphate rises. In turn, the level of glucose 6-phosphate rises because it is in equilibrium with fructose 6-phosphate. Hence, *the inhibition of phosphofructokinase leads to the inhibition of hexokinase*.

Why is phosphofructokinase rather than hexokinase the pacemaker of glycolysis? The reason becomes evident on noting that glucose 6-phosphate is not solely a glycolytic intermediate. In muscle, glucose 6-phosphate can also be converted into glycogen. The first irreversible reaction unique to the glycolytic pathway, the *committed step* (Section 10.1), is the phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate. Thus, it is highly appropriate for phosphofructokinase to be the primary control site in glycolysis. In general, *the enzyme catalyzing the committed step in a metabolic sequence is the most important control element in the pathway*.

**Pyruvate kinase.** Pyruvate kinase, the enzyme catalyzing the third irreversible step in glycolysis, controls the outflow from this pathway. This final step yields ATP and pyruvate, a central metabolic intermediate that can be oxidized further or used as a building block. ATP allosterically inhibits pyruvate kinase to slow glycolysis when the energy charge is high. When the pace of glycolysis increases, fructose 1,6-bisphosphate, the product of the preceding irreversible step in glycolysis, activates the kinase to enable it to keep pace with the oncoming high flux of intermediates. A summary of the regulation of glycolysis in resting and active muscle is shown in Figure 16.18.

**FIGURE 16.18 Regulation of glycolysis in muscle.** At rest (left), glycolysis is not very active (thin arrows). The high concentration of ATP inhibits phosphofructokinase (PFK), pyruvate kinase, and hexokinase. Glucose 6-phosphate is converted into glycogen (Chapter 21). During exercise (right), the decrease in the ATP/AMP ratio resulting from muscle contraction activates phosphofructokinase and hence glycolysis. The flux down the pathway is increased, as represented by the thick arrows.

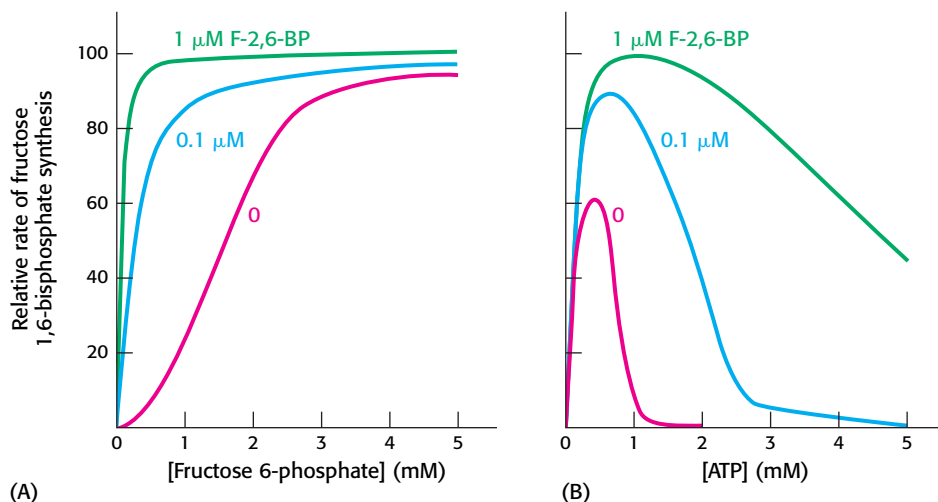

**FIGURE 16.19 Regulation of phosphofructokinase by fructose 2,6-bisphosphate.** In high concentrations, fructose 6-phosphate (F-6P) activates the enzyme phosphofructokinase (PFK) through an intermediary, fructose 2,6-bisphosphate (F-2,6-BP).

**FIGURE 16.20 Activation of phosphofructokinase by fructose 2,6-bisphosphate.** (A) The sigmoidal dependence of velocity on substrate concentration becomes hyperbolic in the presence of  $1 \mu\text{M}$  fructose 2,6-bisphosphate. (B) ATP, acting as a substrate, initially stimulates the reaction. As the concentration of ATP increases, it acts as an allosteric inhibitor. The inhibitory effect of ATP is reversed by fructose 2,6-bisphosphate. [Data from E. Van Schaftingen, M. F. Jett, L. Hue, and H. G. Hers, *Proc. Natl. Acad. Sci. U. S. A.* 78:3483–3486, 1981.]

## The regulation of glycolysis in the liver illustrates the biochemical versatility of the liver

The liver has more diverse biochemical functions than does muscle. Significantly, the liver maintains blood-glucose levels: it stores glucose as glycogen when glucose is plentiful, and it releases glucose when supplies are low. It also uses glucose to generate reducing power for biosynthesis (Section 20.3) as well as to synthesize a host of biochemicals. So, although the liver has many of the regulatory features of muscle glycolysis, the regulation of glycolysis in the liver is more complex.

**Phosphofructokinase.** Liver phosphofructokinase can be regulated by ATP as in muscle, but such regulation is not as important since the liver does not experience the sudden ATP needs that a contracting muscle does. Likewise, low pH is not an important metabolic signal for the liver enzyme, because lactate is not normally produced in the liver. Indeed, as we will see, lactate is converted into glucose in the liver.

Glycolysis in the liver furnishes carbon skeletons for biosyntheses, and so a signal indicating whether building blocks are abundant or scarce should also regulate phosphofructokinase. In the liver, *phosphofructokinase is inhibited by citrate*, an early intermediate in the citric acid cycle (Chapter 17). A high level of citrate in the cytoplasm means that biosynthetic precursors are abundant, and so there is no need to degrade additional glucose for this purpose. Citrate inhibits phosphofructokinase by enhancing the inhibitory effect of ATP.

The key means by which glycolysis in the liver responds to changes in blood glucose is through the signal molecule *fructose 2,6-bisphosphate* (F-2,6-BP), a potent activator of phosphofructokinase (Figure 16.19). In the liver, the concentration of fructose 6-phosphate rises when blood-glucose concentration is high, and the abundance of fructose 6-phosphate accelerates the synthesis of F-2,6-BP (Figure 16.20). Hence, *an abundance of fructose 6-phosphate leads to a higher concentration of F-2,6-BP*. The binding of fructose 2,6-bisphosphate increases the affinity of phosphofructokinase for fructose 6-phosphate and diminishes the inhibitory effect of ATP. Glycolysis is thus accelerated when glucose is abundant. Such a process is called *feedforward stimulation*. We will turn to the synthesis and degradation of this important regulatory molecule after we have considered gluconeogenesis.

**Hexokinase and glucokinase.** The hexokinase reaction in the liver is controlled as in the muscle. However, the liver, in keeping with its role as monitor of blood-glucose levels, possesses another specialized isozyme of hexokinase, called *glucokinase*, which is not inhibited by glucose 6-phosphate. The role of glucokinase is to provide glucose 6-phosphate for the synthesis of glycogen and for the formation of fatty acids (Section 22.1). Remarkably, glucokinase displays the sigmoidal kinetics characteristic of an allosteric enzyme even though it functions as a monomer. Glucokinase phosphorylates glucose only when glucose is abundant because the affinity of glucokinase for glucose is about 50-fold lower than that of hexokinase. Moreover, when glucose concentration is low, glucokinase is inhibited by the liver-specific glucokinase regulatory protein. The low affinity of glucokinase for glucose gives the brain and muscles first call on glucose when its supply is limited, and it ensures that glucose will not be wasted when it is abundant. Drugs that activate liver glucokinase are being evaluated as a treatment for type 2 or insulin-insensitive diabetes. Glucokinase is also present in the  $\beta$  cells of the pancreas, where the increased formation of glucose 6-phosphate by glucokinase when blood-glucose levels are elevated leads to the secretion of the hormone insulin. Insulin signals the need to remove glucose from the blood for storage as glycogen or conversion into fat.

**Pyruvate kinase.** Several isozymic forms of pyruvate kinase (a tetramer of 57-kDa subunits) encoded by different genes are present in mammals: the L type predominates in the liver, and the M type in muscle and the brain. The L and M forms of pyruvate kinase have many properties in common. Indeed, the liver enzyme behaves much like the muscle enzyme with regard to allosteric regulation except that the liver enzyme is also inhibited by alanine (synthesized in one step from pyruvate), a signal that building-blocks are available. Moreover, the isozymic forms differ in their susceptibility to covalent modification. The catalytic properties of the L form—but not of the M form—are also controlled by reversible phosphorylation (Figure 16.21). When the blood-glucose level is low, the glucagon-triggered cyclic AMP cascade (p. 483) leads to the phosphorylation of pyruvate kinase, which diminishes its activity. This hormone-triggered phosphorylation prevents the liver from consuming glucose when it is more urgently needed by the brain and muscle. We see here a clear-cut example of how isoenzymes contribute to the metabolic diversity of different organs. We will return to the control of glycolysis after considering gluconeogenesis.

### A family of transporters enables glucose to enter and leave animal cells

Several glucose transporters mediate the thermodynamically downhill movement of glucose across the plasma membranes of animal cells. Each member of this protein family, named GLUT1 to GLUT5, consists of a single polypeptide chain about 500 residues long (Table 16.4). Each glucose transporter has a 12-transmembrane-helix structure similar to that of lactose permease (Section 13.3).

**FIGURE 16.21 Control of the catalytic activity of pyruvate kinase.** Pyruvate kinase is regulated by allosteric effectors and covalent modification. Fructose 1,6-bisphosphate allosterically stimulates the enzyme, while ATP and alanine are allosteric inhibitors. Glucagon, secreted in response to low blood glucose, promotes phosphorylation and inhibition of the enzyme. When blood glucose levels are adequate, the enzyme is dephosphorylated and activated.

**TABLE 16.4** Family of glucose transporters

Name	Tissue location	$K_M$	Comments
GLUT1	All mammalian tissues	1 mM	Basal glucose uptake
GLUT2	Liver and pancreatic $\beta$ cells	15–20 mM	In the pancreas, plays a role in the regulation of insulin In the liver, removes excess glucose from the blood
GLUT3	All mammalian tissues	1 mM	Basal glucose uptake
GLUT4	Muscle and fat cells	5 mM	Amount in muscle plasma membrane increases with endurance training
GLUT5	Small intestine	—	Primarily a fructose transporter

The members of this family have distinctive roles:

1. GLUT1 and GLUT3, present in nearly all mammalian cells, are responsible for basal glucose uptake. Their  $K_M$  value for glucose is about 1 mM, significantly less than the normal serum-glucose level, which typically ranges from 4 mM to 8 mM. Hence, GLUT1 and GLUT3 continually transport glucose into cells at an essentially constant rate.
2. GLUT2, present in liver and pancreatic  $\beta$  cells, is distinctive in having a very high  $K_M$  value for glucose (15–20 mM). Hence, glucose enters these tissues at a biologically significant rate only when there is much glucose in the blood. The pancreas can sense the glucose level and accordingly adjust the rate of insulin secretion. The high  $K_M$  value of GLUT2 also ensures that glucose rapidly enters liver cells only in times of plenty.
3. GLUT4, which has a  $K_M$  value of 5 mM, transports glucose into muscle and fat cells. The number of GLUT4 transporters in the plasma membrane increases rapidly in the presence of insulin, which signals the fed state. Hence, insulin promotes the uptake of glucose by muscle and fat. Endurance exercise training increases the amount of this transporter present in muscle membranes.
4. GLUT5, present in the small intestine, functions primarily as a fructose transporter.

#### **Aerobic glycolysis is a property of rapidly growing cells.**

 Tumors have been known for decades to display enhanced rates of glucose uptake and glycolysis. Indeed, rapidly growing tumor cells will metabolize glucose to lactate even in the presence of oxygen, a process called *aerobic glycolysis* or the *Warburg effect*, after Otto Warburg, the biochemist who first noted this characteristic of cancer cells in the 1920s. In fact, tumors with a high glucose uptake are particularly aggressive, and the cancer is likely to have a poor prognosis. A nonmetabolizable glucose analog, 2-<sup>18</sup>F-2-D-deoxyglucose, detectable by a combination of positron emission tomography (PET) and computer-aided tomography (CAT), easily visualizes tumors and allows monitoring of the effectiveness of treatment (Figure 16.22).

What selective advantage does aerobic glycolysis offer the tumor over the energetically more efficient oxidative phosphorylation? Research is being actively pursued to answer the question, but we can speculate on the benefits. First, aerobic glycolysis generates lactic acid that is then secreted. Acidification of the tumor environment has been shown to facilitate tumor invasion and inhibit the immune system from attacking the tumor. However, even leukemias perform aerobic glycolysis, and leukemia is not

**FIGURE 16.22** Tumors can be visualized with 2-<sup>18</sup>F-2-D-deoxyglucose (FDG) and positron emission tomography. (A) A nonmetabolizable glucose analog infused into a patient and detected by a combination of positron emission and computer-aided tomography reveals the presence of a malignant tumor (T). (B) After 4 weeks of treatment with a tyrosine kinase inhibitor (Section 14.5), the tumor shows no uptake of FDG, indicating decreased metabolism. Excess FDG, which is excreted in the urine, also visualizes the kidneys (K) and bladder (B). [Images courtesy of A. D. Van den Abbeele, Dana-Farber Cancer Institute, Boston.]

an invasive cancer. Second, and perhaps more importantly, the increased uptake of glucose and formation of glucose 6-phosphate provides substrates for another metabolic pathway, the pentose phosphate pathway (Chapter 20), that generates biosynthetic reducing power. Moreover, the pentose phosphate pathway, in cooperation with glycolysis, produces precursors for biomolecules necessary for growth, such as nucleotides. Finally, cancer cells grow more rapidly than the blood vessels that nourish them; thus, as solid tumors grow, the oxygen concentration in their environment falls. In other words, they begin to experience *hypoxia*, a deficiency of oxygen. The use of aerobic glycolysis reduces the dependence of cell growth on oxygen. Not all of the precursor needs are met by enhanced glucose metabolism. Cancer cells also require glutamine, which is channeled into the mitochondria to replenish citric acid cycle components used for biosynthesis.

What biochemical alterations facilitate the switch to aerobic glycolysis? Again, the answers are not complete, but changes in gene expression of isozymic forms of two glycolytic enzymes may be crucial. Tumor cells express an isozyme of hexokinase that binds to mitochondria. There, the enzyme has ready access to any ATP generated by oxidative phosphorylation and is not susceptible to feedback inhibition by its product, glucose 6-phosphate. More importantly, an embryonic isozyme of pyruvate kinase, pyruvate kinase M, is also expressed. Remarkably, this isozyme has a lower catalytic rate than normal pyruvate kinase and creates a bottleneck, allowing the use of glycolytic intermediates for biosynthetic processes required for

**FIGURE 16.23** Alteration of gene expression in tumors owing to hypoxia. The hypoxic conditions inside a tumor mass lead to the activation of the hypoxia-inducible transcription factor (HIF-1), which induces metabolic adaptation (an increase in glycolytic enzymes) and activates angiogenic factors that stimulate the growth of new blood vessels. [Information from C. V. Dang and G. L. Semenza, *Trends Biochem. Sci.* 24:68–72, 1999.]

cell proliferation. The need for biosynthetic precursors is greater than the need for ATP, suggesting that even glycolysis at a reduced rate produces sufficient ATP to allow cell proliferation. Although originally observed in cancer cells, the Warburg effect is also seen in noncancerous, rapidly dividing cells.

### Cancer and endurance training affect glycolysis in a similar fashion

The hypoxia that some tumors experience with rapid growth activates a transcription factor, *hypoxia-inducible transcription factor* (HIF-1). HIF-1 increases the expression of most glycolytic enzymes and the glucose transporters GLUT1 and GLUT3 (Table 16.5). These adaptations by the cancer cells enable a tumor to survive until blood vessels can grow. HIF-1 also increases the expression of signal molecules, such as vascular endothelial growth factor (VEGF), that facilitate the growth of blood vessels that will provide nutrients to the cells (Figure 16.23). Without new blood vessels, a tumor would cease to grow and either die or remain harmlessly small. Efforts are underway to develop drugs that inhibit the growth of blood vessels in tumors.

Interestingly, anaerobic exercise training—forcing muscles to rely on lactic acid fermentation for ATP production—also activates HIF-1, producing the same effects as those seen in the tumor—enhanced ability to generate ATP anaerobically and a stimulation of blood-vessel growth. These biochemical effects account for the improved athletic performance that results from training and demonstrate how behavior can affect biochemistry. Other signals from sustained muscle contraction trigger muscle mitochondrial biogenesis, allowing for more efficient aerobic energy generation and forestalling the need to resort to lactic acid fermentation for ATP synthesis (Chapter 27).

## 16.3 Glucose Can Be Synthesized from Noncarbohydrate Precursors

We now turn to the *synthesis of glucose from noncarbohydrate precursors*, a process called *gluconeogenesis*. Maintaining levels of glucose is important because the brain depends on glucose as its primary fuel and red blood cells use glucose as their only fuel. The daily glucose requirement of the brain in a typical adult human being is about 120 g, which accounts for most of the 160 g of glucose needed daily by the whole body. The amount of glucose present in body fluids is about 20 g, and that readily available from glycogen is approximately 190 g. Thus, the direct glucose reserves are sufficient to meet glucose needs for about a day. Gluconeogenesis is especially important during a longer period of fasting or starvation (Section 27.5).

*The gluconeogenic pathway converts pyruvate into glucose.* Noncarbohydrate precursors of glucose are first converted into pyruvate or enter the pathway at later intermediates such as oxaloacetate and dihydroxyacetone phosphate (Figure 16.24). The major noncarbohydrate precursors are *lactate*, *amino acids*, and *glycerol*. Lactate is formed by active skeletal muscle when the rate of glycolysis exceeds the rate of oxidative metabolism. Lactate is readily converted into pyruvate by the action of lactate dehydrogenase (p. 464). Amino acids are derived from proteins in the diet and, during starvation, from the breakdown of proteins in skeletal muscle (Section 23.1). The hydrolysis of triacylglycerols (Section 22.2) in fat cells yields glycerol and

**FIGURE 16.24 Pathway of gluconeogenesis.** The reactions and enzymes unique to gluconeogenesis are shown in red. The other reactions are common to glycolysis. The enzymes for gluconeogenesis are located in the cytoplasm, except for pyruvate carboxylase (in the mitochondria) and glucose 6-phosphatase (membrane bound in the endoplasmic reticulum). The entry points for lactate, glycerol, and amino acids are shown.

fatty acids. Glycerol is a precursor of glucose, but animals cannot convert fatty acids into glucose, for reasons that will be given later. Glycerol may enter either the gluconeogenic or the glycolytic pathway at dihydroxyacetone phosphate.

The major site of gluconeogenesis is the *liver*, with a small amount also taking place in the *kidney*. Little gluconeogenesis takes place in the brain, skeletal muscle, or heart muscle. Rather, *gluconeogenesis in the liver and kidney helps to maintain the glucose level in the blood so that the brain and muscle can extract sufficient glucose from it to meet their metabolic demands.*

### Gluconeogenesis is not a reversal of glycolysis

In glycolysis, glucose is converted into pyruvate; in gluconeogenesis, pyruvate is converted into glucose. However, *gluconeogenesis is not a reversal of glycolysis*. Several reactions must differ because the equilibrium of glycolysis lies far on the side of pyruvate formation. The actual free energy change for the formation of pyruvate from glucose is about  $-90 \text{ kJ mol}^{-1}$  ( $-22 \text{ kcal mol}^{-1}$ ) under typical cellular conditions. Most of the decrease in free energy in glycolysis takes place in the three essentially irreversible steps catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase.

In gluconeogenesis, these virtually irreversible reactions of glycolysis must be bypassed.

### The conversion of pyruvate into phosphoenolpyruvate begins with the formation of oxaloacetate

The first step in gluconeogenesis is the carboxylation of pyruvate to form oxaloacetate at the expense of a molecule of ATP, a reaction catalyzed by *pyruvate carboxylase*. This reaction occurs in the mitochondria.

**FIGURE 16.25** Structure of biotin and carboxybiotin.

Pyruvate carboxylase requires *biotin*, a covalently attached prosthetic group, which serves as the *carrier of activated CO<sub>2</sub>*. The carboxylate group of biotin is linked to the ε-amino group of a specific lysine residue by an amide bond (Figure 16.25). Recall that, in aqueous solutions, CO<sub>2</sub> exists primarily as HCO<sub>3</sub><sup>-</sup> with the aid of carbonic anhydrase (Section 9.2).

The carboxylation of pyruvate takes place in three stages:

Pyruvate carboxylase functions as a tetramer composed of four identical subunits, and each subunit consists of four domains (Figure 16.26). The biotin carboxylase domain (BC) catalyzes the formation of carboxyphosphate and the subsequent attachment of CO<sub>2</sub> to the second domain, the biotin carboxyl carrier protein (BCCP), the site of the covalently attached biotin. Once bound to CO<sub>2</sub>, BCCP leaves the biotin carboxylase active site and swings almost the entire length of the subunit (≈75 Å) to the active site of the pyruvate carboxylase domain (PC), which transfers the CO<sub>2</sub> to pyruvate to form oxaloacetate. BCCP in one subunit interacts with the active sites on an adjacent subunit. The fourth domain (PT) facilitates the formation of the tetramer.

**FIGURE 16.26** A subunit of pyruvate carboxylase. Biotin, covalently attached to the BCCP, transports CO<sub>2</sub> from the BC active site to the PC active site of an adjacent subunit. (BC) biotin carboxylase; (BCCP) biotin carboxyl carrier protein; (PC) pyruvate carboxylase; (PT) pyruvate carboxylase tetramerization domain. [Information from G. Lasso, L.P.C. Yu, D. Gil, S. Xiang, L. Tong, and M. Valle, *Structure* 18:1300–1310, 2010.]

**FIGURE 16.27 Compartmental cooperation.** Oxaloacetate used in the cytoplasm for gluconeogenesis is formed in the mitochondrial matrix by the carboxylation of pyruvate. Oxaloacetate leaves the mitochondrion by a specific transport system (not shown) in the form of malate, which is reoxidized to oxaloacetate in the cytoplasm.

The first partial reaction of pyruvate carboxylase, the formation of carboxybiotin, depends on the presence of acetyl CoA. *Biotin is not carboxylated unless acetyl CoA is bound to the enzyme.* Acetyl CoA has no effect on the second partial reaction. The allosteric activation of pyruvate carboxylase by acetyl CoA is an important physiological control mechanism that will be discussed in Section 17.4.

### Oxaloacetate is shuttled into the cytoplasm and converted into phosphoenolpyruvate

Oxaloacetate must thus be transported to the cytoplasm to complete the synthesis of phosphoenolpyruvate. Oxaloacetate is first reduced to malate by malate dehydrogenase. Malate is transported across the mitochondrial membrane and reoxidized to oxaloacetate by a cytoplasmic  $\text{NAD}^+$ -linked malate dehydrogenase (Figure 16.27). The formation of oxaloacetate from malate also provides NADH for use in subsequent steps in gluconeogenesis. Finally, oxaloacetate is simultaneously *decarboxylated* and *phosphorylated* by *phosphoenolpyruvate carboxykinase* (PEPCK) to generate phosphoenolpyruvate. The phosphoryl donor is GTP. The  $\text{CO}_2$  that was added to pyruvate by pyruvate carboxylase comes off in this step.

The sum of the reactions catalyzed by pyruvate carboxylase and phosphoenolpyruvate carboxykinase is

This pair of reactions bypasses the irreversible reaction catalyzed by pyruvate kinase in glycolysis.

Why is a carboxylation and a decarboxylation required to form phosphoenolpyruvate from pyruvate? Recall that, in glycolysis, the presence of a phosphoryl group traps the unstable enol isomer of pyruvate as phosphoenolpyruvate (p. 461). However, the addition of a phosphoryl group to pyruvate is a highly unfavorable reaction: the  $\Delta G^{\circ'}$  of the reverse of the glycolytic reaction catalyzed by pyruvate kinase is  $+31 \text{ kJ mol}^{-1}$  ( $+7.5 \text{ kcal mol}^{-1}$ ). In gluconeogenesis, the use of the carboxylation and decarboxylation steps results in a much more favorable  $\Delta G^{\circ'}$ . The formation of phosphoenolpyruvate from pyruvate in the gluconeogenic pathway has a  $\Delta G^{\circ'}$  of  $+0.8 \text{ kJ mol}^{-1}$  ( $+0.2 \text{ kcal mol}^{-1}$ ). A molecule of ATP is used to power the addition of a molecule of  $\text{CO}_2$  to pyruvate in the carboxylation step. That  $\text{CO}_2$  is then removed to power the formation of phosphoenolpyruvate in the decarboxylation step. *Decarboxylations often drive reactions that are otherwise highly endergonic.* This metabolic motif is used in the citric acid cycle (Chapter 17), the pentose phosphate pathway (Chapter 20), and fatty acid synthesis (Section 22.4).

### The conversion of fructose 1,6-bisphosphate into fructose 6-phosphate and orthophosphate is an irreversible step

On formation, phosphoenolpyruvate is metabolized by the enzymes of glycolysis but in the reverse direction. These reactions are near equilibrium

under intracellular conditions; so, when conditions favor gluconeogenesis, the reverse reactions will take place until the next irreversible step is reached. This step is the hydrolysis of fructose 1,6-bisphosphate to fructose 6-phosphate and  $P_i$ .

The enzyme responsible for this step is *fructose 1,6-bisphosphatase*. Like its glycolytic counterpart, it is an allosteric enzyme that participates in the regulation of gluconeogenesis. We will return to its regulatory properties later in the chapter.

### The generation of free glucose is an important control point

The fructose 6-phosphate generated by fructose 1,6-bisphosphatase is readily converted into glucose 6-phosphate. In most tissues, gluconeogenesis ends here. Free glucose is not generated; rather, the glucose 6-phosphate is processed in some other fashion, notably to form glycogen. One advantage to ending gluconeogenesis at glucose 6-phosphate is that, unlike free glucose, the molecule is not transported out of the cell. The enzyme responsible for the conversion of glucose 6-phosphate into glucose, *glucose 6-phosphatase*, is present only in tissues whose metabolic duty is to maintain blood-glucose homeostasis—tissues that release glucose into the blood. These tissues are the liver and to a lesser extent the kidney.

This final step in the generation of glucose does not take place in the cytoplasm. Rather, glucose 6-phosphate is transported into the lumen of the endoplasmic reticulum, where it is hydrolyzed to glucose by glucose 6-phosphatase, which is bound to the membrane (Figure 16.28). Glucose and  $P_i$  are then shuttled back to the cytoplasm by a pair of transporters. The glucose transporter in the endoplasmic reticulum membrane is like those found in the plasma membrane.

**FIGURE 16.28 Generation of glucose from glucose 6-phosphate.** Several endoplasmic reticulum (ER) proteins play a role in the generation of glucose from glucose 6-phosphate. T1 transports glucose 6-phosphate into the lumen of the ER, whereas T2 and T3 transport  $P_i$  and glucose, respectively, back into the cytoplasm. [Information from A. Buchell and I. D. Waddell, *Biochem. Biophys. Acta* 1092:129–137, 1991.]

### Six high-transfer-potential phosphoryl groups are spent in synthesizing glucose from pyruvate

The formation of glucose from pyruvate is energetically unfavorable unless it is coupled to reactions that are favorable. Compare the stoichiometry of gluconeogenesis with that of the reverse of glycolysis.

The stoichiometry of gluconeogenesis is

In contrast, the stoichiometry for the reversal of glycolysis is

Note that *six* nucleoside triphosphate molecules are hydrolyzed to synthesize glucose from pyruvate in gluconeogenesis, whereas only *two* molecules of ATP are generated in glycolysis in the conversion of glucose into pyruvate.

**TABLE 16.6** Reactions of gluconeogenesis

Step	Reaction
1	Pyruvate + CO <sub>2</sub> + ATP + H <sub>2</sub> O → oxaloacetate + ADP + P <sub>i</sub> + 2H <sup>+</sup>
2	Oxaloacetate + GTP ⇌ phosphoenolpyruvate + GDP + CO <sub>2</sub>
3	Phosphoenolpyruvate + H <sub>2</sub> O ⇌ 2-phosphoglycerate
4	2-Phosphoglycerate ⇌ 3-phosphoglycerate
5	3-Phosphoglycerate + ATP ⇌ 1,3-bisphosphoglycerate + ADP
6	1,3-Bisphosphoglycerate + NADH + H <sup>+</sup> ⇌ glyceraldehyde 3-phosphate + NAD <sup>+</sup> + P <sub>i</sub>
7	Glyceraldehyde 3-phosphate ⇌ dihydroxyacetone phosphate
8	Glyceraldehyde 3-phosphate + dihydroxyacetone phosphate ⇌ fructose 1,6-bisphosphate
9	Fructose 1,6-bisphosphate + H <sub>2</sub> O → fructose 6-phosphate + P <sub>i</sub>
10	Fructose 6-phosphate ⇌ glucose 6-phosphate
11	Glucose 6-phosphate + H <sub>2</sub> O → + glucose + P <sub>i</sub>

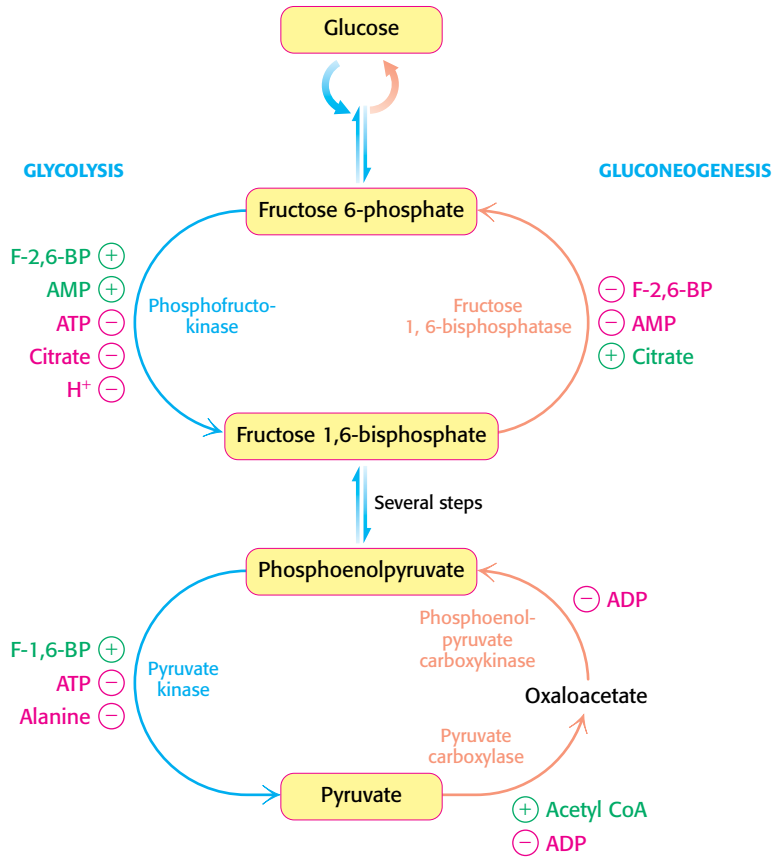

Thus, the extra cost of gluconeogenesis is four high-phosphoryl-transfer-potential molecules for each molecule of glucose synthesized from pyruvate. The four additional molecules having high phosphoryl-transfer potential are needed to turn an energetically unfavorable process (the reversal of glycolysis) into a favorable one (gluconeogenesis). Here we have a clear example of the coupling of reactions: NTP hydrolysis is used to power an energetically unfavorable reaction. The reactions of gluconeogenesis are summarized in Table 16.6.

## 16.4 Gluconeogenesis and Glycolysis Are Reciprocally Regulated

Gluconeogenesis and glycolysis are coordinated so that, within a cell, one pathway is relatively inactive while the other is highly active. If both sets of reactions were highly active at the same time, the net result would be the hydrolysis of four nucleoside triphosphates (two ATP molecules plus two GTP molecules) per reaction cycle. Both glycolysis and gluconeogenesis are highly exergonic under cellular conditions, and so there is no thermodynamic barrier to such simultaneous activity. However, the *amounts* and *activities* of the distinctive enzymes of each pathway are controlled so that both pathways are not highly active at the same time. The rate of glycolysis is also determined by the concentration of glucose, and the rate of gluconeogenesis by the concentrations of lactate and other precursors of glucose. The basic premise of the reciprocal regulation is that, when energy is needed or glycolytic intermediates are needed for biosynthesis, glycolysis will predominate. When there is a surplus of energy and glucose precursors, gluconeogenesis will take over.

### Energy charge determines whether glycolysis or gluconeogenesis will be most active

The first important regulation site is the interconversion of fructose 6-phosphate and fructose 1,6-bisphosphate (Figure 16.29). Consider first a situation in which energy is needed. In this case, the concentration of AMP is high. Under this condition, AMP stimulates phosphofructokinase but inhibits fructose 1,6-bisphosphatase. Thus, glycolysis is turned on and gluconeogenesis is inhibited. Conversely, high levels of ATP and citrate indicate that the energy charge is high and that biosynthetic intermediates are abundant. ATP and citrate inhibit phosphofructokinase, whereas citrate activates fructose 1,6-bisphosphatase. Under these conditions, glycolysis is nearly switched off and gluconeogenesis is promoted. Why does citrate take

**FIGURE 16.29** Reciprocal regulation of gluconeogenesis and glycolysis in the liver. The level of fructose 2,6-bisphosphate is high in the fed state and low in starvation. Another important control is the inhibition of pyruvate kinase by phosphorylation during starvation.

part in this regulatory scheme? As we will see in Chapter 17, citrate reports on the status of the citric acid cycle, the primary pathway for oxidizing fuels in the presence of oxygen. High levels of citrate indicate an energy-rich situation and the presence of precursors for biosynthesis.

Glycolysis and gluconeogenesis are also reciprocally regulated at the interconversion of phosphoenolpyruvate and pyruvate in the liver. The glycolytic enzyme pyruvate kinase is inhibited by allosteric effectors ATP and alanine, which signal that the energy charge is high and that building blocks are abundant. Conversely, pyruvate carboxylase, which catalyzes the first step in gluconeogenesis from pyruvate, is inhibited by ADP. Likewise, ADP inhibits phosphoenolpyruvate carboxykinase. Pyruvate carboxylase is activated by acetyl CoA, which, like citrate, indicates that the citric acid cycle is producing energy and biosynthetic intermediates (Chapter 17). Hence, gluconeogenesis is favored when the cell is rich in biosynthetic precursors and ATP.

### The balance between glycolysis and gluconeogenesis in the liver is sensitive to blood-glucose concentration

In the liver, rates of glycolysis and gluconeogenesis are adjusted to maintain blood-glucose levels. *The signal molecule fructose 2,6-bisphosphate strongly stimulates phosphofructokinase (PFK) and inhibits fructose 1,6-bisphosphatase.* When blood glucose is low, fructose 2,6-bisphosphate loses a phosphoryl group to form fructose 6-phosphate, which is not an allosteric effector of PFK. How is the concentration of fructose 2,6-bisphosphate controlled to rise and fall with blood-glucose levels? Two enzymes regulate the concentration of this molecule: one phosphorylates fructose 6-phosphate and the other dephosphorylates fructose 2,6-bisphosphate. Fructose 2,6-bisphosphate is formed in a reaction catalyzed by *phosphofructokinase 2 (PFK2)*, a different

**FIGURE 16.30 Domain structure of the bifunctional enzyme phosphofructokinase 2.** The kinase domain (purple) is fused to the phosphatase domain (red). The kinase domain is a P-loop NTPase hydrolyase domain, as indicated by the purple shading (Section 9.4). The bar represents the amino acid sequence of the enzyme. [Drawn from 1BIF.pdb.]

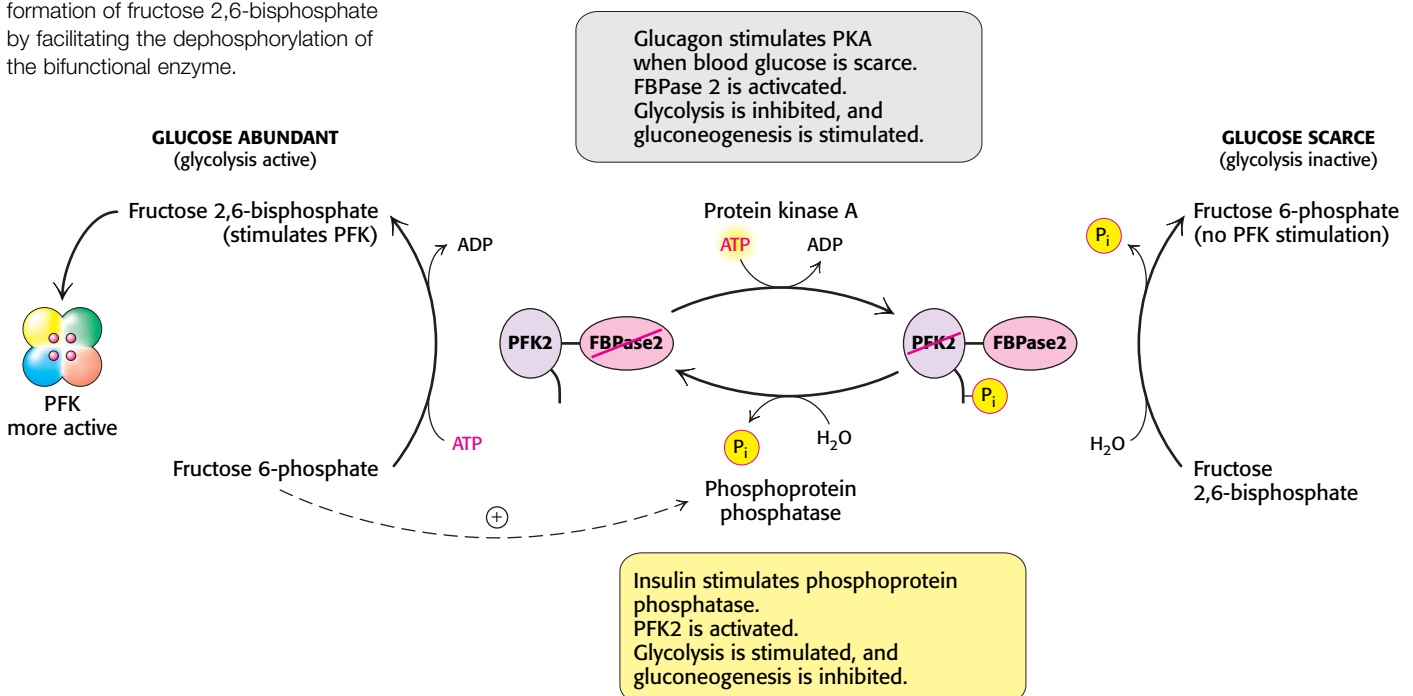

enzyme from phosphofructokinase. Fructose 6-phosphate is formed through the hydrolysis of fructose 2,6-bisphosphate by a specific phosphatase, *fructose bisphosphatase 2* (FBPase2). The striking finding is that *both PFK2 and FBPase2 are present in a single 55-kDa polypeptide chain* (Figure 16.30). This *bifunctional enzyme* contains an N-terminal *regulatory domain*, followed by a *kinase domain* and a *phosphatase domain*. PFK2 resembles adenylate kinase in having a P-loop NTPase domain (Section 9.4), whereas FBPase2 resembles phosphoglycerate mutase (p. 460). Recall that the mutase is essentially a phosphatase. In the bifunctional enzyme, the phosphatase activity evolved to become specific for F-2,6-BP. The bifunctional enzyme itself probably arose by the fusion of genes encoding the kinase and phosphatase domains.

What controls whether PFK2 or FBPase2 dominates the bifunctional enzyme's activities in the liver? The activities of PFK2 and FBPase2 are reciprocally controlled by *phosphorylation of a single serine residue*. When glucose is scarce, such as during a night's fast, a rise in the blood level

of the hormone glucagon triggers a cyclic AMP signal cascade (Section 14.1), leading to the phosphorylation of this bifunctional enzyme by protein kinase A (Figure 16.31). This covalent modification activates FBPase2 and inhibits PFK2, lowering the level of F-2,6-BP. Gluconeogenesis predominates. Glucose formed by the liver under these conditions is essential for the viability of the brain. Glucagon stimulation of protein kinase A also inactivates pyruvate kinase in the liver (p. 473).

Conversely, when blood-glucose levels are high, such as after a meal, gluconeogenesis is not needed. Insulin is secreted and initiates a signal pathway that activates a protein phosphatase, which removes the phosphoryl group from the bifunctional enzyme. This covalent modification activates PFK2 and inhibits FBPase2. The resulting rise in the level of F-2,6-BP accelerates glycolysis. In liver, a key role of glycolysis is to generate metabolites for

**FIGURE 16.31 Control of the synthesis and degradation of fructose 2,6-bisphosphate.** A low blood-glucose level as signaled by glucagon leads to the phosphorylation of the bifunctional enzyme and hence to a lower level of fructose 2,6-bisphosphate, slowing glycolysis. Insulin accelerates the formation of fructose 2,6-bisphosphate by facilitating the dephosphorylation of the bifunctional enzyme.

biosynthesis. The coordinated control of glycolysis and gluconeogenesis is facilitated by the location of the kinase and phosphatase domains on the same polypeptide chain as the regulatory domain.

The hormones insulin and glucagon also regulate the amounts of essential enzymes. These hormones alter gene expression primarily by changing the rate of transcription. Insulin levels rise subsequent to eating, when there is plenty of glucose for glycolysis. To encourage glycolysis, insulin stimulates the expression of phosphofructokinase, pyruvate kinase, and the bifunctional enzyme that makes and degrades F-2,6-BP. Glucagon rises during fasting, when gluconeogenesis is needed to replace scarce glucose. To encourage gluconeogenesis, glucagon inhibits the expression of the three regulated glycolytic enzymes and stimulates instead the production of two key gluconeogenic enzymes, phosphoenolpyruvate carboxykinase and fructose 1,6-bisphosphatase. Transcriptional control in eukaryotes is much slower than allosteric control, taking hours or days instead of seconds to minutes.

### Substrate cycles amplify metabolic signals and produce heat

A pair of reactions such as the phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate and its hydrolysis back to fructose 6-phosphate is called a *substrate cycle*. As already mentioned, both reactions are not fully active at the same time because of reciprocal allosteric controls. However, isotope-labeling studies have shown that some fructose 6-phosphate is phosphorylated to fructose 1,6-bisphosphate even during gluconeogenesis. There also is a limited degree of cycling in other pairs of opposed irreversible reactions. This cycling was regarded as an imperfection in metabolic control, and so substrate cycles have sometimes been called *futile cycles*. In malignant hyperthermia, there is rapid uncontrolled hydrolysis of ATP, which generates heat and can raise the body temperature to 44 °C (111°F). Muscles may become rigid and suffer substantial tissue damage.

Despite such extraordinary circumstances, substrate cycles now seem likely to be biologically important. One possibility is that *substrate cycles amplify metabolic signals*. Suppose that the rate of conversion of A into B is 100 and of B into A is 90, giving an initial net flux of 10. Assume that an allosteric effector increases the  $A \rightarrow B$  rate by 20% to 120 and reciprocally decreases the  $B \rightarrow A$  rate by 20% to 72. The new net flux is 48, and so a 20% change in the rates of the opposing reactions has led to a 380% increase in the net flux. In the example shown in Figure 16.32, this amplification is made possible by the rapid hydrolysis of ATP. The flux down the glycolytic pathway has been suggested to increase as much as 1000-fold at the initiation of intense exercise. Because the allosteric activation of enzymes alone seems unlikely to explain this increased flux, the existence of substrate cycles may partly account for the rapid rise in the rate of glycolysis.

### Lactate and alanine formed by contracting muscle are used by other organs

Lactate produced by active skeletal muscle and erythrocytes is a source of energy for other organs. Erythrocytes lack mitochondria and can never oxidize glucose completely. In contracting fast-twitch skeletal muscle fibers during vigorous exercise, the rate at which glycolysis produces pyruvate exceeds the rate at which the citric acid cycle oxidizes it. In these cells, lactate dehydrogenase reduces excess pyruvate to lactate to restore redox balance (p. 464). However, lactate is a dead end in metabolism. It must be converted back into pyruvate before it can be metabolized. Both pyruvate and lactate diffuse out of these cells through carriers into the

**FIGURE 16.32 Substrate cycle.** This ATP-driven cycle operates at two different rates. A small change in the rates of the two opposing reactions results in a large change in the *net* flux of product B.

**FIGURE 16.33 The Cori cycle.** Lactate formed by active muscle is converted into glucose by the liver. This cycle shifts part of the metabolic burden of active muscle to the liver. The symbol ~P represents nucleoside triphosphates.

blood. In contracting skeletal muscle, the formation and release of lactate lets the muscle generate ATP in the absence of oxygen and shifts the burden of metabolizing lactate from muscle to other organs. The pyruvate and lactate in the bloodstream have two fates. In one fate, the plasma membranes of some cells, particularly cells in cardiac muscle and slow-twitch (type 1) skeletal muscle, contain carriers that make the cells highly permeable to lactate and pyruvate. These molecules diffuse from the blood into such permeable cells. Once inside these well-oxygenated cells, lactate can be reverted back to pyruvate and metabolized through the citric acid cycle and oxidative phosphorylation to generate ATP. The use of lactate in place of glucose by these cells makes more circulating glucose available to the active muscle cells. In the other fate, excess lactate enters the liver and is converted first into pyruvate and then into glucose by the

gluconeogenic pathway. Contracting skeletal muscle supplies lactate to the liver, which uses it to synthesize and release glucose. Thus, the liver restores the level of glucose necessary for active muscle cells, which derive ATP from the glycolytic conversion of glucose into lactate. These reactions constitute the Cori cycle (Figure 16.33).

Studies have shown that alanine, like lactate, is a major precursor of glucose in the liver. The alanine is generated in muscle when the carbon skeletons of some amino acids are used as fuels. The nitrogens from these amino acids are transferred to pyruvate to form alanine; the reverse reaction takes place in the liver. This process also helps maintain nitrogen balance. The interplay between glycolysis and gluconeogenesis is summarized in Figure 16.34, which shows how these pathways help meet the energy needs of different cell types.

**FIGURE 16.34 PATHWAY INTEGRATION: Cooperation between glycolysis and gluconeogenesis during a sprint.**

Glycolysis and gluconeogenesis are coordinated, in a tissue-specific fashion, to ensure that the energy needs of all cells are met. Consider a sprinter. In skeletal leg muscle, glucose will be metabolized aerobically to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  or, more likely (thick arrows) during a sprint, anaerobically to lactate. In cardiac muscle, the lactate can be converted into pyruvate and used as a fuel, along with glucose, to power the heartbeats to keep the sprinter's blood flowing. Gluconeogenesis, a primary function of the liver, will be taking place rapidly (thick arrows) to ensure that enough glucose is present in the blood for skeletal and cardiac muscle, as well as for other tissues. Glycogen, glycerol, and amino acids are other sources of energy that we will learn about in later chapters.

Isozymic forms of lactate dehydrogenase in different tissues catalyze the interconversions of pyruvate and lactate (Section 10.2). Lactate dehydrogenase is a tetramer of two kinds of 35-kDa subunits encoded by similar genes: the H type predominates in the heart, and the homologous M type in skeletal muscle and the liver. These subunits associate to form five types of tetramers:  $H_4$ ,  $H_3M_1$ ,  $H_2M_2$ ,  $H_1M_3$ , and  $M_4$ . The  $H_4$  isozyme (type 1) has higher affinity for substrates than that of the  $M_4$  isozyme (type 5) and, unlike  $M_4$ , is allosterically inhibited by high levels of pyruvate. The other isozymes have intermediate properties, depending on the ratio of the two kinds of chains. The  $H_4$  isozyme oxidizes lactate to pyruvate, which is then used as a fuel by the heart through aerobic metabolism. Indeed, heart muscle never functions anaerobically. In contrast,  $M_4$  is optimized to operate in the reverse direction, to convert pyruvate into lactate to allow glycolysis to proceed under anaerobic conditions. Interestingly, endurance training increases the  $H_4$  isozyme in slow-twitch muscle fibers, enabling these fibers to use the lactate generated by other fiber types.

### Glycolysis and gluconeogenesis are evolutionarily intertwined

The metabolism of glucose has ancient origins. Organisms living in the early biosphere depended on the anaerobic generation of energy until significant amounts of oxygen began to accumulate 2 billion years ago. Glycolytic enzymes were most likely derived independently rather than by gene duplication, because glycolytic enzymes with similar properties do not have similar amino acid sequences. Although there are four kinases and two isomerases in the pathway, sequence and structural comparisons suggest that these sets of enzymes are not related to one another by divergent evolution. The common dinucleotide-binding domain found in the dehydrogenases (Figure 16.12) and the  $\alpha\beta$  barrels are the only major recurring elements.

We can speculate on the relationship between glycolysis and gluconeogenesis if we think of glycolysis as consisting of two segments: the metabolism of hexoses (the upper segment) and the metabolism of trioses (the lower segment). The enzymes of the upper segment are different in some species and are missing entirely in some archaea, whereas enzymes of the lower segment are quite conserved. In fact, four enzymes of the lower segment are present in all species. *This lower part of the pathway is common to glycolysis and gluconeogenesis.* This common part of the two pathways may be the oldest part, constituting the core to which the other steps were added. The upper part would have varied according to the sugars that were available to evolving organisms in particular niches. Interestingly, this core part of carbohydrate metabolism can generate triose precursors for ribose sugars, a component of RNA and a critical requirement for the RNA world. Thus, we are left with the unanswered question, Was the original core pathway used for energy conversion or biosynthesis?

## SUMMARY

### 16.1 Glycolysis Is an Energy-Conversion Pathway in Many Organisms

Glycolysis is the set of reactions that converts glucose into pyruvate. The 10 reactions of glycolysis take place in the cytoplasm. In the first stage, glucose is converted into fructose 1,6-bisphosphate by a phosphorylation, an isomerization, and a second phosphorylation reaction. Fructose 1,6-bisphosphate is then cleaved by aldolase into dihydroxyacetone phosphate and glyceraldehyde 3-phosphate, which are readily interconvertible. Two molecules of ATP are consumed per molecule

of glucose in these reactions. In the second stage, ATP is generated. Glyceraldehyde 3-phosphate is oxidized and phosphorylated to form 1,3-bisphosphoglycerate, an acyl phosphate with a high phosphoryl-transfer potential. This molecule transfers a phosphoryl group to ADP to form ATP and 3-phosphoglycerate. A phosphoryl shift and a dehydration form phosphoenolpyruvate, a second intermediate with a high phosphoryl-transfer potential. Another molecule of ATP is generated as phosphoenolpyruvate is converted into pyruvate. There is a net gain of two molecules of ATP in the formation of two molecules of pyruvate from one molecule of glucose.

The electron acceptor in the oxidation of glyceraldehyde 3-phosphate is  $\text{NAD}^+$ , which must be regenerated for glycolysis to continue. In aerobic organisms, the NADH formed in glycolysis transfers its electrons to  $\text{O}_2$  through the electron-transport chain, which thereby regenerates  $\text{NAD}^+$ . Under anaerobic conditions and in some microorganisms,  $\text{NAD}^+$  is regenerated by the reduction of pyruvate to lactate. In other microorganisms,  $\text{NAD}^+$  is regenerated by the reduction of pyruvate to ethanol. These two processes are examples of fermentations.

### 16.2 The Glycolytic Pathway Is Tightly Controlled

The glycolytic pathway has a dual role: it degrades glucose to generate ATP, and it provides building blocks for the synthesis of cellular components. The rate of conversion of glucose into pyruvate is regulated to meet these two major cellular needs. Under physiological conditions, the reactions of glycolysis are readily reversible except for those catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase. Phosphofructokinase, the most important control element in glycolysis, is inhibited by high levels of ATP and citrate, and it is activated by AMP and fructose 2,6-bisphosphate. In the liver, this bisphosphate signals that glucose is abundant. Hence, phosphofructokinase is active when either energy or building blocks are needed. Hexokinase is inhibited by glucose 6-phosphate, which accumulates when phosphofructokinase is inactive. ATP and alanine allosterically inhibit pyruvate kinase, the other control site, and fructose 1,6-bisphosphate activates the enzyme. Consequently, pyruvate kinase is maximally active when the energy charge is low and glycolytic intermediates accumulate.

### 16.3 Glucose Can Be Synthesized from Noncarbohydrate Precursors

Gluconeogenesis, which occurs primarily in the liver, is the synthesis of glucose from noncarbohydrate sources, such as lactate, amino acids, glycerol, and alanine produced from pyruvate by active skeletal muscle. Several of the reactions that convert pyruvate into glucose are common to glycolysis. Gluconeogenesis, however, requires four new reactions to bypass the essential irreversibility of three reactions in glycolysis. In two of the new reactions, pyruvate is carboxylated in mitochondria to oxaloacetate, which in turn is decarboxylated and phosphorylated in the cytoplasm to phosphoenolpyruvate. ATP and GTP are consumed in these reactions, which are catalyzed by pyruvate carboxylase and phosphoenolpyruvate carboxykinase, respectively. The other distinctive reactions of gluconeogenesis are the hydrolyses of fructose 1,6-bisphosphate and glucose 6-phosphate, which are catalyzed by specific phosphatases.

### 16.4 Gluconeogenesis and Glycolysis Are Reciprocally Regulated

Gluconeogenesis and glycolysis are reciprocally regulated so that one pathway is relatively inactive while the other is highly active. Phosphofructokinase and fructose 1,6-bisphosphatase are key

control points. Fructose 2,6-bisphosphate, an intracellular signal molecule present at higher levels when glucose is abundant, activates glycolysis and inhibits gluconeogenesis by regulating these enzymes. Pyruvate kinase and pyruvate carboxylase are regulated by other effectors so that both are not maximally active at the same time. Allosteric regulation and reversible phosphorylation, which are rapid, are complemented by transcriptional control, which takes place in hours or days.

## KEY TERMS

glycolysis (p. 449)	pyruvate kinase (p. 461)	pyruvate carboxylase (p. 478)
lactic acid fermentation (p. 449)	fermentation (p. 462)	biotin (p. 479)
alcoholic fermentation (p. 449)	obligate anaerobe (p. 464)	phosphoenolpyruvate carboxykinase (p. 480)
gluconeogenesis (p. 449)	facultative anaerobe (p. 464)	fructose 1,6-bisphosphatase (p. 481)
hexokinase (p. 451)	Rossmann fold (p. 465)	glucose 6-phosphatase (p. 481)
kinase (p. 453)	committed step (p. 471)	bifunctional enzyme (p. 484)
phosphofructokinase (PFK) (p. 454)	feedforward stimulation (p. 472)	substrate cycle (p. 485)
thioester intermediate (p. 457)	glucokinase (p. 473)	Cori cycle (p. 486)
substrate-level phosphorylation (p. 460)	aerobic glycolysis (p. 474)	

## PROBLEMS

- Gross versus net.* The gross yield of ATP from the metabolism of glucose to two molecules of pyruvate is four molecules of ATP. However, the net yield is only two molecules of ATP. Why are the gross and net values different?
- Go together like the owl and the pussycat.* Match each term with its description.
 

(a) Hexokinase _____	1. Forms fructose 1,6-bisphosphate
(b) Phosphoglucose isomerase _____	2. Generates the first high-phosphoryl-transfer-potential compound that is not ATP
(c) Phosphofructokinase _____	3. Converts glucose 6-phosphate into fructose 6-phosphate
(d) Aldolase _____	4. Phosphorylates glucose
(e) Triose phosphate isomerase _____	5. Generates the second molecule of ATP
(f) Glyceraldehyde 3-phosphate dehydrogenase _____	6. Cleaves fructose 1, 6-bisphosphate
(g) Phosphoglycerate kinase _____	7. Generates the second high-phosphoryl-transfer-potential compound that is not ATP
(h) Phosphoglycerate mutase _____	8. Catalyzes the interconversion of three-carbon isomers
(i) Enolase _____	9. Converts 3-phosphoglycerate into 2-phosphoglycerate
(j) Pyruvate kinase _____	10. Generates the first molecule of ATP
- Who takes? Who gives?* Lactic acid fermentation and alcoholic fermentation are oxidation–reduction reactions. Identify the ultimate electron donor and electron acceptor.
- ATP yield.* Each of the following molecules is processed by glycolysis to lactate. How much ATP is generated from each molecule?
  - Glucose 6-phosphate
  - Dihydroxyacetone phosphate
  - Glyceraldehyde 3-phosphate
  - Fructose
  - Sucrose
- Enzyme redundancy?* Why is it advantageous for the liver to have both hexokinase and glucokinase to phosphorylate glucose?
- Magic?* The interconversion of DHAP and GAP greatly favors the formation of DHAP at equilibrium. Yet the conversion of DHAP by triose phosphate isomerase proceeds readily. Why?
- Between two extremes.* What is the role of a thioester in the formation of ATP in glycolysis?
- Corporate sponsors.* Some of the early research on glycolysis was supported by the brewing industry. Why would the brewing industry be interested in glycolysis?
- Recommended daily allowance.* The recommended daily allowance for the vitamin niacin is 15 mg per day. How would glycolysis be affected by niacin deficiency?
- Who's on first?* Although both hexokinase and phosphofructokinase catalyze irreversible steps in glycolysis and the hexokinase-catalyzed step is first, phosphofructokinase

is nonetheless the pacemaker of glycolysis. What does this information tell you about the fate of the glucose 6-phosphate formed by hexokinase?

11. *The tortoise and the hare.* Why is the regulation of phosphofructokinase by energy charge not as important in the liver as it is in muscle?

12. *Like Minneapolis and St. Paul.* Match each term with its description.

- |   |  |
|---|--|
| (a) Lactate _____                           | 1. Generates oxaloacetate                                  |
| (b) Pyruvate carboxylase _____              | 2. Readily converted into DHAP                             |
| (c) Acetyl CoA _____                        | 3. Generates a high-phosphoryl-transfer-potential compound |

| (e) Glycerol _____                          | 5. Gluconeogenic counterpart of PFK                        |
| (f) Fructose 1,6-bisphosphatase _____       | 6. Readily converted into pyruvate                         |
| (g) Glucose 6-phosphatase _____             | 7. Required for pyruvate carboxylase activity              |

13. *Running in reverse.* Why can't the reactions of the glycolytic pathway simply be run in reverse to synthesize glucose?

14. *Road blocks.* What reactions of glycolysis are not readily reversible under intracellular conditions?

15. *No pickling.* Why is it in the muscle's best interest to export lactic acid into the blood during intense exercise?

16. *Après vous.* Why is it physiologically advantageous for the pancreas to use GLUT2, with a high  $K_M$ , as the transporter that allows glucose entry into  $\beta$  cells?

17. *Bypass.* In the liver, fructose can be converted into glyceraldehyde 3-phosphate and dihydroxyacetone phosphate without passing through the phosphofructokinase-regulated reaction. Show the reactions that make this conversion possible. Why might ingesting high levels of fructose have deleterious physiological effects?

18. *Match 'em 1.* The following sequence is a part of the sequence of reactions in gluconeogenesis.

Match the capital letters representing the reaction in the gluconeogenic pathway with parts *a*, *b*, *c*, etc.

- takes place in mitochondria
- takes place in the cytoplasm
- produces  $\text{CO}_2$

- consumes  $\text{CO}_2$
- requires NADH
- produces NADH
- requires ATP
- requires GTP
- requires thiamine
- requires biotin
- is regulated by acetyl CoA.

19. *Like Batman and Robin.* Match parts *a* through *j* with parts 1 through 10.

- |  |  |
|--|--|

| (j) $[\text{ATP}] > [\text{AMP}]$ _____              | 10. Stimulates phosphofructokinase                   |

20. *Trouble ahead.* Suppose that a microorganism that was an obligate anaerobe suffered a mutation that resulted in the loss of triose phosphate isomerase activity. How would this loss affect the ATP yield of fermentation? Could such an organism survive?

21. *Kitchen chemistry.* Sucrose is commonly used to preserve fruits. Why is glucose not suitable for preserving foods?

22. *Tracing carbon atoms 1.* Glucose labeled with  $^{14}\text{C}$  at C-1 is incubated with the glycolytic enzymes and necessary cofactors.

- What is the distribution of  $^{14}\text{C}$  in the pyruvate that is formed? (Assume that the interconversion of glyceraldehyde 3-phosphate and dihydroxyacetone phosphate is very rapid compared with the subsequent step.)
- If the specific activity of the glucose substrate is  $10 \text{ mCi mmol}^{-1}$  (millicuries per mole, a measure of radioactivity per mole), what is the specific activity of the pyruvate that is formed?

23. *Lactic acid fermentation.*

- Write a balanced equation for the conversion of glucose into lactate.

(b) Calculate the standard free-energy change of this reaction by using the data given in Table 16.1 and the fact that  $\Delta G^{\circ}$  is  $-25 \text{ kJ mol}^{-1}$  ( $-6 \text{ kcal mol}^{-1}$ ) for the following reaction:

What is the free-energy change ( $\Delta G$ , not  $\Delta G^{\circ}$ ) of this reaction when the concentrations of reactants are: glucose, 5 mM; lactate, 0.05 mM; ATP, 2 mM; ADP, 0.2 mM; and  $P_i$ , 1 mM?

24. *High potential.* What is the equilibrium ratio of phosphoenolpyruvate to pyruvate under standard conditions when  $[\text{ATP}]/[\text{ADP}] = 10$ ?

25. *Hexose-triose equilibrium.* What are the equilibrium concentrations of fructose 1,6-bisphosphate, dihydroxyacetone phosphate, and glyceraldehyde 3-phosphate when 1 mM fructose 1,6-bisphosphate is incubated with aldolase under standard conditions?

26. *Double labeling.* 3-Phosphoglycerate labeled uniformly with  $^{14}\text{C}$  is incubated with 1,3-BPG labeled with  $^{32}\text{P}$  at C-1. What is the radioisotope distribution of the 2,3-BPG that is formed on addition of BPG mutase?

27. *An informative analog.* Xylose has the same structure as that of glucose except that it has a hydrogen atom at G-5 in place of a hydroxymethyl group. The rate of ATP hydrolysis by hexokinase is markedly enhanced by the addition of xylose. Why?

28. *Distinctive sugars.* The intravenous infusion of fructose into healthy volunteers leads to a two- to fivefold increase in the level of lactate in the blood, a far greater increase than that observed after the infusion of the same amount of glucose.

(a) Why is glycolysis more rapid after the infusion of fructose?

(b) Fructose has been used in place of glucose for intravenous feeding. Why is this use of fructose unwise?

29. *It is not hard to meet expenses. They are everywhere.* What energetic barrier prevents glycolysis from simply running in reverse to synthesis glucose? What is the energetic cost to overcome this barrier?

30. *Match 'em 2.* Indicate which of the conditions listed in the right-hand column increase the activity of the glycolytic and gluconeogenic pathways.

- |                           |  |

31. *Waste not, want not.* Why is the conversion of lactic acid from the blood into glucose in the liver in an organism's best interest?

32. *Road blocks bypassed.* How are the irreversible reactions of glycolysis bypassed in gluconeogenesis?

33. *Pointlessness averted.* What are the regulatory means that prevent high levels of activity in glycolysis and gluconeogenesis simultaneously?

34. *Different needs.* Liver is primarily a gluconeogenic tissue, whereas muscle is primarily glycolytic. Why does this division of labor make good physiological sense?

35. *Metabolic mutants.* What would be the effect on an organism's ability to use glucose as an energy source if a mutation inactivated glucose 6-phosphatase in the liver?

36. *Never let me go.* Why does the lack of glucose 6-phosphatase activity in the brain and muscle make good physiological sense?

37. *Counting high-energy compounds 1.* How many NTP molecules are required for the synthesis of one molecule of glucose from two molecules of pyruvate? How many NADH molecules?

38. *Counting high-energy compounds 2.* How many NTP molecules are required to synthesize glucose from each of the following compounds?

- Glucose 6-phosphate
- Fructose 1,6-bisphosphate
- Two molecules of oxaloacetate
- Two molecules of dihydroxyacetone phosphate

39. *Lending a hand.* How might enzymes that remove amino groups from alanine and aspartate contribute to gluconeogenesis?

40. *More metabolic mutants.* Predict the effect of each of the following mutations on the pace of glycolysis in liver cells:

- Loss of the allosteric site for ATP in phosphofructokinase
- Loss of the binding site for citrate in phosphofructokinase
- Loss of the phosphatase domain of the bifunctional enzyme that controls the level of fructose 2,6-bisphosphate
- Loss of the binding site for fructose 1,6-bisphosphate in pyruvate kinase

41. *Yet another metabolic mutant.* What are the likely consequences of a genetic disorder rendering fructose 1,6-bisphosphatase in the liver less sensitive to regulation by fructose 2,6-bisphosphate?

42. *Biotin snatcher.* Avidin, a 70-kDa protein in egg white, has very high affinity for biotin. In fact, it is a highly specific inhibitor of biotin enzymes. Which of the following

conversions would be blocked by the addition of avidin to a cell homogenate?

- Glucose  $\rightarrow$  pyruvate
- Pyruvate  $\rightarrow$  glucose
- Oxaloacetate  $\rightarrow$  glucose
- Malate  $\rightarrow$  oxaloacetate
- Pyruvate  $\rightarrow$  oxaloacetate
- Glyceraldehyde 3-phosphate  $\rightarrow$  fructose 1,6-bisphosphate

43. *Tracing carbon atoms 2.* If cells synthesizing glucose from lactate are exposed to  $\text{CO}_2$  labeled with  $^{14}\text{C}$ , what will be the distribution of label in the newly synthesized glucose?

44. *Arsenate poisoning.* Arsenate ( $\text{AsO}_4^{3-}$ ) closely resembles  $\text{P}_i$  in structure and reactivity. In the reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase, arsenate can replace phosphate in attacking the energy-rich thioester intermediate. The product of this reaction, 1-arseno-3-phosphoglycerate, is unstable. It and other acyl arsenates are rapidly and spontaneously hydrolyzed. What is the effect of arsenate on energy generation in a cell?

45. *Reduce, reuse, recycle.* In the conversion of glucose into two molecules of lactate, the NADH generated earlier in the pathway is oxidized to  $\text{NAD}^+$ . Why is it not to the cell's advantage to simply make more  $\text{NAD}^+$  so that the regeneration would not be necessary? After all, the cell would save much energy because it would no longer need to synthesize lactic acid dehydrogenase.

46. *Adenylate kinase again.* Adenylate kinase, an enzyme considered in great detail in Chapter 9, is responsible for interconverting the adenylate nucleotide pool:

The equilibrium constant for this reaction is close to 1, inasmuch as the number of phosphoanhydride bonds is the same on each side of the equation. Using the equation for the equilibrium constant for this reaction, show why changes in  $[\text{AMP}]$  are a more effective indicator of the adenylate pool than  $[\text{ATP}]$ .

47. *Working at cross-purposes?* Gluconeogenesis takes place during intense exercise, which seems counterintuitive. Why would an organism synthesize glucose and at the same time use glucose to generate energy?

48. *Powering pathways.* Compare the stoichiometries of glycolysis and gluconeogenesis. Recall that the input of one ATP equivalent changes the equilibrium constant of a reaction by a factor of about  $10^8$  (Section 15.2). By what factor do the additional high-phosphoryl-transfer compounds alter the equilibrium constant of gluconeogenesis?

### Mechanism Problem

49. *Argument by analogy.* Propose a mechanism for the conversion of glucose 6-phosphate into fructose 6-phosphate

by phosphoglucose isomerase based on the mechanism of triose phosphate isomerase.

### Chapter Integration Problems

50. *Not just for energy.* People with galactosemia display central nervous system abnormalities even if galactose is eliminated from the diet. The precise reason for it is not known. Suggest a plausible explanation.

51. *Power to the rbc!* Hexokinase in red blood cells has a  $K_M$  of approximately  $50 \mu\text{M}$ . Because life is hard enough as it is, let's assume that the hexokinase displays Michaelis-Menten kinetics. What concentration of blood glucose would yield  $v_o$  equal to  $90\%V_{\text{max}}$ ? What does this result tell you if normal blood glucose levels range between approximately 3.6 and 6.1 mM?

52. *State function.* Fructose 2,6-bisphosphate is a potent stimulator of phosphofructokinase. Explain how fructose 2,6-bisphosphate might function in the concerted model for allosteric enzymes.

### Data Interpretation Problems

53. *Now, that's unusual.* Phosphofructokinase has recently been isolated from the hyperthermophilic archaeon *Pyrococcus furiosus*. It was subjected to standard biochemical analysis to determine basic catalytic parameters. The processes under study were of the form

The assay measured the increase in fructose 1,6-bisphosphate. Selected results are shown in the adjoining graph.

[Data from J. E. Tuininga et al. *J. Biol. Chem.* 274:21023–21028, 1999.]

- How does the *P. furiosus* phosphofructokinase differ from the phosphofructokinase considered in this chapter?
- What effects do AMP and ATP have on the reaction with ADP?

54. *Cool bees.* In principle, a futile cycle that includes phosphofructokinase and fructose 2,6-bisphosphatase could be used to generate heat. The heat could be used to warm

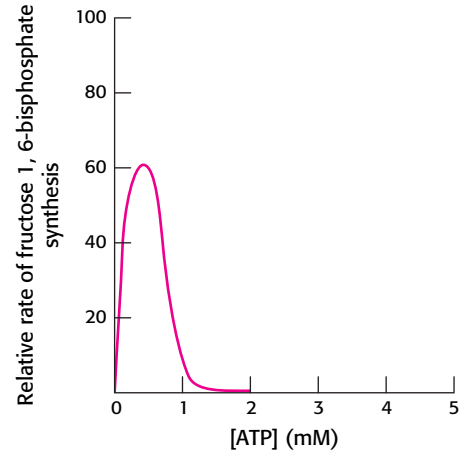

tissues. For instance, certain bumblebees have been reported to use such a futile cycle to warm their flight muscles on cool mornings. Scientists undertook a series of experiments to determine if a number of species of bumblebee use this futile cycle. Their approach was to measure the activity of PFK and F-1,6-BPase in flight muscle.

- What was the rationale for comparing the activities of these two enzymes?
- The data below show the activities of both enzymes for a variety of bumblebee species (genera *Bombus* and *Psithyrus*). Do these results support the notion that bumblebees use futile cycles to generate heat? Explain.
- In which species might futile cycling take place? Explain your reasoning.
- Do these results prove that futile cycling does not participate in heat generation?

[Data from J. F. Staples, E. L. Koen, and T. M. Lavery, *J. Exp. Biol.* 207:749–754, 2004, p. 751.]

55. *Confused?* The adjoining graph shows muscle phosphofructokinase activity as a function of ATP concentration in the presence of a constant concentration of fructose 6-phosphate. Explain these results and discuss how they relate to the role of phosphofructokinase in glycolysis.

# The Citric Acid Cycle

Roundabouts, or traffic circles, function as hubs to facilitate traffic flow. The citric acid cycle is the biochemical hub of the cell, oxidizing carbon fuels, usually in the form of acetyl CoA, as well as serving as a source of precursors for biosynthesis. [(Left) Lynn Saville/Getty Images.]

The metabolism of glucose to pyruvate in glycolysis, an anaerobic process, harvests but a fraction of the ATP available from glucose. Most of the ATP generated in metabolism is provided by the *aerobic* processing of glucose. This process starts with the complete oxidation of glucose derivatives to carbon dioxide. This oxidation takes place in a series of reactions called the *citric acid cycle*, also known as the *tricarboxylic acid* (TCA) cycle or the *Krebs cycle*. The citric acid cycle is the *final common pathway for the oxidation of fuel molecules*—carbohydrates, fatty acids, and amino acids. Most fuel molecules enter the cycle as *acetyl coenzyme A*.

Acetyl coenzyme A (Acetyl CoA)

**FIGURE 17.1 Mitochondrion.** The double membrane of the mitochondrion is evident in this electron micrograph. The numerous invaginations of the inner mitochondrial membrane are called cristae. The oxidative decarboxylation of pyruvate and the sequence of reactions in the citric acid cycle take place within the matrix. [(Left) Omikron/Photo Researchers.]

Under aerobic conditions, the pyruvate generated from glucose is oxidatively decarboxylated to form acetyl CoA. In eukaryotes, the reactions of the citric acid cycle take place in the matrix of the mitochondria (Figure 17.1), in contrast with those of glycolysis, which take place in the cytoplasm.

### The citric acid cycle harvests high-energy electrons

The citric acid cycle is the central metabolic hub of the cell. It is the gateway to the aerobic metabolism of any molecule that can be transformed into an acetyl group or a component of the citric acid cycle. The cycle is also an important source of precursors for the building blocks of many other molecules such as amino acids, nucleotide bases, and porphyrin (the organic component of heme). The citric acid cycle component, oxaloacetate, is also an important precursor to glucose (Section 16.3).

**FIGURE 17.2 Overview of the citric acid cycle.** The citric acid cycle oxidizes two-carbon units, producing two molecules of  $\text{CO}_2$ , one molecule of ATP, and high-energy electrons in the form of NADH and  $\text{FADH}_2$ .

What is the function of the citric acid cycle in transforming fuel molecules into ATP? Recall that fuel molecules are carbon compounds that are capable of being oxidized—that is, of losing electrons (Chapter 15). The citric acid cycle includes a series of oxidation–reduction reactions that result in the oxidation of an acetyl group to two molecules of carbon dioxide. This oxidation generates high-energy electrons that will be used to power the synthesis of ATP. *The function of the citric acid cycle is the harvesting of high-energy electrons from carbon fuels.*

The overall pattern of the citric acid cycle is shown in Figure 17.2. A four-carbon compound (oxaloacetate) condenses with a two-carbon acetyl unit to yield a six-carbon tricarboxylic acid. The six-carbon compound releases  $\text{CO}_2$  twice in two successive oxidative decarboxylations that yield high-energy electrons. A four-carbon compound remains. This four-carbon compound is further processed to regenerate oxaloacetate, which can initiate another round of the cycle. Two carbon atoms enter the cycle as an acetyl unit and two carbon atoms leave the cycle in the form of two molecules of  $\text{CO}_2$ .

Note that the citric acid cycle itself neither generates a large amount of ATP nor includes oxygen as a reactant (Figure 17.3). Instead, the citric acid

**FIGURE 17.3 Cellular respiration.** The citric acid cycle constitutes the first stage in cellular respiration, the removal of high-energy electrons from carbon fuels in the form of NADH and  $\text{FADH}_2$  (blue pathway). These electrons reduce  $\text{O}_2$  to generate a proton gradient (red pathway), which is used to synthesize ATP (green pathway). The reduction of  $\text{O}_2$  and the synthesis of ATP constitute oxidative phosphorylation.

cycle removes electrons from acetyl CoA and uses these electrons to reduce  $\text{NAD}^+$  and FAD to form NADH and  $\text{FADH}_2$ . Three hydride ions (hence, six electrons) are transferred to three molecules of nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ), and one pair of hydrogen atoms (hence, two electrons) is transferred to one molecule of flavin adenine dinucleotide (FAD). Electrons released in the reoxidation of NADH and  $\text{FADH}_2$  flow through a series of membrane proteins (referred to as the *electron-transport chain*) to generate a proton gradient across the inner mitochondrial membrane. These protons then flow through ATP synthase to generate ATP from ADP and inorganic phosphate. These electron carriers yield nine molecules of ATP when they are oxidized by  $\text{O}_2$  in *oxidative phosphorylation* (Chapter 18).

The citric acid cycle, in conjunction with oxidative phosphorylation, provides the preponderance of energy used by aerobic cells—in human beings, greater than 90%. It is highly efficient because the oxidation of a limited number of citric acid cycle molecules can generate large amounts of NADH and  $\text{FADH}_2$ . Note in Figure 17.2 that the four-carbon molecule, oxaloacetate, that initiates the first step in the citric acid cycle is regenerated at the end of one passage through the cycle. Thus, one molecule of oxaloacetate is capable of participating in the oxidation of many acetyl molecules.

### 17.1 The Pyruvate Dehydrogenase Complex Links Glycolysis to the Citric Acid Cycle

Carbohydrates, most notably glucose, are processed by glycolysis into pyruvate (Chapter 16). Under anaerobic conditions, the pyruvate is converted into lactate or ethanol, depending on the organism. Under aerobic conditions, the pyruvate is transported into mitochondria by a specific carrier protein embedded in the mitochondrial membrane. In the mitochondrial matrix, pyruvate is oxidatively decarboxylated by the *pyruvate dehydrogenase complex* to form acetyl CoA.

*This irreversible reaction is the link between glycolysis and the citric acid cycle* (Figure 17.4). Note that the pyruvate dehydrogenase complex produces  $\text{CO}_2$  and captures high-transfer-potential electrons in the form of NADH. Thus, the pyruvate dehydrogenase reaction has many of the key features of the reactions of the citric acid cycle itself.

The pyruvate dehydrogenase complex is a large, highly integrated complex of three distinct enzymes (Table 17.1). Pyruvate dehydrogenase complex is a member of a family of homologous complexes that include the citric acid cycle enzyme  $\alpha$ -ketoglutarate dehydrogenase complex (p. 505). These complexes are giant, larger than ribosomes, with molecular masses ranging from 4 million to 10 million kDa (Figure 17.5). As we will see, their

**FIGURE 17.4** The link between glycolysis and the citric acid cycle. Pyruvate produced by glycolysis is converted into acetyl CoA, the fuel of the citric acid cycle.

**TABLE 17.1** Pyruvate dehydrogenase complex of *E. coli*

Enzyme	Abbreviation	Number of chains	Prosthetic group	Reaction catalyzed
Pyruvate dehydrogenase component	E <sub>1</sub>	24	TPP	Oxidative decarboxylation of pyruvate
Dihydrolipoyl transacetylase	E <sub>2</sub>	24	Lipoamide	Transfer of acetyl group to CoA
Dihydrolipoyl dehydrogenase	E <sub>3</sub>	12	FAD	Regeneration of the oxidized form of lipoamide

elaborate structures allow groups to travel from one active site to another, connected by tethers to the core of the structure.

### Mechanism: The synthesis of acetyl coenzyme A from pyruvate requires three enzymes and five coenzymes

The mechanism of the pyruvate dehydrogenase reaction is wonderfully complex, more so than is suggested by its simple stoichiometry. The reaction requires the participation of the three enzymes of the pyruvate dehydrogenase complex and five coenzymes. The coenzymes *thiamine pyrophosphate* (TPP), *lipoic acid*, and *FAD* serve as catalytic cofactors, and *CoA* and  $\text{NAD}^+$  are stoichiometric cofactors, cofactors that function as substrates.

The conversion of pyruvate into acetyl CoA consists of three steps: decarboxylation, oxidation, and transfer of the resultant acetyl group to CoA. A fourth step is required to regenerate the active enzyme.

These steps must be coupled to preserve the free energy derived from the decarboxylation step to drive the formation of NADH and acetyl CoA:

1. *Decarboxylation*. Pyruvate combines with TPP and is then decarboxylated to yield hydroxyethyl-TPP (Figure 17.6).

This reaction, the rate limiting step in acetyl CoA synthesis, is catalyzed by the *pyruvate dehydrogenase component* ( $E_1$ ) of the multienzyme complex. TPP is the prosthetic group of the pyruvate dehydrogenase component.

2. *Oxidation*. The hydroxyethyl group attached to TPP is *oxidized* to form an acetyl group while being simultaneously transferred to lipoamide, a derivative of lipoic acid that is linked to the side chain of a lysine residue by

**FIGURE 17.6 Mechanism of the  $E_1$  decarboxylation reaction.**  $E_1$  is the pyruvate dehydrogenase component of the pyruvate dehydrogenase complex. A key feature of the prosthetic group, TPP, is that the carbon atom between the nitrogen and sulfur atoms in the thiazole ring is much more acidic than most  $=C-$  groups, with a  $pK_a$  value near 10. (1) This carbon center ionizes to form a *carbanion*. (2) The carbanion readily adds to the carbonyl group of pyruvate. (3) This addition is followed by the decarboxylation of pyruvate. The positively charged ring of TPP acts as an electron sink that stabilizes the negative charge that is transferred to the ring as part of the decarboxylation. (4) Protonation yields hydroxyethyl-TPP.

an amide linkage. Note that this transfer results in the formation of an energy-rich thioester bond.

The oxidant in this reaction is the disulfide group of lipoamide, which is reduced to its disulphydryl form. This reaction, also catalyzed by the pyruvate dehydrogenase component  $E_1$ , yields *acetyl-lipoamide*.

3. *Formation of Acetyl CoA.* The acetyl group is transferred from acetyl-lipoamide to CoA to form acetyl CoA.

*Dihydrolipoyl transacetylase* ( $E_2$ ) catalyzes this reaction. The energy-rich thioester bond is preserved as the acetyl group is transferred to CoA. Recall that CoA serves as a carrier of many activated acyl groups, of which acetyl is the simplest (Section 15.3). Acetyl CoA, the fuel for the citric acid cycle, has now been generated from pyruvate.

4. *Regeneration of oxidized lipoamide.* The pyruvate dehydrogenase complex cannot complete another catalytic cycle until the dihydrolipoamide is oxidized to lipoamide. In the fourth step, the oxidized form of lipoamide is regenerated by *dihydrolipoyl dehydrogenase* ( $E_3$ ). Two electrons are transferred to an FAD prosthetic group of the enzyme and then to  $NAD^+$ .

**FIGURE 17.7 Schematic representation of the pyruvate dehydrogenase complex.** The transacetylase core ( $E_2$ ) is shown in red, the pyruvate dehydrogenase component ( $E_1$ ) in yellow, and the dihydrolipoyl dehydrogenase ( $E_3$ ) in green.

This electron transfer from FAD to  $\text{NAD}^+$  is unusual because the common role for FAD is to receive electrons from NADH. The electron-transfer potential of FAD is increased by its chemical environment within the enzyme, enabling it to transfer electrons to  $\text{NAD}^+$ . Proteins tightly associated with FAD or flavin mononucleotide (FMN) are called *flavoproteins*.

### Flexible linkages allow lipoamide to move between different active sites

The structures of all of the component enzymes of the bacterial pyruvate dehydrogenase complex are known, albeit from different complexes and species. Thus, it is now possible to construct an atomic model of the complex to understand its activity (Figure 17.7).

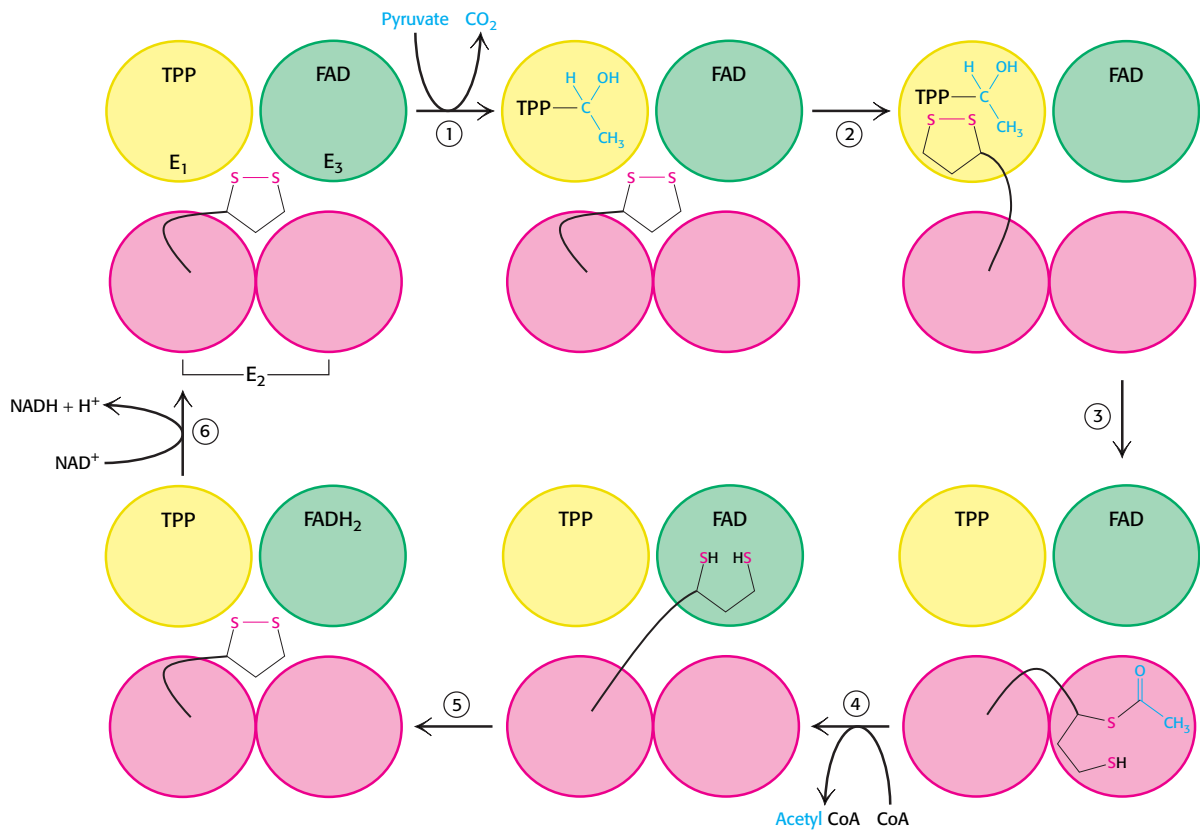

The core of the complex is formed by the transacetylase component  $E_2$ . Transacetylase consists of eight catalytic trimers assembled to form a hollow cube. Each of the three subunits forming a trimer has three major domains (Figure 17.8). At the amino terminus is a small domain that contains a bound flexible lipoamide cofactor attached to a lysine residue. This domain is homologous to biotin-binding domains such as that of pyruvate carboxylase (Figure 16.26). The lipoamide domain is followed by a small domain that interacts with  $E_3$  within the complex. A larger transacetylase domain completes an  $E_2$  subunit.  $E_1$  is an  $\alpha_2\beta_2$  tetramer, and  $E_3$  is an  $\alpha\beta$  dimer. Multiple copies of  $E_1$  and  $E_3$  surround the  $E_2$  core. In mammals, this core contains another protein,  $E_3$ -binding protein ( $E_3$ -BP), which facilitates the interaction between  $E_2$  and  $E_3$ . If  $E_3$ -BP is missing, the complex has greatly reduced activity.

How do the three distinct active sites work in concert (Figure 17.9)? The key is the long, flexible lipoamide arm of the  $E_2$  subunit, which carries substrate from active site to active site:

1. Pyruvate is decarboxylated at the active site of  $E_1$ , forming the hydroxyethyl-TPP intermediate, and  $\text{CO}_2$  leaves as the first product. This active site lies deep within the  $E_1$  complex, connected to the enzyme surface by a 20-Å-long hydrophobic channel.

**FIGURE 17.8 Structure of the transacetylase ( $E_2$ ) core.** Each red ball represents a trimer of three  $E_2$  subunits. Notice that each subunit consists of three domains: a lipoamide-binding domain, a small domain for interaction with  $E_3$ , and a large transacetylase catalytic domain. The transacetylase domains of three identical subunits are shown, with one depicted in red and the others in white in the ribbon representation.

2.  $E_2$  inserts the lipoamide arm of the lipoamide domain into the deep channel in  $E_1$  leading to the active site.
3.  $E_1$  catalyzes the transfer of the acetyl group to the lipoamide. The acetylated arm then leaves  $E_1$  and enters the  $E_2$  cube to visit the active site of  $E_2$ , located deep in the cube at the subunit interface.
4. The acetyl moiety is then transferred to CoA, and the second product, acetyl CoA, leaves the cube. The reduced lipoamide arm then swings to the active site of the  $E_3$  flavoprotein.
5. At the  $E_3$  active site, the lipoamide is oxidized by coenzyme FAD. The reactivated lipoamide is ready to begin another reaction cycle.
6. The final product, NADH, is produced with the reoxidation of  $FADH_2$  to FAD.

*The structural integration of three kinds of enzymes and the long, flexible lipoamide arm make the coordinated catalysis of a complex reaction possible. The proximity of one enzyme to another increases the overall reaction rate and minimizes side reactions. All the intermediates in the oxidative decarboxylation of pyruvate remain bound to the complex throughout the reaction sequence and are readily transferred as the flexible arm of  $E_2$  calls on each active site in turn.*

**FIGURE 17.9 Reactions of the pyruvate dehydrogenase complex.** At the top (left), the enzyme (represented by a yellow, a green, and two red spheres) is unmodified and ready for a catalytic cycle. (1) Pyruvate is decarboxylated to form hydroxyethyl-TPP. (2) The lipoamide arm of  $E_2$  moves into the active site of  $E_1$ . (3)  $E_1$  catalyzes the transfer of the two-carbon group to the lipoamide group to form the acetyl-lipoamide complex. (4)  $E_2$  catalyzes the transfer of the acetyl moiety to CoA to form the product acetyl CoA. The dihydrolipoamide arm then swings to the active site of  $E_3$ .  $E_3$  catalyzes (5) the oxidation of the dihydrolipoamide and (6) the transfer of the protons and electrons to  $NAD^+$  to complete the reaction cycle.

## 17.2 The Citric Acid Cycle Oxidizes Two-Carbon Units

The conversion of pyruvate into acetyl CoA by the pyruvate dehydrogenase complex is the link between glycolysis and cellular respiration because *acetyl CoA is the fuel for the citric acid cycle*. Indeed, all fuels are ultimately metabolized to acetyl CoA or components of the citric acid cycle.

### Citrate synthase forms citrate from oxaloacetate and acetyl coenzyme A

The citric acid cycle begins with the condensation of a four-carbon unit, oxaloacetate, and a two-carbon unit, the acetyl group of acetyl CoA. Oxaloacetate reacts with acetyl CoA and H<sub>2</sub>O to yield citrate and CoA.

This reaction, which is an aldol condensation followed by a hydrolysis, is catalyzed by *citrate synthase*. Oxaloacetate first condenses with acetyl CoA to form *citryl CoA*, a molecule that is energy rich because it contains the thioester bond that originated in acetyl CoA. The hydrolysis of citryl CoA thioester to citrate and CoA drives the overall reaction far in the direction of the synthesis of citrate. In essence, the hydrolysis of the thioester powers the synthesis of a new molecule from two precursors.

#### Synthase

An enzyme catalyzing a synthetic reaction in which two units are joined usually without the direct participation of ATP (or another nucleoside triphosphate).

#### Mechanism: The mechanism of citrate synthase prevents undesirable reactions

Because the condensation of acetyl CoA and oxaloacetate initiates the citric acid cycle, it is very important that side reactions, notably the hydrolysis of acetyl CoA to acetate and CoA, be minimized. Let us briefly consider how the citrate synthase prevents the wasteful hydrolysis of acetyl CoA.

Mammalian citrate synthase is a dimer of identical 49-kDa subunits. Each active site is located in a cleft between the large and the small domains of a subunit, adjacent to the subunit interface. X-ray crystallographic studies of citrate synthase and its complexes with several substrates and inhibitors have revealed that the enzyme undergoes large conformational changes in the course of catalysis. Citrate synthase exhibits sequential, ordered kinetics: oxaloacetate binds first, followed by acetyl CoA. The reason for the ordered binding is that *oxaloacetate induces a major structural rearrangement leading to the creation of a binding site for acetyl CoA*. The binding of oxaloacetate converts the open form of the enzyme into a closed form (Figure 17.10). In each subunit, the small domain rotates 19 degrees relative to the large domain. *Movements as large as 15 Å are produced by the rotation of α helices elicited by quite small shifts of side chains around bound oxaloacetate*. These structural changes create a binding site for acetyl CoA.

Citrate synthase catalyzes the condensation reaction by bringing the substrates into close proximity, orienting them, and polarizing certain bonds (Figure 17.11). The donation and removal of protons transforms acetyl CoA into an *enol intermediate*. The enol attacks oxaloacetate to form a carbon-carbon double bond linking acetyl CoA and oxaloacetate. The newly formed citryl CoA induces additional structural changes in the enzyme, causing the active site to become completely enclosed. The enzyme cleaves the citryl CoA thioester by hydrolysis. CoA leaves the enzyme, followed by citrate, and the enzyme returns to the initial open conformation.

**FIGURE 17.10** Conformational changes in citrate synthase on binding oxaloacetate. The small domain of each subunit of the homodimer is shown in yellow; the large domains are shown in blue. (Left) Open form of enzyme alone. (Right) Closed form of the oxaloacetate-enzyme complex. [Drawn from 5CSC.pdb and 4CTS.pdb.]

We can now understand how the wasteful hydrolysis of acetyl CoA is prevented. Citrate synthase is well suited to hydrolyze *citryl* CoA but not *acetyl* CoA. How is this discrimination accomplished? First, acetyl CoA does not bind to the enzyme until oxaloacetate is bound and ready for condensation. Second, the catalytic residues crucial for the hydrolysis of the thioester linkage are not appropriately positioned *until citryl CoA is formed*. As with hexokinase and triose phosphate isomerase (Section 16.1), *induced fit prevents an undesirable side reaction*.

**FIGURE 17.11** Mechanism of synthesis of citryl CoA by citrate synthase. (1) In the substrate complex (left), His 274 donates a proton to the carbonyl oxygen of acetyl CoA to promote the removal of a methyl proton by Asp 375 to form the enol intermediate (center). (2) Oxaloacetate is activated by the transfer of a proton from His 320 to its carbonyl carbon atom. (3) Simultaneously, the enol of acetyl CoA attacks the carbonyl carbon of oxaloacetate to form a carbon-carbon bond linking acetyl CoA and oxaloacetate. His 274 is re protonated. Citryl CoA is formed. His 274 participates again as a proton donor to hydrolyze the thioester (not shown), yielding citrate and CoA.

### Citrate is isomerized into isocitrate

The hydroxyl group is not properly located in the citrate molecule for the oxidative decarboxylations that follow (Problem 27). Thus, citrate is isomerized into isocitrate to enable the six-carbon unit to undergo oxidative decarboxylation. The isomerization of citrate is accomplished by a *dehydration* step followed by a *hydration* step. The result is an interchange of an H and an OH. The enzyme catalyzing both steps is called *aconitase* because *cis-aconitate* is an intermediate.

Aconitase is an *iron-sulfur protein*, or *nonheme-iron protein*, in that it contains iron that is not bonded to heme. Rather, its four iron atoms are complexed to four inorganic sulfides and three cysteine sulfur atoms, leaving one iron atom available to bind citrate through one of its  $\text{COO}^-$  groups and an OH group (Figure 17.12). This Fe-S cluster participates in dehydrating and rehydrating the bound substrate.

### Isocitrate is oxidized and decarboxylated to alpha-ketoglutarate

We come now to the first of four oxidation-reduction reactions in the citric acid cycle. The oxidative decarboxylation of isocitrate is catalyzed by *isocitrate dehydrogenase*.

The intermediate in this reaction is oxalosuccinate, an unstable  $\beta$ -ketoacid. While bound to the enzyme, it loses  $\text{CO}_2$  to form  $\alpha$ -ketoglutarate.

**FIGURE 17.12** Binding of citrate to the iron-sulfur complex of aconitase. A 4Fe-4S iron-sulfur cluster is a component of the active site of aconitase. Notice that one of the iron atoms of the cluster binds to a  $\text{COO}^-$  group and an OH group of citrate. [Drawn from 1C96.pdb.]

This oxidation generates the first high-transfer-potential electron carrier, NADH, in the cycle.

### Succinyl coenzyme A is formed by the oxidative decarboxylation of alpha-ketoglutarate

The conversion of isocitrate into  $\alpha$ -ketoglutarate is followed by a second oxidative decarboxylation reaction, the formation of succinyl CoA from  $\alpha$ -ketoglutarate.

This reaction is catalyzed by the  $\alpha$ -ketoglutarate dehydrogenase complex, an organized assembly of three kinds of enzymes that is homologous to the pyruvate dehydrogenase complex. In fact, the  $E_3$  component is identical in both enzymes. The oxidative decarboxylation of  $\alpha$ -ketoglutarate closely resembles that of pyruvate, also an  $\alpha$ -ketoacid.

Both reactions include the decarboxylation of an  $\alpha$ -ketoacid and the subsequent formation of a thioester linkage with CoA that has a high transfer potential. The reaction mechanisms are entirely analogous (p. 497).

### A compound with high phosphoryl-transfer potential is generated from succinyl coenzyme A

Succinyl CoA is an energy-rich thioester compound. The  $\Delta G^\circ$  for the hydrolysis of succinyl CoA is about  $-33.5 \text{ kJ mol}^{-1}$  ( $-8.0 \text{ kcal mol}^{-1}$ ), which is comparable to that of ATP ( $-30.5 \text{ kJ mol}^{-1}$ , or  $-7.3 \text{ kcal mol}^{-1}$ ). In the citrate synthase reaction, the cleavage of the thioester bond powers the synthesis of the six-carbon citrate from the four-carbon oxaloacetate and the two-carbon fragment. *The cleavage of the thioester bond of succinyl CoA is coupled to the phosphorylation of a purine nucleoside diphosphate, usually ADP.* This reaction, which is readily reversible, is catalyzed by *succinyl CoA synthetase* (succinate thiokinase).

This reaction is the only step in the citric acid cycle that directly yields a compound with high phosphoryl-transfer potential. In mammals, there are two isozymic forms of the enzyme, one specific for ADP and one for GDP. In tissues that perform large amounts of cellular respiration, such as skeletal and heart muscle, the ADP-requiring isozyme predominates. In tissues that perform many anabolic reactions, such as the liver, the GDP-requiring enzyme is common. The GDP-requiring enzyme is believed to work in reverse of the direction observed in the TCA cycle; that is, GTP is used to power the synthesis of succinyl CoA, which is a precursor for heme synthesis. The *E. coli* enzyme uses either GDP or ADP as the phosphoryl-group acceptor.

Note that the enzyme *nucleoside diphosphokinase*, which catalyzes the following reaction,

allows the  $\gamma$  phosphoryl group to be readily transferred from GTP to form ATP, thereby allowing the adjustment of the concentration of GTP or ATP to meet the cell's need.

**FIGURE 17.13 Reaction mechanism of succinyl CoA synthetase.** The reaction proceeds through a phosphorylated enzyme intermediate. (1) Orthophosphate displaces coenzyme A, which generates another energy-rich compound, succinyl phosphate. (2) A histidine residue removes the phosphoryl group with the concomitant generation of succinate and phosphohistidine. (3) The phosphohistidine residue then swings over to a bound ADP, and (4) the phosphoryl group is transferred to form ATP.

### Mechanism: Succinyl coenzyme A synthetase transforms types of biochemical energy

The mechanism of this reaction is a clear example of an energy transformation: energy inherent in the thioester molecule is transformed into phosphoryl-group-transfer potential (Figure 17.13). The first step is the displacement of coenzyme A by orthophosphate, which generates

another energy-rich compound, succinyl phosphate. A histidine residue plays a key role as a moving arm that detaches the phosphoryl group, then swings over to a bound ADP and transfers the group to form ATP. The participation of high-energy compounds in all the steps is attested to by the fact that the reaction is readily reversible:  $\Delta G^{\circ'} = -3.4 \text{ kJ mol}^{-1}$  ( $-0.8 \text{ kcal mol}^{-1}$ ). The formation of ATP at the expense of succinyl CoA is an example of substrate-level phosphorylation (Section 16.1).

 Succinyl CoA synthetase is an  $\alpha_2\beta_2$  heterodimer; the functional unit is one  $\alpha\beta$  pair. The enzyme mechanism shows that a phosphoryl group is transferred first to succinyl CoA bound in the  $\alpha$  subunit and then to a nucleoside diphosphate bound in the  $\beta$  subunit. Examination of the three-dimensional structure of succinyl CoA synthetase reveals that each subunit comprises two domains (Figure 17.14). The amino-terminal domains of the two subunits have different structures, each characteristic of its role in the mechanism. The amino-terminal domain of the  $\alpha$  subunit forms a Rossmann fold (Section 16.1), which binds the ADP substrate of succinyl CoA synthetase. The amino-terminal domain of the  $\beta$  subunit is an ATP-grasp domain, found in many enzymes, which here binds and activates ADP. Succinyl CoA synthetase has evolved by adopting these domains and harnessing them to capture the energy associated with succinyl CoA cleavage, which is used to drive the generation of a nucleoside triphosphate.

 **FIGURE 17.14 Structure of succinyl CoA synthetase.** The enzyme is composed of two subunits. The  $\alpha$  subunit contains a Rossmann fold that binds the ADP component of CoA, and the  $\beta$  subunit contains a nucleotide-activating region called the ATP-grasp domain. The ATP-grasp domain is shown here binding a molecule of ADP. Notice that the histidine residue is between the CoA and the ADP. This histidine residue picks up the phosphoryl group from near the CoA and swings over to transfer it to the nucleotide bound in the ATP-grasp domain. [Drawn from 1CQL.pdb.]

### Oxaloacetate is regenerated by the oxidation of succinate

Reactions of four-carbon compounds constitute the final stage of the citric acid cycle: the regeneration of oxaloacetate.

The reactions constitute a metabolic motif that we will see again in fatty acid synthesis and degradation as well as in the degradation of some amino acids. A methylene group ( $\text{CH}_2$ ) is converted into a carbonyl group  $\text{C}=\text{O}$  in three steps: an oxidation, a hydration, and a second oxidation reaction. Oxaloacetate is thereby regenerated for another round of the cycle, and more energy is extracted in the form of  $\text{FADH}_2$  and  $\text{NADH}$ .

Succinate is oxidized to fumarate by *succinate dehydrogenase*. The hydrogen acceptor is  $\text{FAD}$  rather than  $\text{NAD}^+$ , which is used in the other three oxidation reactions in the cycle.  $\text{FAD}$  is the hydrogen acceptor in this reaction because the free-energy change is insufficient to reduce  $\text{NAD}^+$ .  $\text{FAD}$  is nearly always the electron acceptor in oxidations that remove two hydrogen atoms from a substrate. In succinate dehydrogenase, the isoalloxazine ring of  $\text{FAD}$  is covalently attached to a histidine side chain of the enzyme (denoted E-FAD).

Succinate dehydrogenase, like aconitase, is an iron–sulfur protein. Indeed, succinate dehydrogenase contains three different kinds of iron–sulfur clusters: 2Fe-2S (two iron atoms bonded to two inorganic sulfides), 3Fe-4S, and 4Fe-4S. Succinate dehydrogenase—which consists of a 70-kDa and a 27-kDa subunit—differs from other enzymes in the citric acid cycle in being embedded in the inner mitochondrial membrane. In fact, *succinate dehydrogenase is directly associated with the electron-transport chain, the link between the citric acid cycle and ATP formation.* FADH<sub>2</sub> produced by the oxidation of succinate does not dissociate from the enzyme, in contrast with NADH produced in other oxidation–reduction reactions. Rather, two electrons are transferred from FADH<sub>2</sub> directly to iron–sulfur clusters of the enzyme, which in turn passes the electrons to coenzyme Q (CoQ). Coenzyme Q, an important member of the electron-transport chain, passes electrons to the ultimate acceptor, molecular oxygen, as we shall see in Chapter 18.

The next step is the hydration of fumarate to form L-malate. *Fumarase* catalyzes a stereospecific trans addition of H<sup>+</sup> and OH<sup>-</sup>. The OH<sup>-</sup> group adds to only one side of the double bond of fumarate; hence, only the L isomer of malate is formed.

Finally, malate is oxidized to form oxaloacetate. This reaction is catalyzed by *malate dehydrogenase*, and NAD<sup>+</sup> is again the hydrogen acceptor.

The standard free energy for this reaction, unlike that for the other steps in the citric acid cycle, is significantly positive ( $\Delta G^{\circ'} = +29.7 \text{ kJ mol}^{-1}$ , or  $+7.1 \text{ kcal mol}^{-1}$ ). The oxidation of malate is driven by the use of the products—oxaloacetate by citrate synthase and NADH by the electron-transport chain.

### The citric acid cycle produces high-transfer-potential electrons, ATP, and CO<sub>2</sub>

The net reaction of the citric acid cycle is

Let us recapitulate the reactions that give this stoichiometry (Figure 17.15 and Table 17.2):

- Two carbon atoms enter the cycle in the condensation of an acetyl unit (from acetyl CoA) with oxaloacetate. Two carbon atoms leave the cycle in the form of CO<sub>2</sub> in the successive decarboxylations catalyzed by isocitrate dehydrogenase and α-ketoglutarate dehydrogenase.
- Four pairs of hydrogen atoms leave the cycle in four oxidation reactions. Two NAD<sup>+</sup> molecules are reduced in the oxidative decarboxylations of isocitrate and α-ketoglutarate, one FAD molecule is reduced in the oxidation

FIGURE 17.15 The citric acid cycle.

Notice that since succinate is a symmetric molecule, the identity of the carbons from the acetyl unit is lost.

TABLE 17.2 Citric acid cycle

Step	Reaction	Enzyme	Prosthetic group	Type*	$\Delta G^{\circ}$	
					kJ mol <sup>-1</sup>	kcal mol <sup>-1</sup>
1	Acetyl CoA + oxaloacetate + H <sub>2</sub> O → citrate + CoA + H <sup>+</sup>	Citrate synthase		a	-31.4	-7.5

8	L-Malate + NAD <sup>+</sup> ⇌ oxaloacetate + NADH + H <sup>+</sup>	Malate dehydrogenase		e	+29.7	+7.1

\*Reaction type: (a) condensation; (b) dehydration; (c) hydration; (d) decarboxylation; (e) oxidation; (f) substrate-level phosphorylation.

of succinate, and one  $\text{NAD}^+$  molecule is reduced in the oxidation of malate. Recall also that one  $\text{NAD}^+$  molecule is reduced in the oxidative decarboxylation of pyruvate to form acetyl CoA.

3. One compound with high phosphoryl-transfer potential, usually ATP, is generated from the cleavage of the thioester linkage in succinyl CoA.
4. Two water molecules are consumed: one in the synthesis of citrate by the hydrolysis of citryl CoA and the other in the hydration of fumarate.

Isotope-labeling studies have revealed that the two carbon atoms that enter each cycle are not the ones that leave. The two carbon atoms that enter the cycle as the acetyl group are retained during the initial two decarboxylation reactions (Figure 17.15) and then remain incorporated in the four-carbon acids of the cycle. Note that succinate is a symmetric molecule. Consequently, the two carbon atoms that enter the cycle can occupy any of the carbon positions in the subsequent metabolism of the four-carbon acids. The two carbons that enter the cycle as the acetyl group will be released as  $\text{CO}_2$  in *subsequent* trips through the cycle. To understand why citrate is not processed as a symmetric molecule, see Problems 34 and 35.

Evidence is accumulating that the enzymes of the citric acid cycle are physically associated with one another. The close arrangement of enzymes enhances the efficiency of the citric acid cycle because a reaction product can pass directly from one active site to the next through connecting channels, a process called *substrate channeling*.

As will be considered in Chapter 18, the electron-transport chain oxidizes the  $\text{NADH}$  and  $\text{FADH}_2$  formed in the citric acid cycle. The transfer of electrons from these carriers to  $\text{O}_2$ , the ultimate electron acceptor, leads to the generation of a proton gradient across the inner mitochondrial membrane. This proton-motive force then powers the generation of ATP; the net stoichiometry is about 2.5 ATP per  $\text{NADH}$ , and 1.5 ATP per  $\text{FADH}_2$ . Consequently, nine high-transfer-potential phosphoryl groups are generated when the electron-transport chain oxidizes 3  $\text{NADH}$  molecules and 1  $\text{FADH}_2$  molecule, and one ATP is directly formed in one round of the citric acid cycle. Thus, one acetyl unit generates approximately 10 molecules of ATP. In dramatic contrast, the anaerobic glycolysis of an entire glucose molecule generates only 2 molecules of ATP (and 2 molecules of lactate).

Recall that molecular oxygen does not participate directly in the citric acid cycle. However, the cycle operates only under aerobic conditions because  $\text{NAD}^+$  and  $\text{FAD}$  can be regenerated in the mitochondrion only by the transfer of electrons to molecular oxygen. *Glycolysis has both an aerobic and an anaerobic mode, whereas the citric acid cycle is strictly aerobic.* Glycolysis can proceed under anaerobic conditions because  $\text{NAD}^+$  is regenerated in the conversion of pyruvate into lactate or ethanol.

---

### 17.3 Entry to the Citric Acid Cycle and Metabolism Through It Are Controlled

The citric acid cycle is the final common pathway for the aerobic oxidation of fuel molecules. Moreover, as we will see shortly (Section 17.4) and repeatedly elsewhere in our study of biochemistry, the cycle is an important source of building blocks for a host of important biomolecules. As befits its role as the metabolic hub of the cell, entry into the cycle and the rate of the cycle itself are controlled at several stages.

## The pyruvate dehydrogenase complex is regulated allosterically and by reversible phosphorylation

As stated earlier, glucose can be formed from pyruvate (Section 16.3). However, the formation of acetyl CoA from pyruvate is an irreversible step in animals and thus they are unable to convert acetyl CoA back into glucose. The oxidative decarboxylation of pyruvate to acetyl CoA commits the carbon atoms of glucose to one of two principal fates: oxidation to CO<sub>2</sub> by the citric acid cycle, with the concomitant generation of energy, or incorporation into lipid (Figure 17.16). As expected of an enzyme at a critical branch point in metabolism, the activity of the pyruvate dehydrogenase complex is stringently controlled. High concentrations of reaction products inhibit the reaction: acetyl CoA inhibits the transacetylase component (E<sub>2</sub>) by binding directly, whereas NADH inhibits the dihydrolipoyl dehydrogenase (E<sub>3</sub>). High concentrations of NADH and acetyl CoA inform the enzyme that the energy needs of the cell have been met or that fatty acids are being degraded to produce acetyl CoA and NADH. In either case, there is no need to metabolize pyruvate to acetyl CoA. This inhibition has the effect of sparing glucose, because most pyruvate is derived from glucose by glycolysis (Section 16.1).

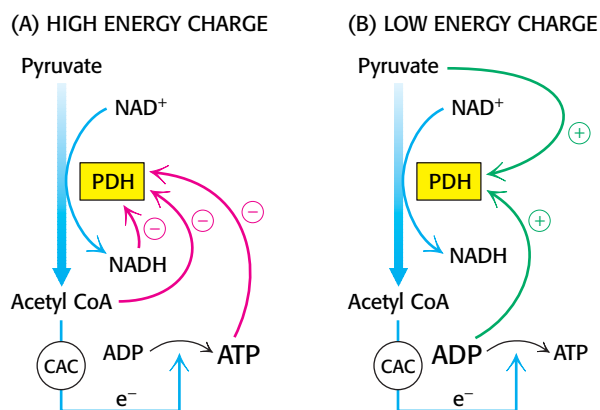

The key means of regulation of the complex in eukaryotes is covalent modification (Figure 17.17). Phosphorylation of the pyruvate dehydrogenase component (E<sub>1</sub>) by pyruvate dehydrogenase kinase (PDK) switches off the activity of the complex. There are four isozymes of PDK that are expressed in a tissue-specific manner. Deactivation is reversed by the pyruvate dehydrogenase phosphatase (PDP), of which there are two isozymic forms. In mammals, the kinase and the phosphatase are associated with the E<sub>2</sub>-E<sub>3</sub>-BP complex, again highlighting the structural and mechanistic importance of this core. Both the kinase and the phosphatase are regulated. To see how this regulation works in biological conditions, consider muscle that is becoming active after a period of rest (Figure 17.18). At rest, the muscle will not have significant energy demands. Consequently, the NADH/NAD<sup>+</sup>, acetyl CoA/CoA, and ATP/ADP ratios will be high. These high ratios promote phosphorylation and inactivation of the complex by activating PDK. In other words, high concentrations of immediate (acetyl CoA and NADH) and ultimate (ATP) products inhibit the activity. Thus, pyruvate dehydrogenase is switched off when the energy charge is high.

**FIGURE 17.16 From glucose to acetyl CoA.** The synthesis of acetyl CoA by the pyruvate dehydrogenase complex is a key irreversible step in the metabolism of glucose.

**FIGURE 17.17 Regulation of the pyruvate dehydrogenase complex.** A specific kinase phosphorylates and inactivates pyruvate dehydrogenase (PDH), and a phosphatase activates the dehydrogenase by removing the phosphoryl group. The kinase and the phosphatase also are highly regulated enzymes.

**FIGURE 17.18 Response of the pyruvate dehydrogenase complex to the energy charge.** The pyruvate dehydrogenase complex is regulated to respond to the energy charge of the cell. (A) The complex is inhibited by its immediate products, NADH and acetyl CoA, as well as by the ultimate product of cellular respiration, ATP. (B) The complex is activated by pyruvate and ADP, which inhibit the kinase that phosphorylates PDH.

As exercise begins, the concentrations of ADP and pyruvate will increase as muscle contraction consumes ATP and glucose is converted into pyruvate to meet the energy demands. Both ADP and pyruvate activate the dehydrogenase by inhibiting the kinase. Moreover, the phosphatase is stimulated by  $\text{Ca}^{2+}$ , the same signal that initiates muscle contraction. A rise in the cytoplasmic  $\text{Ca}^{2+}$  level (Section 35.2) elevates the mitochondrial  $\text{Ca}^{2+}$  level. The rise in mitochondrial  $\text{Ca}^{2+}$  activates the phosphatase, enhancing pyruvate dehydrogenase activity.

In some tissues, the phosphatase is regulated by hormones. In liver, epinephrine binds to the  $\alpha$ -adrenergic receptor to initiate the phosphatidylinositol pathway (Section 14.1), causing an increase in  $\text{Ca}^{2+}$  concentration that activates the phosphatase. In tissues capable of fatty acid synthesis, such as the liver and adipose tissue, insulin, the hormone that signifies the fed state, stimulates the phosphatase, increasing the conversion of pyruvate into acetyl CoA. Acetyl CoA is the precursor for fatty acid synthesis (Section 22.4). In these tissues, the pyruvate dehydrogenase complex is activated to funnel glucose to pyruvate and then to acetyl CoA and ultimately to fatty acids.

In people with a phosphatase deficiency, pyruvate dehydrogenase is always phosphorylated and thus inactive. Consequently, glucose is processed to lactate rather than acetyl CoA. This condition results in unremitting lactic acidosis—high blood levels of lactic acid. In such an acidic environment, many tissues malfunction, most notably the central nervous system (Problems 13 and 14).

### The citric acid cycle is controlled at several points

The rate of the citric acid cycle is precisely adjusted to meet an animal cell's needs for ATP (Figure 17.19). The primary control points are the allosteric enzymes isocitrate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase, the first two enzymes in the cycle to generate high-energy electrons.

*The first control site is isocitrate dehydrogenase.* The enzyme is allosterically stimulated by ADP, which enhances the enzyme's affinity for substrates. The binding of isocitrate,  $\text{NAD}^+$ ,  $\text{Mg}^{2+}$ , and ADP is mutually cooperative. In contrast, ATP is inhibitory. The reaction product NADH also inhibits isocitrate dehydrogenase by directly displacing  $\text{NAD}^+$ . It is important to note that several steps in the cycle require  $\text{NAD}^+$  or FAD, which are abundant only when the energy charge is low.

*A second control site in the citric acid cycle is  $\alpha$ -ketoglutarate dehydrogenase,* which catalyzes the rate-limiting step in the citric acid cycle. Some aspects of this enzyme's control are like those of the pyruvate dehydrogenase complex, as might be expected from the homology of the two enzymes.  $\alpha$ -Ketoglutarate dehydrogenase is inhibited by succinyl CoA and NADH, the products of the reaction that it catalyzes. In addition,  $\alpha$ -ketoglutarate dehydrogenase is inhibited by a high energy charge. Thus, *the rate of the cycle is reduced when the cell has a high level of ATP.*  $\alpha$ -Ketoglutarate dehydrogenase deficiency is observed in a number of neurological disorders, including Alzheimer disease.

The use of isocitrate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase as control points integrates the citric acid cycle with other pathways and highlights the central role of the citric acid cycle in metabolism. For instance, the inhibition of isocitrate dehydrogenase leads to a buildup of citrate, because the interconversion of isocitrate and citrate is readily reversible under intracellular conditions. Citrate can be transported to the cytoplasm, where it signals phosphofructokinase to halt glycolysis (Section 16.2) and where it can serve as a source of acetyl CoA for fatty acid synthesis (Section 22.4). The  $\alpha$ -ketoglutarate that accumulates when  $\alpha$ -ketoglutarate

**FIGURE 17.19 Control of the citric acid cycle.** The citric acid cycle is regulated primarily by the concentration of ATP and NADH. The key control points are the enzymes isocitrate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase.

dehydrogenase is inhibited can be used as a precursor for several amino acids and the purine bases (Chapter 23 and Chapter 25).

In many bacteria, the funneling of two-carbon fragments into the cycle also is controlled. *The synthesis of citrate from oxaloacetate and acetyl CoA carbon units is an important control point in these organisms.* ATP is an allosteric inhibitor of citrate synthase. The effect of ATP is to increase the value of  $K_M$  for acetyl CoA. Thus, as the level of ATP increases, less of this enzyme is bound to acetyl CoA and so less citrate is formed.

### Defects in the citric acid cycle contribute to the development of cancer

Four enzymes crucial to cellular respiration are known to contribute to the development of cancer: succinate dehydrogenase, fumarase, pyruvate dehydrogenase kinase and isocitrate dehydrogenase. Mutations that alter the activity of the first three of these enzymes enhance aerobic glycolysis (Section 16.2). In aerobic glycolysis, cancer cells preferentially metabolize glucose to lactate even in the presence of oxygen. Defects in these enzymes share a common biochemical link: the transcription factor *hypoxia inducible factor 1* (HIF-1).

Normally, HIF-1 up-regulates the enzymes and transporters that enhance glycolysis only when oxygen concentration falls, a condition called hypoxia. Under normal conditions, HIF-1 is hydroxylated by prolyl hydroxylase 2 and is subsequently destroyed by the proteasome, a large complex of proteolytic enzymes (Chapter 23). The degradation of HIF-1 prevents the stimulation of glycolysis. Prolyl hydroxylase 2 requires  $\alpha$ -ketoglutarate, ascorbate, and oxygen for activity. Thus, when oxygen concentration falls, the prolyl hydroxylase 2 is inactive, HIF-1 is not hydroxylated and not degraded, and the synthesis of proteins required for glycolysis is stimulated. As a result, the rate of glycolysis is increased.

Recent research suggests that defects in the enzymes of the citric acid cycle may significantly affect the regulation of prolyl hydroxylase 2. When either succinate dehydrogenase or fumarase is defective, succinate and fumarate accumulate in the mitochondria and spill over into the cytoplasm. Both succinate and fumarate are competitive inhibitors of prolyl hydroxylase 2. The inhibition of prolyl hydroxylase 2 results in the stabilization of HIF-1, since HIF-1 is no longer hydroxylated. Lactate, the end product of glycolysis, also appears to inhibit prolyl hydroxylase 2 by interfering with the action of ascorbate. In addition to increasing the amount of the proteins required for glycolysis, HIF-1 also stimulates the production of pyruvate dehydrogenase kinase (PDK). The kinase inhibits the pyruvate dehydrogenase complex, preventing the conversion of pyruvate into acetyl CoA. The pyruvate remains in the cytoplasm, further increasing the rate of aerobic glycolysis. Moreover, mutations in PDK that lead to enhanced activity contribute to increased aerobic glycolysis and the subsequent development of cancer. By enhancing glycolysis and increasing the concentration of lactate, the mutations in PDK result in the inhibition of hydroxylase and the stabilization of HIF-1.

Mutations in isocitrate dehydrogenase result in the generation of an oncogenic metabolite, 2-hydroxyglutarate. The mutant enzyme catalyzes the conversion of isocitrate to  $\alpha$ -ketoglutarate, but then reduces  $\alpha$ -ketoglutarate to form 2-hydroxyglutarate. 2-Hydroxyglutarate alters the methylation patterns in DNA (Section 32.2) and reduces dependence on growth factors for proliferation. These changes alter gene expression and promote unrestrained cell growth.

These observations linking citric acid cycle enzymes to cancer suggest that cancer is also a metabolic disease, not simply a disease of mutant growth factors and cell cycle control proteins. The realization that there is a metabolic

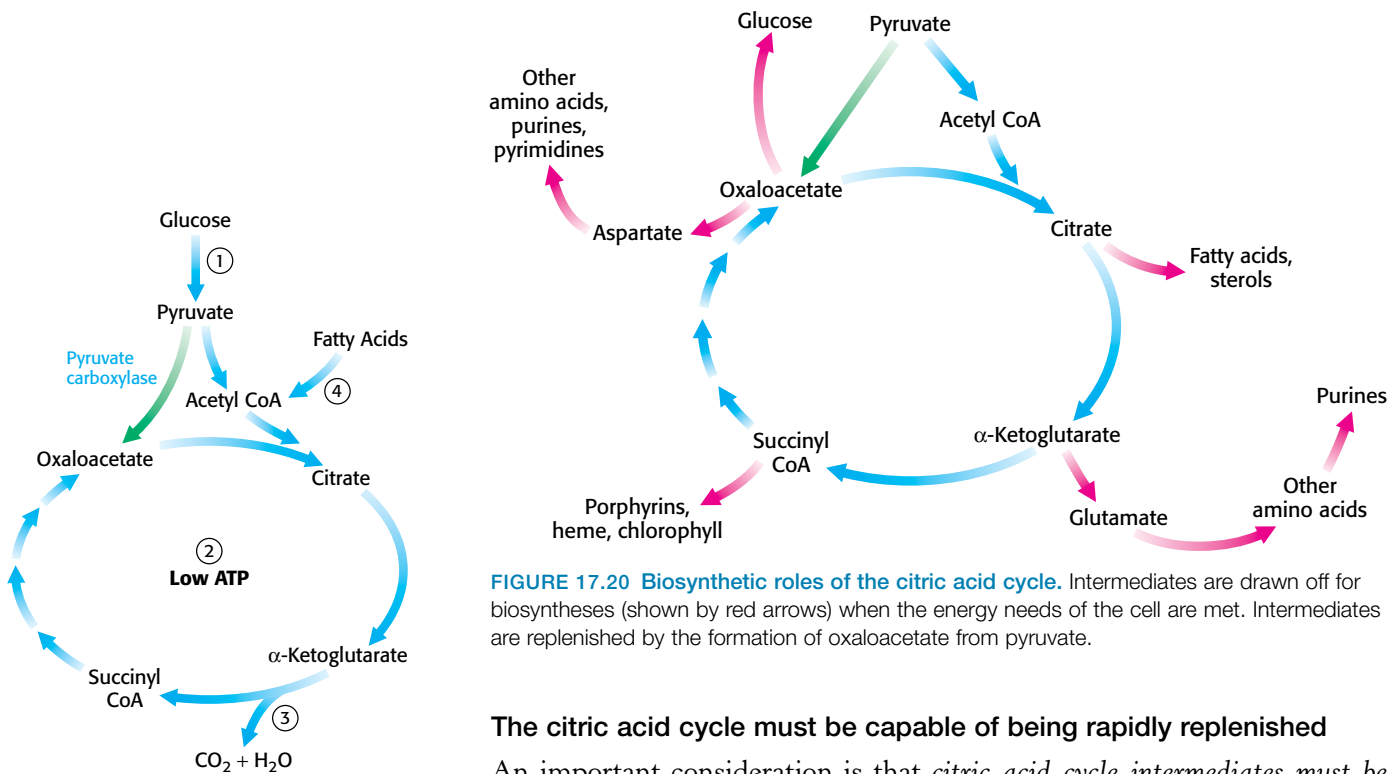

2-Hydroxyglutarate

component to cancer opens the door to new thinking about the control of cancer. Indeed, preliminary experiments suggest that if cancer cells undergoing aerobic glycolysis are forced by pharmacological manipulation to use oxidative phosphorylation, the cancer cells lose their malignant properties. It is also interesting to note that the citric acid cycle, which has been studied for decades, still has secrets to be revealed by future biochemists.

## 17.4 The Citric Acid Cycle Is a Source of Biosynthetic Precursors

Thus far, discussion has focused on the citric acid cycle as the *major degradative pathway for the generation of ATP*. As a major metabolic hub of the cell, the citric acid cycle also *provides intermediates for biosyntheses* (Figure 17.20). For example, most of the carbon atoms in porphyrins come from *succinyl CoA*. Many of the amino acids are derived from *α-ketoglutarate* and *oxaloacetate*. These biosynthetic processes will be considered in subsequent chapters.

**FIGURE 17.20 Biosynthetic roles of the citric acid cycle.** Intermediates are drawn off for biosyntheses (shown by red arrows) when the energy needs of the cell are met. Intermediates are replenished by the formation of oxaloacetate from pyruvate.

### Active pathways

- ① Glycolysis, Ch. 16
- ② Citric acid cycle, Ch. 17
- ③ Oxidative phosphorylation, Ch. 18
- ④ Fatty acid oxidation, Ch. 22

**FIGURE 17.21 PATHWAY INTEGRATION: Pathways active during exercise after a night's rest.** The rate of the citric acid cycle increases during exercise, requiring the replenishment of oxaloacetate and acetyl CoA. Oxaloacetate is replenished by its formation from pyruvate. Acetyl CoA may be produced from the metabolism of both pyruvate and fatty acids.

### The citric acid cycle must be capable of being rapidly replenished

An important consideration is that *citric acid cycle intermediates must be replenished if any are drawn off for biosyntheses*. Suppose that much oxaloacetate is converted into amino acids for protein synthesis and, subsequently, the energy needs of the cell rise. The citric acid cycle will operate to a reduced extent unless new oxaloacetate is formed because acetyl CoA cannot enter the cycle unless it condenses with oxaloacetate. Even though oxaloacetate is recycled, a minimal level must be maintained to allow the cycle to function.

How is oxaloacetate replenished? Mammals lack the enzymes for the net conversion of acetyl CoA into oxaloacetate or any other citric acid cycle intermediate. Rather, oxaloacetate is formed by the carboxylation of pyruvate, in a reaction catalyzed by the biotin-dependent enzyme *pyruvate carboxylase* (Figure 17.21).

Recall that this enzyme plays a crucial role in gluconeogenesis (Section 16.3). It is active only in the presence of acetyl CoA, which signifies the need for more oxaloacetate. If the energy charge is high, oxaloacetate is converted into glucose. If the energy charge is low, oxaloacetate replenishes the citric acid cycle. The synthesis of oxaloacetate by the carboxylation of pyruvate is an example of an *anaplerotic reaction* (*anaplerotic* is of Greek origin, meaning to “fill up”), a reaction that leads to the net synthesis, or replenishment, of pathway components. Note that because the citric acid cycle is a cycle, it can be replenished by the generation of any of the intermediates. Glutamine is an especially important source of citric acid cycle intermediates in rapidly growing cells, including cancer cells. Glutamine is converted into glutamate and then into  $\alpha$ -ketoglutarate.

### The disruption of pyruvate metabolism is the cause of beriberi and poisoning by mercury and arsenic

 *Beriberi*, a neurologic and cardiovascular disorder, is caused by a dietary deficiency of thiamine (also called *vitamin B<sub>1</sub>*). The disease has been and continues to be a serious health problem in the Far East because rice, the major food, has a rather low content of thiamine. This deficiency is partly ameliorated if the whole rice grain is soaked in water before milling; some of the thiamine in the husk then leaches into the rice kernel. The problem is exacerbated if the rice is polished to remove the outer layer (that is, converted from brown to white rice), because only the outer layer contains significant amounts of thiamine. A form of beriberi, called Wernicke’s encephalopathy, is also occasionally seen in alcoholics who are severely malnourished and thus thiamine deficient. The disease is characterized by neurologic and cardiac symptoms. Damage to the peripheral nervous system is expressed as pain in the limbs, weakness of the musculature, and distorted skin sensation. The heart may be enlarged and the cardiac output inadequate.

Which biochemical processes might be affected by a deficiency of thiamine? Thiamine is the precursor of the cofactor thiamine pyrophosphate. *This cofactor is the prosthetic group of three important enzymes: pyruvate dehydrogenase,  $\alpha$ -ketoglutarate dehydrogenase, and transketolase.* Transketolase functions in the pentose phosphate pathway, which will be considered in Chapter 20. *The common feature of enzymatic reactions utilizing TPP is the transfer of an activated aldehyde unit.* In beriberi, the levels of pyruvate and  $\alpha$ -ketoglutarate in the blood are higher than normal. The increase in the level of pyruvate in the blood is especially pronounced after the ingestion of glucose. A related finding is that the activities of the pyruvate and  $\alpha$ -ketoglutarate dehydrogenase complexes *in vivo* are abnormally low. The low transketolase activity of red blood cells in beriberi is an easily measured and reliable diagnostic indicator of the disease.

Why does TPP deficiency lead primarily to neurological disorders? The nervous system relies essentially on glucose as its only fuel. The product of glycolysis, pyruvate, can enter the citric acid cycle only through the pyruvate dehydrogenase complex. With that enzyme deactivated, the nervous system has no source of fuel. In contrast, most other tissues can use fats as a source of fuel for the citric acid cycle.

Symptoms similar to those of beriberi appear in organisms exposed to mercury or arsenite ( $\text{AsO}_3^{3-}$ ). Both materials have a high affinity for neighboring sulfhydryls, such as those in the reduced dihydrolipoyl groups of the  $E_3$  component of the pyruvate dehydrogenase complex (Figure 17.22). The binding of mercury or arsenite to the dihydrolipoyl groups inhibits the complex and leads to central nervous system pathologies. The proverbial phrase “mad as a hatter” refers to the strange behavior of poisoned hat makers who

#### Beriberi

A vitamin-deficiency disease first described in 1630 by Jacob Bonitus, a Dutch physician working in Java:

“A certain very troublesome affliction, which attacks men, is called by the inhabitants Beriberi (which means sheep). I believe those, whom this same disease attacks, with their knees shaking and the legs raised up, walk like sheep. It is a kind of paralysis, or rather Tremor: for it penetrates the motion and sensation of the hands and feet indeed sometimes of the whole body.”

[The Granger Collection.]

**FIGURE 17.22 Arsenite poisoning.** Arsenite inhibits the pyruvate dehydrogenase complex by inactivating the dihydrolipoamide component of the transacetylase. Some sulfhydryl reagents, such as 2,3-dimercaptoethanol, relieve the inhibition by forming a complex with the arsenite that can be excreted.

used mercury nitrate to soften and shape animal furs. This form of mercury is absorbed through the skin. Similar symptoms afflicted the early photographers, who used vaporized mercury to create daguerreotypes.

Treatment for these poisons is the administration of sulfhydryl reagents with adjacent sulfhydryl groups to compete with the dihydrolipoyl residues for binding with the metal ion. The reagent–metal complex is then excreted in the urine. Indeed, 2,3-dimercaptoethanol (Figure 17.22) was developed after World War I as an antidote to lewisite, an arsenic-based chemical weapon. This compound was initially called BAL, for British anti-lewisite.

The manuscript proposing the citric acid cycle was submitted for publication to *Nature* but was rejected in June 1937. That same year it was published in *Enzymologia*. Dr. Krebs proudly displayed the rejection letter throughout his career as encouragement for young scientists.

“The editor of NATURE presents his compliments to Dr. H. A. Krebs and regrets that as he has already sufficient letters to fill the correspondence columns of NATURE for seven or eight weeks, it is undesirable to accept further letters at the present time on account of the time delay which must occur in their publication.

If Dr. Krebs does not mind much delay the editor is prepared to keep the letter until the congestion is relieved in the hope of making use of it.

He returns it now, in case Dr. Krebs prefers to submit it for early publication to another periodical.”

### The citric acid cycle may have evolved from preexisting pathways

 How did the citric acid cycle come into being? Although definitive answers are elusive, informed speculation is possible. We can perhaps begin to comprehend how evolution might work at the level of biochemical pathways.

The citric acid cycle was most likely assembled from preexisting reaction pathways. As noted earlier, many of the intermediates formed in the citric acid cycle are used in metabolic pathways for amino acids and porphyrins. Thus, compounds such as pyruvate,  $\alpha$ -ketoglutarate, and oxaloacetate were likely present early in evolution for biosynthetic purposes. The oxidative decarboxylation of these  $\alpha$ -ketoacids is quite favorable thermodynamically and can be used to drive the synthesis of both acyl CoA derivatives and NADH. These reactions almost certainly formed the core of processes that preceded the citric acid cycle evolutionarily. Interestingly,  $\alpha$ -ketoglutarate and oxaloacetate can be interconverted by transamination of the respective amino acids by aspartate aminotransferase, another key biosynthetic enzyme. Thus, cycles comprising smaller numbers of intermediates used for a variety of biochemical purposes could have existed before the present form evolved.

## 17.5 The Glyoxylate Cycle Enables Plants and Bacteria to Grow on Acetate

Acetyl CoA that enters the citric acid cycle has but one fate: oxidation to CO<sub>2</sub> and H<sub>2</sub>O. Most organisms thus cannot convert acetyl CoA into glucose. Although oxaloacetate, a key precursor to glucose, is formed in the citric acid cycle, the two decarboxylations that take place before

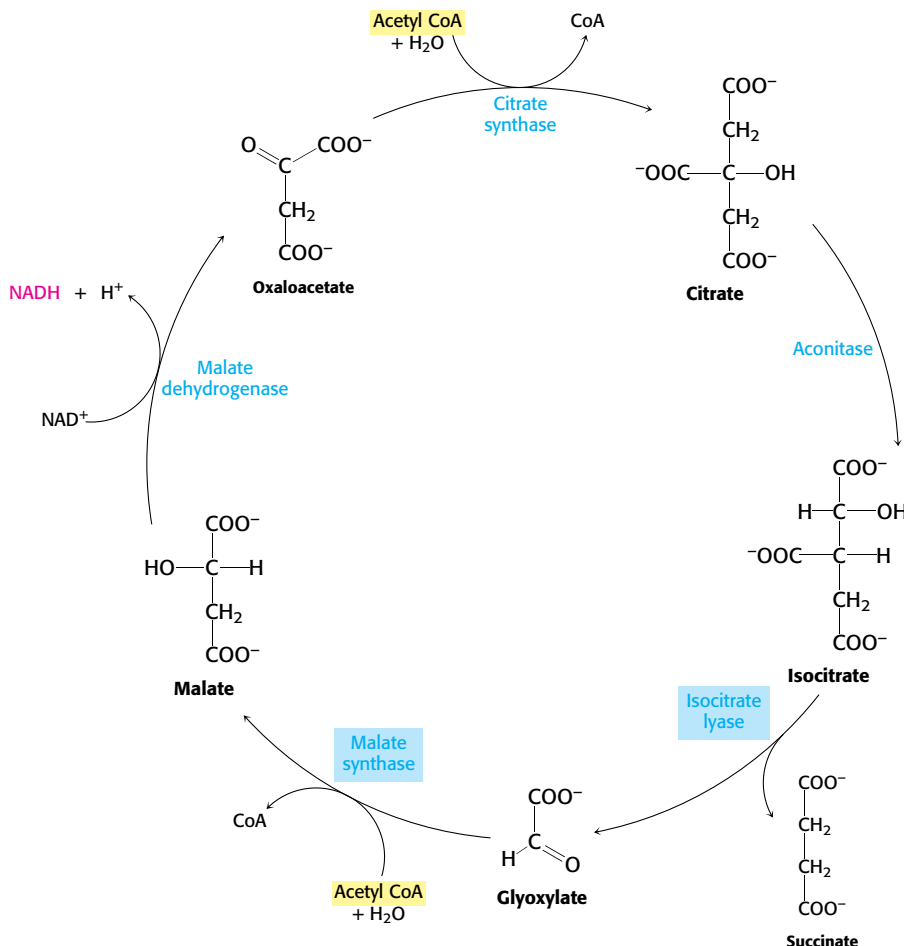

the regeneration of oxaloacetate preclude the *net* conversion of acetyl CoA into glucose.

In plants and in some microorganisms, there is a metabolic pathway that allows the conversion of acetyl CoA generated from fats stores into glucose. This reaction sequence, called the *glyoxylate cycle*, is similar to the citric acid cycle but bypasses the two decarboxylation steps of the cycle. Another important difference is that two molecules of acetyl CoA enter per turn of the glyoxylate cycle, compared with one in the citric acid cycle.

The glyoxylate cycle (Figure 17.23), like the citric acid cycle, begins with the condensation of acetyl CoA and oxaloacetate to form citrate, which is then isomerized to isocitrate. Instead of being decarboxylated, as in the citric acid cycle, isocitrate is cleaved by *isocitrate lyase* into succinate and glyoxylate. The ensuing steps regenerate oxaloacetate from glyoxylate. First, acetyl CoA condenses with glyoxylate to form malate in a reaction catalyzed by *malate synthase*, and then malate is oxidized to oxaloacetate, as in the citric acid cycle. The sum of these reactions is

In plants, these reactions take place in organelles called *glyoxysomes*. This cycle is especially prominent in oil-rich seeds, such as those from sunflowers, cucumbers, and castor beans. Succinate, released midcycle, can be converted into carbohydrates by a combination of the citric acid cycle and gluconeogenesis. The carbohydrates power seedling growth until the cell can begin photosynthesis. Thus, organisms with the glyoxylate cycle gain a metabolic versatility because they can use acetyl CoA as a precursor of glucose and other biomolecules.

**FIGURE 17.23 The glyoxylate cycle.** The glyoxylate cycle allows plants and some microorganisms to grow on acetate because the cycle bypasses the decarboxylation steps of the citric acid cycle. The reactions of this cycle are the same as those of the citric acid cycle except for the ones catalyzed by isocitrate lyase and malate synthase, which are boxed in blue.

## SUMMARY

The citric acid cycle is the final common pathway for the oxidation of fuel molecules. It also serves as a source of building blocks for biosyntheses.

### 17.1 The Pyruvate Dehydrogenase Complex Links Glycolysis to the Citric Acid Cycle

Most fuel molecules enter the cycle as acetyl CoA. The link between glycolysis and the citric acid cycle is the oxidative decarboxylation of pyruvate to form acetyl CoA. In eukaryotes, this reaction and those of the cycle take place inside mitochondria, in contrast with glycolysis, which takes place in the cytoplasm.

**17.2 The Citric Acid Cycle Oxidizes Two-Carbon Units**

The cycle starts with the condensation of oxaloacetate ( $C_4$ ) and the acetyl unit ( $C_2$ ) of acetyl CoA to give citrate ( $C_6$ ), which is isomerized to isocitrate ( $C_6$ ). Oxidative decarboxylation of this intermediate gives  $\alpha$ -ketoglutarate ( $C_5$ ). The second molecule of carbon dioxide comes off in the next reaction, in which  $\alpha$ -ketoglutarate is oxidatively decarboxylated to succinyl CoA ( $C_4$ ). The thioester bond of succinyl CoA is cleaved by orthophosphate to yield succinate, and an ATP is concomitantly generated. Succinate is oxidized to fumarate ( $C_4$ ), which is then hydrated to form malate ( $C_4$ ). Finally, malate is oxidized to regenerate oxaloacetate ( $C_4$ ). Thus, two carbon atoms from acetyl CoA enter the cycle, and two carbon atoms leave the cycle as  $CO_2$  in the successive decarboxylations catalyzed by isocitrate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase. In the four oxidation–reduction reactions in the cycle, three pairs of electrons are transferred to  $NAD^+$  and one pair to FAD. These reduced electron carriers are subsequently oxidized by the electron-transport chain to generate approximately 9 molecules of ATP. In addition, 1 molecule of ATP is directly formed in the citric acid cycle. Hence, a total of 10 molecules of ATP are generated for each two-carbon fragment that is completely oxidized to  $H_2O$  and  $CO_2$ .

**17.3 Entry to the Citric Acid Cycle and Metabolism Through It Are Controlled**

The citric acid cycle operates only under aerobic conditions because it requires a supply of  $NAD^+$  and FAD. These electron acceptors are regenerated when NADH and  $FADH_2$  transfer their electrons to  $O_2$  through the electron-transport chain, with the concomitant production of ATP. Consequently, the rate of the citric acid cycle depends on the need for ATP. The irreversible formation of acetyl CoA from pyruvate is an important regulatory point for the entry of glucose-derived pyruvate into the citric acid cycle. The activity of the pyruvate dehydrogenase complex is stringently controlled by reversible phosphorylation. In eukaryotes, the regulation of two enzymes in the cycle also is important for control. A high energy charge diminishes the activities of isocitrate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase. These mechanisms complement each other in reducing the rate of formation of acetyl CoA when the energy charge of the cell is high and when biosynthetic intermediates are abundant.

**17.4 The Citric Acid Cycle Is a Source of Biosynthetic Precursors**

When the cell has adequate energy available, the citric acid cycle can also provide a source of building blocks for a host of important biomolecules, such as nucleotide bases, proteins, and heme groups. This use depletes the cycle of intermediates. When the cycle again needs to metabolize fuel, anaplerotic reactions replenish the cycle intermediates.

**17.5 The Glyoxylate Cycle Enables Plants and Bacteria to Grow on Acetate**

The glyoxylate cycle enhances the metabolic versatility of many plants and bacteria. This cycle, which uses some of the reactions of the citric acid cycle, enables these organisms to subsist on acetate because it bypasses the two decarboxylation steps of the citric acid cycle.

**KEY TERMS**

citric acid (tricarboxylic acid, TCA; Krebs) cycle (p. 495)

acetyl CoA (p. 495)

oxidative phosphorylation (p. 497)

pyruvate dehydrogenase complex (p. 497)

flavoprotein (p. 500)

citrate synthase (p. 502)

iron–sulfur (nonheme iron) protein (p. 504)

isocitrate dehydrogenase (p. 504)

$\alpha$ -ketoglutarate dehydrogenase (p. 505)

anaplerotic reaction (p. 515)

beriberi (p. 515)

glyoxylate cycle (p. 517)

isocitrate lyase (p. 517)

malate synthase (p. 517)

glyoxysome (p. 517)

## PROBLEMS

1. *A one-way link.* What reaction serves to link glycolysis and the citric acid cycle, and what is the enzyme that catalyzes the reaction?

2. *Naming names.* What are the five enzymes (including regulatory enzymes) that constitute the pyruvate dehydrogenase complex? Which reactions do they catalyze?

3. *Coenzymes.* What coenzymes are required by the pyruvate dehydrogenase complex? What are their roles?

4. *More coenzymes.* Distinguish between catalytic coenzymes and stoichiometric coenzymes in the pyruvate dehydrogenase complex.

5. *Waste and fraud?* Figure 17.9 shows the steps in the pyruvate dehydrogenase complex reaction cycle. A key product, acetyl CoA, is released after the fourth step. What is the purpose of the remaining steps?

6. *Joined at the hip.* List some of the advantages of organizing the enzymes that catalyze the formation of acetyl CoA from pyruvate into a single large complex.

7. *Flow of carbon atoms.* What is the fate of the radioactive label when each of the following compounds is added to a cell extract containing the enzymes and cofactors of the glycolytic pathway, the citric acid cycle, and the pyruvate dehydrogenase complex? (The  $^{14}\text{C}$  label is printed in red.)

(e) Glucose 6-phosphate labeled at C-1.

8.  $\text{C}_2 + \text{C}_2 \rightarrow \text{C}_4$

(a) Which enzymes are required to get *net synthesis* of oxaloacetate from acetyl CoA?

(b) Write a balanced equation for the net synthesis.

(c) Do mammalian cells contain the requisite enzymes?

9. *Driving force.* What is the  $\Delta G^{\circ'}$  for the complete oxidation of the acetyl unit of acetyl CoA by the citric acid cycle?

10. *Acting catalytically.* The citric acid cycle itself, which is composed of enzymatically catalyzed steps, can be thought of essentially as a supramolecular enzyme. Explain.

11. *A potent inhibitor.* Thiamine thiazolone pyrophosphate binds to pyruvate dehydrogenase about 20,000 times as

strongly as does thiamine pyrophosphate, and it competitively inhibits the enzyme. Why?

12. *Like Holmes and Watson.* Match each term with its description.

- |  |   |
|--|---|
| (a) Acetyl CoA _____                     | 1. Catalyzes the link between glycolysis and the citric acid cycle. |

| (j) Beriberi _____                       | 10. Central metabolic hub   |

13. *Lactic acidosis.* Patients in shock often suffer from lactic acidosis owing to a deficiency of  $\text{O}_2$ . Why does a lack of  $\text{O}_2$  lead to lactic acid accumulation? One treatment for shock is to administer dichloroacetate (DCA), which inhibits the kinase associated with the pyruvate dehydrogenase complex. What is the biochemical rationale for this treatment?

14. *DCA again.* Patients with pyruvate dehydrogenase deficiency show high levels of lactic acid in the blood. However, in some cases, treatment with dichloroacetate (DCA) lowers lactic acid levels.

(a) How does DCA act to stimulate pyruvate dehydrogenase activity?

(b) What does this suggest about pyruvate dehydrogenase activity in patients who respond to DCA?

15. *Energy rich.* What are the thioesters in the reaction catalyzed by PDH complex?

16. *Alternative fates.* Compare the regulation of the pyruvate dehydrogenase complex in muscle and in liver.

17. *Mutations.*

- (a) Predict the effect of a mutation that enhances the activity of the kinase associated with the PDH complex.
- (b) Predict the effect of a mutation that reduces the activity of the phosphatase associated with the PDH complex.

18. *Flaking paint, green wallpaper.* Clare Boothe Luce, ambassador to Italy in the 1950s (and Connecticut congressperson, playwright, editor of *Vanity Fair*, and the wife of Henry Luce, founder of *Time* magazine and *Sports Illustrated*) became ill when she was staying at the ambassadorial residence in Rome. The paint on the dining room ceiling, an arsenic-based paint, was flaking; the wallpaper of her bedroom in the ambassadorial residence was colored a mellow green owing to the presence of cupric arsenite in the pigment. Suggest a possible cause of Ambassador Luce's illness.

19. *Like Jack and Jill.* Match each enzyme with its description.

| (j) Pyruvate carboxylase _____                  | 10. Catalyzes the formation of $\alpha$ -ketoglutarate |

20. *A hoax, perhaps?* The citric acid cycle is part of aerobic respiration, but no  $O_2$  is required for the cycle. Explain this paradox.

21. *One of a kind.* How is succinate dehydrogenase unique compared with the other enzymes in the citric acid cycle?

22. *Coupling reactions.* The oxidation of malate by  $NAD^+$  to form oxaloacetate is a highly endergonic reaction under standard conditions [ $\Delta G^\circ = 29 \text{ kJ mol}^{-1}$  (7 kcal mol<sup>-1</sup>)]. The reaction proceeds readily under physiological conditions.

(a) Explain why the reaction proceeds as written under physiological conditions.

(b) Assuming an  $[NAD^+]/[NADH]$  ratio of 8 and a pH of 7, what is the lowest  $[\text{malate}]/[\text{oxaloacetate}]$  ratio at which oxaloacetate can be formed from malate?

23. *Synthesizing  $\alpha$ -ketoglutarate.* It is possible, with the use of the reactions and enzymes considered in this chapter, to convert pyruvate into  $\alpha$ -ketoglutarate without depleting any of the citric acid cycle components. Write a balanced reaction scheme for this conversion, showing cofactors and identifying the required enzymes.

24. *Seven o'clock roadblock.* Malonate is a competitive inhibitor of succinate dehydrogenase. How will the concentrations of citric acid cycle intermediates change immediately after the addition of malonate? Why is malonate not a substrate for succinate dehydrogenase?

25. *No signal, no activity.* Why is acetyl CoA an especially appropriate activator for pyruvate carboxylase?

26. *Power differentials.* As we will see in the next chapter, when NADH reacts with oxygen, 2.5 ATP are generated. When  $FADH_2$  reduces oxygen, only 1.5 ATP are generated. Why then does succinate dehydrogenase produce  $FADH_2$  and not NADH when succinate is reduced to fumarate?

27. *Back to Orgo (or do you say O chem?).* Before any oxidation can occur in the citric acid cycle, citrate must be isomerized into isocitrate. Why is this the case?

28. *A nod is as good as a wink to a blind horse.* Explain why a GTP molecule, or another nucleoside triphosphate, is energetically equivalent to an ATP molecule in metabolism.

29. *One from two.* The synthesis of citrate from acetyl CoA and oxaloacetate is a biosynthetic reaction. What is the energy source that drives formation of citrate?

30. *Versatility.* What is the chief benefit of being able to perform the glyoxylate cycle?

### Chapter Integration Problems

31. *Fats into glucose?* Fats are usually metabolized into acetyl CoA and then further processed through the citric acid cycle. In Chapter 16, we saw that glucose can be synthesized from oxaloacetate, a citric acid cycle intermediate. Why, then, after a long bout of exercise depletes our carbohydrate stores, do we need to replenish those stores by eating carbohydrates? Why do we not simply replace them by converting fats into carbohydrates?

32. *Alternative fuels.* As we will see (Chapter 22), fatty acid breakdown generates a large amount of acetyl CoA. What will be the effect of fatty acid breakdown on pyruvate dehydrogenase complex activity? On glycolysis?

### Mechanism Problems

33. *Theme and variation.* Propose a reaction mechanism for the condensation of acetyl CoA and glyoxylate in the glyoxylate cycle of plants and bacteria.

34. *Symmetry problems.* In experiments carried out in 1941 to investigate the citric acid cycle, oxaloacetate labeled with  $^{14}\text{C}$  in the carboxyl carbon atom farthest from the keto group was introduced to an active preparation of mitochondria.

Analysis of the  $\alpha$ -ketoglutarate formed showed that none of the radioactive label had been lost. Decarboxylation of  $\alpha$ -ketoglutarate then yielded succinate devoid of radioactivity. All the label was in the released  $\text{CO}_2$ . Why were the early investigators of the citric acid cycle surprised that *all* the label emerged in the  $\text{CO}_2$ ?

35. *Symmetric molecules reacting asymmetrically.* The interpretation of the experiments described in Problem 34 was that citrate (or any other symmetric compound) cannot be an intermediate in the formation of  $\alpha$ -ketoglutarate, because of the asymmetric fate of the label. This view seemed compelling until Alexander Ogston incisively pointed out in 1948 that “it is possible that *an asymmetric enzyme which attacks a symmetrical compound can distinguish between its identical groups* [italics added].” For simplicity, consider a molecule in which two hydrogen atoms, a group X, and a different group Y are bonded to a tetrahedral carbon atom as a model for citrate. Explain how a symmetric molecule can react with an enzyme in an asymmetric way.

### Data Interpretation Problem

36. *A little goes a long way.* As will become clearer in Chapter 18, the activity of the citric acid cycle can be monitored by measuring the amount of  $\text{O}_2$  consumed. The greater the rate of  $\text{O}_2$  consumption, the faster the rate of the cycle. Hans Krebs used this assay to investigate the cycle in 1937. He used as his experimental system minced pigeon-breast muscle, which is rich in mitochondria. In one set of experiments, Krebs measured the  $\text{O}_2$  consumption in the presence of carbohydrate only and in

the presence of carbohydrate and citrate. The results are shown in the following table.

#### Effect of citrate on oxygen consumption by minced pigeon-breast muscle

Time (min)	Micromoles of oxygen consumed	
	Carbohydrate only	Carbohydrate plus 3 $\mu\text{mol}$ of citrate
10	26	28
60	43	62
90	46	77
150	49	85

(a) How much  $\text{O}_2$  would be absorbed if the added citrate were completely oxidized to  $\text{H}_2\text{O}$  and  $\text{CO}_2$ ?

(b) On the basis of your answer to part a, what do the results given in the table suggest?

37. *Arsenite poisoning.* The effect of arsenite on the experimental system of Problem 36 was then examined. Experimental data (not presented here) showed that the amount of citrate present did not change in the course of the experiment in the absence of arsenite. However, if arsenite was added to the system, different results were obtained, as shown in the following table.

#### Disappearance of citric acid in pigeon-breast muscle in the presence of arsenite

Micromoles of citrate added	Micromoles of citrate found after 40 minutes	Micromoles of citrate used
22	0.6	21
44	20.0	24
90	56.0	34

(a) What is the effect of arsenite on the disappearance of citrate?

(b) How is the action of arsenite altered by the addition of more citrate?

(c) What do these data suggest about the site of action of arsenite?

38. *Isocitrate lyase and tuberculosis.* The bacterium *Mycobacterium tuberculosis*, the cause of tuberculosis, can invade the lungs and persist in a latent state for years. During this time, the bacteria reside in granulomas—nodular scars containing bacteria and host-cell debris in the center and surrounded by immune cells. The granulomas are lipid-rich, oxygen-poor environments. How these bacteria manage to persist is something of a mystery. The results of recent research suggest that the glyoxylate cycle is required for the persistence. The following data show the amount of bacteria

[presented as colony-forming units (cfu)] in mice lungs in the weeks after an infection.

In graph A, the black circles represent the results for wild-type bacteria and the red circles represent the results for bacteria from which the gene for isocitrate lyase was deleted.

(a) What is the effect of the absence of isocitrate lyase?

The techniques described in Chapter 5 were used to reinsert the gene encoding isocitrate lyase into bacteria from which it had previously been deleted.

In graph B, black circles represent bacteria into which the gene was reinserted and red circles represent bacteria in which the gene was still missing.

(b) Do these results support those obtained in part *a*?

(c) What is the purpose of the experiment in part *b*?

(d) Why do these bacteria perish in the absence of the glyoxylate cycle?

[Data from KcKinney et al., *Nature* 406:735–738, 2000.]

## Oxidative Phosphorylation

Mitochondria, stained green, form a network inside a fibroblast cell (left). Mitochondria oxidize carbon fuels to form cellular energy in the form of ATP. [(Left) Courtesy of Michael P. Yaffee, Department of Biology, University of California at San Diego.]

The amount of ATP that human beings require to go about their lives is staggering. A sedentary male of 70 kg (154 lbs) requires about 8400 kJ (2000 kcal) for a day's worth of activity. To provide this much energy requires 83 kg of ATP. However, human beings possess only about 250 g of ATP at any given moment. The disparity between the amount of ATP that we have and the amount that we require is compensated by recycling ADP back to ATP. Each ATP molecule is recycled approximately 300 times per day. This recycling takes place primarily through *oxidative phosphorylation*.

We begin our study of oxidative phosphorylation by examining the oxidation–reduction reactions that allow the flow of electrons from NADH and FADH<sub>2</sub> to oxygen. The electron flow takes place in four large protein complexes that are embedded in the inner mitochondrial membrane, together called the *respiratory chain* or the *electron-transport chain*.

The overall reaction is exergonic. Importantly, three of the complexes of the electron-transport chain use the energy released by the electron flow to pump protons out of the mitochondrial matrix. In essence, energy is transformed. The resulting unequal distribution of protons generates a pH gradient and a transmembrane electrical potential that creates a *proton-motive force*. ATP is synthesized when protons flow back to the mitochondrial matrix through an enzyme complex.

## OUTLINE

- 18.1 Eukaryotic Oxidative Phosphorylation Takes Place in Mitochondria
- 18.2 Oxidative Phosphorylation Depends on Electron Transfer
- 18.3 The Respiratory Chain Consists of Four Complexes: Three Proton Pumps and a Physical Link to the Citric Acid Cycle
- 18.4 A Proton Gradient Powers the Synthesis of ATP
- 18.5 Many Shuttles Allow Movement Across Mitochondrial Membranes
- 18.6 The Regulation of Cellular Respiration Is Governed Primarily by the Need for ATP

### FIGURE 18.1 Overview of oxidative phosphorylation.

Oxidation and ATP synthesis are coupled by transmembrane proton fluxes. Electrons flow from NADH and  $\text{FADH}_2$  through four protein complexes to reduce oxygen to water (yellow tube). Three of the complexes pump protons from the mitochondrial matrix to the intermembrane space. The protons return to the matrix by flowing through another protein complex, ATP synthase (red structure), powering the synthesis of ATP.

### Respiration

An ATP-generating process in which an inorganic compound (such as molecular oxygen) serves as the ultimate electron acceptor. The electron donor can be either an organic compound or an inorganic one.

Thus, the oxidation of fuels and the phosphorylation of ADP are coupled by a proton gradient across the inner mitochondrial membrane (Figure 18.1).

Collectively, the generation of high-transfer-potential electrons by the citric acid cycle, their flow through the respiratory chain, and the accompanying synthesis of ATP is called *respiration* or *cellular respiration*.

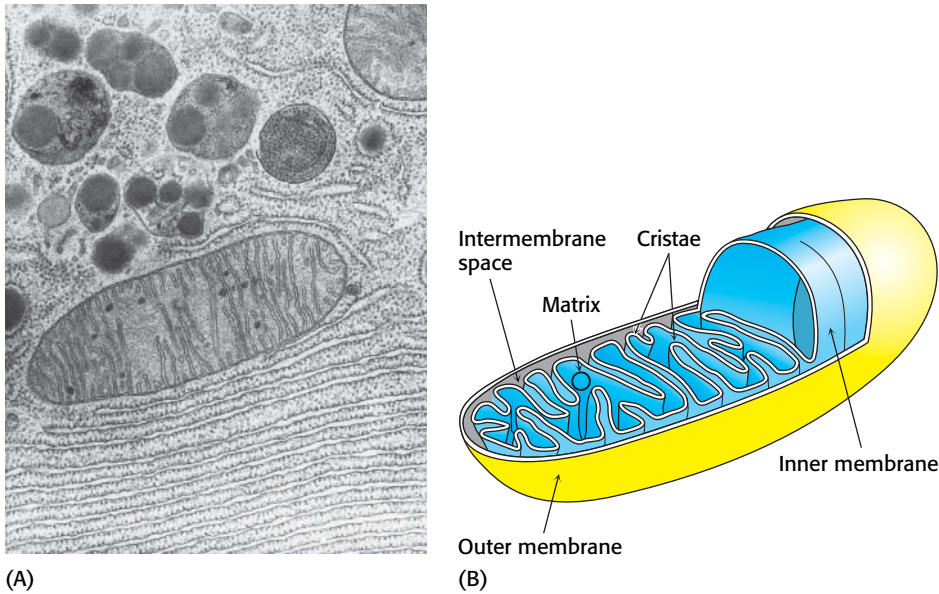

## 18.1 Eukaryotic Oxidative Phosphorylation Takes Place in Mitochondria

Recall that a biochemical role of the citric acid cycle, which takes place in the mitochondrial matrix, is the generation of high-energy electrons. It is fitting, therefore, that oxidative phosphorylation, which will convert the energy of these electrons into ATP, also takes place in mitochondria. Mitochondria are oval-shaped organelles, typically about 2  $\mu\text{m}$  in length and 0.5  $\mu\text{m}$  in diameter, about the size of a bacterium.

### Mitochondria are bounded by a double membrane

Electron microscopic studies revealed that mitochondria have two membrane systems: an *outer membrane* and an extensive, highly folded *inner membrane*. The inner membrane is folded into a series of internal ridges called *cristae*. Hence, there are two compartments in mitochondria: (1) the *intermembrane space* between the outer and the inner membranes and (2) the *matrix*, which is bounded by the inner membrane (Figure 18.2). The mitochondrial matrix is the site of most of the reactions of the citric acid cycle and fatty acid oxidation. In contrast, oxidative phosphorylation takes place in the inner mitochondrial membrane. The increase in surface area of the inner mitochondrial membrane provided by the cristae creates more sites for oxidative phosphorylation than would be the case with a simple, unfolded membrane. Humans contain an estimated 14,000  $\text{m}^2$  of inner mitochondrial membrane, which is the approximate equivalent of three football fields in the United States.

The outer membrane is quite permeable to most small molecules and ions because it contains *mitochondrial porin*, a 30- to 35-kDa pore-forming protein also known as VDAC, for *voltage-dependent anion channel*. VDAC, the most prevalent protein in the outer mitochondrial membrane, plays a role in the regulated flux of metabolites—usually anionic species such as phosphate, chloride, organic anions, and the adenine nucleotides—across the outer membrane. In contrast, the inner membrane is impermeable to nearly all ions and polar molecules. A large family of transporters shuttles metabolites such as ATP, pyruvate, and citrate across the inner mitochondrial membrane. The two faces of this membrane will be referred to as the *matrix side* and the *cytoplasmic side*

**FIGURE 18.2** Electron micrograph (A) and diagram (B) of a mitochondrion. [(A) Keith R. Porter/Science Source. (B) Information from Wolfe, *Biology of the Cell*, 2e, © 1981 Brooks/Cole, a part of Cengage Learning, Inc. Reproduced by permission www.cengage.com/permission 3.]

(the latter because it is freely accessible to most small molecules in the cytoplasm). They are also called the *N* and *P* sides, respectively, because the membrane potential is negative on the matrix side and positive on the cytoplasmic side.

In prokaryotes, the electron-driven proton pumps and ATP-synthesizing complexes are located in the cytoplasmic membrane, the inner of two membranes. The outer membrane of bacteria, like that of mitochondria, is permeable to most small metabolites because of the presence of porins.

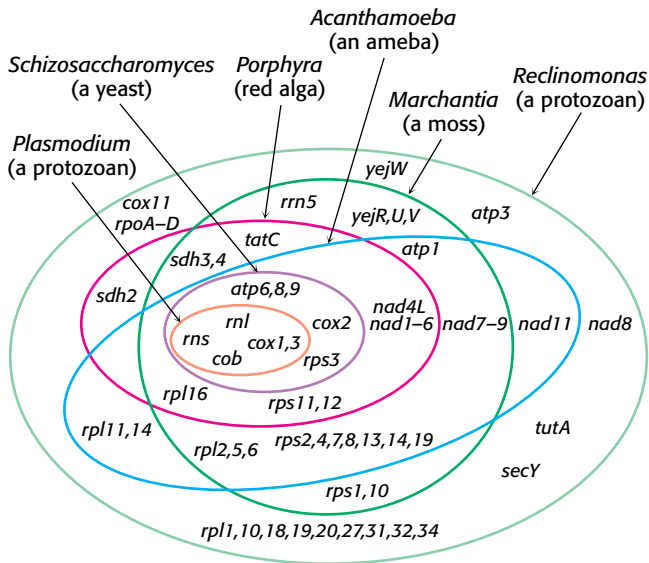

### Mitochondria are the result of an endosymbiotic event

 Mitochondria are semiautonomous organelles that live in an endosymbiotic relation with the host cell. These organelles contain their own DNA, which encodes a variety of different proteins and RNAs. Mitochondrial DNA is usually portrayed as being circular, but recent research suggests that the mitochondrial DNA of many organisms may be linear. The genomes of mitochondria range broadly in size across species. The mitochondrial genome of the protist *Plasmodium falciparum* consists of fewer than 6000 base pairs (bp), whereas those of some land plants comprise more than 200,000 bp (Figure 18.3). Human mitochondrial DNA comprises 16,569 bp and encodes 13 respiratory-chain proteins as well as the small and large ribosomal RNAs and enough tRNAs to translate all codons. However, mitochondria also contain many proteins encoded by nuclear DNA. Cells that contain mitochondria depend on these organelles for oxidative phosphorylation, and the mitochondria in turn depend on the cell for their very existence. How did this intimate symbiotic relation come to exist?

An *endosymbiotic event* is thought to have occurred whereby a free-living organism capable of oxidative phosphorylation was engulfed by another cell. The double-membrane, circular DNA (with exceptions) and the mitochondrial-specific transcription and translation machinery all point to this conclusion. Thanks to the rapid accumulation of sequence data for mitochondrial and bacterial genomes, speculation on the origin of the “original” mitochondrion with some authority is now possible. The most mitochondrial-like bacterial genome is that of *Rickettsia prowazekii*, the cause of louse-borne typhus. The genome for this organism is more than 1 million base pairs in size and contains 834 protein-encoding genes.

**FIGURE 18.3** Sizes of mitochondrial genomes. The sizes of three mitochondrial genomes compared with the genome of *Rickettsia*, a relative of the presumed ancestor of all mitochondria. For genomes of more than 60 kbp, the DNA coding region for genes with known function is shown in red.

**FIGURE 18.4 Overlapping gene complements of mitochondria.**

The genes present within each oval are those present within the organism represented by the oval. Only rRNA- and protein-coding genes are shown. The genome of *Reclinomonas* contains all the protein-coding genes found in all the sequenced mitochondrial genomes. [Data from M. W. Gray, G. Burger, and B. F. Lang, *Science* 283:1476–1481, 1999.]

Sequence data suggest that all extant mitochondria are derived from an ancestor of *R. prowazekii* as the result of a single endosymbiotic event.

The evidence that modern mitochondria result from a single event comes from examination of the most bacteria-like mitochondrial genome, that of the protozoan *Reclinomonas americana*. Its genome contains 97 genes, of which 62 specify proteins. The genes encoding these proteins include all of the protein-coding genes found in all of the sequenced mitochondrial genomes (Figure 18.4). Yet, this genome encodes less than 2% of the protein-coding genes in the bacterium *E. coli*. In other words, a small fraction of bacterial genes—2%—is found in all examined mitochondria. How is it possible that all mitochondria have the same 2% of the bacterial genome? It seems unlikely that mitochondrial genomes resulting from several endosymbiotic events could have been independently reduced to the same set of genes found in *R. americana*. Thus, the simplest explanation is that the endosymbiotic event took place just once and all existing mitochondria are descendants of that ancestor.

Note that transient engulfment of prokaryotic cells by larger cells is not uncommon in the microbial world. In regard to mitochondria, such a transient relationship became permanent as the bacterial cell lost DNA, making it incapable of independent living, and the host cell became dependent on the ATP generated by its tenant.

## 18.2 Oxidative Phosphorylation Depends on Electron Transfer

In Chapter 17, the generation of NADH and FADH<sub>2</sub> by the oxidation of acetyl CoA was identified as an important function of the citric acid cycle. In oxidative phosphorylation, electrons from NADH and FADH<sub>2</sub> are used to reduce molecular oxygen to water. The highly exergonic reduction is accomplished by a number of electron-transfer reactions, which take place in a set of membrane proteins known as the *electron-transport chain*.

**FIGURE 18.5 Measurement of redox potential.** Apparatus for the measurement of the standard oxidation–reduction potential of a redox couple. Electrons flow through the wire connecting the cells, whereas ions flow through the agar bridge.

### The electron-transfer potential of an electron is measured as redox potential

In oxidative phosphorylation, the *electron-transfer potential* of NADH or FADH<sub>2</sub> is converted into the *phosphoryl-transfer potential* of ATP. To better understand this conversion, we need quantitative expressions for these forms of free energy. The measure of phosphoryl-transfer potential is already familiar to us: it is given by  $\Delta G^{\circ'}$  for the hydrolysis of the activated phosphoryl compound. The corresponding expression for the electron-transfer potential is  $E'_0$ , the *reduction potential* (also called the *redox potential* or *oxidation–reduction potential*).

Consider a substance that can exist in an oxidized form X and a reduced form X<sup>-</sup>. Such a pair is called a *redox couple* and is designated X : X<sup>-</sup>. The reduction potential of this couple can be determined by measuring the electromotive force generated by an apparatus called a *sample half-cell* connected to a *standard reference half-cell* (Figure 18.5). The sample half-cell consists of an electrode immersed in a solution of 1 M oxidant (X) and 1 M

reductant ( $X^-$ ). The standard reference half-cell consists of an electrode immersed in a 1 M  $H^+$  solution that is in equilibrium with  $H_2$  gas at 1 atmosphere (1 atm) of pressure. The electrodes are connected to a voltmeter, and an agar bridge allows ions to move from one half-cell to the other, establishing electrical continuity between the half-cells. Electrons then flow from one half-cell to the other through the wire connecting the two half-cells to the voltmeter. If the reaction proceeds in the direction

the reactions in the half-cells (referred to as *half-reactions* or *couples*) must be

Thus, electrons flow from the sample half-cell to the standard reference half-cell, and the sample-cell electrode is taken to be negative with respect to the standard-cell electrode. *The reduction potential of the  $X : X^-$  couple is the observed voltage at the start of the experiment* (when  $X$ ,  $X^-$ , and  $H^+$  are 1 M with 1 atm of  $H_2$ ). *The reduction potential of the  $H^+ : H_2$  couple is defined to be 0 volts.* In oxidation–reduction reactions, the donor of electrons, in this case  $X^-$ , is called the *reductant* or *reducing agent*, whereas the acceptor of electrons,  $H^+$  here, is called the *oxidant* or *oxidizing agent*.

The meaning of the reduction potential is now evident. A negative reduction potential means that the oxidized form of a substance has lower affinity for electrons than does  $H_2$ , as in the preceding example. A positive reduction potential means that the oxidized form of a substance has higher affinity for electrons than does  $H_2$ . These comparisons refer to standard conditions—namely, 1 M oxidant, 1 M reductant, 1 M  $H^+$ , and 1 atm  $H_2$ . Thus, *a strong reducing agent (such as NADH) is poised to donate electrons and has a negative reduction potential, whereas a strong oxidizing agent (such as  $O_2$ ) is ready to accept electrons and has a positive reduction potential.*

The reduction potentials of many biologically important redox couples are known (Table 18.1). Table 18.1 is like those presented in chemistry

**TABLE 18.1** Standard reduction potentials of some reactions

Oxidant	Reductant	$n$	$E'_0$ (V)
Succinate + $CO_2$	$\alpha$ -Ketoglutarate	2	-0.67
Acetate	Acetaldehyde	2	-0.60
Ferredoxin (oxidized)	Ferredoxin (reduced)	1	-0.43
2 $H^+$	$H_2$	2	-0.42
NAD <sup>+</sup>	NADH + $H^+$	2	-0.32
NADP <sup>+</sup>	NADPH + $H^+$	2	-0.32
Lipoate (oxidized)	Lipoate (reduced)	2	-0.29
Glutathione (oxidized)	Glutathione (reduced)	2	-0.23
FAD	FADH <sub>2</sub>	2	-0.22
Acetaldehyde	Ethanol	2	-0.20
Pyruvate	Lactate	2	-0.19
2 $H^+$	$H_2$	2	-0.00 <sup>1</sup>
Fumarate	Succinate	2	+0.03
Cytochrome $b$ (+3)	Cytochrome $b$ (+2)	1	+0.07
Dehydroascorbate	Ascorbate	2	+0.08
Ubiquinone (oxidized)	Ubiquinone (reduced)	2	+0.10
Cytochrome $c$ (+3)	Cytochrome $c$ (+2)	1	+0.22
Fe (+3)	Fe (+2)	1	+0.77
$1/2 O_2 + 2 H^+$	$H_2O$	2	+0.82

Note:  $E'_0$  is the standard oxidation–reduction potential (pH 7, 25°C) and  $n$  is the number of electrons transferred.  $E'_0$  refers to the partial reaction written as Oxidant +  $e^- \rightarrow$  reductant

<sup>1</sup>Standard oxidation – reduction potential at pH = 0.

textbooks, except that a hydrogen ion concentration of  $10^{-7}$  M (pH 7) instead of 1 M (pH 0) is the standard state adopted by biochemists. This difference is denoted by the prime in  $E'_0$ . Recall that the prime in  $\Delta G^{\circ'}$  denotes a standard free-energy change at pH 7.

The standard free-energy change  $\Delta G^{\circ'}$  is related to the change in reduction potential  $\Delta E'_0$  by

$$\Delta G^{\circ'} = -nF\Delta E'_0$$

in which  $n$  is the number of electrons transferred,  $F$  is a proportionality constant called the *Faraday constant* [ $96.48 \text{ kJ mol}^{-1} \text{ V}^{-1}$  ( $23.06 \text{ kcal mol}^{-1} \text{ V}^{-1}$ )],  $\Delta E'_0$  is in volts, and  $\Delta G^{\circ'}$  is in kilojoules or kilocalories per mole.

The free-energy change of an oxidation–reduction reaction can be readily calculated from the reduction potentials of the reactants. For example, consider the reduction of pyruvate by NADH, catalyzed by lactate dehydrogenase. Recall that this reaction maintains redox balance in lactic acid fermentation (Figure 16.11).

The reduction potential of the  $\text{NAD}^+ : \text{NADH}$  couple, or half-reaction, is  $-0.32 \text{ V}$ , whereas that of the pyruvate:lactate couple is  $-0.19 \text{ V}$ . By convention, reduction potentials (as in Table 18.1) refer to partial reactions written as reductions: oxidant +  $e^- \rightarrow$  reductant. Hence,

To obtain reaction A from reactions B and C, we need to reverse the direction of reaction C so that NADH appears on the left side of the arrow. In doing so, the sign of  $E'_0$  must be changed.

For reaction B, the free energy can be calculated with  $n = 2$ .

$$\begin{aligned} \Delta G^{\circ'} &= -2 \times 96.48 \text{ kJ mol}^{-1} \text{ V}^{-1} \times -0.19 \text{ V} \\ &= +36.7 \text{ kJ mol}^{-1} (+8.8 \text{ kcal mol}^{-1}) \end{aligned}$$

Likewise, for reaction D,

$$\begin{aligned} \Delta G^{\circ'} &= -2 \times 96.48 \text{ kJ mol}^{-1} \text{ V}^{-1} \times +0.32 \text{ V} \\ &= -61.8 \text{ kJ mol}^{-1} (-14.8 \text{ kcal mol}^{-1}) \end{aligned}$$

Thus, the free energy for reaction A is given by

$$\begin{aligned} \Delta G^{\circ'} &= \Delta G^{\circ'} (\text{for reaction B}) + \Delta G^{\circ'} (\text{for reaction D}) \\ &= +36.7 \text{ kJ mol}^{-1} - 61.8 \text{ kJ mol}^{-1} \\ &= -25.1 \text{ kJ mol}^{-1} (-6.0 \text{ kcal mol}^{-1}) \end{aligned}$$

### A 1.14-volt potential difference between NADH and molecular oxygen drives electron transport through the chain and favors the formation of a proton gradient

The driving force of oxidative phosphorylation is the electron-transfer potential of NADH or  $\text{FADH}_2$  relative to that of  $\text{O}_2$ . How much energy is released by the reduction of  $\text{O}_2$  with NADH? Let us calculate  $\Delta G^{\circ'}$  for this reaction. The pertinent half-reactions are

The combination of the two half-reactions, as it proceeds in the electron-transport chain, yields

The standard free energy for this reaction is then given by

$$\begin{aligned} \Delta G^{\circ'} &= (-2 \times 96.48 \text{ kJ mol}^{-1} \text{ V}^{-1} \times +0.82 \text{ V}) \\ &\quad + (-2 \times 96.48 \text{ kJ mol}^{-1} \text{ V}^{-1} \times 0.32 \text{ V}) \\ &= -158.2 \text{ kJ mol}^{-1} + (-61.9) \text{ kJ mol}^{-1} \\ &= -220.1 \text{ kJ mol}^{-1} \quad (-52.6 \text{ kcal mol}^{-1}) \end{aligned}$$

This release of free energy is substantial. Recall that  $\Delta G^{\circ'}$  for the synthesis of ATP is  $30.5 \text{ kJ mol}^{-1}$  ( $7.3 \text{ kcal mol}^{-1}$ ). The released energy is initially used to generate a proton gradient that is then used for the synthesis of ATP and the transport of metabolites across the mitochondrial membrane.

How can the energy associated with a proton gradient be quantified? Recall that the free-energy change for a species moving from one side of a membrane where it is at concentration  $c_1$  to the other side where it is at a concentration  $c_2$  is given by

$$\Delta G = RT \ln(c_2/c_1) + ZF\Delta V$$

in which  $Z$  is the electrical charge of the transported species and  $\Delta V$  is the potential in volts across the membrane (Section 13.1). Under typical conditions for the inner mitochondrial membrane, the pH outside is 1.4 units lower than inside [corresponding to  $\ln(c_2/c_1)$  of 3.2] and the membrane potential is 0.14 V, the outside being positive. Because  $Z = +1$  for protons, the free-energy change is  $(8.32 \times 10^{-3} \text{ kJ mol}^{-1} \text{ K}^{-1} \times 310 \text{ K} \times 3.2) + (+1 \times 96.48 \text{ kJ mol}^{-1} \text{ V}^{-1} \times 0.14 \text{ V}) = 21.8 \text{ kJ mol}^{-1}$  ( $5.2 \text{ kcal mol}^{-1}$ ). Thus, each proton that is transported out of the matrix to the cytoplasmic side corresponds to  $21.8 \text{ kJ mol}^{-1}$  of free energy.

### 18.3 The Respiratory Chain Consists of Four Complexes: Three Proton Pumps and a Physical Link to the Citric Acid Cycle

Electrons are transferred from NADH to  $\text{O}_2$  through a chain of three large protein complexes called *NADH-Q oxidoreductase*, *Q-cytochrome c oxidoreductase*, and *cytochrome c oxidase* (Figure 18.6 and Table 18.2). *Electron flow within these transmembrane complexes is highly exergonic and powers the transport of protons across the inner mitochondrial membrane.* A fourth large protein complex, called *succinate-Q reductase*, contains the succinate dehydrogenase that generates  $\text{FADH}_2$  in the citric acid cycle. Electrons from this  $\text{FADH}_2$  enter the electron-transport chain at Q-cytochrome c oxidoreductase. Succinate-Q reductase, in contrast with the other complexes, does not pump protons. NADH-Q oxidoreductase, succinate-Q reductase, Q-cytochrome c oxidoreductase, and cytochrome c oxidase are also called *Complex I*, *II*, *III*, and *IV*, respectively. Complexes I, III, and IV appear to be associated in a supramolecular complex termed the *respirasome*. As we have seen before, such supramolecular complexes facilitate the rapid transfer of substrate and prevent the release of reaction intermediates.

**FIGURE 18.6 Components of the electron-transport chain.** Electrons flow down an energy gradient from  $NADH$  to  $O_2$ . The flow is catalyzed by four protein complexes, and the energy released is used to generate a proton gradient. [Information from D. Sadava et al., *Life*, 8th ed. (Sinauer, 2008), p. 150.]

Two special electron carriers ferry the electrons from one complex to the next. The first is *coenzyme Q* (Q), also known as *ubiquinone* because it is a *ubiquitous quinone* in biological systems. Ubiquinone is a hydrophobic quinone that diffuses rapidly within the inner mitochondrial membrane. Electrons are carried from NADH-Q oxidoreductase to Q-cytochrome *c* oxidoreductase, the third complex of the chain, by the reduced form of Q. Electrons from the  $FADH_2$  generated by the citric acid cycle are transferred first to ubiquinone and then to the Q-cytochrome *c* oxidoreductase complex.

Coenzyme Q is a quinone derivative with a long tail consisting of five-carbon isoprene units that account for its hydrophobic nature. The number of isoprene units in the tail depends on the species. The most common mammalian form contains 10 isoprene units (coenzyme  $Q_{10}$ ). For simplicity, the subscript will be omitted from this abbreviation because all varieties

**TABLE 18.2** Components of the mitochondrial electron-transport chain

Enzyme complex	Mass (kDa)	Subunits	Prosthetic group	Oxidant or reductant		
				Matrix side	Membrane core	Cytoplasmic side

Cytochrome <i>c</i> oxidase	160	13	Heme <i>a</i> Heme $a_3$ Cu $_A$ and Cu $_B$			Cytochrome <i>c</i>

**FIGURE 18.7** Oxidation states of quinones. The reduction of ubiquinone (Q) to ubiquinol (QH<sub>2</sub>) proceeds through a semiquinone intermediate (QH·).

function in an identical manner. Quinones can exist in several oxidation states. In the fully oxidized state (Q), coenzyme Q has two keto groups (Figure 18.7). The addition of one electron and one proton results in the semiquinone form (QH·). The semiquinone can lose a proton to form a semiquinone radical anion (Q<sup>·-</sup>). The addition of a second electron and proton to the semiquinone generates ubiquinol (QH<sub>2</sub>), the fully reduced form of coenzyme Q, which holds its protons more tightly. Thus, *for quinones, electron-transfer reactions are coupled to proton binding and release*, a property that is key to transmembrane proton transport. Because ubiquinone is soluble in the membrane, a pool of Q and QH<sub>2</sub>—the *Q pool*—is thought to exist in the inner mitochondrial membrane, although recent research suggests that the Q pool is confined to the respirasome.

In contrast with Q, the second special electron carrier is a protein. Cytochrome *c*, a small soluble protein, shuttles electrons from Q-cytochrome *c* oxidoreductase to cytochrome *c* oxidase, the final component in the chain and the one that catalyzes the reduction of O<sub>2</sub>.

### Iron–sulfur clusters are common components of the electron transport chain

*Iron–sulfur clusters* in *iron–sulfur proteins* (also called *nonheme iron proteins*) play a critical role in a wide range of reduction reactions in biological systems. Several types of Fe–S clusters are known (Figure 18.8). In the simplest kind, a single iron ion is tetrahedrally coordinated to the sulfhydryl groups of four cysteine residues of the protein (Figure 18.8A). A second kind, denoted by 2Fe–2S, contains two iron ions, two inorganic sulfides, and usually four cysteine residues (Figure 18.8B). A third type, designated 4Fe–4S, contains four iron ions, four inorganic sulfides, and four cysteine residues (Figure 18.8C). NADH–Q oxidoreductase contains both 2Fe–2S and 4Fe–4S clusters. Iron ions in these Fe–S complexes cycle between Fe<sup>2+</sup> (reduced) and Fe<sup>3+</sup> (oxidized) states. Unlike quinones and flavins, iron–sulfur clusters generally undergo oxidation–reduction reactions without releasing or binding protons.

The importance of Fe–S clusters is illustrated by the loss of function of the protein frataxin. Frataxin is a small (14.2-kDa) mitochondrial protein that is crucial for the synthesis of Fe–S clusters. Mutations in frataxin cause Friedreich's ataxia, a disease of varying severity that affects

**FIGURE 18.8 Iron-sulfur clusters.** (A) A single iron ion bound by four cysteine residues. (B) 2Fe-2S cluster with iron ions bridged by sulfide ions. (C) 4Fe-4S cluster. Each of these clusters can undergo oxidation-reduction reactions.

the central and peripheral nervous as well as the heart and skeletal system. Severe cases lead to death in young adult life. The most common mutation is trinucleotide expansion (Section 28.5) in the gene for frataxin.

### The high-potential electrons of NADH enter the respiratory chain at NADH-Q oxidoreductase

The electrons of NADH enter the chain at *NADH-Q oxidoreductase* (also called *Complex I* and *NADH dehydrogenase*), an enormous enzyme (>900 kDa) consisting of approximately 46 polypeptide chains. This proton pump, like that of the other two in the respiratory chain, is encoded by genes residing in both the mitochondria and the nucleus. NADH-Q oxidoreductase is L-shaped, with a horizontal arm lying in the membrane and a vertical arm that projects into the matrix.

The reaction catalyzed by this enzyme appears to be

The initial step is the binding of NADH and the transfer of its two high-potential electrons to the *flavin mononucleotide* (FMN) prosthetic group, yielding the reduced form, FMNH<sub>2</sub> (Figure 18.9). The electron acceptor of FMN, the isoalloxazine ring, is identical with that of FAD. Electrons are then transferred from FMNH<sub>2</sub> to a series of iron-sulfur clusters, the second type of prosthetic group in NADH-Q oxidoreductase.

Recent structural studies have suggested how Complex I acts as a proton pump. What are the structural elements required for proton-pumping? The membrane-embedded part of the complex has four proton half-channels consisting, in part, of vertical helices. One set of half-channels is exposed to the matrix and the other to the inner membrane space (Figure 18.10). The

**FIGURE 18.9 Oxidation states of flavins.**

vertical helices are linked on the matrix side by a long horizontal helix (HL) that connects the matrix half-channels, while the cytoplasmic half-channels are joined by a series of  $\beta$ -hairpin-helix connecting elements ( $\beta$ H). An enclosed Q chamber, the site where Q accepts electrons from NADH, exists near the junction of the hydrophilic portion and the membrane-embedded portion. Finally, a hydrophilic funnel connects the Q chamber to a water-lined channel (into which the half channels open) that extends the entire length of the membrane-embedded portion.

How do these structural elements cooperate to pump protons out of the matrix? When Q accepts two electrons from NADH, generating  $Q^{2-}$ , the negative charges on  $Q^{2-}$  interact electrostatically with negatively-charged amino acid residues in the membrane-embedded arm, causing conformational changes in the long horizontal helix and the  $\beta$ H elements. These changes in turn alter the structures of the connected vertical helices that change the  $pK_a$  of amino acids, allowing protons from the matrix to first bind to the amino acids, then dissociate into the water-lined channel and finally enter the intermembrane space. Thus, *the flow of two electrons from NADH to coenzyme Q through NADH-Q oxidoreductase leads to the pumping of four hydrogen ions out of the matrix of the mitochondrion.*  $Q^{2-}$  subsequently takes up two protons from the matrix as it is reduced to  $QH_2$ . The removal of these protons from the matrix contributes to the formation of the proton motive force. The  $QH_2$  subsequently leaves the enzyme for the Q pool, allowing another reaction cycle to occur.

It is important to note that the citric acid cycle is not the only source of mitochondrial NADH. As we will see in Chapter 22, fatty acid degradation, which also takes place in mitochondria, is another crucial source of NADH for the electron-transport chain. Moreover, electrons from cytoplasmically generated NADH can be transported into mitochondria for use by the electron-transport chain (Section 18.5).

### Ubiquinol is the entry point for electrons from $FADH_2$ of flavoproteins

$FADH_2$  enters the electron-transport chain at the second protein complex of the chain. Recall that  $FADH_2$  is formed in the citric acid cycle, in the oxidation of succinate to fumarate by succinate dehydrogenase (Section 17.2). Succinate dehydrogenase is part of the *succinate-Q reductase complex (Complex II)*, an integral membrane protein of the inner mitochondrial membrane.  $FADH_2$  does not leave the complex. Rather, its electrons are transferred to Fe-S centers and then finally to Q to form  $QH_2$ , which then is ready to transfer electrons further down the electron-transport chain. The succinate-Q reductase complex, in contrast with NADH-Q oxidoreductase, does not pump protons from one side of the membrane to the other. Consequently, less ATP is formed from the oxidation of  $FADH_2$  than from NADH.

### Electrons flow from ubiquinol to cytochrome c through Q-cytochrome c oxidoreductase

What is the fate of ubiquinol generated by Complexes I and II? The electrons from  $QH_2$  are passed on to *cytochrome c* (Cyt c), a water-soluble protein, by

**FIGURE 18.10 Coupled electron-proton transfer reactions through NADH-Q oxidoreductase.** Electrons flow in Complex I from NADH through FMN and a series of iron-sulfur clusters to ubiquinone (Q), forming  $Q^{2-}$ . The charges on  $Q^{2-}$  are electrostatically transmitted to hydrophilic amino acid residues (shown as red (glutamate) and blue (lysine or histidine) balls) that power the movement of HL and  $\beta$ H components. This movement changes the conformation of the transmembrane helices and results in the transport of four protons out of the mitochondrial matrix. [Information from R. Baradaran et al., *Nature* 494:443–448.]

**FIGURE 18.11 Structure of Q-cytochrome c oxidoreductase.**

This enzyme is a homodimer with each monomer consisting of 11 distinct polypeptide chains. Some of the more prominent components in one monomer are colored while the other monomer is white. Although each monomer contains the same components, some are identified in one monomer or the other for ease of viewing. Notice that the major prosthetic groups, three hemes and a 2Fe-2S cluster, are located either near the cytoplasmic edge of the complex bordering the intermembrane space (top) or in the region embedded in the membrane ( $\alpha$  helices represented by tubes). They are well positioned to mediate the electron-transfer reactions between quinones in the membrane and cytochrome c in the intermembrane space. [Drawn from 1BCC.pdb.]

the second of the three proton pumps in the respiratory chain, *Q-cytochrome c oxidoreductase* (also known as *Complex III* and as *cytochrome c reductase*). The flow of a pair of electrons through this complex leads to the effective net transport of 2  $H^+$  to the cytoplasmic side, half the yield obtained with NADH-Q reductase because of a smaller thermodynamic driving force.

Q-cytochrome c oxidoreductase itself contains two types of cytochromes, named *b* and *c*<sub>1</sub> (Figure 18.11). A *cytochrome* is an *electron-transferring protein that contains a heme prosthetic group*. The heme prosthetic group in cytochromes *b*, *c*<sub>1</sub>, and *c* is iron-protoporphyrin IX, the same heme present in myoglobin and hemoglobin (Section 7.1). The iron ion of a cytochrome, in contrast to hemoglobin and myoglobin, alternates between a reduced ferrous (+2) state and an oxidized ferric (+3) state during electron transport. The two cytochrome subunits of Q-cytochrome c oxidoreductase contain a total of three hemes: two hemes within cytochrome *b*, termed heme *b*<sub>L</sub> (L for low affinity) and heme *b*<sub>H</sub> (H for high affinity), and one heme within cytochrome *c*<sub>1</sub>. These identical hemes have different electron affinities because they are in different polypeptide environments. For example, heme *b*<sub>L</sub>, which is located in a cluster of helices near the cytoplasmic face of the membrane, has lower affinity for an electron than does heme *b*<sub>H</sub>, which is near the matrix side.

In addition to the hemes, the enzyme contains an iron-sulfur protein with a 2Fe-2S center. This center, termed the *Rieske center*, is unusual in that one of the iron ions is coordinated by two histidine residues rather than two cysteine residues. This coordination stabilizes the center in its reduced form, raising its reduction potential so that it can readily accept electrons from  $QH_2$ .

### The Q cycle funnels electrons from a two-electron carrier to a one-electron carrier and pumps protons

$\text{QH}_2$  passes two electrons to Q-cytochrome *c* oxidoreductase, but the acceptor of electrons in this complex, cytochrome *c*, can accept only one electron. How does the switch from the two-electron carrier ubiquinol to the one-electron carrier cytochrome *c* take place? The mechanism for the coupling of electron transfer from Q to cytochrome *c* to transmembrane proton transport is known as the *Q cycle* (Figure 18.12). Two  $\text{QH}_2$  molecules bind to the complex consecutively, each giving up two electrons and two  $\text{H}^+$ . These protons are released to the cytoplasmic side of the membrane. The first  $\text{QH}_2$  to exit the Q pool binds to the first Q binding site ( $\text{Q}_o$ ), and its two electrons travel through the complex to different destinations. One electron flows, first, to the Rieske 2Fe-2S cluster; then, to cytochrome  $c_1$ ; and, finally, to a molecule of oxidized cytochrome *c*, converting it into its reduced form. The reduced cytochrome *c* molecule is free to diffuse away from the enzyme to continue down the respiratory chain.

The second electron passes through two heme groups of cytochrome *b* to an oxidized ubiquinone in a second Q binding site ( $\text{Q}_i$ ). The Q in the second binding site is reduced to a semiquinone radical anion ( $\text{Q}^{\cdot-}$ ) by the electron from the first  $\text{QH}_2$ . The now fully oxidized Q leaves the first Q site, free to reenter the Q pool.

A second molecule of  $\text{QH}_2$  binds to the  $\text{Q}_o$  site of Q-cytochrome *c* oxidoreductase and reacts in the same way as the first. One of the electrons is transferred to cytochrome *c* and the second electron is transferred to the partly reduced ubiquinone bound in the  $\text{Q}_i$  binding site. On the addition of the electron from the second  $\text{QH}_2$  molecule, this quinone radical anion takes up two protons from the matrix to form  $\text{QH}_2$ . The removal of these two protons from the matrix contributes to the formation of the proton gradient. In sum, four protons are released on the cytoplasmic side, and two protons are removed from the mitochondrial matrix.

**FIGURE 18.12 Q cycle.** The Q cycle takes place in Complex III, which is represented in outline form. In the first half of the cycle, two electrons of a bound  $\text{QH}_2$  are transferred, one to cytochrome *c* and the other to a bound Q in a second binding site to form the semiquinone radical anion  $\text{Q}^{\cdot-}$ . The newly formed Q dissociates and enters the Q pool. In the second half of the cycle, a second  $\text{QH}_2$  also gives up its electrons to Complex III, one to a second molecule of cytochrome *c* and the other to reduce  $\text{Q}^{\cdot-}$  to  $\text{QH}_2$ . This second electron transfer results in the uptake of two protons from the matrix. The path of electron transfer is shown in red.

In one Q cycle, two  $\text{QH}_2$  molecules are oxidized to form two Q molecules, and then one Q molecule is reduced to  $\text{QH}_2$ . The problem of how to efficiently funnel electrons from a two-electron carrier ( $\text{QH}_2$ ) to a one-electron carrier (cytochrome *c*) is solved by the Q cycle. The cytochrome *b* component of the reductase is in essence a recycling device that enables both electrons of  $\text{QH}_2$  to be used effectively.

### Cytochrome *c* oxidase catalyzes the reduction of molecular oxygen to water

The last of the three proton-pumping assemblies of the respiratory chain is *cytochrome c oxidase* (Complex IV). Cytochrome *c* oxidase catalyzes the transfer of electrons from the reduced form of cytochrome *c* to molecular oxygen, the final acceptor.

**FIGURE 18.13 Structure of cytochrome c oxidase.** This enzyme consists of 13 polypeptide chains. Notice that most of the complex, as well as two major prosthetic groups (heme *a* and heme *a*<sub>3</sub>-Cu<sub>B</sub>) are embedded in the membrane ( $\alpha$  helices represented by vertical tubes). Heme *a*<sub>3</sub>-Cu<sub>B</sub> is the site of the reduction of oxygen to water. The Cu<sub>A</sub>/Cu<sub>A</sub> prosthetic group is positioned near the intermembrane space to better accept electrons from cytochrome *c*. CO(bb) is a carbonyl group of the peptide backbone. [Drawn from 2OCC.pdb.]

The requirement of oxygen for this reaction is what makes “aerobic” organisms aerobic. To obtain oxygen for this reaction is the reason that human beings must breathe. Four electrons are funneled to O<sub>2</sub> to completely reduce it to H<sub>2</sub>O, and, concomitantly, protons are pumped from the matrix to the cytoplasmic side of the inner mitochondrial membrane. This reaction is quite thermodynamically favorable. From the reduction potentials in Table 18.1, the standard free-energy change for this reaction is calculated to be  $\Delta G^{\circ} = -231.8 \text{ kJ mol}^{-1}$  ( $-55.4 \text{ kcal mol}^{-1}$ ). As much of this free energy as possible must be captured in the form of a proton gradient for subsequent use in ATP synthesis.

Bovine cytochrome *c* oxidase is reasonably well understood at the structural level (Figure 18.13). It consists of 13 subunits, 3 of which are encoded by the mitochondrion’s own genome. Cytochrome *c* oxidase contains two heme A groups and three copper ions, arranged as two copper centers, designated A and B. One center, Cu<sub>A</sub>/Cu<sub>A</sub>, contains two copper ions linked by two bridging cysteine residues. This center initially accepts electrons from reduced cytochrome *c*. The remaining copper ion, Cu<sub>B</sub>, is bonded to three histidine residues, one of which is modified by covalent linkage to a tyrosine residue. The copper centers alternate between the reduced Cu<sup>+</sup> (cuprous) form and the oxidized Cu<sup>2+</sup> (cupric) form as they accept and donate electrons.

There are two heme A molecules, called heme *a* and heme *a*<sub>3</sub>, in cytochrome *c* oxidase. Heme A differs from the heme in cytochrome *c* and *c*<sub>1</sub> in three ways: (1) a formyl group replaces a methyl group, (2) a C<sub>17</sub> hydrocarbon chain replaces one of the vinyl groups, and (3) the heme is not covalently attached to the protein.

Histidine covalently bound to tyrosine

Heme *a* and heme *a*<sub>3</sub> have distinct redox potentials because they are located in different environments within cytochrome *c* oxidase. An electron flows from cytochrome *c* to Cu<sub>A</sub>/Cu<sub>A</sub>, to heme *a*, to heme *a*<sub>3</sub>, to Cu<sub>B</sub>, and finally to O<sub>2</sub>. Heme *a*<sub>3</sub> and Cu<sub>B</sub> are directly adjacent. Together, heme *a*<sub>3</sub> and Cu<sub>B</sub> form the active center at which O<sub>2</sub> is reduced to H<sub>2</sub>O.

Four molecules of cytochrome *c* bind consecutively to the enzyme and transfer an electron to reduce one molecule of O<sub>2</sub> to H<sub>2</sub>O (Figure 18.14):

**FIGURE 18.14 Cytochrome *c* oxidase mechanism.** The cycle begins and ends with all prosthetic groups in their oxidized forms (shown in blue). Reduced forms are in red. Four cytochrome *c* molecules donate four electrons, which, in allowing the binding and cleavage of an O<sub>2</sub> molecule, also makes possible the import of four H<sup>+</sup> from the matrix to form two molecules of H<sub>2</sub>O, which are released from the enzyme to regenerate the initial state.

**FIGURE 18.15 Peroxide bridge.** The oxygen bound to heme  $a_3$  is reduced to peroxide by the presence of  $\text{Cu}_B$ .

**FIGURE 18.16 Proton transport by cytochrome  $c$  oxidase.** Four protons are taken up from the matrix side to reduce one molecule of  $\text{O}_2$  to two molecules of  $\text{H}_2\text{O}$ . These protons are called “chemical protons” because they participate in a clearly defined reaction with  $\text{O}_2$ . Four additional “pumped” protons are transported out of the matrix and released on the cytoplasmic side in the course of the reaction. The pumped protons double the efficiency of free-energy storage in the form of a proton gradient for this final step in the electron-transport chain.

1. Electrons from two molecules of reduced cytochrome  $c$  flow down an electron-transfer pathway within cytochrome  $c$  oxidase, one stopping at  $\text{Cu}_B$  and the other at heme  $a_3$ . With both centers in the reduced state, they together can now bind an oxygen molecule.

2. As molecular oxygen binds, it abstracts an electron from each of the nearby ions in the active center to form a peroxide ( $\text{O}_2^{2-}$ ) bridge between them (Figure 18.15).

3. Two more molecules of cytochrome  $c$  bind and release electrons that travel to the active center. The addition of an electron as well as  $\text{H}^+$  to each oxygen atom reduces the two ion–oxygen groups to  $\text{Cu}_B^{2+}\text{—OH}$  and  $\text{Fe}^{3+}\text{—OH}$ .

4. Reaction with two more  $\text{H}^+$  ions allows the release of two molecules of  $\text{H}_2\text{O}$  and resets the enzyme to its initial, fully oxidized form.

The four protons in this reaction come exclusively from the matrix. Thus, the consumption of these four protons contributes directly to the proton gradient. Recall that each proton contributes  $21.8 \text{ kJ mol}^{-1}$  ( $5.2 \text{ kcal mol}^{-1}$ ) to the free energy associated with the proton gradient; so these four protons contribute  $87.2 \text{ kJ mol}^{-1}$  ( $20.8 \text{ kcal mol}^{-1}$ ), an amount substantially less than the free energy available from the reduction of oxygen to water. What is the fate of this missing energy? Remarkably, *cytochrome  $c$  oxidase uses this energy to pump four additional protons from the matrix to the cytoplasmic side of the membrane in the course of each reaction cycle for a total of eight protons removed from the matrix* (Figure 18.16). The details of how these protons are transported through the protein are still under study. However, two effects contribute to the mechanism. First, charge neutrality tends to be maintained in the interior of proteins. Thus, the addition of an electron to a site inside a protein tends to favor the binding of  $\text{H}^+$  to a nearby site. Second, conformational changes take place, particularly around the heme  $a_3$ – $\text{Cu}_B$  center, in the course of the reaction cycle. Presumably, in one conformation, protons may enter the protein exclusively from the matrix side, whereas, in another, they may exit exclusively to the cytoplasmic side. Thus, the overall process catalyzed by cytochrome  $c$  oxidase is

Figure 18.17 summarizes the flow of electrons from NADH and  $\text{FADH}_2$  through the respiratory chain. This series of exergonic reactions is coupled to the pumping of protons from the matrix. As we will see shortly, the energy inherent in the proton gradient will be used to synthesize ATP.

### Toxic derivatives of molecular oxygen such as superoxide radicals are scavenged by protective enzymes

As discussed earlier, molecular oxygen is an ideal terminal electron acceptor, because its high affinity for electrons provides a large thermodynamic driving force. However, danger lurks in the reduction of  $\text{O}_2$ . The transfer of four electrons leads to safe products (two molecules of  $\text{H}_2\text{O}$ ), but partial reduction generates hazardous compounds. In particular, *the transfer of a single electron to  $\text{O}_2$  forms superoxide ion, whereas the transfer of two electrons yields peroxide.*

**FIGURE 18.17 The electron-transport chain.** High-energy electrons in the form of NADH and FADH<sub>2</sub> are generated by the citric acid cycle. These electrons flow through the respiratory chain, which powers proton pumping and results in the reduction of O<sub>2</sub>.

Both compounds are potentially destructive. The strategy for the safe reduction of O<sub>2</sub> is clear: *the catalyst does not release partly reduced intermediates*. Cytochrome *c* oxidase meets this crucial criterion by holding O<sub>2</sub> tightly between Fe and Cu ions.

Although cytochrome *c* oxidase and other proteins that reduce O<sub>2</sub> are remarkably successful in not releasing intermediates, small amounts of superoxide anion and hydrogen peroxide are unavoidably formed. Superoxide, hydrogen peroxide, and species that can be generated from them such as the hydroxyl radical (OH<sup>•</sup>) are collectively referred to as *reactive oxygen species* or ROS. Oxidative damage caused by ROS has been implicated in the aging process as well as in a growing list of diseases (Table 18.3).

What are the cellular defense strategies against oxidative damage by ROS? Chief among them is the enzyme *superoxide dismutase*. This enzyme scavenges superoxide radicals by catalyzing the conversion of two of these radicals into hydrogen peroxide and molecular oxygen.

Eukaryotes contain two forms of this enzyme, a manganese-containing version located in mitochondria and a copper-and-zinc-dependent cytoplasmic form. These enzymes perform the dismutation reaction by a similar

#### Dismutation

A reaction in which a single reactant is converted into two different products.

**FIGURE 18.18 Superoxide dismutase mechanism.** The oxidized form of superoxide dismutase ( $M_{ox}$ ) reacts with one superoxide ion to form  $O_2$  and generate the reduced form of the enzyme ( $M_{red}$ ). The reduced form then reacts with a second superoxide and two protons to form hydrogen peroxide and regenerate the oxidized form of the enzyme.

mechanism (Figure 18.18). The oxidized form of the enzyme is reduced by superoxide to form oxygen. The reduced form of the enzyme, formed in this reaction, then reacts with a second superoxide ion to form peroxide, which takes up two protons along the reaction path to yield hydrogen peroxide.

The hydrogen peroxide formed by superoxide dismutase and by other processes is scavenged by *catalase*, a ubiquitous heme protein that catalyzes the dismutation of hydrogen peroxide into water and molecular oxygen.

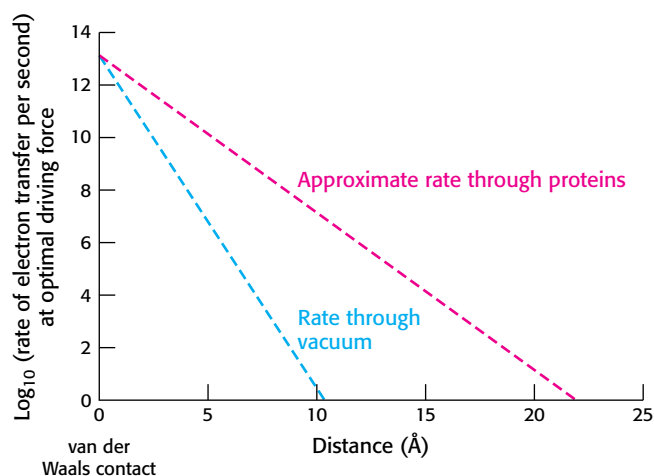

Superoxide dismutase and catalase are remarkably efficient, performing their reactions at or near the diffusion-limited rate (Section 8.4). Glutathione peroxidase also plays a role in scavenging  $\text{H}_2\text{O}_2$  (Section 20.5). Other cellular defenses against oxidative damage include the antioxidant vitamins, vitamins E and C. Because it is lipophilic, vitamin E is especially useful in protecting membranes from lipid peroxidation.

A long-term benefit of exercise may be to increase the amount of superoxide dismutase in the cell. The elevated aerobic metabolism during exercise causes more ROS to be generated. In response, the cell synthesizes more protective enzymes. The net effect is one of protection, because the increase in superoxide dismutase more effectively protects the cell during periods of rest (Problem 48).

Despite the fact that reactive oxygen species are known hazards, recent evidence suggests that, under certain circumstances, the controlled generation of these molecules may be an important component of signal-transduction pathways. For instance, growth factors have been shown to increase ROS levels as part of their signaling pathway, and ROS regulate channels and transcription factors. ROS have been implicated in the control of cell differentiation, the immune response, autophagy as well as other metabolic activities. The dual role of ROS is an excellent example of the wondrous complexity of biochemistry of living systems: even potentially harmful substances can be harnessed to play useful roles.

**FIGURE 18.19 Distance dependence of electron-transfer rate.** The rate of electron transfer decreases as the electron donor and the electron acceptor move apart. In a vacuum, the rate decreases by a factor of 10 for every increase of 0.8 Å. In proteins, the rate decreases more gradually, by a factor of 10 for every increase of 1.7 Å. This rate is only approximate because variations in the structure of the intervening protein medium can affect the rate.

### Electrons can be transferred between groups that are not in contact

How are electrons transferred between electron-carrying groups of the respiratory chain? This question is intriguing because these groups are frequently buried in the interior of a protein in fixed positions and are therefore not directly in contact with one another. Electrons can move through space, even through a vacuum. However, the rate of electron transfer through space falls off rapidly as the electron donor and electron acceptor move apart from each other, decreasing by a factor of 10 for each increase in separation of 0.8 Å. The protein environment provides more-efficient pathways for electron conduction: typically, the rate of electron transfer decreases by a factor of 10 every 1.7 Å (Figure 18.19). For groups in contact, electron-transfer reactions can be quite fast, with rates of approximately  $10^{13} \text{ s}^{-1}$ . Within proteins in the electron-transport chain, electron-carrying groups are typically separated by 15 Å beyond their van der Waals contact distance. For such separations, we expect electron-transfer rates of approximately  $10^4 \text{ s}^{-1}$  (i.e., electron transfer in less than 1 ms), assuming that all other factors

are optimal. Without the mediation of the protein, an electron transfer over this distance would take approximately 1 day.

The case is more complicated when electrons must be transferred between two distinct proteins, such as when cytochrome *c* accepts electrons from Complex III or passes them on to Complex IV. A series of hydrophobic interactions bring the heme groups of cytochrome *c* and *c*<sub>1</sub> to within 4.5 Å of each other, with the iron atoms separated by 17.4 Å. This distance could allow cytochrome *c* reduction at a rate of  $8.3 \times 10^6 \text{ s}^{-1}$ .

### The conformation of cytochrome *c* has remained essentially constant for more than a billion years

 Cytochrome *c* is present in all organisms having mitochondrial respiratory chains: plants, animals, and eukaryotic microorganisms. This electron carrier evolved more than 1.5 billion years ago, before the divergence of plants and animals. Its function has been conserved throughout this period, as evidenced by the fact that *the cytochrome c of any eukaryotic species reacts in vitro with the cytochrome c oxidase of any other species tested thus far*. For example, wheat-germ cytochrome *c* reacts with human cytochrome *c* oxidase. Additionally, some prokaryotic cytochromes, such as cytochrome *c*<sub>2</sub> from the photosynthetic bacterium *Rhodospirillum rubrum* and cytochrome *c*<sub>550</sub> from the denitrifying bacterium *Paracoccus denitrificans*, closely resemble cytochrome *c* from tuna-heart mitochondria (Figure 18.20). This evidence attests to an efficient evolutionary solution to electron transfer bestowed by the structural and functional characteristics of cytochrome *c*.

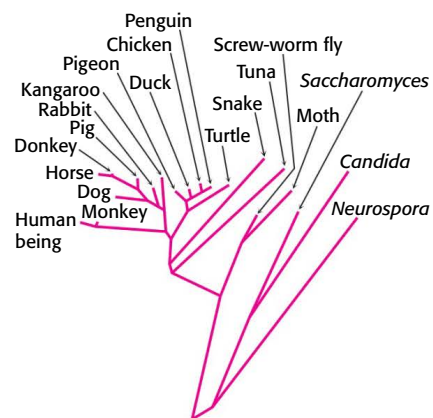

The resemblance among cytochrome *c* molecules extends to the level of amino acid sequence. Because of the molecule's small size and ubiquity, the amino acid sequences of cytochrome *c* from more than 80 widely ranging eukaryotic species have been determined by direct protein sequencing. The striking finding is that *21 of 104 residues have been invariant for more than one and a half billion years of evolution*. A phylogenetic tree, constructed from the amino acid sequences of cytochrome *c*, reveals the evolutionary relationships between many animal species (Figure 18.21).

## 18.4 A Proton Gradient Powers the Synthesis of ATP

Thus far, we have considered the flow of electrons from NADH to O<sub>2</sub>, an exergonic process.

 **FIGURE 18.20 Conservation of the three-dimensional structure of cytochrome *c*.** Notice the overall structural similarity of the different molecules from different sources. The side chains are shown for the 21 conserved amino acids as well as the centrally located planar heme. [Drawn from 3CYT.pdb, 3C2C.pdb, and 155C.pdb.]

**FIGURE 18.21 Evolutionary tree constructed from sequences of cytochrome *c*.** Branch lengths are proportional to the number of amino acid changes that are believed to have occurred. [Information from Walter M. Fitch and Emanuel Margoliash.]

Next, we consider how this process is coupled to the synthesis of ATP, an endergonic process.

A molecular assembly in the inner mitochondrial membrane carries out the synthesis of ATP. This enzyme complex was originally called the *mitochondrial ATPase* or  $F_1F_0$  *ATPase* because it was discovered through its catalysis of the reverse reaction, the hydrolysis of ATP. *ATP synthase*, its preferred name, emphasizes its actual role in the mitochondrion. It is also called *Complex V*.

How is the oxidation of NADH coupled to the phosphorylation of ADP? Electron transfer was first suggested to lead to the formation of a covalent high-energy intermediate that serves as a compound having a high phosphoryl-transfer potential, analogous to the generation of ATP by the formation of 1,3-bisphosphoglycerate in glycolysis (Section 16.1). An alternative proposal was that electron transfer aids the formation of an activated protein conformation, which then drives ATP synthesis. The search for such intermediates for several decades proved fruitless.

In 1961, Peter Mitchell suggested a radically different mechanism, the *chemiosmotic hypothesis*. He proposed that electron transport and ATP synthesis are coupled by a *proton gradient across the inner mitochondrial membrane*. In his model, the transfer of electrons through the respiratory chain leads to the pumping of protons from the matrix to the cytoplasmic side of the inner mitochondrial membrane. The  $\text{H}^+$  concentration becomes lower in the matrix, and an electric field with the matrix side negative is generated (Figure 18.22). Protons then flow back into the matrix to equalize the distribution. Mitchell's idea was that this flow of protons drives the synthesis of ATP by ATP synthase. The energy-rich unequal distribution of protons is called the *proton-motive force*. The proton-motive force is composed of two components: a chemical gradient and a charge gradient. The chemical gradient for protons can be represented as a pH gradient. The charge gradient is created by the positive charge on the unequally distributed protons forming the chemical gradient. Mitchell proposed that both components power the synthesis of ATP.

$$\text{Proton-motive force}(\Delta p) = \text{chemical gradient}(\Delta \text{pH}) + \text{charge gradient}(\Delta \psi)$$

Mitchell's highly innovative hypothesis that oxidation and phosphorylation are coupled by a proton gradient is now supported by a wealth of evidence. Indeed, electron transport does generate a proton gradient across the inner mitochondrial membrane. The pH outside is 1.4 units lower than inside, and the membrane potential is 0.14 V, the outside being positive. As calculated on page 529, this membrane potential corresponds to a free energy of 21.8 kJ (5.2 kcal) per mole of protons.

Some have argued that, along with the elucidation of the structure of DNA, the discovery that ATP synthesis is powered by a proton gradient is one of the two major advances in biology in the twentieth century. Mitchell's initial postulation of the chemiosmotic theory was not warmly received by all. Efraim Racker, one of the early investigators of ATP synthase, recalls that some thought of Mitchell as a court jester, whose work was of no consequence. Peter Mitchell was awarded the Nobel Prize in chemistry in 1978 for his contributions to understanding oxidative phosphorylation.

**FIGURE 18.22 Chemiosmotic hypothesis.**

Electron transfer through the respiratory chain leads to the pumping of protons from the matrix to the cytoplasmic side of the inner mitochondrial membrane. The pH gradient and membrane potential constitute a proton-motive force that is used to drive ATP synthesis.

**FIGURE 18.23 Testing the chemiosmotic hypothesis.** ATP is synthesized when reconstituted membrane vesicles containing bacteriorhodopsin (a light-driven proton pump) and ATP synthase are illuminated.

An artificial system was created to elegantly demonstrate the basic principle of the chemiosmotic hypothesis. The role of the respiratory chain was played by bacteriorhodopsin, a membrane protein from halobacteria that pumps protons when illuminated. Synthetic vesicles containing bacteriorhodopsin and mitochondrial ATP synthase purified from beef heart were created (Figure 18.23). When the vesicles were exposed to light, ATP was formed. This key experiment clearly showed that *the respiratory chain and ATP synthase are biochemically separate systems, linked only by a proton-motive force.*

#### ATP synthase is composed of a proton-conducting unit and a catalytic unit

Two parts of the puzzle of how NADH oxidation is coupled to ATP synthesis are now evident: (1) electron transport generates a proton-motive force, and (2) ATP synthesis by ATP synthase can be powered by a proton-motive force. How is the proton-motive force converted into the high phosphoryl-transfer potential of ATP?

Biochemical, electron microscopic, and crystallographic studies of ATP synthase have revealed many details of its structure (Figure 18.24). It is a large, complex enzyme resembling a ball on a stick. Much of the “stick” part, called the  $F_0$  subunit, is embedded in the inner mitochondrial membrane. The 85-Å-diameter ball, called the  $F_1$  subunit, protrudes into the mitochondrial matrix. The  $F_1$  subunit contains the catalytic activity of the synthase. In fact, isolated  $F_1$  subunits display ATPase activity.

The  $F_1$  subunit consists of five types of polypeptide chains ( $\alpha_3$ ,  $\beta_3$ ,  $\gamma$ ,  $\delta$ , and  $\epsilon$ ) with the indicated stoichiometry. The  $\alpha$  and  $\beta$  subunits, which make up the bulk of the  $F_1$ , are arranged alternately in a hexameric ring; they are homologous to one another and are members of the P-loop NTPase family (Section 9.4). Both bind nucleotides but only the  $\beta$  subunits are catalytically active. Just below the  $\alpha$  and  $\beta$  subunits is a central stalk consisting of the  $\gamma$  and  $\epsilon$  proteins. The  $\gamma$  subunit includes a long helical coiled coil that extends into the center of the  $\alpha_3\beta_3$  hexamer. *The  $\gamma$  subunit breaks the symmetry of the  $\alpha_3\beta_3$  hexamer: each of the  $\beta$  subunits is distinct by virtue of its interaction with a different face of  $\gamma$ .* Distinguishing the three  $\beta$  subunits is crucial for understanding the mechanism of ATP synthesis.

The  $F_0$  subunit is a hydrophobic segment that spans the inner mitochondrial membrane.  $F_0$  contains the proton channel of the complex. This channel consists of a ring comprising from 8 to 14  $c$  subunits that are embedded in the membrane. A single  $a$  subunit binds

**FIGURE 18.24 Structure of ATP synthase.** A schematic structure is shown along with representations of the components for which structures have been determined to high resolution. The P-loop NTPase domains of the  $\alpha$  and  $\beta$  subunits are indicated by purple shading. Notice that part of the enzyme complex is embedded in the inner mitochondrial membrane, whereas the remainder resides in the matrix. [Drawn from 1E79.pdb and 1COV.pdb.]

**FIGURE 18.25 ATPase assists in the formation of cristae.** Oligomers of ATP synthase dimers facilitate cristae formation, creating an area where the protons (red balls) are concentrated and have ready access to the  $F_0$  portion of the ATP synthase. The electron transport chain is represented by the yellow cylinders embedded in the inner mitochondrial membrane. [Information from K. M. Davies et al., *Proc. Natl. Acad. Sci. U.S.A.* 108: 14121–14126, 2011.]

to the outside of the ring. The  $F_0$  and  $F_1$  subunits are connected in two ways: by the central  $\gamma$  stalk and by an exterior column. The exterior column consists of one **a** subunit, two **b** subunits, and the  $\delta$  subunit.

ATP synthases associate with one another to form dimers, which then associate to form large oligomers of dimers. This association stabilizes the individual enzymes to the rotational forces required for catalysis and facilitates the curvature of the inner mitochondrial membrane. The formation of the cristae allows the proton pumps of the electron transport chain to localize the proton gradient in the vicinity of the synthases, which are located at the tips of the cristae, thereby enhancing the efficiency of ATP synthesis (Figure 18.25).

### Proton flow through ATP synthase leads to the release of tightly bound ATP: The binding-change mechanism

ATP synthase catalyzes the formation of ATP from ADP and orthophosphate.

The actual substrates are ADP and ATP complexed with  $\text{Mg}^{2+}$ , as in all known phosphoryl-transfer reactions with these nucleotides. A terminal oxygen atom of ADP attacks the phosphorus atom of  $\text{P}_i$  to form a pentacovalent intermediate, which then dissociates into ATP and  $\text{H}_2\text{O}$  (Figure 18.26).

How does the flow of protons drive the synthesis of ATP? Isotopic-exchange experiments unexpectedly revealed that *enzyme-bound ATP forms readily in the absence of a proton-motive force*. When ADP and  $\text{P}_i$  were added to ATP synthase in  $\text{H}_2^{18}\text{O}$ ,  $^{18}\text{O}$  became incorporated into  $\text{P}_i$  through the

**FIGURE 18.26 ATP-synthesis mechanism.** One of the oxygen atoms of ADP attacks the phosphorus atom of  $\text{P}_i$  to form a pentacovalent intermediate, which then forms ATP and releases a molecule of  $\text{H}_2\text{O}$ .

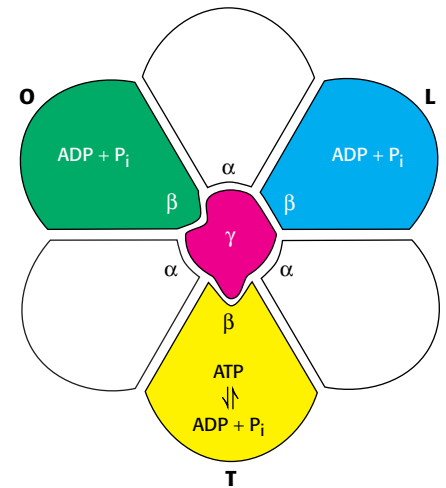

**FIGURE 18.27 ATP forms without a proton-motive force but is not released.** The results of isotopic-exchange experiments indicate that enzyme-bound ATP is formed from ADP and  $P_i$  in the absence of a proton-motive force.

synthesis of ATP and its subsequent hydrolysis (Figure 18.27). The rate of incorporation of  $^{18}O$  into  $P_i$  showed that about equal amounts of bound ATP and ADP are in equilibrium at the catalytic site, even in the absence of a proton gradient. However, ATP does not leave the catalytic site unless protons flow through the enzyme. Thus, *the role of the proton gradient is not to form ATP but to release it from the synthase.*

The fact that three  $\beta$  subunits are components of the  $F_1$  moiety of the ATPase means that there are three active sites on the enzyme, each performing one of three different functions at any instant. The proton-motive force causes the three active sites to sequentially change functions as protons flow through the membrane-embedded component of the enzyme. Indeed, we can think of the enzyme as consisting of a moving part and a stationary part: (1) the moving unit, or *rotor*, consists of the  $c$  ring and the  $\gamma$  stalk and (2) the stationary unit, or *stator*, is composed of the remainder of the molecule.

How do the three active sites of ATP synthase respond to the flow of protons? A number of experimental observations suggested a *binding-change mechanism* for proton-driven ATP synthesis. This proposal states that a  $\beta$  subunit can perform each of three sequential steps in the synthesis of ATP by changing conformation. These steps are (1) ADP and  $P_i$  binding, (2) ATP synthesis, and (3) ATP release. As already noted, interactions with the  $\gamma$  subunit make the three  $\beta$  subunits structurally distinct (Figure 18.28). At any given moment, one  $\beta$  subunit will be in the L, or loose, conformation. This conformation binds ADP and  $P_i$ . A second subunit will be in the T, or tight, conformation. This conformation binds ATP with great avidity, so much so that it will convert bound ADP and  $P_i$  into ATP. Both the T and L conformations are sufficiently constrained that they cannot release bound nucleotides. The final subunit will be in the O, or open, form. This form has a more open conformation and can bind or release adenine nucleotides.

The rotation of the  $\gamma$  subunit drives the interconversion of these three forms (Figure 18.29). ADP and  $P_i$  bound in the subunit in the T form are transiently combining to form ATP. Suppose that the  $\gamma$  subunit is rotated by

**FIGURE 18.28 ATP synthase nucleotide-binding sites are not equivalent.** The  $\gamma$  subunit passes through the center of the  $\alpha_3\beta_3$  hexamer and makes the nucleotide-binding sites in the  $\beta$  subunits distinct from one another. The  $\beta$  subunits are colored to distinguish them from one another.

**Progressive alteration of the forms of the three active sites of ATP synthase**

- Subunit 1 L  $\rightarrow$  T  $\rightarrow$  O  $\rightarrow$  L  $\rightarrow$  T  $\rightarrow$  O.....
- Subunit 2 O  $\rightarrow$  L  $\rightarrow$  T  $\rightarrow$  O  $\rightarrow$  L  $\rightarrow$  T.....
- Subunit 3 T  $\rightarrow$  O  $\rightarrow$  L  $\rightarrow$  T  $\rightarrow$  O  $\rightarrow$  L.....

**FIGURE 18.29 Binding-change mechanism for ATP synthase.** The rotation of the  $\gamma$  subunit interconverts the three  $\beta$  subunits. The subunit in the T (tight) form interconverts ADP and  $P_i$  and ATP but does not allow ATP to be released. When the  $\gamma$  subunit is rotated by 120 degrees in a counterclockwise (CCW) direction, the T-form subunit is converted into the O form, allowing ATP release. ADP and  $P_i$  can then bind to the O-form subunit. An additional 120-degree rotation (not shown) traps these substrates in an L-form subunit.

**FIGURE 18.30 Direct observation of ATP-driven rotation in ATP synthase.**

The  $\alpha_3\beta_3$  hexamer of ATP synthase is fixed to a surface, with the  $\gamma$  subunit projecting upward and linked to a fluorescently labeled actin filament. The addition and subsequent hydrolysis of ATP result in the counterclockwise rotation of the  $\gamma$  subunit, which can be directly seen under a fluorescence microscope.

120 degrees in a counterclockwise direction (as viewed from the top). This rotation converts the T-form site into an O-form site with the nucleotide bound as ATP. Concomitantly, the L-form site is converted into a T-form site, enabling the transformation of an additional ADP and P<sub>i</sub> into ATP. The ATP in the O-form site can now depart from the enzyme to be replaced by ADP and P<sub>i</sub>. An additional 120-degree rotation converts this O-form site into an L-form site, trapping these substrates. Each subunit progresses from the T to the O to the L form with no two subunits ever present in the same conformational form. This mechanism suggests that ATP can be synthesized and released by driving the rotation of the  $\gamma$  subunit in the appropriate direction.

**Rotational catalysis is the world's smallest molecular motor**

Is it possible to observe the proposed rotation directly? Elegant experiments, using single-molecule techniques (Section 8.6), have demonstrated the rotation through the use of a simple experimental system consisting solely of cloned  $\alpha_3\beta_3\gamma$  subunits (Figure 18.30). The  $\beta$  subunits were engineered to contain amino-terminal polyhistidine tags, which have a high affinity for nickel ions (Section 3.1). This property of the tags allowed the  $\alpha_3\beta_3$  assembly to be immobilized on a glass surface that had been coated with nickel ions. The  $\gamma$  subunit was linked to a fluorescently labeled actin filament to provide a long segment that could be observed under a fluorescence microscope. Remarkably, the addition of ATP caused the actin filament to rotate unidirectionally in a counterclockwise direction. *The  $\gamma$  subunit was rotating, driven by the hydrolysis of ATP.* Thus, the catalytic activity of an individual molecule could be observed. The counterclockwise rotation is consistent with the predicted mechanism for hydrolysis because the molecule was viewed from below relative to the view shown in Figure 18.30.

More-detailed analysis in the presence of lower concentrations of ATP revealed that the  $\gamma$  subunit rotates in 120-degree increments. Each increment corresponds to the hydrolysis of a single ATP molecule. In addition, from the results obtained by varying the length of the actin filament and measuring the rate of rotation, the enzyme appears to operate near 100% efficiency; that is, essentially all of the energy released by ATP hydrolysis is converted into rotational motion.

**Proton flow around the c ring powers ATP synthesis**

The direct observation of rotary motion of the  $\gamma$  subunit is strong evidence for the rotational mechanism for ATP synthesis. The last remaining question is: How does proton flow through F<sub>0</sub> drive the rotation of the  $\gamma$  subunit? The mechanism depends on the structures of the **a** and **c** subunits of F<sub>0</sub> (Figure 18.31). The stationary **a** subunit directly abuts the membrane-spanning ring formed by 8 to 14 **c** subunits. The **a** subunit includes two

**FIGURE 18.31 Components of the proton-conducting unit of ATP synthase.**

The **c** subunit consists of two  $\alpha$  helices that span the membrane. In *E. coli*, an aspartic acid residue in one of the helices lies on the center of the membrane. The structure of the **a** subunit has not yet been directly observed, but it appears to include two half-channels that allow protons to enter and pass partway but not completely through the membrane.

**FIGURE 18.32 Proton motion across the membrane drives rotation of the c ring.** A proton enters from the intermembrane space into the cytoplasmic half-channel to neutralize the charge on an aspartate residue in a c subunit. With this charge neutralized, the c ring can rotate clockwise by one c subunit, moving an aspartic acid residue out of the membrane into the matrix half-channel. This proton can move into the matrix, resetting the system to its initial state.

hydrophilic half-channels that do not span the membrane (Figure 18.31). Thus, protons can pass into either of these channels, but they cannot move completely across the membrane. The a subunit is positioned such that each half-channel directly interacts with one c subunit.

The structure of the c subunit was determined both by NMR methods and by x-ray crystallography. Each polypeptide chain forms a pair of  $\alpha$  helices that span the membrane. A glutamic acid (or aspartic acid) residue is found in the middle of one of the helices. If the glutamate is charged (unprotonated), the c subunit will not move into the membrane. The key to proton movement across the membrane is that, in a proton-rich environment, such as the cytoplasmic side of the inner mitochondrial membrane, a proton will enter a channel and bind the glutamate residue, while the glutamic acid in a proton-poor environment of the other half-channel will release a proton (Figure 18.32). The c subunit with the bound proton then moves into the membrane as the ring rotates by one c subunit. This rotation brings the newly deprotonated c subunit from the matrix half-channel to the proton rich cytoplasmic half-channel, where it can bind a proton. *The movement of protons through the half-channels from the high proton concentration of the cytoplasm to the low proton concentration of the matrix powers the rotation of the c ring.* The a unit remains stationary as the c ring rotates. Each proton that enters the cytoplasmic half-channel of the a unit moves through the membrane by riding around on the rotating c ring to exit through the matrix half-channel into the proton-poor environment of the matrix (Figure 18.33).

How does the rotation of the c ring lead to the synthesis of ATP? The c ring is tightly linked to the  $\gamma$  and  $\epsilon$  subunits. Thus, as the c ring turns, the

**FIGURE 18.33 Proton path through the membrane.** Each proton enters the cytoplasmic half-channel, follows a complete rotation of the c ring, and exits through the other half-channel into the matrix.

**A little goes a long way**

Despite the various molecular machinations and the vast numbers of ATPs synthesized and protons pumped, a resting human being requires surprisingly little power. Approximately 116 watts, the energy output of a typical light bulb, provides enough energy to sustain a resting person.

$\gamma$  and  $\epsilon$  subunits are turned inside the  $\alpha_3\beta_3$  hexamer unit of  $F_1$ . The rotation of the  $\gamma$  subunit in turn promotes the synthesis of ATP through the binding-change mechanism. The exterior column formed by the two **b** chains and the  $\delta$  subunit prevents the  $\alpha_3\beta_3$  hexamer from rotating in sympathy with the **c** ring. Recall that the number of **c** subunits in the **c** ring appears to range between 8 and 14. This number is significant because it determines the number of protons that must be transported to generate a molecule of ATP. Each 360-degree rotation of the  $\gamma$  subunit leads to the synthesis and release of three molecules of ATP. Thus, if there are 10 **c** subunits in the ring (as was observed in a crystal structure of yeast mitochondrial ATP synthase), each ATP generated requires the transport of  $10/3 = 3.33$  protons. Recent evidence shows that the **c** rings of all vertebrates are composed of 8 subunits, making vertebrate ATP synthase the most-efficient ATP synthase known, with the transport of only 2.7 protons required for ATP synthesis. For simplicity, we will assume that three protons must flow into the matrix for each ATP formed, but we must keep in mind that the true value may differ. As we will see, the electrons from NADH pump enough protons to generate 2.5 molecules of ATP, whereas those from  $FADH_2$  yield 1.5 molecules of ATP.

Let us return for a moment to the example with which we began this chapter. If a resting human being requires 85 kg of ATP per day for bodily functions, then  $3.3 \times 10^{25}$  protons must flow through the ATP synthase per day, or  $3.3 \times 10^{21}$  protons per second. Figure 18.34 summarizes the process of oxidative phosphorylation.

**ATP synthase and G proteins have several common features**

The  $\alpha$  and  $\beta$  subunits of ATP synthase are members of the P-loop NTPase family of proteins. In Chapter 14, we learned that the signaling properties of other members of this family, the G proteins, depend on their ability to bind nucleoside triphosphates and diphosphates with great

**FIGURE 18.34 Overview of oxidative phosphorylation.** The electron-transport chain generates a proton gradient, which is used to synthesize ATP.

tenacity. They do not exchange nucleotides unless they are stimulated to do so by interaction with other proteins. The binding-change mechanism of ATP synthase is a variation on this theme. The P-loop regions of the  $\beta$  subunits will bind either ADP or ATP (or release ATP), depending on which of three different faces of the  $\gamma$  subunit they interact with. The conformational changes take place in an orderly way, driven by the rotation of the  $\gamma$  subunit.

## 18.5 Many Shuttles Allow Movement Across Mitochondrial Membranes

The inner mitochondrial membrane must be impermeable to most molecules, yet much exchange has to take place between the cytoplasm and the mitochondria. This exchange is mediated by an array of membrane-spanning transporter proteins (Section 13.4).

### Electrons from cytoplasmic NADH enter mitochondria by shuttles

One function of the respiratory chain is to regenerate  $\text{NAD}^+$  for use in glycolysis. NADH generated by the citric acid cycle and fatty acid oxidation is already in the mitochondrial matrix, but how is cytoplasmic NADH reoxidized to  $\text{NAD}^+$  under aerobic conditions? NADH cannot simply pass into mitochondria for oxidation by the respiratory chain, because the inner mitochondrial membrane is impermeable to NADH and  $\text{NAD}^+$ . The solution is that *electrons from NADH*, rather than NADH itself, are carried across the mitochondrial membrane. One of several means of introducing electrons from NADH into the electron-transport chain is the *glycerol 3-phosphate shuttle* (Figure 18.35). The first step in this shuttle is the transfer of a pair of electrons from NADH to dihydroxyacetone phosphate, a glycolytic intermediate, to form glycerol 3-phosphate. This reaction is catalyzed by a glycerol 3-phosphate dehydrogenase in the cytoplasm. Glycerol 3-phosphate is reoxidized to dihydroxyacetone phosphate on the outer surface of the inner mitochondrial membrane by a membrane-bound isozyme of glycerol 3-phosphate dehydrogenase. An electron pair from glycerol 3-phosphate is

**FIGURE 18.35 Glycerol 3-phosphate shuttle.** Electrons from NADH can enter the mitochondrial electron-transport chain by being used to reduce dihydroxyacetone phosphate to glycerol 3-phosphate. Glycerol 3-phosphate is reoxidized by electron transfer to an FAD prosthetic group in a membrane-bound glycerol 3-phosphate dehydrogenase. Subsequent electron transfer to Q to form  $\text{QH}_2$  allows these electrons to enter the electron-transport chain.

transferred to an FAD prosthetic group in this enzyme to form  $\text{FADH}_2$ . This reaction also regenerates dihydroxyacetone phosphate.

The reduced flavin transfers its electrons to the electron carrier Q, which then enters the respiratory chain as  $\text{QH}_2$ . When cytoplasmic NADH transported by the glycerol 3-phosphate shuttle is oxidized by the respiratory chain, 1.5 rather than 2.5 molecules of ATP are formed. The yield is lower because FAD rather than  $\text{NAD}^+$  is the electron acceptor in mitochondrial glycerol 3-phosphate dehydrogenase. The use of FAD enables electrons from cytoplasmic NADH to be transported into mitochondria against an NADH concentration gradient. The price of this transport is one molecule of ATP per two electrons. This glycerol 3-phosphate shuttle is especially prominent in muscle and enables it to sustain a very high rate of oxidative phosphorylation. Indeed, some insects lack lactate dehydrogenase and are completely dependent on the glycerol 3-phosphate shuttle for the regeneration of cytoplasmic  $\text{NAD}^+$ .

In the heart and liver, electrons from cytoplasmic NADH are brought into mitochondria by the *malate-aspartate shuttle*, which is mediated by two membrane carriers and four enzymes (Figure 18.36). Electrons are transferred from NADH in the cytoplasm to oxaloacetate, forming malate, which traverses the inner mitochondrial membrane in exchange for  $\alpha$ -ketoglutarate and is then reoxidized by  $\text{NAD}^+$  in the matrix to form NADH in a reaction catalyzed by the citric acid cycle enzyme malate dehydrogenase. The resulting oxaloacetate does not readily cross the inner mitochondrial membrane and so a transamination reaction (Section 23.3) is needed to form aspartate, which can be transported to the cytoplasmic side in exchange for glutamate. Glutamate donates an amino group to oxaloacetate, forming aspartate and  $\alpha$ -ketoglutarate. In the cytoplasm, aspartate is then deaminated to form oxaloacetate and the cycle is restarted.

### The entry of ADP into mitochondria is coupled to the exit of ATP by ATP-ADP translocase

The major function of oxidative phosphorylation is to generate ATP from ADP. ATP and ADP do not diffuse freely across the inner mitochondrial membrane. How are these highly charged molecules moved across the inner membrane into the cytoplasm? A specific transport protein, *ATP-ADP translocase*, enables these molecules to transverse this permeability barrier.

FIGURE 18.36 Malate-aspartate shuttle.

**FIGURE 18.37 Mechanism of mitochondrial ATP-ADP translocase.** The translocase catalyzes the coupled entry of ADP into the matrix and the exit of ATP from it. The binding of ADP (1) from the cytoplasm favors eversion of the transporter (2) to release ADP into the matrix (3). Subsequent binding of ATP from the matrix to the everted form (4) favors eversion back to the original conformation (5), releasing ATP into the cytoplasm (6).

Most important, the flows of ATP and ADP are coupled. *ADP enters the mitochondrial matrix only if ATP exits, and vice versa.* This process is carried out by the translocase, an antiporter:

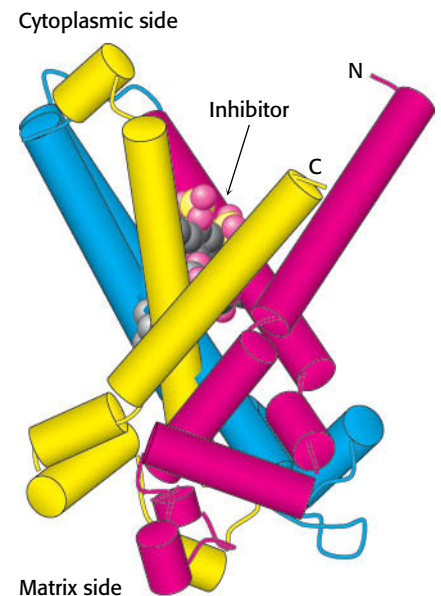

ATP-ADP translocase is highly abundant, constituting about 15% of the protein in the inner mitochondrial membrane. The abundance is a manifestation of the fact that human beings exchange the equivalent of their weight in ATP each day. Despite the fact that mitochondria are the sites of ATP synthesis, both the cytoplasm and the nucleus have more ATP than the mitochondria, a testament to the efficiency of transport.

The 30-kDa translocase contains a single nucleotide-binding site that alternately faces the matrix and the cytoplasmic sides of the membrane (Figure 18.37). ATP and ADP bind to the translocase without  $\text{Mg}^{2+}$ , and ATP has one more negative charge than that of ADP. Thus, in an actively respiring mitochondrion with a positive membrane potential, ATP transport out of the mitochondrial matrix and ADP transport into the matrix are favored. This ATP-ADP exchange is energetically expensive; about a quarter of the proton-motive force generated by the respiratory chain is consumed by this exchange process. The inhibition of the translocase leads to the subsequent inhibition of cellular respiration as well (p. 557).

### Mitochondrial transporters for metabolites have a common tripartite structure

Examination of the amino acid sequence of the ATP-ADP translocase revealed that this protein consists of three tandem repeats of a 100-amino-acid module, each of which appears to have two transmembrane segments. This tripartite structure has recently been confirmed by the determination of the three-dimensional structure of this transporter (Figure 18.38). The transmembrane helices form a tepee-like structure with the nucleotide-binding site (marked by a bound inhibitor) lying in the center. Each of the three repeats adopts a similar structure.

**FIGURE 18.38 Structure of mitochondrial transporters.** The structure of the ATP-ADP translocase is shown. Notice that this structure comprises three similar units (shown in red, blue, and yellow) that come together to form a binding site, here occupied by atractyloside, an inhibitor of this transporter. Other members of the mitochondrial transporter family adopt similar tripartite structures. [Drawn from 1OKC.pdb.]

**FIGURE 18.39 Mitochondrial transporters.** Transporters (also called carriers) are transmembrane proteins that carry specific ions and charged metabolites across the inner mitochondrial membrane.

ATP-ADP translocase is but one of many mitochondrial transporters for ions and charged metabolites (Figure 18.39). The *phosphate carrier*, which works in concert with ATP-ADP translocase, mediates the electro-neutral exchange of  $\text{H}_2\text{PO}_4^-$  for  $\text{OH}^-$ . The combined action of these two transporters leads to the exchange of cytoplasmic ADP and  $\text{P}_i$  for matrix ATP at the cost of the influx of one  $\text{H}^+$  (owing to the transport of one  $\text{OH}^-$  out of the matrix). These two transporters, which provide ATP synthase with its substrates, are associated with the synthase to form a large complex called the *ATP synthasome*.

Other homologous carriers also are present in the inner mitochondrial membrane. The dicarboxylate carrier enables malate, succinate, and fumarate to be exported from the mitochondrial matrix in exchange for  $\text{P}_i$ . The tricarboxylate carrier exchanges citrate and  $\text{H}^+$  for malate. In all, more than 40 such carriers are encoded in the human genome. A different type of carrier is responsible for pyruvate transport into the mitochondria. Pyruvate in the cytoplasm enters the mitochondrial membrane by way of a heterodimer composed of two small transmembrane proteins.

## 18.6 The Regulation of Cellular Respiration Is Governed Primarily by the Need for ATP

Because ATP is the end product of cellular respiration, the ATP needs of the cell are the ultimate determinant of the rate of respiratory pathways and their components.

### The complete oxidation of glucose yields about 30 molecules of ATP

We can now estimate how many molecules of ATP are formed when glucose is completely oxidized to  $\text{CO}_2$ . The number of ATP molecules formed in glycolysis and the citric acid cycle is unequivocally known because it is determined by the stoichiometries of chemical reactions. In contrast, the ATP yield of oxidative phosphorylation is less certain because the stoichiometries of proton pumping, ATP synthesis, and metabolite-transport processes need not be an integer or even have fixed values. As stated earlier, the best current estimates for the number of protons pumped out of the matrix by NADH-Q oxidoreductase, Q-cytochrome *c* oxidoreductase, and cytochrome *c* oxidase per electron pair are four, two, and four, respectively. The synthesis of a molecule of ATP is driven by the flow of about three protons through ATP synthase. An additional proton is consumed in transporting ATP from the matrix to the cytoplasm. Hence, about 2.5 molecules of cytoplasmic ATP are generated as a result of the flow of a pair of electrons from NADH to  $\text{O}_2$ . For electrons that enter at the level of

**TABLE 18.4** ATP yield from the complete oxidation of glucose

Reaction sequence	ATP yield per glucose molecule
<b>Glycolysis: Conversion of glucose into pyruvate (in the cytoplasm)</b>	
Phosphorylation of glucose	-1
Phosphorylation of fructose 6-phosphate	-1
Dephosphorylation of 2 molecules of 1,3-BPG	+2
Dephosphorylation of 2 molecules of phosphoenolpyruvate	+2
2 molecules of NADH are formed in the oxidation of 2 molecules of glyceraldehyde 3-phosphate	
<b>Conversion of pyruvate into acetyl CoA (inside mitochondria)</b>	
2 molecules of NADH are formed	
<b>Citric acid cycle (inside mitochondria)</b>	
2 molecules of adenosine triphosphate are formed from 2 molecules of succinyl CoA	+2
6 molecules of NADH are formed in the oxidation of 2 molecules each of isocitrate, $\alpha$ -ketoglutarate, and malate	
2 molecules of FADH <sub>2</sub> are formed in the oxidation of 2 molecules of succinate	
<b>Oxidative phosphorylation (inside mitochondria)</b>	
2 molecules of NADH formed in glycolysis; each yields 1.5 molecules of ATP (assuming transport of NADH by the glycerol 3-phosphate shuttle)	+3
2 molecules of NADH formed in the oxidative decarboxylation of pyruvate; each yields 2.5 molecules of ATP	+5
2 molecules of FADH <sub>2</sub> formed in the citric acid cycle; each yields 1.5 molecules of ATP	+3
6 molecules of NADH formed in the citric acid cycle; each yields 2.5 molecules of ATP	+15
Net Yield per Molecule of Glucose	+30

Information on the ATP yield of oxidative phosphorylation is from values given in P. C. Hinkle, M. A. Kumar, A. Resetar, and D. L. Harris, *Biochemistry* 30:3576, 1991.

Note: The current value of 30 molecules of ATP per molecule of glucose supersedes the earlier value of 36 molecules of ATP. The stoichiometries of proton pumping, ATP synthesis, and metabolite transport should be regarded as estimates. About 2 more molecules of ATP are formed per molecule of glucose oxidized when the malate-aspartate shuttle rather than the glycerol 3-phosphate shuttle is used.

Q-cytochrome *c* oxidoreductase, such as those from the oxidation of succinate or cytoplasmic NADH transferred by the glycerol-phosphate shuttle, the yield is about 1.5 molecules of ATP per electron pair. Hence, as tallied in Table 18.4, *about 30 molecules of ATP are formed when glucose is completely oxidized to CO<sub>2</sub>*. Most of the ATP, 26 of 30 molecules formed, is generated by oxidative phosphorylation. Recall that the anaerobic metabolism of glucose yields only 2 molecules of ATP. One of the effects of endurance exercise, a practice that calls for much ATP for an extended period of time, is to increase the number of mitochondria and blood vessels in muscle and thus increase the extent of ATP generation by oxidative phosphorylation.

### The rate of oxidative phosphorylation is determined by the need for ATP

How is the rate of the electron-transport chain controlled? Under most physiological conditions, electron transport is tightly coupled to phosphorylation. *Electrons do not usually flow through the electron-transport chain to O<sub>2</sub> unless ADP is simultaneously phosphorylated to ATP.* When ADP concentration rises, as would be the case in active muscle, the rate of oxidative phosphorylation increases to meet the ATP needs of the muscle. The regulation of the rate of oxidative phosphorylation by the ADP level is called *respiratory control* or *acceptor control*. Experiments on isolated mitochondria demonstrate the

**FIGURE 18.40 Respiratory control.** Electrons are transferred to  $O_2$  only if ADP is concomitantly phosphorylated to ATP.

importance of ADP level (Figure 18.40). The rate of oxygen consumption by mitochondria increases markedly when ADP is added and then returns to its initial value when the added ADP has been converted into ATP.

The level of ADP likewise affects the rate of the citric acid cycle. At low concentrations of ADP, as in a resting muscle, NADH and  $FADH_2$  are not consumed by the electron-transport chain. The citric acid cycle slows because there is less  $NAD^+$  and FAD to feed the cycle. As the ADP level rises and oxidative phosphorylation speeds up, NADH and  $FADH_2$  are oxidized, and the citric acid cycle becomes more active. *Electrons do not flow from fuel molecules to  $O_2$  unless ATP needs to be synthesized.* We see here another example of the regulatory significance of the energy charge (Figure 18.41).

**FIGURE 18.41 Energy charge regulates the use of fuels.** The synthesis of ATP from ADP and  $P_i$  controls the flow of electrons from NADH and  $FADH_2$  to oxygen. The availability of  $NAD^+$  and FAD in turn control the rate of the citric acid cycle (CAC).

### ATP synthase can be regulated

Mitochondria contain an evolutionarily conserved protein, *inhibitory factor 1* (IF1), that specifically inhibits the potential hydrolytic activity of the  $F_0F_1$  ATP synthase. What is the function of IF1? Consider a circumstance where tissues may be deprived of oxygen (ischemia). Without oxygen as the electron acceptor, the electron transport chain will be unable to generate the proton-motive force. The ATP in the mitochondria would be hydrolyzed by the synthase, working in reverse (Problem 18.45). The role of IF1 is to prevent the wasteful hydrolysis of ATP by inhibiting the hydrolytic activity of the synthase.

 IF1 is overexpressed in many types of cancer. This over-expression plays a role in the induction of the Warburg effect, the switch from oxidative phosphorylation to aerobic glycolysis as the principle means for ATP synthesis (Section 16.2).

### Regulated uncoupling leads to the generation of heat

*Some organisms possess the ability to uncouple oxidative phosphorylation from ATP synthesis to generate heat.* Such uncoupling is a means to maintain body temperature in hibernating animals, in some newborn animals (including human beings), and in many adult mammals, especially those adapted to cold. The skunk cabbage uses an analogous mechanism to heat its floral spikes in early spring, increasing the evaporation of odoriferous molecules that attract insects to fertilize its flowers. In animals, the uncoupling is in *brown adipose tissue* (BAT), which is specialized tissue for the process of *nonshivering*

thermogenesis. In contrast, *white adipose tissue* (WAT), which constitutes the bulk of adipose tissue, plays no role in thermogenesis but serves as an energy source and an endocrine gland (Chapters 26 and 27).

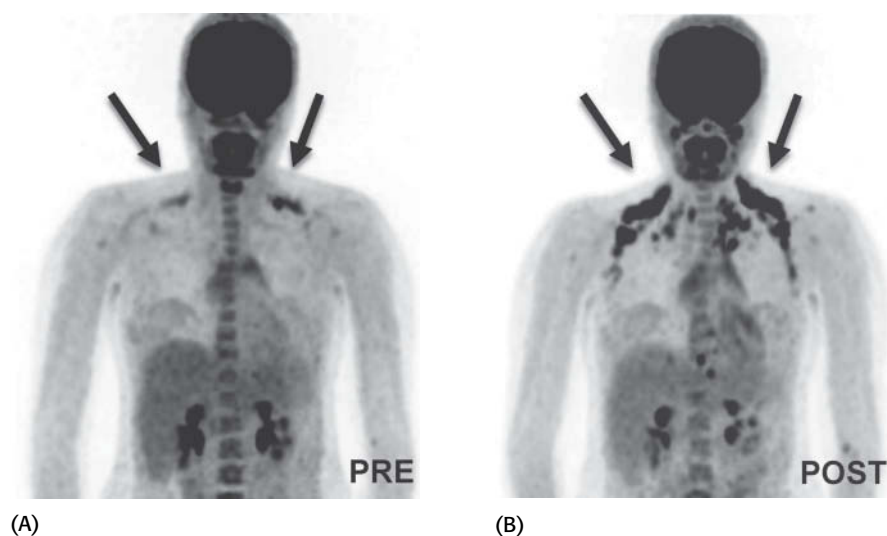

Brown adipose tissue is very rich in mitochondria, often called *brown fat mitochondria*. The tissue appears brown from the combination of the greenish-colored cytochromes in the numerous mitochondria and the red hemoglobin present in the extensive blood supply, which helps to carry the heat through the body. The inner mitochondrial membrane of these mitochondria contains a large amount of *uncoupling protein* (UCP-1), or *thermogenin*, a dimer of 33-kDa subunits that resembles ATP-ADP translocase.

UCP-1 transports protons from the cytoplasm to the matrix with the assistance of fatty acids. In essence, *UCP-1 generates heat by short-circuiting the mitochondrial proton battery*. The energy of the proton gradient, normally captured as ATP, is released as heat as the protons flow through UCP-1 to the mitochondrial matrix. This dissipative proton pathway is activated when the core body temperature begins to fall. In response to a temperature drop,  $\alpha$ -adrenergic hormones stimulate the release of free fatty acids from triacylglycerols stored in cytoplasmic lipid granules (Section 22.2) (Figure 18.42). Long chain fatty acids bind to the cytoplasmic face of UCP-1, and the carboxyl group binds a proton. This causes a structural change in UCP-1 so that the protonated carboxyl now faces the proton-poor environment of the matrix, and the proton is released. Proton release resets UCP-1 to the initial state.

**FIGURE 18.42 Action of an uncoupling protein.** Uncoupling protein (UCP-1) generates heat by permitting the influx of protons into the mitochondria without the synthesis of ATP.

Until recently, adult humans were believed to lack brown fat tissue. However, new studies have established that adults, especially females, have brown adipose tissue in the neck and upper chest regions that is activated by cold (Figure 18.43). Obesity leads to a decrease in brown adipose tissue.

**FIGURE 18.43 Brown adipose tissue is revealed on exposure to cold.** The results of PET-CT scanning show the uptake and distribution of  $^{18}\text{F}$ -fluorodeoxyglucose ( $^{18}\text{F}$ -FDG) in adipose tissue. The patterns of  $^{18}\text{F}$ -FDG uptake in the same subject are dramatically different under thermoneutral conditions (A) and after exposure to cold (B). [Republished with permission of American Society for Clinical Investigation from *J Clin Invest.* 2013;123(8):3395–3403. doi:10.1172/JCI68993. Permission conveyed through Copyright Clearance Center, Inc.]

 We can witness the effects of a lack of nonshivering thermogenesis by examining pig behavior. Pigs are unusual mammals in that they have large litters and are the only ungulates (hoofed animals) that build nests for birth. These behavioral characteristics appear to be the result of a biochemical deficiency. Pigs lack UCP-1 and, hence, brown fat. Piglets must rely on other means of thermogenesis, such as nesting, large litter size, and shivering.

 In addition to UCP-1, two other uncoupling proteins have been identified. UCP-2, which is 56% identical in sequence with UCP-1, is found in a wide variety of tissues. UCP-3 (57% identical with UCP-1 and 73% identical with UCP-2) is localized to skeletal muscle and brown fat. This family of uncoupling proteins, especially UCP-2 and UCP-3, may play a role in energy homeostasis. In fact, the genes for UCP-2 and UCP-3 map to regions of the human and mouse chromosomes that have been linked to obesity, supporting the notion that they function as a means of regulating body weight.

### Oxidative phosphorylation can be inhibited at many stages

Many potent and lethal poisons exert their effect by inhibiting oxidative phosphorylation at one of a number of different locations (Figure 18.44):

FIGURE 18.44 Sites of action of some inhibitors of electron transport.

1. *Inhibition of the electron-transport chain.* Rotenone, which is used as a fish and insect poison, and amytal, a barbiturate sedative, block electron transfer in NADH-Q oxidoreductase and thereby prevent the utilization of NADH as a substrate. Rotenone, as an electron-transport-chain inhibitor, may play a role, along with genetic susceptibility, in the development of Parkinson disease. In the presence of rotenone and amytal, electron flow resulting from the oxidation of succinate is unimpaired, because these electrons enter through QH<sub>2</sub>, beyond the block. Antimycin A interferes with electron flow from cytochrome b<sub>H</sub> in Q-cytochrome c oxidoreductase. Furthermore, electron flow in cytochrome c oxidase can be blocked by cyanide (CN<sup>-</sup>), azide (N<sub>3</sub><sup>-</sup>), and carbon monoxide (CO). Cyanide and azide react with the ferric form of heme a<sub>3</sub>, whereas carbon monoxide inhibits the ferrous form. Inhibition of the electron-transport chain also inhibits ATP synthesis because the proton-motive force can no longer be generated.

2. *Inhibition of ATP synthase.* Oligomycin, an antibiotic used as an antifungal agent, and dicyclohexylcarbodiimide (DCC) prevent the influx of protons through ATP synthase by binding to the carboxylate group of the c subunits required for proton binding. Modification of only one c subunit by DCC is sufficient to inhibit the rotation of the entire c ring and hence ATP synthesis. If actively respiring mitochondria are exposed to an inhibitor of ATP synthase, the electron-transport chain ceases to operate. This observation clearly illustrates that electron transport and ATP synthesis are normally tightly coupled.

3. *Uncoupling electron transport from ATP synthase.* The tight coupling of electron transport and phosphorylation in mitochondria can be uncoupled by 2,4-dinitrophenol (DNP) and certain other acidic aromatic compounds. These substances carry protons across the inner mitochondrial membrane, down their concentration gradient. In the presence of these uncouplers, electron transport from NADH to O<sub>2</sub> proceeds in a normal fashion, but ATP is not formed by mitochondrial ATP synthase, because the proton-motive force across the inner mitochondrial membrane is continuously dissipated. This loss of respiratory control leads to increased oxygen consumption and oxidation of NADH. Indeed, in the accidental ingestion of uncouplers, large amounts of metabolic fuels are consumed, but no energy is captured as ATP. Rather, energy is released as heat. DNP is the active

ingredient in some herbicides and fungicides. Remarkably, some people consume DNP as a weight-loss drug, despite the fact that the FDA banned its use in 1938. There are also reports that Soviet soldiers were given DNP to keep them warm during the long Russian winters. Chemical uncouplers are nonphysiological, unregulated counterparts of uncoupling proteins.

Drugs are being sought that would function as mild uncouplers, uncouplers not as potentially lethal as DNP, for use in treatment of obesity and related pathologies. Xanthohumol, a prenylated chalcone found in hops and beer, shows promise in this regard. Xanthohumol also scavenges free radicals and is used for treatment of certain types of cancers.

4. *Inhibition of ATP export.* ATP-ADP translocase is specifically inhibited by very low concentrations of *atractyloside* (a plant glycoside) or *bongkreikic acid* (an antibiotic from a mold). Atractyloside binds to the translocase when its nucleotide site faces the cytoplasm, whereas bongkreikic acid binds when this site faces the mitochondrial matrix. Oxidative phosphorylation stops soon after either inhibitor is added, showing that ATP-ADP translocase is essential for maintaining adequate amounts of ADP to accept the energy associated with the proton-motive force.

### Mitochondrial diseases are being discovered

The number of diseases that can be attributed to mitochondrial mutations is steadily growing in step with our growing understanding of the biochemistry and genetics of mitochondria. The prevalence of mitochondrial diseases is estimated to be from 10 to 15 per 100,000 people, roughly equivalent to the prevalence of the muscular dystrophies. The first mitochondrial disease to be understood was Leber hereditary optic neuropathy (LHON), a form of blindness that strikes in midlife as a result of mutations in Complex I. Some of these mutations impair NADH utilization, whereas others block electron transfer to Q. Mutations in Complex I are the most frequent cause of mitochondrial diseases. The accumulation of mutations in mitochondrial genes in a span of several decades may contribute to aging, degenerative disorders, and cancer.

A human egg harbors several hundred thousand molecules of mitochondrial DNA, whereas a sperm contributes only a few hundred and thus has little effect on the mitochondrial genotype. Because the maternally inherited mitochondria are present in large numbers and not all of the mitochondria may be affected, the pathologies of mitochondrial mutants can be quite complex. Even within a single family carrying an identical mutation, chance fluctuations in the percentage of mitochondria with the mutation lead to large variations in the nature and severity of the symptoms of the pathological condition as well as the time of onset. As the percentage of defective mitochondria increases, energy-generating capacity diminishes until, at some threshold, the cell can no longer function properly. Defects in cellular respiration are doubly dangerous. Not only does energy transduction decrease, but also the likelihood that reactive oxygen species will be generated increases. Organs that are highly dependent on oxidative phosphorylation, such as the nervous system, the retina, and the heart, are most vulnerable to mutations in mitochondrial DNA.

### Mitochondria play a key role in apoptosis

In the course of development or in cases of significant cell damage, individual cells within multicellular organisms undergo *programmed cell death*, or *apoptosis*. Mitochondria act as control centers regulating this process. Although the details have not yet been established, the outer membrane of

damaged mitochondria becomes highly permeable, a process referred to as *mitochondrial outer membrane permeabilization* (MOMP). This permeabilization is instigated by a family of proteins (Bcl family) that were initially discovered because of their role in cancer. One of the most potent activators of apoptosis, cytochrome *c*, exits the mitochondria and interacts with apoptotic peptidase-activating factor 1 (APAF-1), which leads to the formation of the *apoptosome*. The apoptosome recruits and activates a proteolytic enzyme called *caspase 9*, a member of the cysteine protease family (Section 9.1) that in turn activates a cascade of other caspases. Each caspase type destroys a particular target, such as the proteins that maintain cell structure. Another target is a protein that inhibits an enzyme that destroys DNA (an enzyme called caspase-activated DNase or CAD), freeing CAD to cleave the genetic material. This cascade of proteolytic enzymes has been called “death by a thousand tiny cuts.”

### Power transmission by proton gradients is a central motif of bioenergetics

The main concept presented in this chapter is that mitochondrial electron transfer and ATP synthesis are linked by a transmembrane proton gradient. ATP synthesis in bacteria and chloroplasts also is driven by proton gradients. In fact, proton gradients power a variety of energy-requiring processes such as the active transport of calcium ions by mitochondria, the entry of some amino acids and sugars into bacteria, the rotation of bacterial flagella, and the transfer of electrons from  $\text{NADP}^+$  to NADPH. Proton gradients can also be used to generate heat, as in nonshivering thermogenesis. It is evident that *proton gradients are a central interconvertible currency of free energy in biological systems* (Figure 18.45). Mitchell noted that the proton-motive force is a marvelously simple and effective store of free energy because it requires only a thin, closed lipid membrane between two aqueous phases.

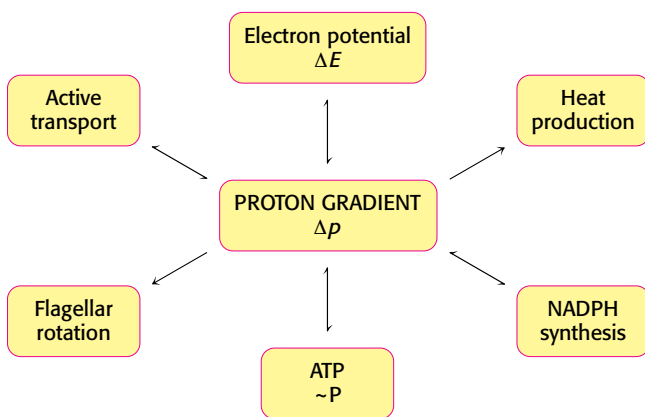

FIGURE 18.45 The proton gradient is an interconvertible form of free energy.

## SUMMARY

### 18.1 Eukaryotic Oxidative Phosphorylation Takes Place in Mitochondria

Mitochondria generate most of the ATP required by aerobic cells through a joint endeavor of the reactions of the citric acid cycle, which take place in the mitochondrial matrix, and oxidative phosphorylation, which takes place in the inner mitochondrial membrane. Mitochondria are descendants of a free-living bacterium that established a symbiotic relation with another cell.

### 18.2 Oxidative Phosphorylation Depends on Electron Transfer

In oxidative phosphorylation, the synthesis of ATP is coupled to the flow of electrons from NADH or  $\text{FADH}_2$  to  $\text{O}_2$  by a proton gradient across the inner mitochondrial membrane. Electron flow through three asymmetrically oriented transmembrane complexes results in the pumping of protons out of the mitochondrial matrix and the generation of a membrane potential. ATP is synthesized when protons flow back to the matrix through a channel in an ATP-synthesizing complex, called ATP synthase (also known as  $\text{F}_0\text{F}_1$ -ATPase). Oxidative phosphorylation exemplifies a fundamental theme of bioenergetics: the transmission of free energy by proton gradients.

### 18.3 The Respiratory Chain Consists of Four Complexes: Three Proton Pumps and a Physical Link to the Citric Acid Cycle

The electron carriers in the respiratory assembly of the inner mitochondrial membrane are quinones, flavins, iron–sulfur complexes, heme groups of cytochromes, and copper ions. Electrons from NADH are transferred to the FMN prosthetic group of NADH-Q oxidoreductase (Complex I), the first of four complexes. This oxidoreductase also contains Fe-S centers. The electrons emerge in  $\text{QH}_2$ , the reduced form of ubiquinone (Q). The citric acid cycle enzyme succinate dehydrogenase is a component of the succinate-Q reductase complex (Complex II), which donates electrons from  $\text{FADH}_2$  to Q to form  $\text{QH}_2$ . This hydrophobic carrier transfers its electrons to Q-cytochrome *c* oxidoreductase (Complex III), a complex that contains cytochromes *b* and *c*<sub>1</sub> and an Fe-S center. This complex reduces cytochrome *c*, a water-soluble peripheral membrane protein. Cytochrome *c* transfers electrons to cytochrome *c* oxidase (Complex IV). This complex contains cytochromes *a* and *a*<sub>3</sub> and three copper ions. A heme iron ion and a copper ion in this oxidase transfer electrons to  $\text{O}_2$ , the ultimate acceptor, to form  $\text{H}_2\text{O}$ .

### 18.4 A Proton Gradient Powers the Synthesis of ATP

The flow of electrons through Complexes I, III, and IV leads to the transfer of protons from the matrix side to the cytoplasmic side of the inner mitochondrial membrane. A proton-motive force consisting of a pH gradient (matrix side basic) and a membrane potential (matrix side negative) is generated. The flow of protons back to the matrix side through ATP synthase drives ATP synthesis. The enzyme complex is a molecular motor made of two operational units: a rotating component and a stationary component. The rotation of the  $\gamma$  subunit induces structural changes in the  $\beta$  subunit that result in the synthesis and release of ATP from the enzyme. Proton influx provides the force for the rotation.

The flow of two electrons through NADH-Q oxidoreductase, Q-cytochrome *c* oxidoreductase, and cytochrome *c* oxidase generates a gradient sufficient to synthesize 1, 0.5, and 1 molecule of ATP, respectively. Hence, 2.5 molecules of ATP are formed per molecule of NADH oxidized in the mitochondrial matrix, whereas only 1.5 molecules of ATP are made per molecule of  $\text{FADH}_2$  oxidized, because its electrons enter the chain at  $\text{QH}_2$ , after the first proton-pumping site.

### 18.5 Many Shuttles Allow Movement Across Mitochondrial Membranes

Mitochondria employ a host of transporters, or carriers, to move molecules across the inner mitochondrial membrane. The electrons of cytoplasmic NADH are transferred into mitochondria by the glycerol phosphate shuttle to form  $\text{FADH}_2$  from FAD or by the malate–aspartate shuttle to form mitochondrial NADH. The entry of ADP into the mitochondrial matrix is coupled to the exit of ATP by ATP-ADP translocase, a transporter driven by membrane potential.

### 18.6 The Regulation of Cellular Respiration Is Governed Primarily by the Need for ATP

About 30 molecules of ATP are generated when a molecule of glucose is completely oxidized to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Electron transport is normally tightly coupled to phosphorylation. NADH and  $\text{FADH}_2$  are oxidized only if ADP is simultaneously phosphorylated to ATP, a form of regulation called acceptor or respiratory control. Proteins have been identified that uncouple electron transport and ATP synthesis for the generation of heat.

## KEY TERMS

oxidative phosphorylation (p. 523)	succinate-Q reductase (Complex II) (p. 533)	glycerol 3-phosphate shuttle (p. 549)
electron-transport chain (p. 523)	cytochrome <i>c</i> (Cyt <i>c</i> ) (p. 533)	malate–aspartate shuttle (p. 550)
proton-motive force (p. 523)	Q-cytochrome <i>c</i> oxidoreductase (Complex III) (p. 534)	ATP-ADP translocase (adenine nucleotide translocase, ANT) (p. 550)
cellular respiration (p. 524)	Rieske center (p. 534)	respiratory (acceptor) control (p. 553)
reduction (redox, oxidation–reduction, $E'_0$ ) potential (p. 526)	Q cycle (p. 535)	uncoupling protein (UCP) (p. 555)
coenzyme Q (Q, ubiquinone) (p. 530)	cytochrome <i>c</i> oxidase (Complex IV) (p. 535)	programmed cell death (apoptosis) (p. 557)
Q pool (p. 531)	superoxide dismutase (p. 539)	mitochondrial outer membrane permeabilization (MOMP) (p. 558)
iron–sulfur (nonheme iron) protein (p. 531)	catalase (p. 540)	apoptosome (p. 558)
NADH-Q oxidoreductase (Complex I) (p. 532)	ATP synthase (Complex V, $F_1F_0$ ATPase) (p. 542)	caspase (p. 558)
flavin mononucleotide (FMN) (p. 532)		

## PROBLEMS

- Breathe or ferment?* Compare fermentation and respiration with respect to electron donors and electron acceptors.
- Reference states.* The standard oxidation–reduction potential for the reduction of  $O_2$  to  $H_2O$  is given as 0.82 V in Table 18.1. However, the value given in textbooks of chemistry is 1.23 V. Account for this difference.
- Less energetic electrons.* Why are electrons carried by  $FADH_2$  not as energy rich as those carried by  $NADH$ ? What is the consequence of this difference?
- Now prove it.* Calculate the energy released by the reduction of  $O_2$  with  $FADH_2$ .
- Thermodynamic constraint.* Compare the  $\Delta G^{\circ'}$  values for the oxidation of succinate by  $NAD^+$  and by  $FAD$ . Use the data given in Table 18.1 to find the  $E'_0$  of the  $NAD^+$ – $NADH$  and fumarate–succinate couples, and assume that  $E'_0$  for the  $FAD$ – $FADH_2$  redox couple is nearly 0.05 V. Why is  $FAD$  rather than  $NAD^+$  the electron acceptor in the reaction catalyzed by succinate dehydrogenase?
- Give and accept.* Distinguish between an oxidizing agent and a reducing agent.
- The benefactor and beneficiary.* Identify the oxidant and the reductant in the following reaction.  
$$\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{lactate} + \text{NAD}^+$$
- Six of one, half dozen of the other.* How is the redox potential ( $\Delta E'_0$ ) related to the free-energy change of a reaction ( $\Delta G^{\circ'}$ )?
- Location, location, location.* Iron is a component of many of the electron carriers of the electron-transport chain. How can it participate in a series of coupled redox reactions if the  $E'_0$  value is +0.77 V, as seen in Table 18.1?
- Line up.* Place the following components of the electron-transport chain in their proper order:
  - cytochrome *c*
  - Q-cytochrome *c* oxidoreductase
  - NADH-Q reductase
  - cytochrome *c* oxidase
  - ubiquinone
- Like mac and cheese.* Match each term with its description.
 

(a) Respiration _____	1. Converts reactive oxygen species into hydrogen peroxide
(b) Redox potential _____	2. Electron flow from $NADH$ and $FADH_2$ to $O_2$
(c) Electron-transport chain _____	3. Facilitates electron flow from FMN to coenzyme Q in Complex I
(d) Flavin mononucleotide (FMN) _____	4. An ATP-generating process in which an inorganic compound serves as the final electron acceptor
(e) Iron–sulfur protein _____	5. Measure of the tendency to accept or donate electrons
(f) Coenzyme Q _____	6. Converts hydrogen peroxide into oxygen and water
(g) Cytochrome <i>c</i> _____	7. Funnel electrons from a two-electron carrier to a one-electron carrier
(h) Q cycle _____	8. Lipid-soluble electron carrier
(i) Superoxide dismutase _____	9. Donates electrons to Complex IV
(j) Catalase _____	10. Accepts electrons from $NADH$ in Complex I

12. *Match 'em.*

- |                      |   |
|----------------------|---|
| (a) Complex I ____   | 1. Q-cytochrome <i>c</i> oxidoreductase |
| (b) Complex II ____  | 2. Coenzyme Q                           |
| (c) Complex III ____ | 3. Succinate-Q reductase                |
| (d) Complex IV ____  | 4. NADH-Q oxidoreductase                |
| (e) Ubiquinone ____  | 5. Cytochrome <i>c</i> oxidase          |

13. *Structural considerations.* Explain why coenzyme Q is an effective mobile electron carrier in the electron-transport chain.

14. *Inhibitors.* Rotenone inhibits electron flow through NADH-Q oxidoreductase. Antimycin A blocks electron flow between cytochromes *b* and *c*<sub>1</sub>. Cyanide blocks electron flow through cytochrome oxidase to O<sub>2</sub>. Predict the relative oxidation–reduction state of each of the following respiratory-chain components in mitochondria that are treated with each of the inhibitors:

- |                           |                                      |
|---------------------------|--------------------------------------|
| (a) NAD <sup>+</sup>      | (d) cytochrome <i>c</i> <sub>1</sub> |
| (b) NADH-Q oxidoreductase | (e) cytochrome <i>c</i>              |
| (c) coenzyme Q            | (f) cytochrome <i>a</i>              |

15. *Rumored to be a favorite of Elvis.* Amytal is a barbiturate sedative that inhibits electron flow through Complex I. How would the addition of amytal to actively respiring mitochondria affect the relative oxidation–reduction states of the components of the electron-transport chain and the citric acid cycle?

16. *Efficiency.* What is the advantage of having Complexes I, III, and IV associated with one another in the form of a respirasome?

17. *Linked In.* What citric acid cycle enzyme is also a component of the electron-transport chain?

18. *ROS, not ROUS.* What are the reactive oxygen species and why are they especially dangerous to cells?

19. *Reclaim resources.* Humans have only about 250 g of ATP, but even a couch potato needs about 83 kg of ATP to open the bag of chips and use the remote. How is this discrepancy between requirements and resources reconciled?

20. *Energy harvest.* What is the yield of ATP when each of the following substrates is completely oxidized to CO<sub>2</sub> by a mammalian cell homogenate? Assume that glycolysis, the citric acid cycle, and oxidative phosphorylation are fully active.

- |                               |                                |
|-------------------------------|--------------------------------|
| (a) Pyruvate                  | (d) Phosphoenolpyruvate        |
| (b) Lactate                   | (e) Galactose                  |
| (c) Fructose 1,6-bisphosphate | (f) Dihydroxyacetone phosphate |

21. *Potent poisons.* What is the effect of each of the following inhibitors on electron transport and ATP formation by the respiratory chain?

- |                   |                     |
|-------------------|---------------------|
| (a) Azide         | (d) DNP             |
| (b) Atractyloside | (e) Carbon monoxide |
| (c) Rotenone      | (f) Antimycin A     |

22. *A question of coupling.* What is the mechanistic basis for the observation that the inhibitors of ATP synthase also lead to an inhibition of the electron-transport chain?

23. *A Brownian ratchet wrench.* What causes the *c* subunits of ATP synthase to rotate? What determines the direction of rotation?

24. *An essential residue.* The conduction of protons by the F<sub>0</sub> unit of ATP synthase is blocked by dicyclohexylcarbodiimide, which reacts readily with carboxyl groups. What are the most likely targets of action of this reagent? How might you use site-specific mutagenesis to determine whether this residue is essential for proton conduction?

25. *Alternative routes.* The most common metabolic sign of mitochondrial disorders is lactic acidosis. Why?

26. *Connections.* How does the inhibition of ATP-ADP translocase affect the citric acid cycle? Glycolysis?

27. *O<sub>2</sub> consumption.* Oxidative phosphorylation in mitochondria is often monitored by measuring oxygen consumption. When oxidative phosphorylation is proceeding rapidly, the mitochondria will rapidly consume oxygen. If there is little oxidative phosphorylation, only small amounts of oxygen will be used. You are given a suspension of isolated mitochondria and directed to add the following compounds in the order from *a* to *h*. With the addition of each compound, all of the previously added compounds remain present. Predict the effect of each addition on oxygen consumption by the isolated mitochondria.

- |                          |                   |
|--------------------------|-------------------|
| (a) Glucose              | (e) Succinate     |
| (b) ADP + P <sub>i</sub> | (f) Dinitrophenol |
| (c) Citrate              | (g) Rotenone      |
| (d) Oligomycin           | (h) Cyanide       |

28. *P : O ratios.* The number of molecules of inorganic phosphate incorporated into organic form per atom of oxygen consumed, termed the *P : O ratio*, was frequently used as an index of oxidative phosphorylation.

- (a) What is the relation of the *P : O* ratio to the ratio of the number of protons translocated per electron pair (H<sup>+</sup>/2 e<sup>-</sup>) and the ratio of the number of protons needed to synthesize ATP and transport it to the cytoplasm (P/H<sup>+</sup>)?
- (b) What are the *P : O* ratios for electrons donated by matrix NADH and by succinate?

29. *Cyanide antidote.* The immediate administration of nitrite is a highly effective treatment for cyanide poisoning. What is the basis for the action of this antidote? (Hint: Nitrite oxidizes ferrohemoglobin to ferrihemoglobin.)

30. *Runaway mitochondria 1.* Suppose that the mitochondria of a patient oxidize NADH irrespective of whether ADP is present. The P : O ratio for oxidative phosphorylation by these mitochondria is less than normal. Predict the likely symptoms of this disorder.

31. *Recycling device.* The cytochrome *b* component of Q-cytochrome *c* oxidoreductase enables both electrons of QH<sub>2</sub> to be effectively utilized in generating a proton-motive force. Cite another recycling device in metabolism that brings a potentially dead end reaction product back into the mainstream.

32. *Crossover point.* The precise site of action of a respiratory-chain inhibitor can be revealed by the *crossover technique*. Britton Chance devised elegant spectroscopic methods for determining the proportions of the oxidized and reduced forms of each carrier. This determination is feasible because the forms have distinctive absorption spectra, as illustrated in the adjoining graph for cytochrome *c*. You are given a new inhibitor and find that its addition to respiring mitochondria causes the carriers between NADH and QH<sub>2</sub> to become more reduced and those between cytochrome *c* and O<sub>2</sub> to become more oxidized. Where does your inhibitor act?

33. *Runaway mitochondria 2.* Years ago, uncouplers were suggested to make wonderful diet drugs. Explain why this idea was proposed and why it was rejected. Why might the producers of antiperspirants be supportive of the idea?

34. *Everything is connected.* If actively respiring mitochondria are exposed to an inhibitor of ATP-ADP translocase, the electron-transport chain ceases to operate. Why?

35. *Identifying the inhibition.* You are asked to determine whether a chemical is an electron-transport-chain inhibitor or an inhibitor of ATP synthase. Design an experiment to make this determination.

36. *To each according to its needs.* It has been noted that the mitochondria of muscle cells often have more cristae than the mitochondria of liver cells. Provide an explanation for this observation.

37. *Opposites attract.* An arginine residue (Arg 210) in the *a* subunit of the *E. coli* ATP synthase is near the aspartate residue (Asp 61) in the matrix-side proton channel. How might Arg 210 assist proton flow?

38. *Variable c subunits.* Recall that the number of *c* subunits in the *c* ring appears to range between 8 and 14. This number is significant because it determines the number of protons that must be transported to generate a molecule of ATP. Each 360-degree rotation of the  $\gamma$  subunit leads to the synthesis and release of three molecules of ATP. Thus, if there are 10 *c* subunits in the ring (as was observed in a crystal structure of yeast mitochondrial ATP synthase), each ATP generated requires the transport of  $10/3 = 3.33$  protons. How many protons are required to form ATP if the ring has 12 *c* subunits? 14?

39. *Counterintuitive.* Under some conditions, mitochondrial ATP synthase has been observed to actually run in reverse. How would that situation affect the proton-motive force?

40. *Etiology? What does that mean?* What does the fact that rotenone appears to increase the susceptibility to Parkinson disease indicate about the etiology of Parkinson disease?

41. *Exaggerating the difference.* Why must ATP-ADP translocase (also called adenine nucleotide translocase or ANT) use Mg<sup>2+</sup>-free forms of ATP and ADP?

42. *Respiratory control.* The rate of oxygen consumption by mitochondria increases markedly when ADP is added and then returns to its initial value when the added ADP has been converted into ATP (Figure 18.39). Why does the rate decrease?

43. *Same, but different.* Why is the electroneutral exchange of H<sub>2</sub>PO<sub>4</sub><sup>-</sup> for OH<sup>-</sup> indistinguishable from the electroneutral symport of H<sub>2</sub>PO<sub>4</sub><sup>-</sup> and H<sup>+</sup>?

44. *Multiple uses.* Give an example of the use of the proton-motive force in ways other than for the synthesis of ATP.

### Chapter Integration Problems

45. *Just obeying the laws.* Why do isolated F<sub>1</sub> subunits of ATP synthase catalyze ATP hydrolysis?

46. *The right location.* Some cytoplasmic kinases, enzymes that phosphorylate substrates at the expense of ATP, bind to voltage-dependent anion channels. What might the advantage of this binding be?

47. *No exchange.* Mice that completely lack ATP-ADP translocase (ANT<sup>-</sup>/ANT<sup>-</sup>) can be made by using the knockout technique. Remarkably, these mice are viable but have the following pathological conditions: (1) high serum levels of

lactate, alanine, and succinate; (2) little electron transport; and (3) a six- to eightfold increase in the level of mitochondrial  $H_2O_2$  compared with that in normal mice. Provide a possible biochemical explanation for each of these conditions.

48. *Maybe you shouldn't take your vitamins.* Exercise is known to increase insulin sensitivity and to ameliorate type 2 diabetes (Chapter 27). Recent research suggests that taking antioxidant vitamins might mitigate the beneficial effects of exercise with respect to ROS protection.

- What are the antioxidant vitamins?
- How does exercise protect against ROS?
- Explain why vitamins might counteract the effects of exercise.

### Chapter Integration and Data Interpretation Problem

49. *Monitoring energy sources.* XF technology (Seahorse Bioscience) now allows the measurement of the rate of aerobic respiration and lactic acid fermentation simultaneously in real time in cultured cells. The extent of aerobic respiration is determined by measuring the oxygen consumption rate (OCR, measured in picomoles of oxygen consumed per minute) while the rate of glycolysis correlates with the extracellular acidification rate [ECAR—milli pH per minute (the changes in pH that occur over time)]. The graph below shows the results of an experiment using the new technology.

Dinitrophenol (DNP), the glycolysis inhibitor 2-deoxyglucose (DG), and rotenone were added sequentially to cell cultures.

- What is the effect on OCR and ECAR of adding DNP to the cell culture? Explain these results.
- Explain the effect of the addition of 2-deoxyglucose.
- Explain how 2-deoxyglucose acts as an inhibitor of glycolysis?
- Explain the effect of the addition of rotenone.

### Data Interpretation Problem

50. *Mitochondrial disease.* A mutation in a mitochondrial gene encoding a component of ATP synthase has been

identified. People who have this mutation suffer from muscle weakness, ataxia, and retinitis pigmentosa. A tissue biopsy was performed on each of three patients having this mutation, and submitochondrial particles were isolated that were capable of succinate-sustained ATP synthesis. First, the activity of the ATP synthase was measured on the addition of succinate and the following results were obtained.

	ATP synthase activity (nmol of ATP formed $\text{min}^{-1} \text{mg}^{-1}$ )
Controls	3.0
Patient 1	0.25
Patient 2	0.11
Patient 3	0.17

- What was the purpose of the addition of succinate?
- What is the effect of the mutation on succinate-coupled ATP synthesis?

Next, the ATPase activity of the enzyme was measured by incubating the submitochondrial particles with ATP in the absence of succinate.

	ATP hydrolysis (nmol of ATP hydrolyzed $\text{min}^{-1} \text{mg}^{-1}$ )
Controls	33
Patient 1	30
Patient 2	25
Patient 3	31

- Why was succinate omitted from the reaction?
- What is the effect of the mutation on ATP hydrolysis?
- What do these results, in conjunction with those obtained in the first experiment, tell you about the nature of the mutation?

### Mechanism Problem

51. *Chiral clue.* ATP $\gamma$ S, a slowly hydrolyzed analog of ATP, can be used to probe the mechanism of phosphoryl-transfer reactions. Chiral ATP $\gamma$ S has been synthesized containing  $^{18}\text{O}$  in a specific  $\gamma$  position and ordinary  $^{16}\text{O}$  elsewhere in the molecule. The hydrolysis of this chiral molecule by ATP synthase in  $^{17}\text{O}$ -enriched water yields inorganic [ $^{16}\text{O}, ^{17}\text{O}, ^{18}\text{O}$ ]thiophosphate having the following absolute configuration. In contrast, the hydrolysis of this chiral ATP $\gamma$ S by a calcium-pumping ATPase from muscle gives thiophosphate of the opposite configuration. What is the simplest interpretation of these data?

50. *Mitochondrial disease.* A mutation in a mitochondrial gene encoding a component of ATP synthase has been

# The Light Reactions of Photosynthesis

Chloroplasts (left) convert light energy into chemical energy. High-energy electrons in chloroplasts are transported through two photosystems (right). In this transit, which culminates in the generation of reducing power, ATP is synthesized in a manner analogous to mitochondrial ATP synthesis. In contrast with mitochondrial electron transport, however, electrons in chloroplasts are energized by light. [(Left) John Durham/ Science Source.]

Every year, Earth is bathed in photons with a total energy content of approximately  $10^{24}$  kJ. By comparison, a major hurricane has  $10^{-9}$  that amount of energy. The source of the energy is, of course, the electromagnetic radiation from the sun. On our planet, there are organisms capable of collecting a fraction, approximately 1%, of this solar energy and converting it into chemical energy. Green plants are the most obvious of these organisms, although 60% of this conversion is carried out by algae and bacteria. Although only a small amount of the incident energy is captured, it is enough to power all life on Earth. This transformation is perhaps the most important of all of the energy transformations that we will see in our study of biochemistry; without it, life as we know it on our planet simply could not exist.

The process of converting electromagnetic radiation into chemical energy is called *photosynthesis*, which uses light energy to convert carbon dioxide and water into carbohydrates and oxygen.

In this equation,  $\text{CH}_2\text{O}$  represents carbohydrate, primarily sucrose and starch. Photosynthetic carbohydrate synthesis is the most common metabolic pathway on Earth. These carbohydrates provide not only the energy to

- 19.6 The Ability to Convert Light into Chemical Energy Is Ancient

run the biological world, but also the carbon molecules to make a wide array of biomolecules. Photosynthetic organisms are called *autotrophs* (literally, “self-feeders”) because they can synthesize chemical fuels such as glucose from carbon dioxide and water by using sunlight as an energy source and then recover some of this energy from the synthesized glucose through the glycolytic pathway and aerobic metabolism. Organisms that obtain energy from chemical fuels only are called *heterotrophs*, which ultimately depend on autotrophs for their fuel.

Photosynthesis is composed of two parts: the light reactions and the dark reactions. In the *light reactions*, light energy is transformed into two forms of biochemical energy with which we are already familiar: reducing power and ATP. The products of the light reactions are then used in the dark reactions to drive the reduction of  $\text{CO}_2$  and its conversion into glucose and other sugars. The dark reactions are also called the *Calvin cycle* or *light-independent reactions* and will be discussed in Chapter 20.

### Photosynthesis converts light energy into chemical energy

The light reactions of photosynthesis closely resemble the events of oxidative phosphorylation. In Chapters 17 and 18, we learned that cellular respiration is the oxidation of glucose to  $\text{CO}_2$  with the reduction of  $\text{O}_2$  to water, a process that generates ATP. In photosynthesis, this process must be reversed—reducing  $\text{CO}_2$  and oxidizing  $\text{H}_2\text{O}$  to synthesize glucose.

Although the processes of respiration and photosynthesis are chemically opposite each other, the biochemical principles governing the two processes are nearly identical. The key to both processes is the generation of high-energy electrons. The citric acid cycle oxidizes carbon fuels to  $\text{CO}_2$  to generate high-energy electrons. The flow of these high-energy electrons down an electron-transport chain generates a proton-motive force. This proton-motive force is then transduced by ATP synthase to form ATP. To synthesize glucose from  $\text{CO}_2$ , high-energy electrons are required for two purposes: (1) to provide reducing power in the form of NADPH to reduce  $\text{CO}_2$ , and (2) to generate ATP to power the reduction. How can high-energy electrons be generated without using a chemical fuel? *Photosynthesis uses energy from light to boost electrons from a low-energy state to a high-energy state.* In the high-energy, unstable state, nearby molecules can abscond with the excited electrons. These electrons are used to produce reducing power, and to generate a proton-motive force across a membrane, which subsequently drives the synthesis of ATP. The reactions that are powered by sunlight are called the *light reactions* (Figure 19.1).

#### Photosynthetic yield

“If a year’s yield of photosynthesis were amassed in the form of sugar cane, it would form a heap over two miles high and with a base 43 square miles.”

—G. E. Fogge

If all of this sugar cane were converted into sugar cubes (0.5 inch, or 1.27 cm, on a side) and stacked end to end, the sugar cubes would extend  $1.6 \times 10^{10}$  miles ( $2.6 \times 10^{10}$  kilometers) or to the dwarf planet Pluto.

**FIGURE 19.1** The light reactions of photosynthesis.

Light is absorbed and the energy is used to drive electrons from water to generate NADPH and to drive protons across a membrane. These protons return through ATP synthase (purple structure) to make ATP.

Photosynthesis in green plants is mediated by two kinds of light reactions. Photosystem I generates reducing power in the form of NADPH, but, in the process, becomes electron deficient. Photosystem II oxidizes water and transfers the electrons to replenish the electrons lost by photosystem I. A side product of these reactions is  $O_2$ . Electron flow from photosystem II to photosystem I generates the transmembrane proton gradient, augmented by the protons released by the oxidation of water, that drives the synthesis of ATP. In keeping with the similarity of their principles of operation, both processes take place in double-membrane organelles: mitochondria for cellular respiration and chloroplasts for photosynthesis.

## 19.1 Photosynthesis Takes Place in Chloroplasts

Photosynthesis, the means of converting light into chemical energy, takes place in organelles called *chloroplasts*, typically 5  $\mu\text{m}$  long. Like a mitochondrion, a chloroplast has an outer membrane and an inner membrane, with an intervening intermembrane space (Figure 19.2). The inner membrane surrounds a space called the *stroma*, which is the site of the dark reactions of photosynthesis (Section 20.1). In the stroma are membranous structures called *thylakoids*, which are flattened sacs, or discs. The thylakoid sacs are stacked to form a *granum*. Different grana are linked by regions of thylakoid membrane called *stroma lamellae* (Figure 19.3). The thylakoid membranes separate the thylakoid space from the stroma space. Thus, chloroplasts have three different membranes (*outer, inner, and thylakoid membranes*) and three separate spaces (*intermembrane, stroma, and thylakoid spaces*). In developing chloroplasts, thylakoids arise from budding of the inner membrane, and so they are analogous to the mitochondrial cristae. Like the mitochondrial cristae, they are the site of coupled oxidation–reduction reactions of the light reactions that generate the proton-motive force.

FIGURE 19.2 Diagram of a chloroplast.

### The primary events of photosynthesis take place in thylakoid membranes

The thylakoid membranes contain the energy-transforming machinery: light-harvesting proteins, reaction centers, electron-transport chains, and ATP synthase. These membranes contain nearly equal amounts of lipids and proteins. The lipid composition is highly distinctive: about 75% of the total lipids are *galactolipids* and 10% are *sulfolipids*, whereas only 10% are phospholipids. The thylakoid membrane and the inner membrane, like the

### Photosynthetic catastrophe

If photosynthesis were to cease, all higher forms of life would be extinct in about 25 years. A milder version of such a catastrophe ended the Cretaceous period 65.1 million years ago when a large asteroid struck the Yucatan Peninsula of Mexico. Enough dust was sent into the atmosphere that photosynthetic capacity was greatly diminished, which apparently led to the disappearance of the dinosaurs and allowed the mammals to rise to prominence.

FIGURE 19.3 Electron micrograph of a chloroplast from a spinach leaf. The thylakoid membranes pack together to form grana. [Courtesy of Dr. Kenneth Miller.]

inner mitochondrial membrane, are impermeable to most molecules and ions. The outer membrane of a chloroplast, like that of a mitochondrion, is highly permeable to small molecules and ions. The stroma contains the soluble enzymes that utilize the NADPH and ATP synthesized by the thylakoids to convert  $\text{CO}_2$  into sugar. Plant-leaf cells contain between 1 and 100 chloroplasts, depending on the species, cell type, and growth conditions.

### Chloroplasts arose from an endosymbiotic event

 Chloroplasts contain their own DNA and the machinery for replicating and expressing it. However, chloroplasts are not autonomous: they also contain many proteins encoded by nuclear DNA. How did the intriguing relation between the cell and its chloroplasts develop? We now believe that, in a manner analogous to the evolution of mitochondria (Section 18.1), chloroplasts are the result of endosymbiotic events in which a photosynthetic microorganism, most likely an ancestor of a cyanobacterium (Figure 19.4), was engulfed by a eukaryotic host. Evidence suggests that chloroplasts in higher plants and green algae are derived from a single endosymbiotic event, whereas those in red and brown algae are derived from at least one additional event.

The chloroplast genome is smaller than that of a cyanobacterium, but the two genomes have key features in common. Both are circular and have a single start site for DNA replication, and the genes of both are arranged in operons—sequences of functionally related genes under common control (Chapter 31). In the course of evolution, many of the genes of the chloroplast ancestor were transferred to the plant cell's nucleus or, in some cases, lost entirely, thus establishing a fully dependent relation.

## 19.2 Light Absorption by Chlorophyll Induces Electron Transfer

The trapping of light energy is the key to photosynthesis. The first event is the absorption of light by a photoreceptor molecule. The principal photoreceptor in the chloroplasts of most green plants is the pigment molecule *chlorophyll a*, a substituted tetrapyrrole (Figure 19.5). The four nitrogen atoms of

**FIGURE 19.5 Chlorophyll.** Like heme, chlorophyll *a* is a cyclic tetrapyrrole. One of the pyrrole rings (shown in red) is reduced, and an additional five-carbon ring (shown in blue) is fused to another pyrrole ring. A phytol chain (shown in green) is connected by an ester linkage. Magnesium ion binds at the center of the structure.

the pyrroles are coordinated to a magnesium ion. Unlike a porphyrin such as heme, chlorophyll has a reduced pyrrole ring and an additional 5-carbon ring fused to one of the pyrrole rings. Another distinctive feature of chlorophyll is the presence of *phytol*, a highly hydrophobic 20-carbon alcohol, esterified to an acid side chain.

Chlorophylls are very effective photoreceptors because they contain networks of conjugated double bonds—alternating single and double bonds. Such compounds are called conjugated *polyenes*. In polyenes, the electrons are not localized to a particular atomic nucleus. Upon the absorption of light energy, the electron transitions from a low energy molecular orbital to a higher energy orbital. Chlorophylls have very strong absorption bands in the visible region of the spectrum, where the solar output reaching Earth is maximal (Figure 19.6). Chlorophyll *a*'s peak molar extinction coefficient ( $\epsilon$ ), a measure of a compound's ability to absorb light, is greater than  $10^5 \text{ M}^{-1} \text{ cm}^{-1}$ , among the highest observed for organic compounds.

What happens when light is absorbed by a pigment molecule? The energy from the light excites an electron from its ground energy level to an excited energy level (Figure 19.7). This high-energy electron can have one of two fates. For most compounds that absorb light, the electron simply returns to the ground state and the absorbed energy is converted into heat. However, if a suitable electron acceptor is nearby, as is the case for chlorophyll in photosynthetic systems, the excited electron can move from the initial molecule to the acceptor (Figure 19.8). A positive charge forms on the initial molecule, owing to the loss of an electron, and a negative charge forms on the acceptor, owing to the gain of an electron. Hence, this process is referred to as *photoinduced charge separation*.

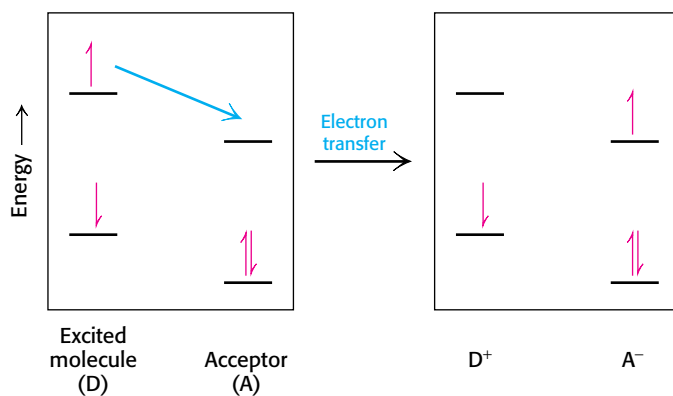

In chloroplasts, the site at which the charge separation takes place within each photosystem is called the *reaction center*. The photosynthetic apparatus is arranged to maximize photoinduced charge separation and minimize an unproductive return of the electron to its ground state. The electron, extracted from its initial site by the absorption of light, now has reducing power: it can reduce other molecules to store the energy originally obtained from light in chemical forms.

**FIGURE 19.6** Light absorption by chlorophyll *a*. Chlorophyll *a* absorbs visible light efficiently, as judged by the extinction coefficient near  $10^5 \text{ M}^{-1} \text{ cm}^{-1}$ .

**FIGURE 19.7** Light absorption. The absorption of light leads to the excitation of an electron from its ground state to a higher energy level.

**FIGURE 19.8** Photoinduced charge separation. If a suitable electron acceptor is nearby, an electron that has been moved to a high energy level by light absorption can move from the excited molecule to the acceptor.

### A special pair of chlorophylls initiate charge separation

Photosynthetic bacteria such as *Rhodospseudomonas viridis* contain a photosynthetic reaction center that has been revealed at atomic resolution.

**FIGURE 19.9 Bacterial photosynthetic reaction center.** The core of the reaction center from *Rhodospseudomonas viridis* consists of two similar chains: L (red) and M (blue). An H chain (white) and a cytochrome subunit (yellow) complete the structure. Notice that the L and M subunits are composed largely of  $\alpha$  helices that span the membrane. Also notice that a chain of electron-carrying prosthetic groups, beginning with a special pair of bacteriochlorophylls and ending at a bound quinone, runs through the structure from bottom to top in this view. [Drawn from 1PRC.pdb.]

The bacterial reaction center consists of four polypeptides: L (31 kDa, red), M (36 kDa, blue), and H (28 kDa, white) subunits and C, a *c*-type cytochrome with four *c*-type hemes (yellow) (Figure 19.9). Sequence comparisons and low-resolution structural studies have revealed that the bacterial reaction center is homologous to the more complex plant systems. Thus, many of our observations of the bacterial system apply to plant systems as well.

The L and M subunits form the structural and functional core of the bacterial photosynthetic reaction center (Figure 19.9). Each of these homologous subunits contains five transmembrane helices, in contrast with the H subunit, which has just one. The H subunit lies on the cytoplasmic side of the cell membrane, and the cytochrome subunit lies on the exterior face of the cell membrane, called the *periplasmic side* because it faces the periplasm, the space between the cell membrane and the cell wall. Four bacteriochlorophyll *b* (BChl-*b*) molecules, two bacteriopheophytin *b* (BPh) molecules, two quinones ( $Q_A$  and  $Q_B$ ), and a ferrous ion are associated with the L and M subunits.

Bacteriochlorophylls are photoreceptors similar to chlorophylls, except for the reduction of an additional pyrrole ring and other minor differences that shift their absorption maxima to the near infrared, to wavelengths as long as 1000 nm. Bacteriopheophytin is the term for a bacteriochlorophyll that has two protons instead of a magnesium ion at its center.

The reaction begins with light absorption by a pair of BChl-*b* molecules that lie near the periplasmic side of the membrane in the L–M dimer. The pair of BChl-*b* molecules is called the *special pair* because of

**FIGURE 19.10 Electron chain in the photosynthetic bacterial reaction center.** The absorption of light by the special pair (P960) results in the rapid transfer of an electron from this site to a bacteriopheophytin (BPh), creating a photoinduced charge separation (steps 1 and 2). (The asterisk on P960 stands for excited state.) The possible return of the electron from the pheophytin to the oxidized special pair is suppressed by the “hole” in the special pair being refilled with an electron from the cytochrome subunit and the electron from the pheophytin being transferred to a quinone (Q<sub>A</sub>) that is farther away from the special pair (steps 3 and 4). Q<sub>A</sub> passes the electron to Q<sub>B</sub>. The reduction of a quinone (Q<sub>B</sub>) on the cytoplasmic side of the membrane results in the uptake of two protons from the cytoplasm (steps 5 and 6). The reduced quinone can move into the quinone pool in the membrane (step 7).

its fundamental role in photosynthesis. The special pair absorbs light maximally at 960 nm, and, for this reason, is often called P960 (*P* stands for pigment). After absorbing light, the excited special pair ejects an electron, which is transferred through another BChl-*b* to a bacteriopheophytin (Figure 19.10, steps 1 and 2). This initial charge separation yields a positive charge on the special pair (P960<sup>+</sup>) and a negative charge on BPh (BPh<sup>-</sup>). The electron ejection and transfer take place in less than 10 picoseconds (10<sup>-11</sup> s).
