A nearby electron acceptor, a tightly bound quinone (Q<sub>A</sub>), quickly grabs the electron away from BPh<sup>-</sup> before the electron has a chance to fall back to the P960 special pair. From Q<sub>A</sub>, the electron moves to a more loosely associated quinone, Q<sub>B</sub>. The absorption of a second photon and the movement of a second electron from the special pair through the bacteriopheophytin to the quinones completes the two-electron reduction of Q<sub>B</sub> from Q to QH<sub>2</sub>. Because the Q<sub>B</sub>-binding site lies near the cytoplasmic side of the membrane, *two protons are taken up from the cytoplasm, contributing to the development of a proton gradient across the cell membrane* (Figure 19.10, steps 5, 6, and 7).

In their high-energy states, P960<sup>+</sup> and BPh<sup>-</sup> could undergo charge recombination; that is, the electron on BPh<sup>-</sup> could move back to neutralize the positive charge on the special pair. Its return to the special pair would waste a valuable high-energy electron and simply convert the absorbed light energy into heat. How is charge recombination prevented? Two factors in the structure of the reaction center work together to suppress charge recombination nearly completely (Figure 19.10, steps 3 and 4). First, the next electron acceptor (Q<sub>A</sub>) is less than 10 Å away from BPh<sup>-</sup>, and so the electron is rapidly transferred farther away from the special pair. Second, one of

**FIGURE 19.11 Cyclic electron flow in the bacterial reaction center.** Excited electrons from the P960 reaction center flow through bacteriopheophytin (BPh), a pair of quinone molecules ( $Q_A$  and  $Q_B$ ), cytochrome  $bc_1$  complex, and finally through cytochrome  $c_2$  to the reaction center. The cytochrome  $bc_1$  complex pumps protons as a result of electron flow, which powers the formation of ATP.

the hemes of the cytochrome subunit is less than  $10 \text{ \AA}$  away from the special pair, and so the positive charge on P960 is neutralized by the transfer of an electron from the reduced cytochrome.

### Cyclic electron flow reduces the cytochrome of the reaction center

The cytochrome subunit of the reaction center must regain an electron to complete the cycle. It does so by taking back two electrons from reduced quinone ( $QH_2$ ).  $QH_2$  first enters the Q pool in the membrane where it is reoxidized to Q by complex  $bc_1$ , which is homologous to complex III of the respiratory electron-transport chain. Complex  $bc_1$  transfers the electrons from  $QH_2$  to cytochrome  $c_2$ , a water-soluble protein in the periplasm, and in the process pumps protons into the periplasmic space. The electrons now on cytochrome  $c_2$  flow to the cytochrome subunit of the reaction center. The flow of electrons is thus cyclic (Figure 19.11). The proton gradient generated in the course of this cycle drives the synthesis of ATP through the action of ATP synthase.

## 19.3 Two Photosystems Generate a Proton Gradient and NADPH in Oxygenic Photosynthesis

Photosynthesis is more complicated in green plants than in photosynthetic bacteria. In green plants, photosynthesis depends on the interplay of two kinds of membrane-bound, light-sensitive complexes—*photosystem I* (PS I) and *photosystem II* (PS II), as shown in Figure 19.12. There are similarities in photosynthesis between green plants and photosynthetic bacteria. Both require light to energize reaction centers consisting of special pairs, called  $P700$  for photosystem I and  $P680$  for photosystem II, and both transfer electrons by using electron-transport chains. However, in plants, electron flow is not cyclic but progresses from photosystem II to photosystem I under most circumstances.

Photosystem I, which responds to light with wavelengths shorter than  $700 \text{ nm}$ , uses light-derived high-energy electrons to create biosynthetic reducing power in the form of NADPH, a versatile reagent for driving biosynthetic processes. The electrons for creating one molecule of NADPH are taken from two molecules of water by photosystem II, which responds to wavelengths shorter than  $680 \text{ nm}$ . A molecule of  $O_2$  is generated as a side product of the actions of photosystem II. The electrons travel from photosystem II to photosystem I through cytochrome  $bf$ , a membrane-bound complex homologous to Complex III in oxidative phosphorylation. Cytochrome  $bf$  generates a proton gradient across the thylakoid membrane that drives the formation of ATP. Thus, the two photosystems cooperate to produce NADPH and ATP.

**FIGURE 19.12 Two photosystems.** The absorption of photons by two distinct photosystems (PS I and PS II) is required for complete electron flow from water to  $NADP^+$ .

### Photosystem II transfers electrons from water to plastoquinone and generates a proton gradient

Photosystem II, an enormous transmembrane assembly of more than 20 subunits, catalyzes the light-driven transfer of electrons from water to plastoquinone. This electron acceptor closely resembles ubiquinone, a component of the mitochondrial electron-transport chain. Plastoquinone cycles

between an oxidized form (Q) and a reduced form (QH<sub>2</sub>, plastoquinol). The overall reaction catalyzed by photosystem II is

The electrons in QH<sub>2</sub> are at a higher redox potential than those in H<sub>2</sub>O. Recall that, in oxidative phosphorylation, electrons flow from ubiquinol to an acceptor, O<sub>2</sub>, which is at a *lower* potential. Photosystem II drives the reaction in a thermodynamically uphill direction by using the free energy of light.

This reaction is similar to one catalyzed by the bacterial system in that a quinone is converted from its oxidized into its reduced form. Photosystem II is reasonably similar to the bacterial reaction center (Figure 19.13). The core of the photosystem is formed by D1 and D2, a pair of similar 32-kDa subunits that span the thylakoid membrane. These subunits are homologous to the L and M chains of the bacterial reaction center. Unlike the bacterial system, photosystem II contains a large number of additional subunits that bind more than 30 chlorophyll molecules altogether and increase the efficiency with which light energy is absorbed and transferred to the reaction center (Section 19.5).

**FIGURE 19.13** The structure of photosystem II. The D<sub>1</sub> (red) and D<sub>2</sub> (blue) subunits and the numerous bound chlorophyll molecules (green). Notice that the special pair and the water-oxidizing complex lay toward the thylakoid-lumen side of the membrane. [Drawn from 1S5L.pdb.]

The photochemistry of photosystem II begins with excitation of a special pair of chlorophyll molecules that are bound by the D1 and D2 subunits (Figure 19.14). Because the chlorophyll *a* molecules of the special pair absorb light at 680 nm, the special pair is often called *P680*. On excitation, P680 rapidly transfers an electron to a nearby pheophytin. From there, the electron is transferred first to a tightly bound plastoquinone at site Q<sub>A</sub> and then to a mobile plastoquinone at site Q<sub>B</sub>. This electron flow is entirely analogous to that in the bacterial system. With the arrival of a second electron and the uptake of two protons, the mobile plastoquinone is reduced to QH<sub>2</sub>. At this point, the energy of two photons has been safely and efficiently stored in the reducing potential of QH<sub>2</sub>.

The major difference between the bacterial system and photosystem II is the source of the electrons that are used to neutralize the positive charge formed on the special pair. P680<sup>+</sup>, a *very strong oxidant*, extracts electrons from water

**FIGURE 19.14** Electron flow through photosystem II. Light absorption induces electron transfer from P680 down an electron-transfer pathway to an exchangeable plastoquinone. The positive charge on P680 is neutralized by electron flow from water molecules bound at the manganese center.

**FIGURE 19.15 The core of the water-oxidizing complex.** (A) The deduced core structure of the water-oxidizing complex (WOC), including four manganese ions and one calcium ion, is shown. The valence states of the individual manganese ions are not indicated because of uncertainty about the charge on the individual ions. The center is oxidized, one electron at a time, until two  $\text{H}_2\text{O}$  molecules are oxidized to form a molecule of  $\text{O}_2$ , which is then released from the complex. (B) The absorption of photons by the reaction center generates a tyrosine radical (red arrows), which then extracts electrons from the manganese ions. The structures are designated  $S_0$  to  $S_4$  to indicate the number of electrons that have been removed.

Evolution of oxygen is evident by the generation of bubbles in the aquatic plant *Elodea*. [Colin Milkins/Oxford Scientific Films/Photolibrary.]

molecules bound at the water-oxidizing complex (WOC), also called the *manganese center*. The core of this complex includes a calcium ion, four manganese ions, and four water molecules (Figure 19.15A). Manganese was apparently evolutionarily selected for this role because of its ability to exist in multiple oxidation states and to form strong bonds with oxygen-containing species. In its reduced form, the WOC oxidizes two molecules of water to form a single molecule of oxygen. Each time the absorbance of a photon powers the removal of an electron from P680, the positively charged special pair extracts an electron from a tyrosine residue (often designated Z) of subunit D1 of the WOC, forming a tyrosine radical (Figure 19.15B). The tyrosine radical then removes an electron from a manganese ion. This process occurs four times, with the result that  $\text{H}_2\text{O}$  is oxidized to generate  $\text{O}_2$  and  $\text{H}^+$ . Four photons must be absorbed to extract four electrons from a water molecule (Figure 19.16). The four electrons harvested from water are used to reduce two molecules of Q to  $\text{QH}_2$ . All oxygenic phototrophs, the most common type of photosynthetic organism, use the same inorganic core and protein components for capturing the energy of sunlight. A single solution to the biochemical problem of extracting electrons from water evolved billions of years ago, and has been conserved for use under a wide variety of phylogenetic and ecological circumstances.

Photosystem II spans the thylakoid membrane such that the site of quinone reduction is on the side of the stroma, whereas WOC lies in the

**FIGURE 19.16 Four photons are required to generate one oxygen molecule.** When dark-adapted chloroplasts are exposed to a brief flash of light, one electron passes through photosystem II. Monitoring the  $\text{O}_2$  released after each flash reveals that four flashes are required to generate each  $\text{O}_2$  molecule. The peaks in  $\text{O}_2$  release are after the 3rd, 7th, and 11th flashes because the dark-adapted chloroplasts start in the  $S_1$  state—that is, the one-electron reduced state.

thylakoid lumen. Thus, the two protons that are taken up with the reduction of Q to  $\text{QH}_2$  come from the stroma, and the four protons that are liberated in the course of water oxidation are released into the lumen. This distribution of protons generates a proton gradient across the thylakoid membrane characterized by an excess of protons in the thylakoid lumen compared with the stroma (Figure 19.17).

### Cytochrome *bf* links photosystem II to photosystem I

Electrons flow from photosystem II to photosystem I through the *cytochrome bf* complex. This complex catalyzes the transfer of electrons from plastoquinol ( $\text{QH}_2$ ) to plastocyanin (Pc), a small, soluble copper protein in the thylakoid lumen.

The two protons from plastoquinol are released into the thylakoid lumen. This reaction is reminiscent of that catalyzed by Complex III in oxidative phosphorylation, and most components of the *cytochrome bf* complex are homologous to those of Complex III. The *cytochrome bf* complex includes four subunits: a 23-kDa cytochrome with two *b*-type hemes, a 20-kDa Rieske-type Fe-S protein (p. 534), a 33-kDa cytochrome *f* with a *c*-type cytochrome, and a 17-kDa chain.

This complex catalyzes the reaction by proceeding through the Q cycle (Figure 18.12). In the first half of the Q cycle, plastoquinol ( $\text{QH}_2$ ) is oxidized to plastoquinone (Q), one electron at a time. The electrons from plastoquinol flow through the Fe-S protein to convert oxidized plastocyanin (Pc) into its reduced form.

In the second half of the Q cycle, *cytochrome bf* reduces a molecule of plastoquinone from the Q pool to plastoquinol, taking up two protons from one side of the membrane, and then reoxidizes plastoquinol to release these protons on the other side. The enzyme is oriented so that protons are released into the thylakoid lumen and taken up from the stroma, contributing further to the proton gradient across the thylakoid membrane (Figure 19.18).

### Photosystem I uses light energy to generate reduced ferredoxin, a powerful reductant

The final stage of the light reactions is catalyzed by photosystem I, a transmembrane complex consisting of about 15 polypeptide chains and multiple associated proteins and cofactors (Figure 19.19). The core of this system is a

**FIGURE 19.17 Proton-gradient direction.** Photosystem II releases protons into the thylakoid lumen and takes them up from the stroma. The result is a pH gradient across the thylakoid membrane with an excess of protons (low pH) inside.

**FIGURE 19.18 Cytochrome *bf* contribution to proton gradient.** The *cytochrome bf* complex oxidizes  $\text{QH}_2$  to Q through the Q cycle. Four protons are released into the thylakoid lumen in each cycle.

**FIGURE 19.19 The structure of photosystem I.** The *psaA* and *psaB* subunits are shown in red and blue, respectively. Notice the numerous bound chlorophyll molecules, shown in green, including the special pair, as well as the iron-sulfur clusters that facilitate electron transfer from the stroma. [Drawn from 1JBO.pdb.]

**FIGURE 19.20 Electron flow through photosystem I to ferredoxin.** Light absorption induces electron transfer from P700 down an electron-transfer pathway that includes a chlorophyll molecule, a quinone molecule, and three 4Fe-4S clusters to reach ferredoxin. The positive charge left on P700 is neutralized by electron transfer from reduced plastocyanin.

pair of similar subunits, *psaA* (83 kDa, red) and *psaB* (82 kDa, blue), which bind 80 chlorophyll molecules as well as other redox factors. These subunits are quite a bit larger than the core subunits of photosystem II and the bacterial reaction center. Nonetheless, they appear to be homologous; the terminal 40% of each subunit is similar to a corresponding subunit of photosystem II. A special pair of chlorophyll *a* molecules lie at the center of the structure and absorb light maximally at 700 nm. This center, called *P700*, initiates photoinduced charge separation (Figure 19.20). The electron travels from *P700* down a pathway through chlorophyll at site *A<sub>0</sub>* and quinone at site *A<sub>1</sub>* to a set of 4Fe-4S clusters. The next step is the transfer of the electron to ferredoxin (Fd), a soluble protein containing a 2Fe-2S cluster coordinated to four cysteine residues (Figure 19.21). Ferredoxin transfers electrons to NADP<sup>+</sup>. Meanwhile, *P700*<sup>+</sup> captures an electron from reduced plastocyanin provided by photosystem II to return to *P700* so that *P700* can be excited again. Thus, the overall reaction catalyzed by photosystem I is a simple one-electron oxidation–reduction reaction.

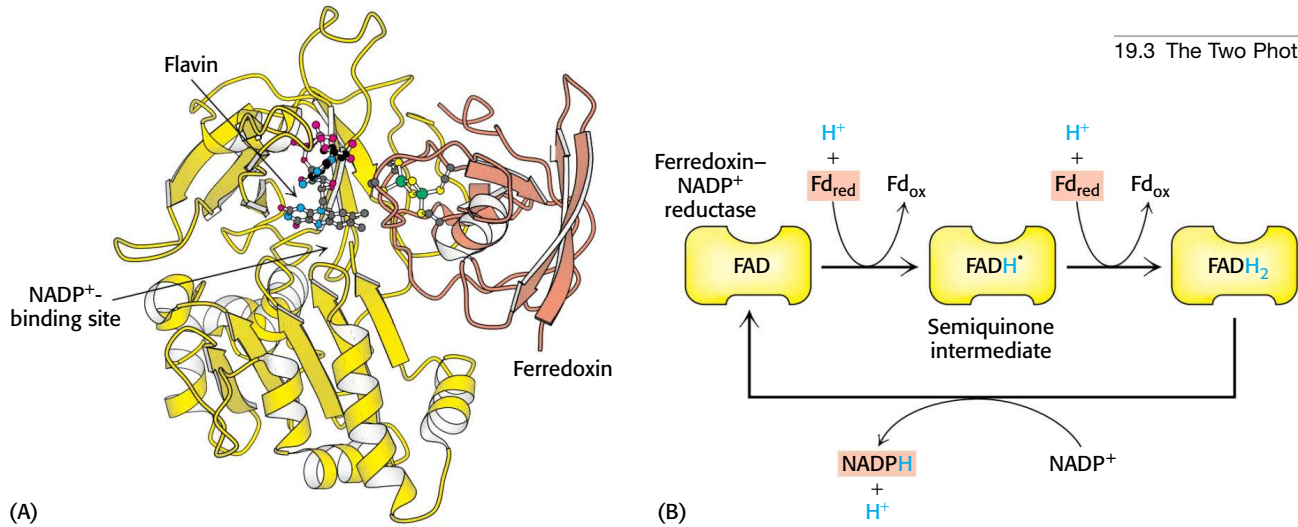

Given that the reduction potentials for plastocyanin and ferredoxin are +0.37 V and –0.45 V, respectively, the standard free energy for this reaction is +79.1 kJ mol<sup>–1</sup> (+18.9 kcal mol<sup>–1</sup>). This uphill reaction is driven by the absorption of a 700-nm photon, which has an energy of 171 kJ mol<sup>–1</sup> (40.9 kcal mol<sup>–1</sup>).

**FIGURE 19.21 Structure of ferredoxin.** In plants, ferredoxin contains a 2Fe-2S cluster. This protein accepts electrons from photosystem I and carries them to ferredoxin–NADP<sup>+</sup> reductase. [Drawn from 1FXA.pdb.]

### Ferredoxin–NADP<sup>+</sup> reductase converts NADP<sup>+</sup> into NADPH

The reduced ferredoxin generated by photosystem I is a strong reductant that is used as an electron source for a variety of reactions, most notably the fixation of N<sub>2</sub> into NH<sub>3</sub> (Section 24.1). However, ferredoxin is not useful for driving many reactions, in part because ferredoxin carries only one available electron. In contrast, NADPH, a two-electron reductant, is a widely used electron donor in biosynthetic processes, including the reactions of the Calvin cycle (Chapter 20). How is reduced ferredoxin used to drive the reduction of NADP<sup>+</sup> to NADPH? This reaction is catalyzed by *ferredoxin–NADP<sup>+</sup> reductase*, a flavoprotein with an FAD prosthetic

**FIGURE 19.22 Structure and function of ferredoxin-NADP<sup>+</sup> reductase.** (A) Structure of ferredoxin-NADP<sup>+</sup> reductase. This enzyme accepts electrons, one at a time, from ferredoxin (shown in orange). (B) Ferredoxin-NADP<sup>+</sup> reductase first accepts two electrons, generated by photosystem I, and two protons from the lumen to form two molecules of reduced ferredoxin (Fd). Reduced ferredoxin is then used to form FADH<sub>2</sub>, which then transfers two electrons and a proton to NADP<sup>+</sup> to form NADPH in the stroma. [Drawn from 1EWY.pdb.]

group (Figure 19.22A). The bound FAD moiety accepts two electrons and two protons from two molecules of reduced ferredoxin to form FADH<sub>2</sub> (Figure 19.22B). The enzyme then transfers a hydride ion (H<sup>-</sup>) to NADP<sup>+</sup> to form NADPH. This reaction takes place on the stromal side of the membrane. Hence, the uptake of a proton in the reduction of NADP<sup>+</sup> further contributes to the generation of the proton gradient across the thylakoid membrane.

The cooperation between photosystem I and photosystem II creates a flow of electrons from H<sub>2</sub>O to NADP<sup>+</sup>. The pathway of electron flow is called the *Z scheme of photosynthesis* because the redox diagram from P680 to P700\* looks like the letter Z (Figure 19.23).

**FIGURE 19.23 Pathway of electron flow from H<sub>2</sub>O to NADP<sup>+</sup> in photosynthesis.** This endergonic reaction is made possible by the absorption of light by photosystem II (P680) and photosystem I (P700). ## 19.4 A Proton Gradient across the Thylakoid Membrane Drives ATP Synthesis

**FIGURE 19.24 Jagendorf's demonstration.** Chloroplasts synthesize ATP after the imposition of a pH gradient.

In 1966, André Jagendorf showed that chloroplasts synthesize ATP in the dark when an artificial pH gradient is imposed across the thylakoid membrane. To create this transient pH gradient, he soaked chloroplasts in a pH 4 buffer for several hours and then rapidly mixed them with a pH 8 buffer containing ADP and  $P_i$ . The pH of the stroma suddenly increased to 8, whereas the pH of the thylakoid space remained at 4. A burst of ATP synthesis then accompanied the disappearance of the pH gradient across the thylakoid membrane (Figure 19.24). This incisive experiment was one of the first to unequivocally support the hypothesis put forth by Peter Mitchell that ATP synthesis is driven by proton-motive force (Section 18.4).

The principles of ATP synthesis in chloroplasts are nearly identical with those in mitochondria. ATP formation is driven by a proton-motive force in both photophosphorylation and oxidative phosphorylation. We have seen how light induces electron transfer through photosystems II and I and the cytochrome *bf* complex. At various stages in this process, protons are released into the thylakoid lumen or taken up from the stroma, generating a proton gradient. The gradient is maintained because the thylakoid membrane is essentially impermeable to protons. The thylakoid space becomes markedly acidic, with the pH approaching 4. The light-induced transmembrane proton gradient is about 3.5 pH units. As discussed in Section 18.4, energy inherent in the proton gradient, called the proton-motive force ( $\Delta p$ ), is described as the sum of two components: a charge gradient and a chemical gradient. In chloroplasts, nearly all of  $\Delta p$  arises from the pH gradient, whereas in mitochondria, the contribution from the membrane potential is larger. The reason for this difference is that the thylakoid membrane is quite permeable to  $Cl^-$  and  $Mg^{2+}$ . The light-induced transfer of  $H^+$  into the thylakoid space is accompanied by the transfer of either  $Cl^-$  in the same direction or  $Mg^{2+}$  (1  $Mg^{2+}$  per 2  $H^+$ ) in the opposite direction. Consequently, electrical neutrality is maintained and no membrane potential is generated. The influx of  $Mg^{2+}$  into the stroma plays a role in the regulation of the Calvin Cycle (Section 20.2). A pH gradient of 3.5 units across the thylakoid membrane corresponds to a proton-motive force of 0.20 V or a  $\Delta G$  of  $-20.0 \text{ kJ mol}^{-1}$  ( $-4.8 \text{ kcal mol}^{-1}$ ).

### The ATP synthase of chloroplasts closely resembles those of mitochondria and prokaryotes

The proton-motive force generated by the light reactions is converted into ATP by the ATP synthase of chloroplasts, also called the  $CF_1$ - $CF_0$  complex (*C* stands for chloroplast; *F* for factor).  $CF_1$ - $CF_0$  ATP synthase closely resembles the  $F_1$ - $F_0$  complex of mitochondria (Section 18.4).  $CF_0$  conducts protons across the thylakoid membrane, whereas  $CF_1$  catalyzes the formation of ATP from ADP and  $P_i$ .

$CF_0$  is embedded in the thylakoid membrane. It consists of four different polypeptide chains known as I (17 kDa), II (16.5 kDa), III (8 kDa), and IV (27 kDa) having an estimated stoichiometry of 1 : 2 : 10–14 : 1. Subunits I and II have sequence similarity to subunit **b** of the mitochondrial  $F_0$  subunit, III corresponds to subunit **c** of the mitochondrial complex, and subunit IV is similar in sequence to subunit **a**.  $CF_1$ , the site of ATP synthesis, has a subunit composition  $\alpha_3\beta_3\gamma\delta\epsilon$ . The  $\beta$  subunits contain the catalytic sites, similarly to the  $F_1$  subunit of mitochondrial ATP synthase. Remarkably, the  $\beta$  subunits of ATP synthase in corn chloroplasts are more

**FIGURE 19.25 Comparison of photosynthesis and oxidative phosphorylation.** The light-induced electron transfer in photosynthesis drives protons into the thylakoid lumen. The excess protons flow out of the lumen through ATP synthase to generate ATP in the stroma. In oxidative phosphorylation, electron flow down the electron-transport chain pumps protons out of the mitochondrial matrix. Excess protons from the intermembrane space flow into the matrix through ATP synthase to generate ATP in the matrix.

than 60% identical in amino acid sequence with those of human ATP synthase, despite the passage of approximately 1 billion years since the separation of the plant and animal kingdoms.

Note that the membrane orientation of  $CF_1$ – $CF_0$  is reversed compared with that of the mitochondrial ATP synthase (Figure 19.25). However, the functional orientation of the two synthases is identical: protons flow from the lumen through the enzyme to the stroma or matrix where ATP is synthesized. Because  $CF_1$  is on the stromal surface of the thylakoid membrane, the newly synthesized ATP is released directly into the stromal space. Likewise, NADPH formed by photosystem I is released into the stromal space. Thus, *ATP and NADPH, the products of the light reactions of photosynthesis, are appropriately positioned for the subsequent dark reactions, in which  $CO_2$  is converted into carbohydrate.*

### The activity of chloroplast ATP synthase is regulated

The activity of the ATP synthase is sensitive to the redox conditions in the chloroplast. For maximal activity, a specific disulfide bond in the  $\gamma$  subunit must be reduced to two cysteines. The reductant is reduced thioredoxin,

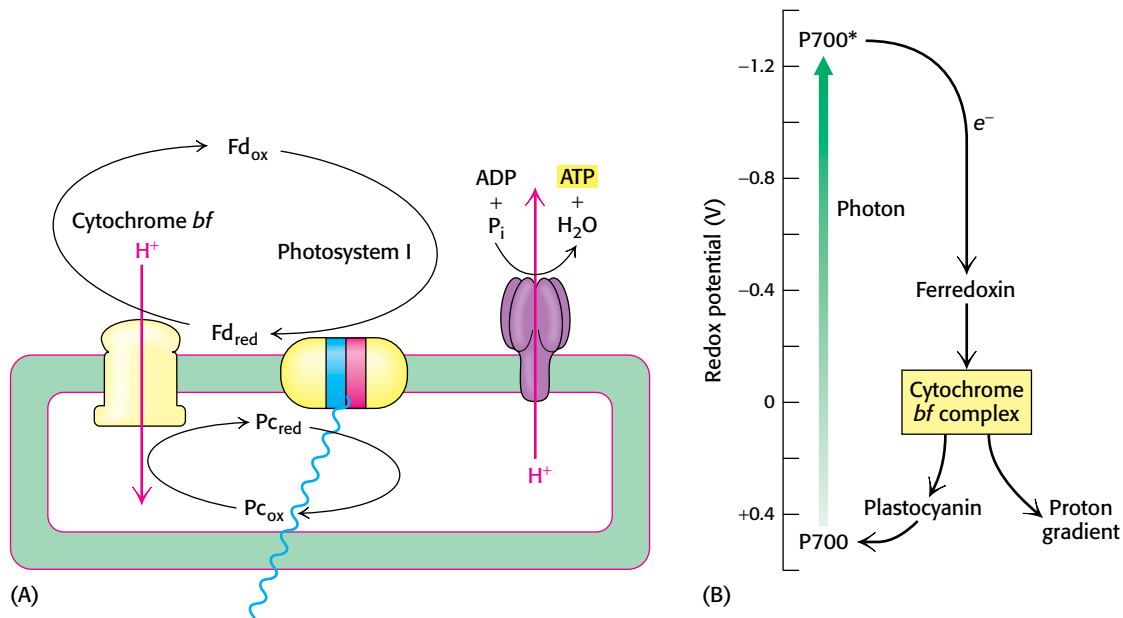

which is formed from ferredoxin generated in photosystem I, by ferredoxin–thioredoxin reductase, an iron–sulfur containing enzyme.

Conformational changes in the  $\epsilon$  subunit also contribute to synthase regulation. The  $\epsilon$  subunit appears to exist in two conformations. One conformation inhibits ATP hydrolysis by the synthase, while the other, which is generated by an increase in the proton-motive force, allows ATP synthesis and facilitates the reduction of the disulfide bond in the  $\gamma$  subunit. Thus, synthase activity is maximal when biosynthetic reducing power and a proton gradient are available. We will see in Chapter 20 that redox regulation is also important in photosynthetic carbon metabolism.

### Cyclic electron flow through photosystem I leads to the production of ATP instead of NADPH

On occasion, when the ratio of NADPH to NADP<sup>+</sup> is very high, as might be the case if there was another source of electrons to form NADPH (Section 20.3), NADP<sup>+</sup> may be unavailable to accept electrons from reduced ferredoxin. In these circumstances, specific large protein complexes allow cyclic electron flow that powers ATP synthesis. Electrons arising from P700, the reaction center of photosystem I, generate reduced ferredoxin. The electron in reduced ferredoxin is transferred to the cytochrome *bf* complex rather than to NADP<sup>+</sup>. This electron then flows back through the cytochrome *bf* complex to reduce plastocyanin, which can then be reoxidized by P700<sup>+</sup> to complete a cycle. The net outcome of this cyclic flow of electrons is the pumping of protons by the cytochrome *bf* complex. The resulting proton gradient then drives the synthesis of ATP. In this process, called *cyclic photophosphorylation*, ATP is generated without the concomitant formation of NADPH (Figure 19.26). Photosystem II does not participate in cyclic photophosphorylation, and so O<sub>2</sub> is not formed from H<sub>2</sub>O.

**FIGURE 19.26 Cyclic photophosphorylation.** (A) In this pathway, electrons from reduced ferredoxin are transferred to cytochrome *bf* rather than to ferredoxin–NADP<sup>+</sup> reductase. The flow of electrons through cytochrome *bf* pumps protons into the thylakoid lumen. These protons flow through ATP synthase to generate ATP. Neither NADPH nor O<sub>2</sub> is generated by this pathway. (B) A scheme showing the energetic basis for cyclic photophosphorylation. Abbreviations: Fd, ferredoxin; Pc, plastocyanin.

## The absorption of eight photons yields one O<sub>2</sub>, two NADPH, and three ATP molecules

We can now estimate the overall stoichiometry for the light reactions. The absorption of four photons by photosystem II generates one molecule of O<sub>2</sub> and releases four protons into the thylakoid lumen. The two molecules of plastoquinol are oxidized by the Q cycle of the cytochrome *bf* complex to release eight protons into the lumen. Finally, the electrons from four molecules of reduced plastocyanin are driven to ferredoxin by the absorption of four additional photons. The four molecules of reduced ferredoxin generate two molecules of NADPH. Thus, the overall reaction is

The 12 protons released in the lumen can then flow through ATP synthase. Let us assume that there are 12 subunit III components in CF<sub>0</sub>. We expect that 12 protons must pass through CF<sub>0</sub> to complete one full rotation of CF<sub>1</sub>. A single rotation generates three molecules of ATP. Given the ratio of 3 ATP for 12 protons, the overall reaction is

Thus, eight photons are required to yield three molecules of ATP (2.7 photons/ATP).

Cyclic photophosphorylation is a somewhat more productive way to synthesize ATP than noncyclic photophosphorylation (the Z scheme). The absorption of four photons by photosystem I leads to the release of eight protons into the lumen by the cytochrome *bf* system. These protons flow through ATP synthase to yield two molecules of ATP. Thus, each two absorbed photons yield one molecule of ATP. No NADPH is produced.

## 19.5 Accessory Pigments Funnel Energy into Reaction Centers

A light-harvesting system that relied only on the chlorophyll *a* molecules of the special pair would be rather inefficient for two reasons. First, chlorophyll *a* molecules absorb light only at specific wavelengths (Figure 19.6). A large gap is present in the middle of the visible region between approximately 450 and 650 nm. This gap falls right at the peak of the solar spectrum, and so failure to collect this light would constitute a considerable lost opportunity. Second, even on a cloudless day, many photons that can be absorbed by chlorophyll *a* pass through the chloroplast without being absorbed, because the density of chlorophyll *a* molecules in a reaction center is not very great. Accessory pigments, both additional chlorophylls and other classes of molecules, are closely associated with reaction centers. *These pigments absorb light and funnel the energy to the reaction center for conversion into chemical forms.* Accessory pigments prevent the reaction center from sitting idle.

*Chlorophyll b* and *carotenoids* are important accessory pigments that funnel energy to the reaction center. Chlorophyll *b* differs from chlorophyll *a* in having a formyl group in place of a methyl group. This small difference shifts its two major absorption peaks toward the center of the visible region.

**Chlorophyll b**

FIGURE 19.27 Absorption spectra of chlorophylls *a* and *b*.

In particular, chlorophyll *b* efficiently absorbs light with wavelengths between 450 and 500 nm (Figure 19.27).

Carotenoids are extended polyenes that absorb light between 400 and 500 nm. The carotenoids are responsible for most of the yellow and red colors of fruits and flowers, and they provide the brilliance of fall, when the chlorophyll molecules degrade, revealing the carotenoids. Tomatoes are especially rich in lycopene, which accounts for their red color, whereas carrots and pumpkins have abundant  $\beta$ -carotene, accounting for their orange color.

In addition to their role in transferring energy to reaction centers, the carotenoids serve a safeguarding function. Carotenoids suppress damaging photochemical reactions, particularly those including oxygen, that can be induced by bright sunlight. This protection may be especially important in the fall, when the primary pigment chlorophyll is being degraded and thus not able to absorb light energy. Plants lacking carotenoids are quickly killed on exposure to light and oxygen.

### Resonance energy transfer allows energy to move from the site of initial absorbance to the reaction center

How is energy funneled from accessory pigments to a reaction center? The absorption of a photon does not always lead to electron excitation and transfer. More commonly, excitation energy is transferred from one molecule to a nearby molecule through electromagnetic interactions through space (Figure 19.28). The rate of this process, called *resonance energy transfer*, depends strongly on the distance between the energy-donor and the energy-acceptor molecules; an increase in the distance between the donor and the acceptor by a factor of 2 typically results in a decrease in the energy-transfer rate by a factor of  $2^6 = 64$ . For reasons of conservation of energy, energy

FIGURE 19.28 Resonance energy transfer. (1) An electron can accept energy from electromagnetic radiation of appropriate wavelength and jump to a higher energy state. (2) When the excited electron falls back to its lower energy state, the absorbed energy is released. (3) The released energy can be absorbed by an electron in a nearby molecule, and this electron jumps to a high energy state.

transfer must be from a donor in the excited state to an acceptor of equal or lower energy. *The excited state of the special pair of chlorophyll molecules is lower in energy than that of single chlorophyll molecules, allowing reaction centers to trap the energy transferred from other molecules.*

What is the structural relationship between the accessory pigment and the reaction center? The accessory pigments are arranged in numerous *light-harvesting complexes* that completely surround the reaction center (Figure 19.29). The 26-kDa subunit of light-harvesting complex II (LHC-II) is the most abundant membrane protein in chloroplasts. This subunit binds seven chlorophyll *a* molecules, six chlorophyll *b* molecules, and two carotenoid molecules. Similar light-harvesting assemblies exist in photosynthetic bacteria (Figure 19.30).

### The components of photosynthesis are highly organized

The intricacy of photosynthesis, seen already in the elaborate interplay of complex components, extends even to the placement of the components in the thylakoid membranes. *Thylakoid membranes of most plants are differentiated into stacked (appressed) and unstacked (nonappressed) regions* (Figures 19.2 and 19.3). Stacking increases the amount of thylakoid membrane in a given chloroplast volume. Both regions surround a common internal thylakoid space, but only unstacked regions make direct contact with the chloroplast stroma. Stacked and unstacked regions differ in the nature of their photosynthetic assemblies (Figure 19.31). Photosystem I and ATP synthase are located almost exclusively in unstacked regions, whereas photosystem II is present mostly in stacked regions. The cytochrome *bf* complex is found in both regions. Plastoquinone and plastocyanin are the mobile carriers of electrons between assemblies located in different regions of the thylakoid membrane. A common internal thylakoid space enables protons liberated by photosystem II in stacked membranes to be utilized by ATP synthase molecules that are located far away in unstacked membranes.

**FIGURE 19.29 Energy transfer from accessory pigments to reaction centers.** Light energy absorbed by accessory chlorophyll molecules or other pigments can be transferred to reaction centers by resonance energy transfer (yellow arrows), where it drives photoinduced charge separation. [Source: D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry*, 5th ed. (W. H. Freeman and Company, 2008), Fig. 19.52.]

**FIGURE 19.30 Structure of a bacterial light-harvesting complex.** Eight polypeptides, each of which binds three chlorophyll molecules (green) and a carotenoid molecule (red), surround a central cavity that contains the reaction center (not shown). Notice the high concentration of accessory pigments that surround the reaction center. [Drawn from 1LGH.pdb.]

**FIGURE 19.31 Location of photosynthesis components.** Photosynthetic assemblies are differentially distributed in the stacked (appressed) and unstacked (nonappressed) regions of thylakoid membranes. [Information from Dr. Jan M. Anderson and Dr. Bertil Andersson.]

What is the functional significance of this lateral differentiation of the thylakoid membrane system? The positioning of photosystem I in the unstacked membranes also gives it direct access to the stroma for the reduction of  $\text{NADP}^+$ . ATP synthase is also located in the unstacked region to provide space for its large  $\text{CF}_1$  globule and to give access to ADP. In contrast, the tight quarters of the appressed region pose no problem for photosystem II, which interacts with a small polar electron donor ( $\text{H}_2\text{O}$ ) and a highly lipid soluble electron carrier (plastoquinone).

### Many herbicides inhibit the light reactions of photosynthesis

Many commercial herbicides kill weeds by interfering with the action of photosystem II or photosystem I. Inhibitors of photosystem II block electron flow, whereas inhibitors of photosystem I divert electrons from the terminal part of this photosystem. Photosystem II inhibitors include urea derivatives such as *diuron* and triazine derivatives such as *atrazine*. These chemicals bind to the  $\text{Q}_\text{B}$  site of the D1 subunit of photosystem II and block the formation of plastoquinol ( $\text{QH}_2$ ).

Paraquat (1,1'-dimethyl-4,4'-bipyridinium) is an inhibitor of photosystem I. Paraquat, a dication, can accept electrons from photosystem I to become a radical. This radical reacts with  $\text{O}_2$  to produce reactive oxygen species such as superoxide ( $\text{O}_2^-$ ) and hydroxyl radical ( $\text{OH}\cdot$ ). Such reactive oxygen species react with many biomolecules, including double bonds in membrane lipids, damaging the membrane.

## 19.6 The Ability to Convert Light into Chemical Energy Is Ancient

The ability to convert light energy into chemical energy is a tremendous evolutionary advantage. Geological evidence suggests that oxygenic photosynthesis became important approximately 2 billion years ago. Anoxygenic photosynthetic systems arose much earlier in the 3.5-billion-year history of life on Earth (Table 19.1). The photosynthetic system of the nonsulfur purple bacterium *Rhodospseudomonas viridis* has most features common to oxygenic photosynthetic systems and clearly predates them. Green sulfur bacteria such as *Chlorobium thiosulfatophilum* carry out a reaction that also seems to have appeared before oxygenic photosynthesis and is even more similar to oxygenic photosynthesis than the photosystem of

**TABLE 19.1** Major groups of photosynthetic prokaryotes

Bacteria	Photosynthetic electron donor	O <sub>2</sub> use
Green sulfur	H <sub>2</sub> , H <sub>2</sub> S, S	Anoxygenic
Green nonsulfur	Variety of amino acids and organic acids	Anoxygenic
Purple sulfur	H <sub>2</sub> , H <sub>2</sub> S, S	Anoxygenic
Purple nonsulfur	Usually organic molecules	Anoxygenic
Cyanobacteria	H <sub>2</sub> O	Oxygenic

*R. viridis*. Reduced sulfur species such as H<sub>2</sub>S are electron donors in the overall photosynthetic reaction

Nonetheless, photosynthesis did not evolve immediately at the origin of life. No photosynthetic organisms have been discovered in the domain of Archaea, implying that photosynthesis evolved in the domain of Bacteria after Archaea and Bacteria diverged from a common ancestor. All domains of life do have electron-transport chains in common, however. As we have seen, components such as the ubiquinone–cytochrome *c* oxidoreductase and cytochrome *bf* family are present in both respiratory and photosynthetic electron-transport chains. These components were the foundations on which light-energy-capturing systems evolved.

### Artificial photosynthetic systems may provide clean, renewable energy

As we have learned, photosynthetic organisms use sunlight to oxidize H<sub>2</sub>O, producing O<sub>2</sub> and protons used to power ATP synthesis and generate NADPH. Research is currently underway to try to mimic this process in order to provide clean energy. Photovoltaic cells can use light energy to oxidize water, producing O<sub>2</sub> as well as H<sub>2</sub>. Hydrogen gas is a fuel that, upon reaction with oxygen, generates energy and only water as a waste product. Major difficulties in creating efficient photovoltaic cells are that the materials required are not durable and often not readily available. Recent work suggests that semiconductors composed of organic–inorganic material show great promise. One such material, perovskite (CH<sub>3</sub>NH<sub>3</sub>PbI<sub>3</sub>), is remarkably efficient at capturing sunlight. It is humbling to realize that, although photosynthetic organisms have been oxidizing water for billions of years, researchers today struggle to replicate the process.

## SUMMARY

### 19.1 Photosynthesis Takes Place in Chloroplasts

The proteins that participate in the light reactions of photosynthesis are located in the thylakoid membranes of chloroplasts. The light reactions result in (1) the creation of reducing power for the production of NADPH, (2) the generation of a transmembrane proton gradient for the formation of ATP, and (3) the production of O<sub>2</sub>.

### 19.2 Light Absorption by Chlorophyll Induces Electron Transfer

Chlorophyll molecules absorb light quite efficiently because they are polyenes. An electron excited to a high-energy state by the absorption of a photon can move to nearby electron acceptors. In photosynthesis, an excited electron leaves a pair of associated chlorophyll molecules known as the special pair. The functional core of photosynthesis, a reaction center from a photosynthetic bacterium, has been studied in great detail.

In this system, the electron moves from the special pair (containing bacteriochlorophyll) to bacteriopheophytin (a bacteriochlorophyll lacking the central magnesium ion) to quinones. The reduction of quinones leads to the generation of a proton gradient, which drives ATP synthesis in a manner analogous to that of oxidative phosphorylation.

### 19.3 Two Photosystems Generate a Proton Gradient and NADPH in Oxygenic Photosynthesis

Photosynthesis in green plants is mediated by two linked photosystems. In photosystem II, the excitation of a special pair of chlorophyll molecules called P680 leads to electron transfer to plastoquinone in a manner analogous to that of the bacterial reaction center. The electrons are replenished by the extraction of electrons from a water molecule at the water-oxidizing complex, which contains four manganese ions. One molecule of  $O_2$  is generated at this center for each four electrons transferred. The plastoquinol produced at photosystem II is reoxidized by the cytochrome *bf* complex, which transfers the electrons to plastocyanin, a soluble copper protein. From plastocyanin, the electrons enter photosystem I. In photosystem I, the excitation of special pair P700 releases electrons that flow to ferredoxin, a powerful reductant. Ferredoxin–NADP<sup>+</sup> reductase, a flavo-protein, then catalyzes the formation of NADPH. A proton gradient is generated as electrons pass through photosystem II, through the cytochrome *bf* complex, and through ferredoxin–NADP<sup>+</sup> reductase.

### 19.4 A Proton Gradient across the Thylakoid Membrane Drives ATP Synthesis

The proton gradient across the thylakoid membrane creates a proton-motive force, used by ATP synthase to form ATP. The ATP synthase of chloroplasts (also called the  $CF_0$ – $CF_1$  complex) closely resembles the ATP-synthesizing assemblies of bacteria and mitochondria. If the NADPH:NADP<sup>+</sup> ratio is high, electrons transferred to ferredoxin by photosystem I can reenter the cytochrome *bf* complex. This process, called cyclic photophosphorylation, leads to the generation of a proton gradient by the cytochrome *bf* complex without the formation of NADPH or  $O_2$ .

### 19.5 Accessory Pigments Funnel Energy into Reaction Centers

Light-harvesting complexes that surround the reaction centers contain additional molecules of chlorophyll *a*, as well as carotenoids and chlorophyll *b* molecules, which absorb light in the center of the visible spectrum. These accessory pigments increase the efficiency of light capture by absorbing light and transferring the energy to reaction centers through resonance energy transfer.

### 19.6 The Ability to Convert Light into Chemical Energy Is Ancient

The photosystems have structural features in common that suggest a common evolutionary origin. Similarities in organization and molecular structure to those of oxidative phosphorylation suggest that the photosynthetic apparatus evolved from an early energy-transduction system.

## PROBLEMS

1. *A crucial prereq.* Human beings do not produce energy by photosynthesis, yet this process is critical to our survival. Explain.

2. *The accounting.* What is the overall reaction for the light reactions of photosynthesis?

3. *Like a fife and drum.* Match each term with its description.

- |  |  |
|--|--|
| (a) Light reactions _____              | 1. Uses resonance energy transfer to reach the reaction center |
| (b) Chloroplasts _____                 | 2. Powers the formation of NADPH                               |
| (c) Reaction center _____              | 3. Pumps protons   |
| (d) Chlorophyll _____                  | 4. Site of photoinduced charge separation                      |
| (e) Light-harvesting complex _____     | 5. Cellular location of photosynthesis                         |

| (j) ATP synthase _____                 | 10. Primary photosynthetic pigment                             |

4. *A single wavelength.* Photosynthesis can be measured by measuring the rate of oxygen production. When plants are exposed to light of wavelength 680 nm, more oxygen is evolved than if the plants are exposed to light of 700 nm. Explain.

5. *Combining wavelengths.* If plants described in problem 4 are illuminated by a combination of light of 680 nm and 700 nm, the oxygen production exceeds that of either wavelength alone. Explain.

6. *Complementary powers.* Photosystem I produces a powerful reductant, whereas photosystem II produces a powerful oxidant. Identify the reductant and oxidant and describe their roles.

7. *If a little is good.* What is the advantage of having an extensive set of thylakoid membranes in the chloroplasts?

8. *Cooperation.* Explain how light-harvesting complexes enhance the efficiency of photosynthesis.

9. *One thing leads to another.* What is the ultimate electron acceptor in photosynthesis? The ultimate electron donor? What powers the electron flow between the donor and the acceptor?

10. *Neutralization compensation.* In chloroplasts, a greater pH gradient across the thylakoid membrane is required to

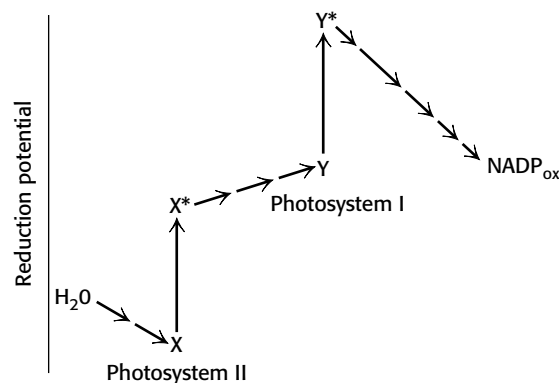

power the synthesis of ATP than is required across the mitochondrial inner membrane. Explain this difference.

11. *Environmentally appropriate.* Chlorophyll is a hydrophobic molecule. Why is this property crucial for the function of chlorophyll?

12. *Proton origins.* What are the various sources of protons that contribute to the generation of a proton gradient in chloroplasts?

13. *Efficiency matters.* What fraction of the energy of 700-nm light absorbed by photosystem I is trapped as high-energy electrons?

14. *That's not right.* Explain the defect or defects in the hypothetical scheme for the light reactions of photosynthesis depicted here.

15. *Electron transfer.* Calculate the  $\Delta E'_0$  and  $\Delta G^{\circ'}$  for the reduction of  $NADP^+$  by ferredoxin. Use data given in Table 18.1.

16. *To boldly go.* (a) It can be argued that, if life were to exist elsewhere in the universe, it would require some process like photosynthesis. Why is this argument reasonable? (b) If the starship *Enterprise* were to land on a distant planet and find no measurable oxygen in the atmosphere, could the crew conclude that photosynthesis is not taking place?

17. *Weed killer 1.* Dichlorophenyldimethylurea (DCMU), a herbicide, interferes with photophosphorylation and  $O_2$  evolution. However, it does not block  $O_2$  evolution in the presence of an artificial electron acceptor such as ferricyanide. Propose a site for the inhibitory action of DCMU.

18. *Weed killer 2.* Predict the effect of the herbicide dichlorophenyldimethylurea (DCMU) on a plant's ability to perform cyclic photophosphorylation.

19. *Infrared harvest.* Consider the relation between the energy of a photon and its wavelength.

(a) Some bacteria are able to harvest 1000-nm light. What is the energy (in kilojoules or kilocalories) of a mole (also called an *einstein*) of 1000-nm photons?

(b) What is the maximum increase in redox potential that can be induced by a 1000-nm photon?

(c) What is the minimum number of 1000-nm photons needed to form ATP from ADP and  $P_i$ ? Assume a  $\Delta G$  of  $50 \text{ kJ mol}^{-1}$  ( $12 \text{ kcal mol}^{-1}$ ) for the phosphorylation reaction.

20. *Missing acceptors.* Suppose that a bacterial reaction center containing only the special pair and the quinones has been prepared. Given the separation of  $22 \text{ \AA}$  between the special pair and the closest quinone, estimate the rate of electron transfer between the excited special pair and this quinone.

21. *Close approach.* Suppose that energy transfer between two chlorophyll *a* molecules separated by  $10 \text{ \AA}$  takes place in 10 picoseconds. Suppose that this distance is increased to  $20 \text{ \AA}$  with all other factors remaining the same. How long would energy transfer take?

### Chapter Integration Problems

22. *Functional equivalents.* What structural feature of mitochondria corresponds to the thylakoid membranes?

23. *Compare and contrast.* Compare and contrast oxidative phosphorylation and photosynthesis.

24. *Energy accounts.* On page 597, the balance sheet for the cost of the photosynthetically powered synthesis of glucose is presented. Eighteen molecules of ATP are required. Yet, when glucose undergoes combustion in cellular respiration, 30 molecules of ATP are produced. Account for the difference.

25. *Looking for a place to rest.* Albert Szent-Györgyi, Nobel Prize-winning biochemist, once said, "Life is nothing but an electron looking for a place to rest." Explain how this pithy statement applies to photosynthesis and cellular respiration.

### Mechanism Problem

26. *Hill reaction.* In 1939, Robert Hill discovered that chloroplasts evolve  $O_2$  when they are illuminated in the presence of an artificial electron acceptor such as ferricyanide  $[\text{Fe}^{3+}(\text{CN})_6]^{3-}$ . Ferricyanide is reduced to ferrocyanide  $[\text{Fe}^{2+}(\text{CN})_6]^{4-}$  in this process. No NADPH or reduced

plastocyanin is produced. Propose a mechanism for the Hill reaction.

### Data Interpretation and Chapter Integration Problems

27. *The same, but different.* The  $\alpha_3\beta_3\gamma$  complex of mitochondrial or chloroplast ATP synthase functions as an ATPase in vitro. The chloroplast enzyme (both synthase and ATPase activity) is sensitive to redox control, whereas the mitochondrial enzyme is not. To determine where the enzymes differ, a segment of the mitochondrial  $\gamma$  subunit was removed and replaced with the equivalent segment from the chloroplast  $\gamma$  subunit. The ATPase activity of the modified enzyme was then measured as a function of redox conditions. Dithiothreitol (DTT) is a reducing agent.

(a) What is the redox regulator of the chloroplast ATP synthase in vivo? The adjoining graph shows the ATPase activity of modified and control enzymes under various redox conditions.

[Data from O. Bald et al. *J. Biol. Chem.* 275:12757–12762, 2000.]

(b) What is the effect of increasing the reducing power of the reaction mixture for the control and the modified enzymes?

(c) What is the effect of the addition of thioredoxin? How do these results differ from those in the presence of DTT alone? Suggest a possible explanation for the difference.

(d) Did the researchers succeed in identifying the region of the  $\gamma$  subunit responsible for redox regulation?

(e) What is the biological rationale of regulation by high concentrations of reducing agents?

(f) What amino acids in the  $\gamma$  subunit are most likely affected by the reducing conditions?

(g) What experiments might confirm your answer to part e?

# The Calvin Cycle and the Pentose Phosphate Pathway

Atmospheric carbon dioxide measurements at Mauna Loa, Hawaii. These measurements show the increase in carbon dioxide since 1960. The saw-tooth appearance of the curve is the result of annual cycles resulting from seasonal variation in CO<sub>2</sub> fixation by the Calvin cycle in terrestrial plants (see insert). Much of this fixation takes place in rain forests, which account for approximately 50% of terrestrial fixation. [(Left) stillfx/ age fotostock. (Right) Data from <http://www.esrl.noaa.gov/gmd/ccgg/trends>]

Photosynthesis proceeds in two parts: the light reactions and the dark reactions. The light reactions, discussed in Chapter 19, transform light energy into ATP and biosynthetic reducing power, NADPH. The dark reactions use the ATP and NADPH produced by the light reactions to reduce carbon atoms from their fully oxidized state as carbon dioxide to a more reduced state as a hexose. Carbon dioxide is thereby trapped in a form that is useful for many processes and most especially as a fuel. Together, *the light reactions and dark reactions of photosynthesis cooperate to transform light energy into carbon fuel*. The dark reactions are called either the *Calvin-Benson cycle*, after Melvin Calvin and Andrew Benson, the biochemists who elucidated the pathway, or simply the Calvin cycle. The components of the Calvin cycle are called the *dark reactions* because, in contrast with the light reactions, these reactions do not directly depend on the presence of light.

The second half of this chapter examines a pathway common to all organisms, known variously as the *pentose phosphate pathway*, the *hexose monophosphate pathway*, the *phosphogluconate pathway*, or the *pentose shunt*. The pathway provides a means by which glucose can be oxidized to generate NADPH, *the currency of readily available reducing power in cells*. The phosphoryl group on the 2'-hydroxyl group of one of the ribose units of NADPH distinguishes NADPH from NADH. *There is a fundamental distinction*

## OUTLINE

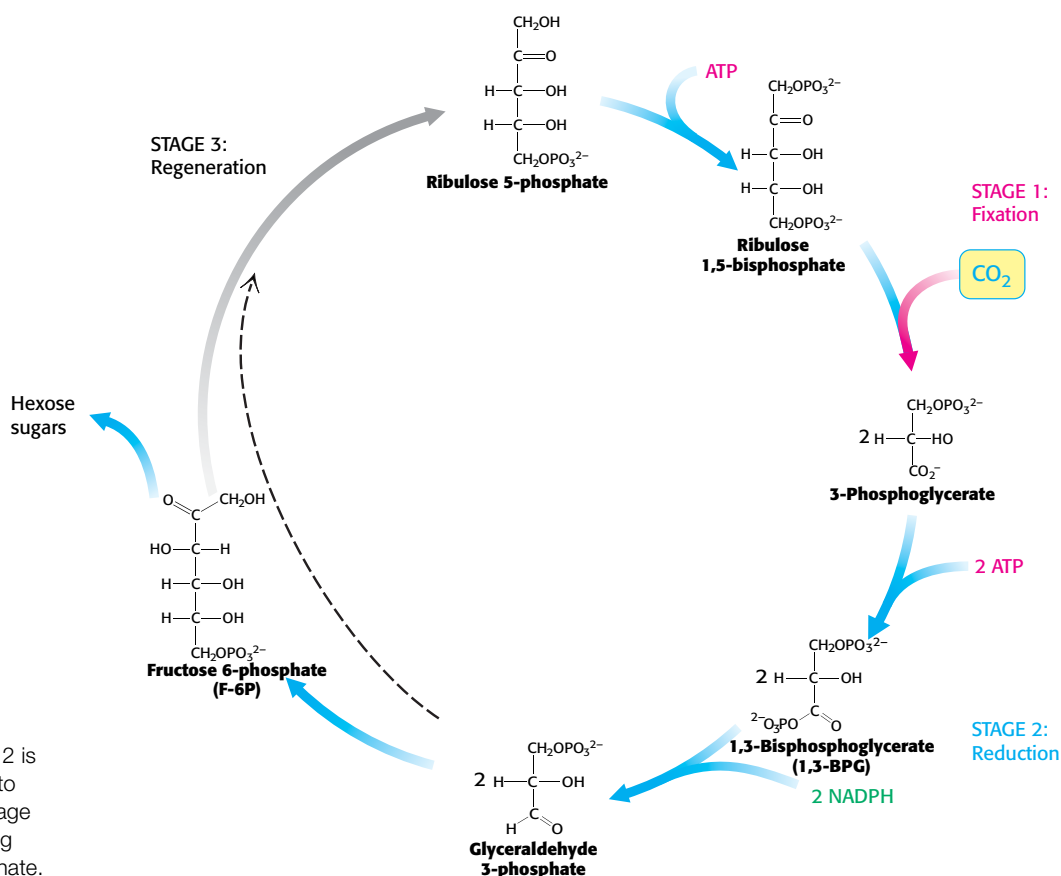

- 20.1** The Calvin Cycle Synthesizes Hexoses from Carbon Dioxide and Water
- 20.2** The Activity of the Calvin Cycle Depends on Environmental Conditions
- 20.3** The Pentose Phosphate Pathway Generates NADPH and Synthesizes Five-Carbon Sugars
- 20.4** The Metabolism of Glucose 6-phosphate by the Pentose Phosphate Pathway Is Coordinated with Glycolysis
- 20.5** Glucose 6-phosphate Dehydrogenase Plays a Key Role in Protection Against Reactive Oxygen Species

between NADPH and NADH in biochemistry: NADH is oxidized by the respiratory chain to generate ATP, whereas NADPH serves as a reductant in biosynthetic processes. The pentose phosphate pathway can also be used for the catabolism of pentose sugars from the diet, the synthesis of pentose sugars for nucleotide biosynthesis, and the catabolism and synthesis of less common four- and seven-carbon sugars. The pentose phosphate pathway and the Calvin cycle have in common several enzymes and intermediates that attest to an evolutionary kinship. Like glycolysis and gluconeogenesis, these pathways are mirror images of each other: the Calvin cycle uses NADPH to reduce carbon dioxide to generate hexoses, whereas the pentose phosphate pathway oxidizes glucose to carbon dioxide to generate NADPH.

## 20.1 The Calvin Cycle Synthesizes Hexoses from Carbon Dioxide and Water

As stated in Chapter 16, glucose can be formed from noncarbohydrate precursors, such as lactate and amino acids, by gluconeogenesis. The energy powering gluconeogenesis ultimately comes from previous catabolism of carbon fuels. In contrast, photosynthetic organisms can use the Calvin cycle to synthesize glucose from carbon dioxide gas and water, by using sunlight as an energy source. The Calvin cycle introduces into life all the carbon atoms that will be used as fuel and as the carbon backbones of biomolecules. Photosynthetic organisms are called *autotrophs* (literally, *self-feeders*) because they can convert sunlight into chemical energy, which they subsequently use to power their biosynthetic processes. Organisms that obtain energy from chemical fuels only are called *heterotrophs*, and such organisms ultimately depend on autotrophs for their fuel.

The Calvin cycle comprises three stages (Figure 20.1):

**FIGURE 20.1** Calvin cycle.

The Calvin cycle consists of three stages. Stage 1 is the fixation of carbon by the carboxylation of ribulose 1,5-bisphosphate. Stage 2 is the reduction of the fixed carbon to begin the synthesis of hexose. Stage 3 is the regeneration of the starting compound ribulose 1,5-bisphosphate.

1. The fixation of  $\text{CO}_2$  by ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate;
2. The reduction of 3-phosphoglycerate to form hexose sugars; and
3. The regeneration of ribulose 1,5-bisphosphate so that more  $\text{CO}_2$  can be fixed.

This set of reactions takes place in the stroma of chloroplasts, the photosynthetic organelles.

### Carbon dioxide reacts with ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate

The first step in the Calvin cycle is the fixation of  $\text{CO}_2$ . This begins with the conversion of ribulose 1,5-bisphosphate into a highly reactive enediolate intermediate. The  $\text{CO}_2$  molecule condenses with the enediolate intermediate to form an unstable six-carbon compound, which is rapidly hydrolyzed to two molecules of 3-phosphoglycerate.

This highly exergonic reaction [ $\Delta G^{\circ\prime} = -51.9 \text{ kJ mol}^{-1}$  ( $-12.4 \text{ kcal mol}^{-1}$ )] is catalyzed by *ribulose 1,5-bisphosphate carboxylase/oxygenase* (usually called *rubisco*), an enzyme located on the stromal surface of the thylakoid membranes of chloroplasts. This important reaction is the rate-limiting step in hexose synthesis. In plants and green algae, rubisco consists of eight large (L, 55-kDa) subunits and eight small (S, 15-kDa) ones (Figure 20.2). Each L chain contains a catalytic site and a regulatory site. The S chains enhance the catalytic activity of the L chains. This enzyme is abundant in chloroplasts, accounting for approximately 30% of the total leaf protein in some plants. In fact, rubisco is the most abundant enzyme and probably the most abundant protein in the biosphere. Large amounts are present because rubisco is a slow enzyme; its maximal catalytic rate is only  $3 \text{ s}^{-1}$ .

**FIGURE 20.2 Structure of rubisco.** The enzyme ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco) comprises eight large subunits (one shown in red and the others in yellow) and eight small subunits (one shown in blue and the others in white). The active sites lie in the large subunits. [Drawn from 1RXO.pdb.]

### Rubisco activity depends on magnesium and carbamate

Rubisco requires a bound divalent metal ion for activity, usually magnesium ion. Like the zinc ion in the active site of carbonic anhydrase (Section 9.2), this metal ion serves to activate a bound substrate molecule by stabilizing a negative charge. Interestingly, a  $\text{CO}_2$  molecule other than the substrate is required to complete the assembly of the  $\text{Mg}^{2+}$ -binding site in rubisco. This  $\text{CO}_2$  molecule adds to the uncharged  $\epsilon$ -amino group of lysine 201 to form a *carbamate*. This negatively charged adduct then binds the  $\text{Mg}^{2+}$  ion.

**FIGURE 20.3 Role of the magnesium ion in the rubisco mechanism.** Ribulose 1,5-bisphosphate binds to a magnesium ion that is linked to rubisco through a glutamate residue, an aspartate residue, and the lysine carbamate. The coordinated ribulose 1,5-bisphosphate gives up a proton to form a reactive enediolate species that reacts with  $\text{CO}_2$  to form a new carbon–carbon bond.

The metal center plays a key role in binding ribulose 1,5-bisphosphate and activating it so that it reacts with  $\text{CO}_2$  (Figure 20.3). Ribulose 1,5-bisphosphate binds to  $\text{Mg}^{2+}$  through its keto group and an adjacent hydroxyl group. This complex is readily deprotonated to form an enediolate intermediate. This reactive species, analogous to the zinc–hydroxide species in carbonic anhydrase, couples with  $\text{CO}_2$ , forming the new carbon–carbon bond. The resulting 2-carboxy-3-keto-D-arabinitol 1,5-bisphosphate is coordinated to the  $\text{Mg}^{2+}$  ion through three groups, including the newly formed carboxylate. A molecule of  $\text{H}_2\text{O}$  is then added to this  $\beta$ -ketoacid to form an intermediate that cleaves to form two molecules of 3-phosphoglycerate (Figure 20.4).

**FIGURE 20.4 Formation of 3-phosphoglycerate.** The overall pathway for the conversion of ribulose 1,5 bisphosphate and  $\text{CO}_2$  into two molecules of 3-phosphoglycerate. Although the free species are shown, these steps take place on the magnesium ion.

### Rubisco activase is essential for rubisco activity

In the absence of  $\text{CO}_2$ , rubisco binds to its substrate, ribulose 1,5-bisphosphate, so tightly that its enzyme activity is inhibited. The enzyme *rubisco activase* uses ATP to induce structural changes in rubisco that allow release of the bound substrate and formation of the required carbamate. The ATP requirement of rubisco activase coordinates rubisco activity with the light reactions.

The activase contains a P-loop domain (Section 9.4) and assembles into a hexameric ring-like structure. The enzyme binds to the C-terminal end of the polypeptide chain that forms that large subunit. Using the energy of ATP hydrolysis, the C-terminal is transiently pulled in to the central pore of the activase. This releases the bound ribulose 1,5-bisphosphate and activates rubisco. Activase is a member of the large AAA family of ATPases that usually assemble into ring-shaped oligomeric structures and use the ATP hydrolysis to power conformational changes in their substrates. AAA ATPases play a variety of roles in biological systems. They are crucial for protein degradation (Chapter 23) and DNA replication (Chapter 28), and also function as molecular motors (Chapter 35).

### Rubisco also catalyzes a wasteful oxygenase reaction:

#### Catalytic imperfection

The reactive enediolate intermediate generated on the  $\text{Mg}^{2+}$  ion sometimes reacts with  $\text{O}_2$  instead of  $\text{CO}_2$ ; thus, rubisco also catalyzes a deleterious oxygenase reaction. The products of this reaction are *phosphoglycolate* and *3-phosphoglycerate* (Figure 20.5). The rate of the carboxylase reaction is four times that of the oxygenase reaction under normal atmospheric conditions at  $25^\circ\text{C}$ ; the stromal concentration of  $\text{CO}_2$  is then  $10\ \mu\text{M}$  and that of  $\text{O}_2$  is  $250\ \mu\text{M}$ . The oxygenase reaction, like the carboxylase reaction, requires that lysine 201 be in the carbamate form. Because this carbamate forms only in the presence of  $\text{CO}_2$ , rubisco is prevented from catalyzing the oxygenase reaction exclusively when  $\text{CO}_2$  is absent.

Phosphoglycolate is not a versatile metabolite. A salvage pathway recovers part of its carbon skeleton (Figure 20.6). A specific phosphatase converts phosphoglycolate into *glycolate*, which enters *peroxisomes* (also called *microbodies*; Figure 20.7). Glycolate is then oxidized to *glyoxylate* by *glycolate oxidase*, an enzyme with a flavin mononucleotide prosthetic group. The  $\text{H}_2\text{O}_2$  produced in this reaction is cleaved by *catalase* to  $\text{H}_2\text{O}$  and  $\text{O}_2$ . Transamination of glyoxylate then yields *glycine*, which then enters the mitochondria. Two glycine molecules can unite to form serine with the release of  $\text{CO}_2$  and ammonium ion ( $\text{NH}_4^+$ ). The ammonium ion, used in the synthesis of nitrogen-containing compounds, is salvaged by a glutamine synthetase reaction (Figure 20.6 and Section 23.3). Serine reenters the peroxisome, where it donates its ammonia to glyoxylate and is subsequently converted back into 3-phosphoglycerate.

This salvage pathway serves to recycle three of the four carbon atoms of two molecules of glycolate. However, one carbon atom is lost as  $\text{CO}_2$ . This

**FIGURE 20.5 A wasteful side reaction.** The reactive enediolate intermediate on rubisco also reacts with molecular oxygen to form a hydroperoxide intermediate, which then proceeds to form one molecule of 3-phosphoglycerate and one molecule of phosphoglycolate.

**FIGURE 20.7 Electron micrograph of three peroxisomes.** The peroxisomes are surrounded by rough endoplasmic reticulum. [Don W. Fawcett/Science Source.]

**FIGURE 20.6 Photorespiratory reactions.** Phosphoglycolate is formed as a product of the oxygenase reaction in chloroplasts. After dephosphorylation, glycolate is transported into peroxisomes where it is converted into glyoxylate and then glycine. In mitochondria, two glycines are converted into serine, after losing a carbon as  $\text{CO}_2$  and ammonium ion. The serine is converted back into 3-phosphoglycerate and the ammonium ion is salvaged in chloroplasts.

process is called *photorespiration* because  $\text{O}_2$  is consumed and  $\text{CO}_2$  is released. Photorespiration is wasteful because organic carbon is converted into  $\text{CO}_2$  without the production of ATP, NADPH, or another energy-rich metabolite. Although evolutionary processes have presumably enhanced the preference of rubisco for carboxylation—for instance, the rubisco of higher plants is eightfold as specific for carboxylation as that of photosynthetic bacteria—photorespiration still accounts for the loss of up to 25% of the carbon fixed.

Much research has been undertaken to generate recombinant forms of rubisco that display reduced oxygenase activity, but all such attempts have failed. This raises the following question: What is the biochemical basis of this inefficiency? Structural studies show that when the reactive enediolate intermediate is formed, loops close over the active site to protect the enediolate. A channel to the environment is maintained to allow access by  $\text{CO}_2$ . However, like  $\text{CO}_2$ ,  $\text{O}_2$  is a linear molecule that also fits the channel. In essence, the problem lies not with the enzyme but in the unremarkable structure of  $\text{CO}_2$ .  $\text{CO}_2$  lacks any chemical features that would allow discrimination between it and other gases such as  $\text{O}_2$ , and thus the oxygenase activity is an inevitable failing of the enzyme. Another possibility exists, however. The oxygenase activity may not be an imperfection of the enzyme, but rather an imperfection in our understanding. Perhaps the oxygenase activity performs a biochemically important role that we have not yet discovered.

### Hexose phosphates are made from phosphoglycerate, and ribulose 1,5-bisphosphate is regenerated

The 3-phosphoglycerate product of rubisco is next converted into fructose 6-phosphate, which readily isomerizes to glucose 1-phosphate and glucose 6-phosphate. The mixture of the three phosphorylated hexoses is called the

*hexose monophosphate pool*. The steps in this conversion (Figure 20.8) are like those of the gluconeogenic pathway (Figure 16.24), except that glyceraldehyde 3-phosphate dehydrogenase in chloroplasts, which generates glyceraldehyde 3-phosphate (GAP), is specific for NADPH rather than NADH. These reactions and that catalyzed by rubisco bring CO<sub>2</sub> to the level of a hexose, converting CO<sub>2</sub> into a chemical fuel at the expense of NADPH and ATP generated from the light reactions.

The third phase of the Calvin cycle is the regeneration of ribulose 1,5-bisphosphate, the acceptor of CO<sub>2</sub> in the first step. The problem is to construct a five-carbon sugar from six-carbon and three-carbon sugars. A transketolase and an aldolase play the major role in the rearrangement of the carbon atoms. The *transketolase*, which we will see again in the pentose phosphate pathway, requires the coenzyme thiamine pyrophosphate (TPP) to transfer a two-carbon unit (CO—CH<sub>2</sub>OH) from a ketose to an aldose.

*Aldolase*, which we have already encountered in glycolysis (Section 16.1), catalyzes an aldol condensation between dihydroxyacetone phosphate (DHAP) and an aldehyde. This enzyme is highly specific for dihydroxyacetone phosphate, but it accepts a wide variety of aldehydes.

With these enzymes, the construction of the five-carbon sugar proceeds as shown in Figure 20.9.

Finally, ribose 5-phosphate is converted into ribulose 5-phosphate by *phosphopentose isomerase*, whereas xylulose 5-phosphate is converted into ribulose 5-phosphate by *phosphopentose epimerase*. Ribulose 5-phosphate is converted into ribulose 1,5-bisphosphate through the action of *phosphoribulokinase* (Figure 20.10). The sum of these reactions is

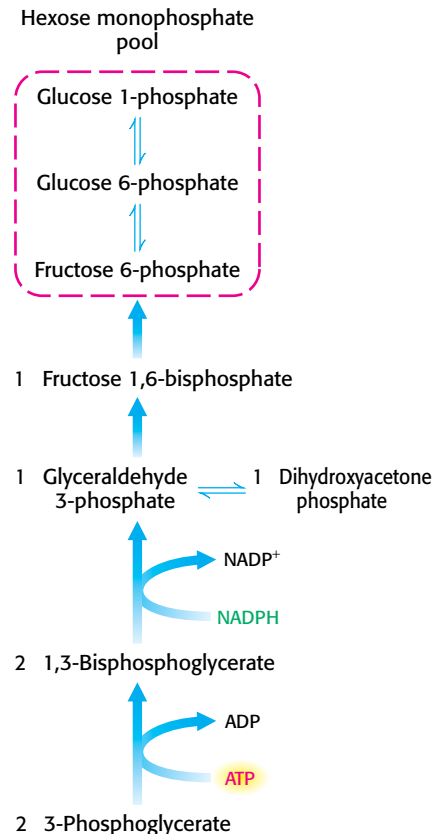

Figure 20.11 presents the required reactions with the proper stoichiometry to convert three molecules of CO<sub>2</sub> into one molecule of DHAP. However, two molecules of DHAP are required for the synthesis of a member of the hexose monophosphate pool. Consequently, the cycle as presented must take place twice to yield a hexose monophosphate. The outcome of the Calvin cycle is the generation of a hexose and the regeneration of the starting compound, ribulose 1,5-bisphosphate. In essence, ribulose 1,5-bisphosphate acts catalytically, similarly to oxaloacetate in the citric acid cycle.

**FIGURE 20.8 Hexose phosphate formation.** 3-Phosphoglycerate is converted into fructose 6-phosphate in a pathway parallel to that of gluconeogenesis.

**FIGURE 20.9 Formation of five-carbon sugars.** First, transketolase converts a six-carbon sugar and a three-carbon sugar into a four-carbon sugar and a five-carbon sugar. Then, aldolase combines the four-carbon product and a three-carbon sugar to form a seven-carbon sugar. Finally, this seven-carbon sugar reacts with another three-carbon sugar to form two additional five-carbon sugars.

**FIGURE 20.10 Regeneration of ribulose 1,5-bisphosphate.** Both ribose 5-phosphate and xylulose 5-phosphate are converted into ribulose 5-phosphate, which is then phosphorylated to complete the regeneration of ribulose 1,5-bisphosphate.

**FIGURE 20.11 Calvin cycle.** The diagram shows the reactions necessary with the correct stoichiometry to convert three molecules of  $\text{CO}_2$  into one molecule of dihydroxyacetone phosphate (DHAP). The cycle is not as simple as presented in Figure 20.1; rather, it entails many reactions that lead ultimately to the synthesis of glucose and the regeneration of ribulose 1,5-bisphosphate. [Information from J. R. Bowyer and R. C. Leegood. "Photosynthesis," in *Plant Biochemistry*, P. M. Dey and J. B. Harborne, Eds. (Academic Press, 1997), p. 85.]

### Three ATP and two NADPH molecules are used to bring carbon dioxide to the level of a hexose

What is the energy expenditure for synthesizing a hexose? Six rounds of the Calvin cycle are required, because one carbon atom is reduced in each round. Twelve molecules of ATP are expended in phosphorylating 12 molecules of 3-phosphoglycerate to 1,3-bisphosphoglycerate, and 12 molecules of NADPH are consumed in reducing 12 molecules of 1,3-bisphosphoglycerate to glyceraldehyde 3-phosphate. An additional six molecules of ATP are spent in regenerating ribulose 1,5-bisphosphate.

We can now write a balanced equation for the net reaction of the Calvin cycle:

Thus, three molecules of ATP and two molecules of NADPH are consumed in incorporating a single  $\text{CO}_2$  molecule into a hexose such as glucose or fructose.

### Starch and sucrose are the major carbohydrate stores in plants

What are the fates of the members of the hexose monophosphate pool? These molecules are used in a variety of ways, but there are two primary roles. Plants contain two major storage forms of sugar: *starch* and *sucrose*. Starch, like its animal counterpart glycogen, is a polymer of glucose residues, but it is less branched than glycogen because it contains a smaller proportion of  $\alpha$ -1,6-glycosidic linkages (Section 11.2). Another difference is that ADP-glucose, not UDP-glucose, is the activated precursor. Starch is synthesized and stored in chloroplasts.

**FIGURE 20.12 Synthesis of sucrose.** Sucrose 6-phosphate is formed by the reaction between fructose 6-phosphate and the activated intermediate uridine diphosphate glucose (UDP-glucose). Sucrose phosphatase subsequently generates free sucrose (not shown).

In contrast, sucrose (common table sugar), a disaccharide, is synthesized in the cytoplasm. Plants lack the ability to transport hexose phosphates across the chloroplast membrane, but they are able to transport triose phosphates from chloroplasts to the cytoplasm. Triose phosphate intermediates such as glyceraldehyde 3-phosphate cross into the cytoplasm in exchange for phosphate through the action of an abundant triose phosphate-phosphate antiporter. Fructose 6-phosphate formed from triose phosphates joins the glucose unit of UDP-glucose to form sucrose 6-phosphate (Figure 20.12). The hydrolysis of the phosphate ester by sucrose phosphatase yields sucrose, a readily transportable and mobilizable sugar that is stored in many plant cells, such as those in sugar beets and sugar cane.

**FIGURE 20.13 Light regulation of the Calvin cycle.** The light reactions of photosynthesis transfer electrons out of the thylakoid lumen into the stroma and transfer protons from the stroma into the thylakoid lumen. As a consequence of these processes, the concentrations of NADPH, reduced ferredoxin (Fd), and  $Mg^{2+}$  in the stroma are higher in the light than in the dark. The stromal pH is also increased (the concentration of  $H^+$  is lowered) in the light as a result of proton pumping from the stroma to the thylakoid lumen. Each of these concentration changes helps couple the Calvin cycle reactions to the light reactions.

## 20.2 The Activity of the Calvin Cycle Depends on Environmental Conditions

How do the light reactions communicate with the dark reactions to regulate this crucial process of fixing  $CO_2$  into biomolecules? *The principal means of regulation is alteration of the stromal environment by the light reactions.* The light reactions lead to an increase in stromal pH (a decrease in the  $H^+$  concentration), as well as an increase in the stromal concentrations of  $Mg^{2+}$ , NADPH, and reduced ferredoxin—changes that contribute to the activation of certain Calvin-cycle enzymes, located in the stroma (Figure 20.13).

### Rubisco is activated by light-driven changes in proton and magnesium ion concentrations

As stated earlier, the rate-limiting step in the Calvin cycle is the carboxylation of ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate. *The activity of rubisco increases markedly on illumination because light facilitates the carbamate formation necessary for enzyme activity* (p. 593). In the stroma, the pH increases from 7 to 8, and the level of  $Mg^{2+}$  rises. Both effects are consequences of the light-driven pumping of protons into the thylakoid space.  $Mg^{2+}$  ions from the thylakoid space are released into the

**TABLE 20.1** Enzymes regulated by thioredoxin

Enzyme	Pathway

NADP <sup>+</sup> -malate dehydrogenase	C <sub>4</sub> pathway
CF <sub>1</sub> -CF <sub>0</sub> ATP synthase	The light reactions

stroma to compensate for the influx of protons. Carbamate formation is favored at alkaline pH. CO<sub>2</sub> adds to a deprotonated form of lysine 201 of rubisco, and Mg<sup>2+</sup> ion binds to the carbamate to generate the active form of the enzyme. Thus, light leads to the generation of regulatory signals as well as ATP and NADPH.

### Thioredoxin plays a key role in regulating the Calvin cycle

Light-driven reactions lead to electron transfer from water to ferredoxin and, eventually, to NADPH. The presence of reduced ferredoxin and NADPH are good signals that conditions are right for biosynthesis. One way in which this information is conveyed to biosynthetic enzymes is by *thioredoxin*, a 12-kDa protein containing neighboring cysteine residues that cycle between a reduced sulfhydryl and an oxidized disulfide form (Figure 20.14). The reduced form of thioredoxin activates many biosynthetic enzymes, including the chloroplast ATP synthase (p. 579), by reducing disulfide bridges that control their activity. Reduced thioredoxin also inhibits several degradative enzymes by the same means (Table 20.1). In chloroplasts, oxidized thioredoxin is reduced by ferredoxin in a reaction catalyzed by *ferredoxin–thioredoxin reductase* (p. 580). Thus, *the activities of the light and dark reactions of photosynthesis are coordinated through electron transfer from reduced ferredoxin to thioredoxin and then to component enzymes containing regulatory disulfide bonds* (Figure 20.15). We shall return to thioredoxin when we consider the reduction of ribonucleotides (Section 25.3).

NADPH is a signal molecule that activates two biosynthetic enzymes, phosphoribulokinase and glyceraldehyde 3-phosphate dehydrogenase. In the dark, these enzymes are inhibited by association with an 8.5-kDa protein called *CP12*, an intrinsically disordered protein (Section 2.6). NADPH disrupts this association by promoting the formation of two disulfide bonds in CP12, leading to the release of the active enzymes.

### The C<sub>4</sub> pathway of tropical plants accelerates photosynthesis by concentrating carbon dioxide

The oxygenase activity of rubisco presents a biochemical challenge to tropical plants because the oxygenase activity increases more rapidly with temperature than does the carboxylase activity. How, then, do plants that grow in hot climates, such as sugar cane, prevent very high rates of wasteful photorespiration? Their solution to this problem is to achieve a high local concentration of CO<sub>2</sub> at the site of the Calvin cycle in their photosynthetic cells. The essence of this process, which was elucidated by Marshall Davidson Hatch and C. Roger Slack, is that *four-carbon (C<sub>4</sub>) compounds such as oxaloacetate and malate carry CO<sub>2</sub> from mesophyll cells, which are in*

**FIGURE 20.14 Thioredoxin.** The oxidized form of thioredoxin contains a disulfide bond. When thioredoxin is reduced by reduced ferredoxin, the disulfide bond is converted into two free sulfhydryl groups. Reduced thioredoxin can cleave disulfide bonds in enzymes, activating certain Calvin cycle enzymes and inactivating some degradative enzymes. [Drawn from 1F9M.pdb.]

**FIGURE 20.15 Enzyme activation by thioredoxin.** Reduced thioredoxin activates certain Calvin cycle enzymes by cleaving regulatory disulfide bonds.

**FIGURE 20.16**  $C_4$  pathway. Carbon dioxide is concentrated in bundle-sheath cells by the expenditure of ATP in mesophyll cells.

contact with air, to bundle-sheath cells, which are the major sites of photosynthesis (Figure 20.16). The decarboxylation of the four-carbon compound in a bundle-sheath cell maintains a high concentration of  $CO_2$  at the site of the Calvin cycle. The three-carbon product returns to the mesophyll cell for another round of carboxylation.

The  $C_4$  pathway for the transport of  $CO_2$  starts in a mesophyll cell with the condensation of  $CO_2$  and phosphoenolpyruvate to form oxaloacetate in a reaction catalyzed by *phosphoenolpyruvate carboxylase*. In some species, oxaloacetate is converted into malate by an  $NADP^+$ -linked malate dehydrogenase. Malate enters the bundle-sheath cell and is oxidatively decarboxylated within the chloroplasts by an  $NADP^+$ -linked malate dehydrogenase. The released  $CO_2$  enters the Calvin cycle in the usual way by condensing with ribulose 1,5-bisphosphate. Pyruvate formed in this decarboxylation reaction returns to the mesophyll cell. Finally, phosphoenolpyruvate is formed from pyruvate by *pyruvate- $P_i$  dikinase*.

The net reaction of this  $C_4$  pathway is

Thus, *the energetic equivalent of two ATP molecules is consumed in transporting  $CO_2$  to the chloroplasts of the bundle-sheath cells*. In essence, this process is active transport: the pumping of  $CO_2$  into the bundle-sheath cell is driven by the hydrolysis of one molecule of ATP to one molecule of AMP and two molecules of orthophosphate. The  $CO_2$  concentration can be 20-fold as great in the bundle-sheath cells as in the mesophyll cells.

When the  $C_4$  pathway and the Calvin cycle operate together, the net reaction is

Note that 30 molecules of ATP are consumed per hexose molecule formed when the  $C_4$  pathway delivers  $CO_2$  to the Calvin cycle, in contrast with 18 molecules of ATP per hexose molecule in the absence of the  $C_4$  pathway. The high concentration of  $CO_2$  in the bundle-sheath cells of  $C_4$  plants, which is the result of the expenditure of the additional 12 molecules of ATP, is critical for their rapid photosynthetic rate, because  $CO_2$  is limiting when light is abundant. A high  $CO_2$  concentration also minimizes the energy loss caused by photorespiration.

*Tropical plants with a  $C_4$  pathway do little photorespiration because the high concentration of  $CO_2$  in their bundle-sheath cells accelerates the carboxylase reaction relative to the oxygenase reaction.* This effect is especially important at higher temperatures. The geographic distribution of plants

having this pathway ( $C_4$  plants) and those lacking it ( $C_3$  plants) can now be understood in molecular terms.  $C_4$  plants have the advantage in a hot environment and under high illumination, which accounts for their prevalence in the tropics.  $C_3$  plants, which consume only 18 molecules of ATP per hexose molecule formed in the absence of photorespiration (compared with 30 molecules of ATP for  $C_4$  plants), are more efficient at temperatures lower than about 28°C, and so they predominate in temperate environments.

Rubisco is present in bacteria, eukaryotes, and even archaea, although other photosynthetic components have not been found in archaea. Thus, rubisco emerged early in evolution, when the atmosphere was rich in  $CO_2$  and almost devoid of  $O_2$ . The enzyme was not originally selected to operate in an environment like the present one, which is almost devoid of  $CO_2$  and rich in  $O_2$ . Photorespiration became significant about 600 million years ago, when the  $CO_2$  concentration fell to present levels. The  $C_4$  pathway is thought to have evolved in response no more than 30 million years ago and possibly as recently as 7 million years ago. It is interesting that none of the enzymes are unique to  $C_4$  plants, suggesting that this pathway made use of already existing enzymes.

### Crassulacean acid metabolism permits growth in arid ecosystems

Many plants, including some that grow in hot, dry climates, keep the stomata of their leaves closed in the heat of the day to prevent water loss (Figure 20.17). As a consequence,  $CO_2$  cannot be absorbed during the daylight hours, when it is needed for glucose synthesis. Rather,  $CO_2$  enters the leaf when the stomata open at the cooler temperatures of night. To store the  $CO_2$  until it can be used during the day, such plants make use of an adaptation called *crassulacean acid metabolism* (CAM), named after the genus *Crassulaceae* (the succulents). Carbon dioxide is fixed by the  $C_4$  pathway into malate, which is stored in vacuoles. During the day, malate is decarboxylated and the  $CO_2$  becomes available to the Calvin cycle. In contrast with  $C_4$  plants, CAM plants separate  $CO_2$  accumulation from  $CO_2$  utilization temporally rather than spatially.

Although CAM plants do prevent water loss, the use of malate as the sole source of  $CO_2$  comes at a metabolic cost. Because the malate storage is limited, CAM plants cannot generate  $CO_2$  as rapidly as it can be imported by  $C_3$  and  $C_4$  plants. Consequently, the growth rate of CAM plants is slower than that of  $C_3$  and  $C_4$  plants. The saguaro cactus, which can live up to 200 years and reach a height of 60 feet, can take 15 years to grow to only 1 foot in height.

**FIGURE 20.17** Scanning electron micrograph of an open stoma and a closed stoma. [Power and Syred/Science Photo Library.]

## 20.3 The Pentose Phosphate Pathway Generates NADPH and Synthesizes Five-Carbon Sugars

Photosynthetic organisms can use the light reactions for generation of some NADPH. Another pathway, present in all organisms, meets the NADPH needs of nonphotosynthetic organisms and of the nonphotosynthetic tissues in plants. The *pentose phosphate pathway*, which occurs in the cytoplasm, is a crucial source of NADPH for use in reductive biosynthesis (Table 20.2) as well as for protection against oxidative stress. This pathway consists of two phases: (1) the oxidative generation of NADPH and (2) the nonoxidative interconversion of sugars (Figure 20.18). In the oxidative phase, NADPH is generated when glucose 6-phosphate is oxidized to ribulose 5-phosphate.

**TABLE 20.2** Pathways requiring NADPH

Synthesis
Fatty acid biosynthesis
Cholesterol biosynthesis
Neurotransmitter biosynthesis
Nucleotide biosynthesis
Detoxification
Reduction of oxidized glutathione
Cytochrome P450 monooxygenases

**FIGURE 20.18 Pentose phosphate pathway.** The pathway consists of (1) an oxidative phase that generates NADPH and (2) a nonoxidative phase that interconverts phosphorylated sugars.

In the nonoxidative phase, the pathway catalyzes the interconversion of three-, four-, five-, six-, and seven-carbon sugars in a series of nonoxidative reactions. Excess five-carbon sugars may be converted into intermediates of the glycolytic pathway. All these reactions take place in the cytoplasm. These interconversions rely on the same reactions that lead to the regeneration of ribulose 1,5-bisphosphate in the Calvin cycle.

### Two molecules of NADPH are generated in the conversion of glucose 6-phosphate into ribulose 5-phosphate

The oxidative phase of the pentose phosphate pathway starts with the dehydrogenation of glucose 6-phosphate at carbon 1, a reaction catalyzed by *glucose 6-phosphate dehydrogenase* (Figure 20.19). This enzyme is highly specific for  $\text{NADP}^+$ ; the  $K_M$  for  $\text{NADP}^+$  is about a thousand times as great as that for  $\text{NAD}^+$ . The product is *6-phosphoglucono- $\delta$ -lactone*, which is an intramolecular ester between the C-1 carboxyl group and the C-5 hydroxyl group. The next step is the hydrolysis of 6-phosphoglucono- $\delta$ -lactone by a specific *lactonase* to give *6-phosphogluconate*. This six-carbon sugar acid is then oxidatively decarboxylated by *6-phosphogluconate dehydrogenase* to yield *ribulose 5-phosphate*.  $\text{NADP}^+$  is again the electron acceptor.

### The pentose phosphate pathway and glycolysis are linked by transketolase and transaldolase

The preceding reactions yield two molecules of NADPH and one molecule of ribulose 5-phosphate for each molecule of glucose 6-phosphate oxidized. The ribulose 5-phosphate is subsequently isomerized to ribose 5-phosphate by phosphopentose isomerase.

**FIGURE 20.19 Oxidative phase of the pentose phosphate pathway.** Glucose 6-phosphate is oxidized to 6-phosphoglucono- $\delta$ -lactone to generate one molecule of NADPH. The lactone product is hydrolyzed to 6-phosphogluconate, which is oxidatively decarboxylated to ribulose 5-phosphate with the generation of a second molecule of NADPH.

Ribulose 5-phosphate and its derivatives are components of RNA and DNA, as well as of ATP, NADH, FAD, and coenzyme A. Although ribulose 5-phosphate is a precursor to many biomolecules, many cells need NADPH for reductive biosyntheses much more than they need ribulose 5-phosphate for incorporation into nucleotides. For instance, adipose tissue, the liver, and mammary glands require large amounts of NADPH for fatty acid synthesis (Chapter 22). In these cases, ribulose 5-phosphate is converted into the glycolytic intermediates glyceraldehyde 3-phosphate and fructose 6-phosphate by *transketolase* and *transaldolase*. These enzymes create a reversible link between the pentose phosphate pathway and glycolysis by catalyzing these three successive reactions.

The net result of these reactions is the formation of two hexoses and one triose from three pentoses:

The first of the three reactions linking the pentose phosphate pathway and glycolysis is the formation of *glyceraldehyde 3-phosphate* and *sedoheptulose 7-phosphate* from two pentoses.

The donor of the two-carbon unit in this reaction is xylulose 5-phosphate, an epimer of ribulose 5-phosphate. A ketose is a substrate of transketolase

only if its hydroxyl group at C-3 has the configuration of xylulose rather than ribulose. Ribulose 5-phosphate is converted into the appropriate epimer for the transketolase reaction by *phosphopentose epimerase* in the reverse reaction of that which takes place in the Calvin cycle.

Glyceraldehyde 3-phosphate and sedoheptulose 7-phosphate generated by the transketolase then react to form *fructose 6-phosphate* and *erythrose 4-phosphate*.

This synthesis of a four-carbon sugar and a six-carbon sugar is catalyzed by *transaldolase*.

In the third reaction, transketolase catalyzes the synthesis of *fructose 6-phosphate* and *glyceraldehyde 3-phosphate* from erythrose 4-phosphate and xylulose 5-phosphate.

The sum of these reactions is

Xylulose 5-phosphate can be formed from ribose 5-phosphate by the sequential action of phosphopentose isomerase and phosphopentose epimerase, and so the net reaction starting from ribose 5-phosphate is

Thus, *excess ribose 5-phosphate formed by the pentose phosphate pathway can be completely converted into glycolytic intermediates*. Moreover, any ribose

Sedoheptulose 7-phosphate + glyceraldehyde 3-phosphate ⇌ fructose 6-phosphate + erythrose 4-phosphate	Transaldolase
Xylulose 5-phosphate + erythrose 4-phosphate ⇌ fructose 6-phosphate + glyceraldehyde 3-phosphate	Transketolase

ingested in the diet can be processed into glycolytic intermediates by this pathway. It is evident that the carbon skeletons of sugars can be extensively rearranged to meet physiological needs (Table 20.3).

### Mechanism: Transketolase and transaldolase stabilize carbanionic intermediates by different mechanisms

The reactions catalyzed by transketolase and transaldolase are distinct, yet similar in many ways. One difference is that transketolase transfers a two-carbon unit, whereas transaldolase transfers a three-carbon unit. Each of these units is transiently attached to the enzyme in the course of the reaction and thus these enzymes are examples of double displacement reactions (Section 8.4).

**Transketolase reaction.** Transketolase contains a tightly bound thiamine pyrophosphate as its prosthetic group. The enzyme transfers a two-carbon glycoaldehyde from a ketose donor to an aldose acceptor. The site of the addition of the two-carbon unit is the thiazole ring of TPP. Transketolase is homologous to the E<sub>1</sub> subunit of the pyruvate dehydrogenase complex (Section 17.1) and the reaction mechanism is similar (Figure 20.20).

**FIGURE 20.20 Transketolase mechanism.** (1) Thiamine pyrophosphate (TPP) ionizes to form a carbanion. (2) The carbanion of TPP attacks the ketose substrate. (3) Cleavage of a carbon-carbon bond frees the aldose product and leaves a two-carbon fragment joined to TPP. (4) This activated glycoaldehyde intermediate attacks the aldose substrate to form a new carbon-carbon bond. (5) The ketose product is released, freeing the TPP for the next reaction cycle.

The reaction proceeds as follows:

1. The C-2 carbon atom of bound TPP readily ionizes to give a *carbanion*.
2. The negatively charged carbon atom of this reactive intermediate attacks the carbonyl group of the ketose substrate.
3. The resulting addition compound releases the aldose product to yield an *activated glycoaldehyde unit*.
4. The positively charged nitrogen atom in the thiazole ring acts as an *electron sink* in the development of this activated intermediate. The carbonyl group of a suitable aldose acceptor then condenses with the activated glycoaldehyde unit to form a new ketose.
5. The ketose is then released from the enzyme.

**FIGURE 20.21 Transaldolase mechanism.**

(1) The reaction begins with the formation of a Schiff base between a lysine residue in transaldolase and the ketose substrate. (2) Protonation of the Schiff base occurs. (3) Deprotonation leads to the release of the aldose product, leaving a three-carbon fragment attached to the lysine residue. (4) This intermediate adds to the aldose substrate. (5) Protonation occurs, forming a new carbon-carbon bond. (6) Subsequent deprotonation and (7) hydrolysis of the Schiff base releases the ketose product from the lysine side chain, completing the reaction cycle.

**Transaldolase reaction.** Transaldolase transfers a three-carbon *dihydroxyacetone* unit from a ketose donor to an aldose acceptor. Transaldolase, in contrast to transketolase, does not contain a prosthetic group. Rather, a *Schiff base is formed between the carbonyl group of the ketose substrate and the  $\epsilon$ -amino group of a lysine residue at the active site of the enzyme* (Figure 20.21). This kind of covalent enzyme–substrate intermediate is like that formed in fructose 1,6-bisphosphate aldolase in the glycolytic pathway (Section 16.1) and, indeed, the enzymes are homologous. (1) The reaction begins with the formation of the Schiff base. (2) The Schiff base becomes protonated and the bond between C-3 and C-4 is split. (3) Upon reprotonation, the aldose product is released leaving a three-carbon fragment bound to the enzyme. The negative charge on the Schiff-base carbanion moiety is stabilized by resonance (Figure 20.22). The positively charged nitrogen atom of the protonated Schiff base acts as an electron sink. (4) The Schiff-base adduct is stable until a suitable aldose becomes bound. (5) The dihydroxyacetone moiety then reacts with the carbonyl group of the aldose.

**FIGURE 20.22 Carbanion intermediates.** For transketolase and transaldolase, a carbanion intermediate is stabilized by resonance. In transketolase, TPP stabilizes this intermediate; in transaldolase, a protonated Schiff base plays this role.

Protonation allows the formation of a new carbon–carbon bond. (6) Subsequent deprotonation followed by (7) hydrolysis of the Schiff base releases the ketose product. The nitrogen atom of the protonated Schiff base plays the same role in transaldolase as the thiazole-ring nitrogen atom does in transketolase. In each enzyme, a group within an intermediate reacts like a carbanion in attacking a carbonyl group to form a new carbon–carbon bond. In each case, the charge on the carbanion is stabilized by resonance (Figure 20.22).

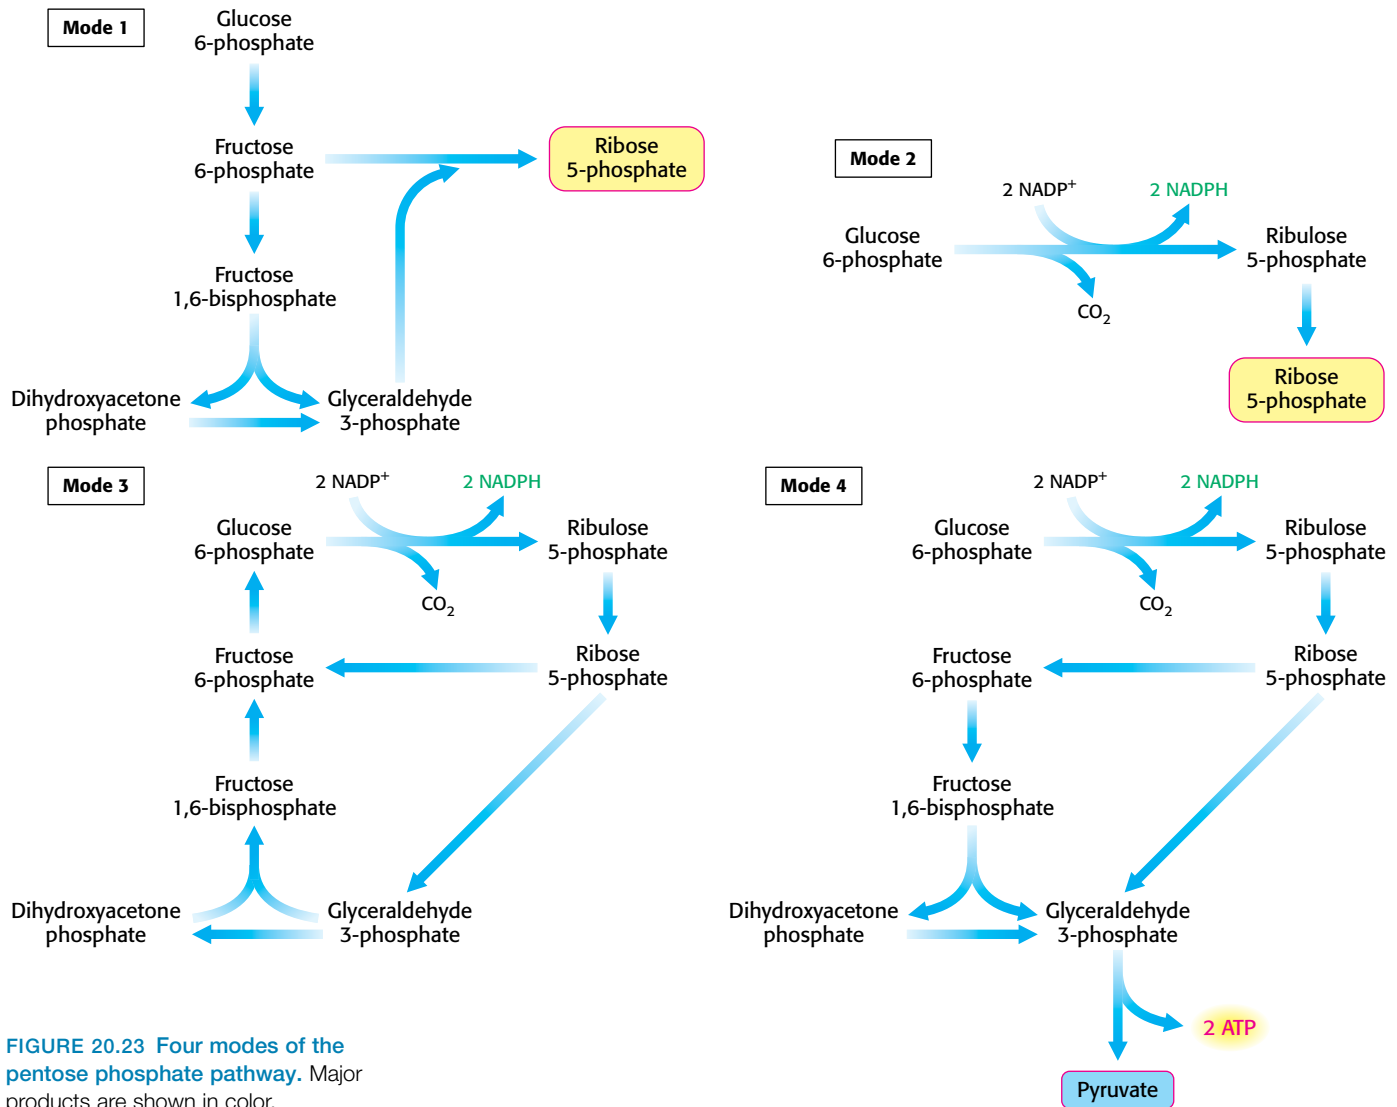

## 20.4 The Metabolism of Glucose 6-Phosphate by the Pentose Phosphate Pathway Is Coordinated with Glycolysis

Glucose 6-phosphate is metabolized by both the glycolytic pathway (Chapter 16) and the pentose phosphate pathway. How is the processing of this important metabolite partitioned between these two metabolic routes? The cytoplasmic concentration of  $\text{NADP}^+$  plays a key role in determining the fate of glucose 6-phosphate.

### The rate of the pentose phosphate pathway is controlled by the level of $\text{NADP}^+$

The first reaction in the oxidative branch of the pentose phosphate pathway, the dehydrogenation of glucose 6-phosphate, is essentially irreversible. In fact, this reaction is rate limiting under physiological conditions and serves as the control site for the oxidative branch of the pathway. The most important regulatory factor is the level of  $\text{NADP}^+$ . Low levels of  $\text{NADP}^+$  reduce the dehydrogenation of glucose 6-phosphate because it is needed as the electron acceptor. The effect of low levels of  $\text{NADP}^+$  is intensified by the fact that  $\text{NADPH}$  competes with  $\text{NADP}^+$  in binding to the enzyme. The ratio of  $\text{NADP}^+$  to  $\text{NADPH}$  in the cytoplasm of a liver cell from a well-fed rat is about 0.014. The marked effect of the  $\text{NADP}^+$  level on the rate of the oxidative phase ensures that  $\text{NADPH}$  is not generated unless the supply needed for reductive biosyntheses or protection against oxidative stress is low. The nonoxidative phase of the pentose phosphate pathway is controlled primarily by the availability of substrates.

**FIGURE 20.23** Four modes of the pentose phosphate pathway. Major products are shown in color.

### The flow of glucose 6-phosphate depends on the need for NADPH, ribose 5-phosphate, and ATP

We can grasp the intricate interplay between glycolysis and the pentose phosphate pathway by examining the metabolism of glucose 6-phosphate in four different metabolic situations (Figure 20.23).

**Mode 1.** *Much more ribose 5-phosphate than NADPH is required.* For example, rapidly dividing cells need ribose 5-phosphate for the synthesis of nucleotide precursors of DNA. Most of the glucose 6-phosphate is converted into fructose 6-phosphate and glyceraldehyde 3-phosphate by the glycolytic pathway. Transaldolase and transketolase then convert two molecules of fructose 6-phosphate and one molecule of glyceraldehyde 3-phosphate into three molecules of ribose 5-phosphate by a reversal of the reactions described earlier. The stoichiometry of mode 1 is

**Mode 2.** *The needs for NADPH and for ribose 5-phosphate are balanced.* Under these conditions, glucose 6-phosphate is processed to one molecule of ribulose 5-phosphate while generating two molecules of NADPH. Ribulose

**TABLE 20.4** Tissues with active pentose phosphate pathways

Tissue	Function
Adrenal gland	Steroid synthesis
Liver	Fatty acid and cholesterol synthesis
Testes	Steroid synthesis
Adipose tissue	Fatty acid synthesis
Ovary	Steroid synthesis
Mammary gland	Fatty acid synthesis
Red blood cells	Maintenance of reduced glutathione

5-phosphate is then converted into ribose 5-phosphate. The stoichiometry of mode 2 is

**Mode 3.** *Much more NADPH than ribose 5-phosphate is required.* For example, adipose tissue requires a high level of NADPH for the synthesis of fatty acids (Table 20.4). In this case, glucose 6-phosphate is completely oxidized to  $\text{CO}_2$ . Three groups of reactions are active in this situation. First, the oxidative phase of the pentose phosphate pathway forms two molecules of NADPH and one molecule of ribulose 5-phosphate. Then, ribulose 5-phosphate is converted into fructose 6-phosphate and glyceraldehyde 3-phosphate by transketolase and transaldolase. Finally, glucose 6-phosphate is resynthesized from fructose 6-phosphate and glyceraldehyde 3-phosphate by the gluconeogenic pathway. The stoichiometries of these three sets of reactions are

The sum of the mode 3 reactions is

Thus, *the equivalent of glucose 6-phosphate can be completely oxidized to  $\text{CO}_2$  with the concomitant generation of NADPH.* In essence, ribose 5-phosphate produced by the pentose phosphate pathway is recycled into glucose 6-phosphate by transketolase, transaldolase, and some of the enzymes of the gluconeogenic pathway.

**Mode 4.** *Both NADPH and ATP are required.* Alternatively, ribulose 5-phosphate formed from glucose 6-phosphate can be converted into pyruvate. Fructose 6-phosphate and glyceraldehyde 3-phosphate derived from ribose 5-phosphate enter the glycolytic pathway rather than reverting to glucose 6-phosphate. In this mode, *ATP and NADPH are concomitantly generated, and five of the six carbons of glucose 6-phosphate emerge in pyruvate.*

Pyruvate formed by these reactions can be oxidized to generate more ATP or it can be used as a building block in a variety of biosyntheses.

### The pentose phosphate pathway is required for rapid cell growth

Rapidly dividing cells, such as cancer cells, require ribose 5-phosphate for nucleic acid synthesis and NADPH for fatty acid synthesis, which in turn is required to form membrane lipids (Section 26.1). Recall that rapidly dividing cells switch to aerobic glycolysis to meet their ATP needs (Section 16.2). Glucose 6-phosphate and glycolytic intermediates are then used to generate NADPH and ribose 5-phosphate using the pentose phosphate pathway as described in Modes 1 and 3. The diversion of glycolytic intermediates into the nonoxidative phase is facilitated by the expression of the gene for a pyruvate kinase isozyme, PKM. PKM has a low catalytic activity, creating a bottleneck in the glycolytic pathway. Glycolytic intermediates accumulate and are then used by the pentose phosphate pathway to synthesize NADPH and ribose 5-phosphate. The shunting of phosphorylated intermediates into the nonoxidative phase of the pentose phosphate pathway is further enabled by the inhibition of triose phosphate isomerase by phosphoenolpyruvate, the substrate of PKM.

### Through the looking-glass: The Calvin cycle and the pentose phosphate pathway are mirror images

 The complexities of the Calvin cycle and the pentose phosphate pathway are easier to comprehend if we consider them as functional mirror images of each other. The Calvin cycle begins with the fixation of CO<sub>2</sub> and proceeds to use NADPH in the synthesis of glucose. The pentose phosphate pathway begins with the oxidation of a glucose-derived carbon atom to CO<sub>2</sub> and concomitantly generates NADPH. The regeneration phase of the Calvin cycle converts C<sub>6</sub> and C<sub>3</sub> molecules back into the starting material—the C<sub>5</sub> molecule ribulose 1,5-bisphosphate. The pentose phosphate pathway converts a C<sub>5</sub> molecule, ribulose 5-phosphate, into C<sub>6</sub> and C<sub>3</sub> intermediates of the glycolytic pathway. Not surprisingly, in photosynthetic organisms, many enzymes are common to the two pathways. We see the economy of evolution: the use of identical enzymes for similar reactions with different ends.

## 20.5 Glucose 6-Phosphate Dehydrogenase Plays a Key Role in Protection Against Reactive Oxygen Species

The NADPH generated by the pentose phosphate pathway plays a vital role in protecting the cells from reactive oxygen species (ROS). Reactive oxygen species generated in oxidative metabolism inflict damage on all classes of macromolecules and can ultimately lead to cell death. Indeed, ROS are implicated in a number of human diseases (Table 18.3). Reduced *glutathione* (GSH), a tripeptide with a free sulfhydryl group, combats oxidative stress by reducing ROS to harmless forms. Its task accomplished, the glutathione is now in the oxidized form (GSSG) and must be reduced to regenerate GSH. The reducing power is supplied by the NADPH generated by glucose 6-phosphate dehydrogenase in the pentose phosphate pathway. Indeed, cells with reduced levels of glucose 6-phosphate dehydrogenase are especially sensitive to oxidative stress.

### Glucose 6-phosphate dehydrogenase deficiency causes a drug-induced hemolytic anemia

 The importance of the pentose phosphate pathway is highlighted by some people's anomalous responses to certain drugs. For instance, pamaquine, the first synthetic antimalarial drug introduced in 1926, was associated with the appearance of severe and mysterious ailments. Most patients tolerated the drug well, but a few developed severe symptoms within a few days after therapy was started. Their urine turned black,

jaundice developed, and the hemoglobin content of the blood dropped sharply. In some cases, massive destruction of red blood cells caused death.

This drug-induced *hemolytic anemia* was shown 30 years later to be caused by a *deficiency of glucose 6-phosphate dehydrogenase*, the enzyme catalyzing the first step in the oxidative branch of the pentose phosphate pathway. The result is a dearth of NADPH in all cells, but this deficiency is most acute in red blood cell because they lack mitochondria and have no alternative means of generating reducing power. This defect, which is inherited on the X chromosome, is the most common disease that results from an enzyme malfunction, affecting hundreds of millions of people.

Pamaquine sensitivity is not simply a historical oddity about malaria treatment many decades ago. Primaquine, an antimalarial closely related to pamaquine, is widely used in malaria-infested regions of the world. Vicine, a purine glycoside of fava beans (which are consumed in countries surrounding the Mediterranean), also induces hemolysis. People deficient in glucose 6-phosphate dehydrogenase suffer hemolysis from eating fava beans or inhaling the pollen of the fava flowers, a response called *favism*. How can we explain hemolysis caused by pamaquine, primaquine, and vicine biochemically? These chemicals are oxidative agents that generate peroxides, reactive oxygen species that can damage membranes as well as other biomolecules. Peroxides are usually eliminated by the enzyme *glutathione peroxidase*, which uses reduced glutathione as a reducing agent.

**Vicia faba.** The Mediterranean plant *Vicia faba* is a source of fava beans that contain the purine glycoside vicine. [FLPA/RichardBecker/age footstock.]

The major role of NADPH in red cells is to reduce the disulfide form of glutathione to the sulfhydryl form. The enzyme that catalyzes the regeneration of reduced glutathione is *glutathione reductase*.

Red blood cells with a lowered level of reduced glutathione are more susceptible to hemolysis. In the absence of glucose 6-phosphate dehydrogenase, peroxides continue to damage membranes because no NADPH is being produced to restore reduced glutathione. Thus, the answer to our question is that *glucose 6-phosphate dehydrogenase is required to maintain reduced glutathione levels to protect against oxidative stress*. In the absence of oxidative stress, however, the deficiency is quite benign. The sensitivity to oxidative agents of people having this dehydrogenase deficiency also clearly demonstrates that *atypical reactions to drugs may have a genetic basis*.

Reduced glutathione is also essential for maintaining the normal structure of red blood cells by maintaining the structure of hemoglobin.

**FIGURE 20.24 Red blood cells with Heinz bodies.** The light micrograph shows red blood cells obtained from a person deficient in glucose 6-phosphate dehydrogenase. The dark particles, called *Heinz bodies*, inside the cells are clumps of denatured hemoglobin that adhere to the plasma membrane and stain with basic dyes. Red blood cells in such people are highly susceptible to oxidative damage. [Courtesy of Dr. Stanley Schrier.]

The reduced form of glutathione serves as a sulfhydryl buffer that keeps the residues of hemoglobin in the reduced sulfhydryl form. Without adequate levels of reduced glutathione, the hemoglobin sulfhydryl groups can no longer be maintained in the reduced form. Hemoglobin molecules then cross-link with one another to form aggregates called *Heinz bodies* on cell membranes (Figure 20.24). Membranes damaged by Heinz bodies and reactive oxygen species become deformed, and the cell is likely to undergo lysis.

### A deficiency of glucose 6-phosphate dehydrogenase confers an evolutionary advantage in some circumstances

 The incidence of the most common form of glucose 6-phosphate dehydrogenase deficiency, characterized by a 10-fold reduction in enzymatic activity in red blood cells, is 11% among Americans of African heritage. This high frequency suggests that the deficiency may be advantageous under certain environmental conditions. Indeed, *glucose 6-phosphate dehydrogenase deficiency protects against falciparum malaria*. The parasites causing this disease require NADPH for growth. Moreover, infection by the parasites induces oxidative stress in the infected cell. Because the pentose phosphate pathway is compromised, the cell and parasite die from oxidative damage. Thus, glucose 6-phosphate dehydrogenase deficiency is a mechanism of protection against malaria, which accounts for its high frequency in malaria-infested regions of the world. We see here once again the interplay of heredity and environment in the production of disease.

The ability of glucose 6-phosphate dehydrogenase deficiency to protect against malaria does, however, create a public health conundrum. Primaquine is a commonly used and highly effective antimalarial drug. However, indiscriminate use of primaquine causes hemolysis in individuals deficient in glucose 6-phosphate dehydrogenase. A solution to this problem may be in the offing, as recent work shows that an anti-malaria vaccine may be within reach.

## SUMMARY

### 20.1 The Calvin Cycle Synthesizes Hexoses from Carbon Dioxide and Water

ATP and NADPH formed in the light reactions of photosynthesis are used to convert  $\text{CO}_2$  into hexoses and other organic compounds. The dark phase of photosynthesis, called the *Calvin cycle*, starts with the reaction of  $\text{CO}_2$  and ribulose 1,5-bisphosphate to form two molecules of 3-phosphoglycerate. This reaction is catalyzed by rubisco (ribulose 1,5-bisphosphate carboxylase/oxygenase). The steps in the conversion of 3-phosphoglycerate into fructose 6-phosphate and glucose 6-phosphate are like those of gluconeogenesis, except that glyceraldehyde 3-phosphate dehydrogenase in chloroplasts is specific for NADPH rather than NADH. Ribulose 1,5-bisphosphate is regenerated from fructose 6-phosphate, glyceraldehyde 3-phosphate, and dihydroxyacetone phosphate by a complex series of reactions. Several of the steps in the regeneration of ribulose 1,5-bisphosphate are like those of the pentose phosphate pathway. Three molecules of ATP and two molecules of NADPH are consumed for each molecule of  $\text{CO}_2$  converted into a hexose. Starch in chloroplasts and sucrose in the cytoplasm are the major carbohydrate stores in plants.

Rubisco also catalyzes a competing oxygenase reaction, which produces phosphoglycolate and 3-phosphoglycerate. The recycling of phosphoglycolate leads to the release of  $\text{CO}_2$  and further consumption of  $\text{O}_2$  in a process called photorespiration.

## 20.2 The Activity of the Calvin Cycle Depends on Environmental Conditions

Reduced thioredoxin formed by the light-driven transfer of electrons from ferredoxin activates enzymes of the Calvin cycle by reducing disulfide bridges. The light-induced increase in pH and  $Mg^{2+}$  level of the stroma is important in stimulating the carboxylation of ribulose 1,5-bisphosphate by rubisco. Photorespiration is minimized in tropical plants, which have an accessory pathway—the  $C_4$  pathway—for concentrating  $CO_2$  at the site of the Calvin cycle. This pathway enables tropical plants to take advantage of high levels of light and minimize the oxygenation of ribulose 1,5-bisphosphate. Other plants use crassulacean acid metabolism (CAM) to prevent dehydration. In CAM plants, the  $C_4$  pathway is active during the night, when the plant exchanges gases with the air. During the day, gas exchange is eliminated and  $CO_2$  is generated from malate stored in vacuoles.

## 20.3 The Pentose Phosphate Pathway Generates NADPH and Synthesizes Five-Carbon Sugars

Whereas the Calvin cycle is present only in photosynthetic organisms, the pentose phosphate pathway is present in all organisms. The pentose phosphate pathway consists of two phases: an oxidative phase and a nonoxidative phase. The oxidative phase generates NADPH and ribulose 5-phosphate in the cytoplasm. NADPH is used in reductive biosyntheses. The oxidative phase starts with the dehydrogenation of glucose 6-phosphate to form a lactone, which is hydrolyzed to give 6-phosphogluconate and then oxidatively decarboxylated to yield ribulose 5-phosphate.  $NADP^+$  is the electron acceptor in both of these oxidations. The nonoxidative phase begins with the isomerization of ribulose 5-phosphate (a ketose) to ribose 5-phosphate (an aldose). Ribose 5-phosphate is converted into glyceraldehyde 3-phosphate and fructose 6-phosphate by *transketolase* and *transaldolase*. These two enzymes create a reversible link between the pentose phosphate pathway and glycolysis. Xylulose 5-phosphate, sedoheptulose 7-phosphate, and erythrose 4-phosphate are intermediates in these interconversions. When NADPH needs are paramount, fructose 6-phosphate and glyceraldehyde 3-phosphate from the nonoxidative phase are used to synthesize glucose 6-phosphate for metabolism in the oxidative phase. In this way, 12 molecules of NADPH can be generated for each molecule of glucose 6-phosphate that is completely oxidized to  $CO_2$ .

## 20.4 The Metabolism of Glucose 6-Phosphate by the Pentose Phosphate Pathway Is Coordinated with Glycolysis

Only the nonoxidative branch of the pathway is significantly active when much more ribose 5-phosphate than NADPH must be synthesized. Under these conditions, fructose 6-phosphate and glyceraldehyde 3-phosphate (formed by the glycolytic pathway) are converted into ribose 5-phosphate without the formation of NADPH. Alternatively, ribose 5-phosphate formed by the oxidative branch can be converted into pyruvate through fructose 6-phosphate and glyceraldehyde 3-phosphate. In this mode, ATP and NADPH are generated, and five of the six carbons of glucose 6-phosphate emerge in pyruvate. The interplay of the glycolytic and pentose phosphate pathways enables the levels of NADPH, ATP, and building blocks such as ribose 5-phosphate and pyruvate to be continuously adjusted to meet cellular needs.

## 20.5 Glucose 6-Phosphate Dehydrogenase Plays a Key Role in Protection Against Reactive Oxygen Species

NADPH generated by glucose 6-phosphate dehydrogenase maintains the appropriate levels of reduced glutathione required to combat

oxidative stress and ensures the proper reducing environment in the cell. Cells with diminished glucose 6-phosphate dehydrogenase activity are especially sensitive to oxidative stress.

## KEY TERMS

Calvin cycle (dark reactions) (p. 589)	transketolase (p. 595)	crassulacean acid metabolism (CAM) (p. 601)
autotroph (p. 590)	aldolase (p. 595)	pentose phosphate pathway (p. 601)
heterotroph (p. 590)	starch (p. 597)	glucose 6-phosphate dehydrogenase (p. 602)
rubisco (ribulose 1,5-bisphosphate carboxylase/oxygenase) (p. 591)	sucrose (p. 597)	glutathione (p. 610)
peroxisome (microbody) (p. 593)	thioredoxin (p. 599)	
photorespiration (p. 594)	C <sub>4</sub> pathway (p. 599)	
hexose monophosphate pool (p. 595)	C <sub>4</sub> plant (p. 601)	
	C <sub>3</sub> plant (p. 601)	

## PROBLEMS

- A vital cycle.* Why is the Calvin cycle crucial to the functioning of all life forms?
- Be nice to plants.* Differentiate between autotrophs and heterotrophs.
- Cabalistic reactions?* Why are the reactions of the Calvin cycle sometimes referred to as the dark reactions? Do they take place only at night or are they grim, secret reactions?
- Compare and contrast.* Identify the similarities and differences between the Krebs cycle and the Calvin cycle.
- Labeling experiments.* When Melvin Calvin performed his initial experiments on carbon fixation, he exposed algae to radioactive carbon dioxide. After 5 seconds, only a single organic compound contained radioactivity but, after 60 seconds, many compounds had incorporated radioactivity. (a) What compound initially contained the radioactivity? (b) What compounds contained radioactivity after 60 seconds?
- Three-part harmony.* The Calvin cycle can be thought of as occurring in three parts or stages. Describe the stages.
- Not always to the swiftest.* Suggest a reason why rubisco might be the most abundant enzyme in the world.
- A requirement.* In an atmosphere devoid of CO<sub>2</sub> but rich in O<sub>2</sub>, the oxygenase activity of rubisco disappears. Why?
- Reduce locally.* Glyceraldehyde 3-phosphate dehydrogenase in chloroplasts uses NADPH to participate in the synthesis of glucose. In gluconeogenesis in the cytoplasm, the isozyme of the dehydrogenase uses NADH. Why is it advantageous for the chloroplast enzyme to use NADPH?
- Total eclipse.* An illuminated suspension of the green alga *Chlorella* is actively carrying out photosynthesis. Suppose that the light is suddenly switched off. How would the levels of 3-phosphoglycerate and ribulose 1,5-bisphosphate change in the next minute?
- CO<sub>2</sub> deprivation.* An illuminated suspension of *Chlorella* is actively carrying out photosynthesis in the presence of 1% CO<sub>2</sub>. The concentration of CO<sub>2</sub> is abruptly reduced to 0.003%. What effect would this reduction have on the levels of 3-phosphoglycerate and ribulose 1,5-bisphosphate in the next minute?
- Salvage operation.* Write a balanced equation for the transamination of glyoxylate to yield glycine.
- Dog days of August.* Before the days of pampered lawns, most homeowners practiced horticultural Darwinism. A result was that the lush lawns of early summer would often convert into robust cultures of crabgrass in the dog days of August. Provide a possible biochemical explanation for this transition.
- Is it hot in here, or is it just me?* Why is the C<sub>4</sub> pathway valuable for tropical plants?
- No free lunch.* Explain why maintaining a high concentration of CO<sub>2</sub> in the bundle-sheath cells of C<sub>4</sub> plants is an example of active transport. How much ATP is required per CO<sub>2</sub> to maintain a high concentration of CO<sub>2</sub> in the bundle-sheath cells of C<sub>4</sub> plants?
- Breathing pictures?* What is photorespiration, what is its cause, and why is it believed to be wasteful?
- Global warming.* C<sub>3</sub> plants are most common in higher latitudes and become less common at latitudes near the equator. The reverse is true of C<sub>4</sub> plants. How might global warming affect this distribution?
- Communication.* What are the light-dependent changes in the stroma that regulate the Calvin cycle?

19. *Match 'em.* Match each term with its description.

20. *Linked in.* Describe how the pentose phosphate pathway and glycolysis are linked by transaldolase and transketolase.

21. *Biochemical taxonomy.*

- Identify 6-phosphoglucono-δ-lactone. \_\_\_\_\_
- Which reactions produce NADPH? \_\_\_\_\_
- Identify ribulose 5-phosphate. \_\_\_\_\_
- What reaction generates CO<sub>2</sub>? \_\_\_\_\_
- Identify 6-phosphogluconate. \_\_\_\_\_
- Which reaction is catalyzed by phosphopentose isomerase? \_\_\_\_\_
- Identify ribose 5-phosphate \_\_\_\_\_
- Which reaction is catalyzed by lactonase? \_\_\_\_\_
- Identify glucose 6-phosphate. \_\_\_\_\_
- Which reaction is catalyzed by 6-phosphogluconate dehydrogenase? \_\_\_\_\_
- Which reaction is catalyzed by glucose 6-phosphate dehydrogenase? \_\_\_\_\_

22. *Tracing glucose.* Glucose labeled with <sup>14</sup>C at C-6 is added to a solution containing the enzymes and cofactors of the oxidative phase of the pentose phosphate pathway. What is the fate of the radioactive label?

23. *Recurring decarboxylations.* Which reaction in the citric acid cycle is most analogous to the oxidative decarboxylation of 6-phosphogluconate to ribulose 5-phosphate? What kind of enzyme-bound intermediate is formed in both reactions?

24. *Synthetic stoichiometries.* What is the stoichiometry of the synthesis of (a) ribose 5-phosphate from glucose 6-phosphate without the concomitant generation of NADPH? (b) NADPH from glucose 6-phosphate without the concomitant formation of pentose sugars?

25. *Offal or awful?* Liver and other organ meats contain large quantities of nucleic acids. In the course of digestion, RNA is hydrolyzed to ribose, among other chemicals. Explain how ribose can be used as a fuel.

26. *A required ATP.* The metabolism of glucose 6-phosphate into ribose 5-phosphate by the joint efforts of the pentose phosphate pathway and glycolysis can be summarized by the following equation.

Which reaction requires the ATP?

27. *No respiration.* Glucose is normally completely oxidized to CO<sub>2</sub> in the mitochondria. In what circumstance can glucose be completely oxidized to CO<sub>2</sub> in the cytoplasm?

28. *Watch your diet, doctor.* The noted psychiatrist Hannibal Lecter once remarked to FBI Agent Clarice Starling that he enjoyed liver with some fava beans and a nice Chianti. Why might this diet be dangerous for some people?

29. *No redundancy.* Why do deficiencies in glucose 6-phosphate dehydrogenase frequently present as anemia?

30. *Damage control.* What is the role of glutathione in protection against damage by reactive peroxides? Why is the pentose phosphate pathway crucial to this protection?

31. *Reductive power.* What ratio of NADPH to NADP<sup>+</sup> is required to sustain [GSH] = 10 mM and [GSSG] = 1 mM? Use the redox potentials given in Table 18.1.

## Mechanism Problems

32. *An alternative approach.* The mechanisms of some aldolases do not include Schiff-base intermediates. Instead, these enzymes require bound metal ions. Propose such a mechanism for the conversion of dihydroxyacetone phosphate and glyceraldehyde 3-phosphate into fructose 1,6-bisphosphate.

33. *A recurring intermediate.* Phosphopentose isomerase interconverts the aldose ribose 5-phosphate and the ketose ribulose 5-phosphate. Propose a mechanism.

## Chapter Integration Problems

34. *Catching carbons.* Radioactive-labeling experiments can yield estimates of how much glucose 6-phosphate is metabolized by the pentose phosphate pathway and how much is metabolized by the combined action of glycolysis and the citric acid cycle. Suppose that you have samples of two different tissues as well as two radioactively labeled glucose samples, one with glucose labeled with  $^{14}\text{C}$  at C-1 and the other with glucose labeled with  $^{14}\text{C}$  at C-6. Design an experiment that would enable you to determine the relative activity of the aerobic metabolism of glucose compared with metabolism by the pentose phosphate pathway.

35. *You do what you can do.* Red blood cells lack mitochondria. These cells process glucose to lactate, but they also generate  $\text{CO}_2$ . What is the purpose of producing lactate? How can red blood cells generate  $\text{CO}_2$  if they lack mitochondria?

36. *Better to focus on one.* Rubisco catalyzes both a carboxylation reaction and a wasteful oxygenase reaction. Below are the kinetic parameters for the two reactions.

$K_M^{\text{CO}_2}$ ( $\mu\text{M}$ )	$K_M^{\text{O}_2}$ ( $\mu\text{M}$ )	$k_{\text{cat}}^{\text{CO}_2}$ ( $\text{s}^{-1}$ )	$k_{\text{cat}}^{\text{O}_2}$ ( $\text{s}^{-1}$ )
10	500	3	2

(a) Determine the values of  $k_{\text{cat}}^{\text{CO}_2}/K_M^{\text{CO}_2}$  and  $k_{\text{cat}}^{\text{O}_2}/K_M^{\text{O}_2}$  as  $\text{s}^{-1}\text{M}^{-1}$ .

(b) In light of the  $k_{\text{cat}}/K_M$  values for the two reactions, why does the oxygenation reaction occur?

37. *Photosynthetic efficiency.* Use the following information to estimate the efficiency of photosynthesis.

The  $\Delta G^\circ$  for the reduction of  $\text{CO}_2$  to the level of hexose is  $+477 \text{ kJ mol}^{-1}$  ( $+114 \text{ kcal mol}^{-1}$ ).

A mole of 600-nm photons has an energy content of 199 kJ (47.6 kcal).

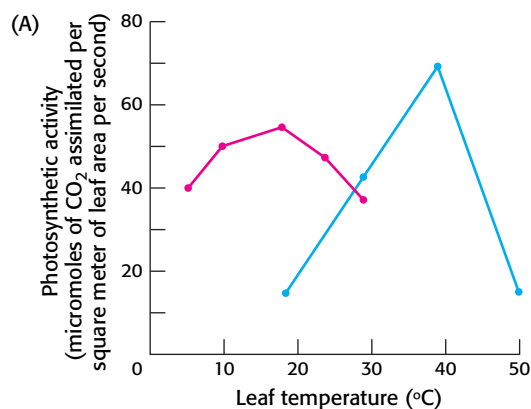

Assume that the proton gradient generated in producing the required NADPH is sufficient to drive the synthesis of the required ATP.

38. *A violation of the First Law?* The complete combustion of glucose to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  yields 30 ATP, as shown in

Table 18.4. However, the synthesis of glucose requires only 18 ATP. How is it possible that glucose synthesis from  $\text{CO}_2$  and  $\text{H}_2\text{O}$  requires only 18 ATP, but combustion to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  yields 30 ATP? Is it a violation of the First Law of Thermodynamics, or perhaps a miracle?

## Data Interpretation Problem

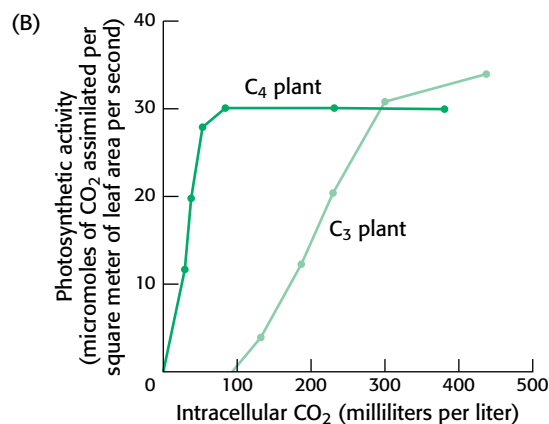

39. *Deciding between 3 and 4.* Graph A shows the photosynthetic activity of two species of plant, one a  $\text{C}_4$  plant and the other a  $\text{C}_3$  plant, as a function of leaf temperature.

(a) Which data were most likely generated by the  $\text{C}_4$  plant and which by the  $\text{C}_3$  plant? Explain.

(b) Suggest some possible explanations for why the photosynthetic activity falls at higher temperatures.

Graph B illustrates how the photosynthetic activity of  $\text{C}_3$  and  $\text{C}_4$  plants varies with  $\text{CO}_2$  concentration when temperature ( $30^\circ\text{C}$ ) and light intensity (high) are constant.

(c) Why can  $\text{C}_4$  plants thrive at  $\text{CO}_2$  concentrations that do not support the growth of  $\text{C}_3$  plants?

(d) Suggest a plausible explanation why  $\text{C}_3$  plants continue to increase photosynthetic activity at higher  $\text{CO}_2$  concentrations, whereas  $\text{C}_4$  plants reach a plateau.

## Glycogen Metabolism

Signaling cascades lead to the mobilization of glycogen to produce glucose, an energy source for cyclists. [(Left) Jonathan Devich/Epic Images.]

Glucose is an important fuel and, as we will see, a key precursor for the biosynthesis of many molecules. However, glucose cannot be stored, because high concentrations of glucose disrupt the osmotic balance of the cell, which would cause cell damage or death. How can adequate stores of glucose be maintained without damaging the cell? The solution to this problem is to store glucose as a nonosmotically active polymer called *glycogen*.

Glycogen is a *readily mobilized storage form of glucose*. It is a very large, branched polymer of glucose residues that can be broken down to yield glucose molecules when energy is needed (Figure 21.1). A glycogen molecule has approximately 12 layers of glucose molecules and can be as large as 40 nm, containing approximately 55,000 glucose residues. Most of the glucose residues in glycogen are linked by  $\alpha$ -1,4-glycosidic bonds (Figure 21.2). Branches at about every 12 residues are created by  $\alpha$ -1,6-glycosidic bonds. Recall that  $\alpha$ -glycosidic linkages form open helical polymers, whereas  $\beta$  linkages produce nearly straight strands that form structural fibrils, as in cellulose (Figure 11.14).

Glycogen is not as reduced as fatty acids are and consequently are not as energy rich. Why isn't all excess fuel stored as fatty acids rather than as glycogen? The controlled release of glucose from glycogen maintains blood-glucose concentration between meals. The circulating blood keeps the brain supplied with glucose, which is virtually the only fuel used by the brain, except during prolonged starvation (Chapter 27). Moreover, the readily mobilized glucose from glycogen is a good source of energy for sudden, strenuous activity. Unlike fatty acids, the released glucose can be metabolized in the absence of oxygen and can thus supply energy for anaerobic activity (Section 16.1).

**FIGURE 21.1 Glycogen.** At the core of the glycogen molecule is the protein glycogenin (yellow). Each line represents glucose molecules joined by an  $\alpha$ -1,4-glycosidic linkage. The nonreducing ends of the glycogen molecule form the surface of the glycogen granule. Degradation takes place at this surface. [Information from R. Melendez et al. *Biophys. J.* 77:1327–1332, 1999.]

**FIGURE 21.2 Glycogen structure.** In this structure of two outer branches of a glycogen molecule, the residues at the nonreducing ends are shown in red and the residue that starts a branch is shown in green. The rest of the glycogen molecule is represented by R.

Glycogen is present in bacteria, archae, and eukaryotes. Recall that plants store glucose as starch, a similar chemical. Thus, storing energy as glucose polymers is common to all forms of life. In humans, most tissues have some glycogen, although the two major sites of glycogen storage are the liver and skeletal muscle. The concentration of glycogen is higher in the liver than in muscle (10% versus 2% by weight), but more glycogen is stored in skeletal muscle overall because of muscle's much greater mass. Glycogen is present in the cytoplasm, with the molecule appearing as granules (Figure 21.3). In the liver, glycogen synthesis and degradation are regulated to maintain blood-glucose levels as required to meet the needs of the organism as a whole. In contrast, in muscle, these processes are regulated to meet the energy needs of the muscle itself.

Glycogen granules

### Glycogen metabolism is the regulated release and storage of glucose

Glycogen degradation and synthesis are simple biochemical processes. Glycogen degradation consists of three steps: (1) the release of glucose 1-phosphate from glycogen, (2) the remodeling of the glycogen substrate to permit further degradation, and (3) the conversion of glucose 1-phosphate into glucose 6-phosphate for further metabolism. The glucose 6-phosphate derived from the breakdown of glycogen has three possible fates (Figure 21.4): (1) It can be metabolized by glycolysis, (2) it can be converted into free

**FIGURE 21.4 Fates of glucose 6-phosphate.** Glucose 6-phosphate derived from glycogen can (1) be used as a fuel for anaerobic or aerobic metabolism as in, for instance, muscle; (2) be converted into free glucose in the liver and subsequently released into the blood; (3) be processed by the pentose phosphate pathway to generate NADPH or ribose in a variety of tissues.

glucose for release into the bloodstream, and (3) it can be processed by the pentose phosphate pathway to yield NADPH and ribose derivatives. The conversion of glycogen into free glucose takes place mainly in the liver.

Glycogen synthesis, which takes place when glucose is abundant, requires an activated form of glucose, uridine diphosphate glucose (UDP-glucose), formed by the reaction of UTP and glucose 1-phosphate. As is the case for glycogen degradation, the glycogen molecule must be remodeled for continued synthesis.

The regulation of glycogen degradation and synthesis is complex and is facilitated by the fact that all of the enzymes involved in glycogen metabolism and its regulation are associated with the glycogen particle. Several enzymes taking part in glycogen metabolism allosterically respond to metabolites that signal the energy needs of the cell. *Through these allosteric responses, enzyme activity is adjusted to meet the needs of the cell.* In addition, hormones may initiate signal cascades that lead to the reversible phosphorylation of enzymes, which alters their catalytic rates. *Regulation by hormones adjusts glycogen metabolism to meet the needs of the entire organism.*

## 21.1 Glycogen Breakdown Requires the Interplay of Several Enzymes

The efficient breakdown of glycogen to provide glucose 6-phosphate for further metabolism requires four enzyme activities: one to degrade glycogen, two to remodel glycogen so that it can remain a substrate for degradation, and one to convert the product of glycogen breakdown into a form suitable for further metabolism. We will examine each of these activities in turn.

### Phosphorylase catalyzes the phosphorolytic cleavage of glycogen to release glucose 1-phosphate

*Glycogen phosphorylase*, the key enzyme in glycogen breakdown, cleaves its substrate by the addition of orthophosphate ( $P_i$ ) to yield *glucose 1-phosphate*. The cleavage of a bond by the addition of orthophosphate is referred to as *phosphorolysis*.

Phosphorylase catalyzes the sequential removal of glucosyl residues from the nonreducing ends of the glycogen molecule (the ends with a free OH group on carbon 4). Orthophosphate splits the glycosidic linkage between C-1 of the terminal residue and C-4 of the adjacent one. Specifically, it cleaves the bond between the C-1 carbon atom and the glycosidic oxygen atom, and the  $\alpha$  configuration at C-1 is retained.

Glucose 1-phosphate released from glycogen can be readily converted into glucose 6-phosphate, an important metabolic intermediate, by the enzyme phosphoglucomutase.

The reaction catalyzed by phosphorylase is readily reversible *in vitro*. At pH 6.8, the equilibrium ratio of orthophosphate to glucose 1-phosphate is 3.6. The value of  $\Delta G^{\circ'}$  for this reaction is small because a glycosidic bond is replaced by a phosphoryl ester bond that has a nearly equal transfer potential. However, phosphorylase proceeds far in the direction of glycogen breakdown *in vivo* because the  $[P_i]/[\text{glucose 1-phosphate}]$  ratio is usually greater than 100, substantially favoring phosphorylase. We see here an example of how the cell can alter the free-energy change to favor a reaction's occurrence by altering the ratio of substrate and product.

The phosphorylase cleavage of glycogen is energetically advantageous because the released sugar is already phosphorylated. In contrast, a hydrolytic cleavage would yield glucose, which would then have to be phosphorylated at the expense of a molecule of ATP to enter the glycolytic pathway. An additional advantage of phosphorylase cleavage for muscle cells is that no transporters exist for glucose 1-phosphate, which is negatively charged under physiological conditions, and so it cannot be transported or diffuse out of the cell.

**FIGURE 21.5 Structure of glycogen phosphorylase.** This enzyme forms a homodimer: one subunit is shown in white and the other in yellow. Each catalytic site includes a pyridoxal phosphate (PLP) group, linked to lysine 680 of the enzyme. The binding site for the phosphate ( $P_i$ ) substrate is shown. Notice that the catalytic site lies between the C-terminal domain and the glycogen-binding site. A narrow crevice, which binds four or five glucose units of glycogen, connects the two sites. The separation of the sites allows the catalytic site to phosphorylate several glucose units before the enzyme must rebind the glycogen substrate. [Drawn from 1NOI.pdb.]

### Mechanism: Pyridoxal phosphate participates in the phosphorylase cleavage of glycogen

The special challenge faced by phosphorylase is to cleave glycogen phosphorylase rather than hydrolytically to save the ATP required to phosphorylate free glucose. Thus, water must be excluded from the active site. Phosphorylase is a dimer of two identical 97-kDa subunits. Each subunit is compactly folded into an *amino-terminal domain* (480 residues) containing a *glycogen-binding site* and a *carboxyl-terminal domain* (360 residues; Figure 21.5). The catalytic site in each subunit is located in a deep crevice formed by residues from both domains. Substrates bind synergistically, causing the crevice to narrow, thereby excluding water. What is the mechanistic basis of the phosphorylase cleavage of glycogen?

Several clues suggest a mechanism. First, both the glycogen substrate and the glucose 1-phosphate product have an  $\alpha$  configuration at C-1. A direct attack by phosphate on C-1 of a sugar would invert the configuration at this carbon atom because the reaction would proceed through a pentacovalent transition state. The fact that the glucose 1-phosphate formed has an  $\alpha$  rather than a  $\beta$  configuration suggests that an even number of steps (most simply, two) is required. A likely explanation for these results is that a *carbonium ion intermediate* is formed from the glucose residue.

A second clue to the catalytic mechanism of phosphorylase is its requirement for the coenzyme *pyridoxal phosphate* (PLP), a derivative of pyridoxine (vitamin B<sub>6</sub>, Section 15.4). The aldehyde group of this coenzyme forms a Schiff-base linkage with a specific lysine side chain of the enzyme (Figure 21.6). Structural studies indicate that the reacting orthophosphate group takes a position between the 5'-phosphate group of PLP and the glycogen substrate (Figure 21.7). *The 5'-phosphate group of PLP acts in tandem with orthophosphate by serving as a proton donor and then as a proton acceptor (i.e., as a general acid–base catalyst).* Orthophosphate (in the  $\text{HPO}_4^{2-}$  form) donates a proton to the oxygen atom attached to carbon 4 of the departing glycogen chain and simultaneously acquires a proton from PLP. The carbonium ion intermediate formed in this step is then attacked by orthophosphate to form  $\alpha$ -glucose 1-phosphate, with the concomitant return of a proton to pyridoxal phosphate. The special role of pyridoxal phosphate in the reaction is necessary because water is excluded from the active site.

The glycogen-binding site is 30 Å away from the catalytic site (Figure 21.5), but it is connected to the catalytic site by a narrow crevice able to accommodate four or five glucose units. The large separation between the binding site and the catalytic site enables the enzyme to phosphorylate many residues without having to dissociate and reassociate after each catalytic cycle. An enzyme that can catalyze many reactions without having to dissociate and reassociate after each catalytic step is said to be *processive*—a property of enzymes that synthesize and degrade large polymers. We will see such enzymes again when we consider DNA and RNA synthesis.

### A debranching enzyme also is needed for the breakdown of glycogen

Glycogen phosphorylase acting alone degrades glycogen to a limited extent. The enzyme can break  $\alpha$ -1,4-glycosidic bonds on glycogen branches but soon encounters an obstacle. The  $\alpha$ -1,6-glycosidic bonds at the branch points are not susceptible to cleavage by phosphorylase. Indeed, phosphorylase stops cleaving  $\alpha$ -1,4 linkages when it reaches a terminal residue four residues away from a branch point. Because about 1 in 12 residues is branched, cleavage by the phosphorylase alone would come to a halt after the release of eight glucose molecules per branch.

**FIGURE 21.6 PLP–Schiff-base linkage.**

A pyridoxal phosphate (PLP) group (red) forms a Schiff base with a lysine residue (blue) at the active site of phosphorylase, where it functions as a general acid–base catalyst.

A Schiff base, also called an *imine*, is a compound containing a carbon–nitrogen double bond with the nitrogen atom bonded to an organic compound, not a hydrogen atom. A Schiff base is formed by the reaction of a primary amine with an aldehyde or ketone.

**FIGURE 21.7 Phosphorylase mechanism.**

A bound  $\text{HPO}_4^{2-}$  group (red) favors the cleavage of the glycosidic bond by donating a proton to the C-4 oxygen of the departing glycosyl group (black). This reaction results in the formation of a carbonium ion and is favored by the transfer of a proton from the protonated phosphate group of the bound pyridoxal phosphate (PLP) group (blue). The carbonium ion and the orthophosphate combine to form glucose 1-phosphate.

How can the remainder of the glycogen molecule be mobilized for use as a fuel? Two additional enzymes, a *transferase* and  $\alpha$ -1,6-*glucosidase*, remodel the glycogen for continued degradation by the phosphorylase (Figure 21.8). The *transferase* shifts a block of three glucosyl residues from one outer branch to another. This transfer exposes a single glucose residue joined by an  $\alpha$ -1,6-glycosidic linkage.  $\alpha$ -1,6-Glucosidase, also known as the debranching enzyme, hydrolyzes the  $\alpha$ -1,6-glycosidic bond.

A free glucose molecule is released and then phosphorylated by the glycolytic enzyme hexokinase. Thus, the transferase and  $\alpha$ -1,6-glucosidase convert the branched structure into a linear one, which paves the way for further cleavage by phosphorylase. In eukaryotes, the transferase and the  $\alpha$ -1,6-glucosidase activities are present in a single 160-kDa polypeptide chain, providing yet another example of a bifunctional enzyme (Figure 16.29).

**FIGURE 21.8 Glycogen remodeling.** First,  $\alpha$ -1,4-glycosidic bonds on each branch are cleaved by phosphorylase, leaving four residues along each branch. The transferase shifts a block of three glucosyl residues from one outer branch to the other. In this reaction, the  $\alpha$ -1,4-glycosidic link between the blue and the green residues is broken and a new  $\alpha$ -1,4 link between the blue and the yellow residues is formed. The green residue is then removed by  $\alpha$ -1,6-glucosidase, leaving a linear chain with all  $\alpha$ -1,4 linkages, suitable for further cleavage by phosphorylase.

### Phosphoglucomutase converts glucose 1-phosphate into glucose 6-phosphate

Glucose 1-phosphate formed in the phosphorolytic cleavage of glycogen must be converted into glucose 6-phosphate to enter the metabolic mainstream. This shift of a phosphoryl group is catalyzed by *phosphoglucomutase*. Recall that this enzyme is also used in galactose metabolism (Section 16.1). To effect this shift, the enzyme exchanges a phosphoryl group with the substrate (Figure 21.9). The catalytic site of an active mutase molecule contains a phosphorylated serine residue. The phosphoryl group is transferred from the serine residue to the C-6 hydroxyl group of glucose 1-phosphate to form glucose 1,6-bisphosphate. The C-1 phosphoryl group of this intermediate is then shuttled to the same serine residue, resulting in the formation of glucose 6-phosphate and the regeneration of the phosphoenzyme.

These reactions are like those of *phosphoglycerate mutase*, a glycolytic enzyme (Section 16.1). The role of glucose 1,6-bisphosphate in the interconversion of the phosphoglucoses is like that of 2,3-bisphosphoglycerate (2,3-BPG) in the interconversion of 2-phosphoglycerate and 3-phosphoglycerate in glycolysis. A phosphoenzyme intermediate participates in both reactions.

### The liver contains glucose 6-phosphatase, a hydrolytic enzyme absent from muscle

A major function of the liver is to maintain a nearly constant level of glucose in the blood. The liver releases glucose into the blood between meals and

**FIGURE 21.9 Reaction catalyzed by phosphoglucomutase.** A phosphoryl group is transferred from the enzyme to the substrate, and a different phosphoryl group is transferred back to restore the enzyme to its initial state.

during muscular activity. The released glucose is taken up primarily by the brain, skeletal muscle, and red blood cells. In contrast with unmodified glucose, however, the phosphorylated glucose produced by glycogen breakdown is not transported out of cells. The liver contains a hydrolytic enzyme, *glucose 6-phosphatase*, that enables glucose to leave that organ. This enzyme cleaves the phosphoryl group to form free glucose and orthophosphate. This glucose 6-phosphatase is the same enzyme that releases free glucose at the conclusion of gluconeogenesis. It is located on the luminal side of the smooth endoplasmic reticulum membrane. Recall that glucose 6-phosphate is transported into the endoplasmic reticulum; glucose and orthophosphate formed by hydrolysis are then shuttled back into the cytoplasm (Section 16.1).

Glucose 6-phosphatase is absent from most other tissues. Muscle tissues retain glucose 6-phosphate for the generation of ATP. In contrast, glucose is not a major fuel for the liver.

## 21.2 Phosphorylase Is Regulated by Allosteric Interactions and Reversible Phosphorylation

Glycogen degradation is precisely controlled by multiple interlocking mechanisms. The focus of this control is the enzyme glycogen phosphorylase. *Phosphorylase is regulated by several allosteric effectors that signal the energy state of the cell as well as by reversible phosphorylation, which is responsive to hormones such as insulin, epinephrine, and glucagon.* We will examine the differences in the control of two isozymic forms of glycogen phosphorylase: one specific to liver and one specific to skeletal muscle. These differences are due to the fact that *the liver maintains glucose homeostasis of the organism as a whole, whereas the muscle uses glucose to produce energy for itself.*

### Liver phosphorylase produces glucose for use by other tissues

The dimeric phosphorylase exists in two interconvertible forms: a *usually active* phosphorylase *a* and a *usually inactive* phosphorylase *b* (Figure 21.10). Each of these two forms exists in equilibrium between an active relaxed (R) state and a much less active tense (T) state, but the equilibrium for phosphorylase *a* favors the active R state, whereas the equilibrium for phosphorylase *b* favors the less-active T state (Figure 21.11). The role of glycogen degradation in the liver is to form glucose for export to other tissues when the blood-glucose level is low. Consequently, we can think of the

**FIGURE 21.10 Structures of phosphorylase *a* and phosphorylase *b*.** Phosphorylase *a* is phosphorylated on serine 14 of each subunit. This modification favors the structure of the more-active R state. One subunit is shown in white, with helices and loops important for regulation shown in blue and red. The other subunit is shown in yellow, with the regulatory structures shown in orange and green. Phosphorylase *b* is not phosphorylated and exists predominantly in the T state. Notice that the catalytic sites are partly occluded in the T state. [Drawn from 1GPA.pdb and 1NOJ.pdb.]

**FIGURE 21.11 Phosphorylase regulation.** Both phosphorylase *b* and phosphorylase *a* exist as equilibria between an active R state and a less-active T state. Phosphorylase *b* is usually inactive because the equilibrium favors the T state. Phosphorylase *a* is usually active because the equilibrium favors the R state. Regulatory structures are shown in blue and green.

default state of liver phosphorylase as being the *a* form: glucose is to be generated unless the enzyme is signaled otherwise. The liver phosphorylase *a* form thus exhibits the most responsive  $R \leftrightarrow T$  transition (Figure 21.12). The binding of glucose to the active site shifts the *a* form from the active R state to the less-active T state. In essence, the enzyme reverts to the low-activity T state only when it detects the presence of sufficient glucose. If glucose is present in the diet, there is no need to degrade glycogen.

**FIGURE 21.12 Allosteric regulation of liver phosphorylase.** The binding of glucose to phosphorylase *a* shifts the equilibrium to the T state and inactivates the enzyme. Thus, glycogen is not mobilized when glucose is already abundant.

## Muscle phosphorylase is regulated by the intracellular energy charge

In contrast to the liver isozyme, the default state of muscle phosphorylase is the *b* form, owing to the fact that, for muscle, phosphorylase must be active primarily during muscle contraction. Muscle phosphorylase *b* is activated by the presence of high concentrations of AMP, which binds to a nucleotide-binding site and stabilizes the conformation of phosphorylase *b* in the active R state (Figure 21.13). Thus, when a muscle contracts and ATP is converted into AMP by the sequential action of myosin (Section 9.4) and adenylate kinase (Section 16.2), the phosphorylase is signaled to degrade glycogen. ATP acts as a negative allosteric effector by competing with AMP. Thus, *the transition of phosphorylase b between the active R state and the less-active T state is controlled by the energy charge of the muscle cell.* Glucose 6-phosphate also binds at the same site as ATP and stabilizes the less-active state of phosphorylase *b*, an example of feedback inhibition. Under most physiological conditions, *phosphorylase b is inactive because of the inhibitory effects of ATP and glucose 6-phosphate.* In contrast, *phosphorylase a is fully active*, regardless of the levels of AMP, ATP, and glucose 6-phosphate. In resting muscle, nearly all the enzyme is in the inactive *b* form.

Unlike the enzyme in muscle, the liver phosphorylase is insensitive to regulation by AMP because the liver does not undergo the dramatic changes in energy charge seen in a contracting muscle. We see here a clear example of the use of isozymes to establish the tissue-specific biochemical properties of the liver and muscle. In human beings, liver phosphorylase and muscle phosphorylase are approximately 90% identical in amino acid sequence, yet the 10% difference results in subtle but important shifts in the stability of various forms of the enzyme.

## Biochemical characteristics of muscle fiber types differ

Not only do the biochemical needs of liver and muscle differ with respect to glycogen metabolism, but the biochemical needs of different muscle fiber types also vary. Skeletal muscle consists of three different fiber types: type I, or slow-twitch muscle; type IIb (also called type IIx), or fast-twitch fibers; and type IIa fibers that have properties intermediate between the other two fiber types. Type I fibers rely predominantly on cellular respiration to derive energy. These fibers are powered by fatty acid degradation and are rich in mitochondria, the site of fatty acid degradation and the citric acid cycle. As we will see in Chapter 22, fatty acids are an excellent energy storage form, but generating ATP from fatty acids is slower than from glycogen. Glycogen is not an important fuel for type I fibers, and consequently the amount of glycogen phosphorylase is low. Type I fibers power endurance activities. Type IIb fibers use glycogen as their main fuel. Consequently, the glycogen and glycogen phosphorylase are abundant. These fibers are also rich in glycolytic enzymes needed to process glucose quickly in the absence of oxygen and poor in mitochondria. Type IIb fibers power burst activities such as sprinting and weight lifting. No amount of training can interconvert type I fibers and type IIb fibers. However, there is some evidence that type IIa fibers are “trainable”; that is, endurance training enhances the oxidative capacity of type IIa fibers while burst activity training enhances the glycolytic capacity. Table 21.1 shows the biochemical profile of the fiber types.

**FIGURE 21.13** Allosteric regulation of muscle phosphorylase. A low energy charge, represented by high concentrations of AMP, favors the transition to the R state. ATP and glucose 6-phosphate stabilize the T state.

**TABLE 21.1** Biochemical characteristics of muscle fiber types

Characteristic	Type I	Type IIa	Type IIb
Fatigue resistance	High	Intermediate	Low
Mitochondrial density	High	Intermediate	Low
Metabolic type	Oxidative	Oxidative/glycolytic	Glycolytic
Myoglobin content	High	Intermediate	Low
Glycogen content	Low	Intermediate	High
Triacylglycerol content	High	Intermediate	Low
Glycogen phosphorylase activity	Low	Intermediate	High
Phosphofructokinase activity	Low	Intermediate	High
Citrate synthase activity	High	Intermediate	Low

### Phosphorylation promotes the conversion of phosphorylase *b* to phosphorylase *a*

In both liver and muscle, phosphorylase *b* is converted into phosphorylase *a* by the phosphorylation of a single serine residue (serine 14) in each subunit. This conversion is initiated by hormones. Low blood levels of glucose lead to the secretion of the hormone glucagon. Fear or the excitement of exercise will cause levels of the hormone epinephrine to increase. The rise in glucagon and epinephrine levels results in phosphorylation of the enzyme to the phosphorylase *a* form in liver and muscle respectively. The regulatory enzyme *phosphorylase kinase* catalyzes this covalent modification.

Comparison of the structures of phosphorylase *a* in the R state and phosphorylase *b* in the T state reveals that subtle structural changes at the subunit interfaces are transmitted to the active sites (Figure 21.10). The transition from the T state (the prevalent state of phosphorylase *b*) to the R state (the prevalent state of phosphorylase *a*) entails a 10-degree rotation around the twofold axis of the dimer. Most important, this transition is associated with structural changes in  $\alpha$  helices that move a loop out of the active site of each subunit. Thus, the T state is less active because the catalytic site is partly blocked. In the R state, the catalytic site is more accessible and a binding site for orthophosphate is well organized.

### Phosphorylase kinase is activated by phosphorylation and calcium ions

Phosphorylase kinase activates phosphorylase *b* by attaching a phosphoryl group. The subunit composition of phosphorylase kinase in skeletal muscle is  $(\alpha\beta\gamma\delta)_4$ , and the mass of this very large protein is 1300 kDa. The enzyme consists of two  $(\alpha\beta\gamma\delta)_2$  lobes that are joined by a  $\beta_4$  bridge that is the core of the enzyme and serves as a scaffold for the remaining subunits. The  $\gamma$  subunit contains the active site, while all of the remaining subunits ( $\approx 90\%$  by mass) play regulatory roles. The  $\delta$  subunit is the calcium binding protein *calmodulin*, a calcium sensor that stimulates many enzymes in eukaryotes (Section 14.1). The  $\alpha$  and  $\beta$  subunits are targets of protein kinase A. The  $\beta$  subunit is phosphorylated first, followed by the phosphorylation of the  $\alpha$  subunit.

Activation of phosphorylase kinase is initiated when  $\text{Ca}^{2+}$  binds to the  $\delta$  subunit. This mode of activation of the kinase is especially noteworthy in muscle, where contraction is triggered by the release of  $\text{Ca}^{2+}$  from the sarcoplasmic reticulum (Figure 21.14). Maximal activation is achieved with the phosphorylation of the  $\beta$  and  $\alpha$  subunits of the  $\text{Ca}^{2+}$ -bound kinase. The stimulation of phosphorylase kinase is one step in a signal-transduction cascade initiated by signal molecules such as glucagon and epinephrine.

**FIGURE 21.14 Activation of phosphorylase kinase.** Phosphorylase kinase, an  $(\alpha\beta\gamma\delta)_4$  assembly, is partly activated by  $\text{Ca}^{2+}$  binding to the  $\delta$  subunit. Activation is maximal when the  $\beta$  and  $\alpha$  subunits are phosphorylated in response to hormonal signals. When active, the enzyme converts phosphorylase *b* into phosphorylase *a*.

## 21.3 Epinephrine and Glucagon Signal the Need for Glycogen Breakdown

Protein kinase A activates phosphorylase kinase, which in turn activates glycogen phosphorylase. What activates protein kinase A? What is the signal that ultimately triggers an increase in glycogen breakdown?

### G proteins transmit the signal for the initiation of glycogen breakdown

Several hormones greatly affect glycogen metabolism. Glucagon and epinephrine trigger the breakdown of glycogen. Muscular activity or its anticipation leads to the release of *epinephrine* (*adrenaline*), a catecholamine derived from tyrosine, from the adrenal medulla. Epinephrine markedly stimulates glycogen breakdown in muscle and, to a lesser extent, in the liver. The liver is more responsive to *glucagon*, a polypeptide hormone secreted by the  $\alpha$  cells of the pancreas when the blood-sugar level is low. Physiologically, glucagon signifies the starved state (Figure 21.15).

How do hormones trigger the breakdown of glycogen? They initiate a cyclic AMP signal-transduction cascade, already discussed in Section 14.1 (Figure 21.16).

1. The signal molecules epinephrine and glucagon bind to specific seven-transmembrane (7TM) receptors in the plasma membranes of target cells (Section 14.1). Epinephrine binds to the  $\beta$ -adrenergic receptor in muscle, whereas glucagon binds to the glucagon receptor in the liver. These binding events activate the  $G_s$  protein. *A specific external signal has been transmitted into the cell through structural changes, first in the receptor and then in the G protein.*

**FIGURE 21.15 PATHWAY INTEGRATION: Hormonal control of glycogen breakdown.** Glucagon stimulates liver-glycogen breakdown when blood glucose is low. Epinephrine enhances glycogen breakdown in muscle and the liver to provide fuel for muscle contraction.

2. The GTP-bound subunit of G<sub>s</sub> activates the transmembrane protein adenylate cyclase. This enzyme catalyzes the formation of the second messenger cyclic AMP (cAMP) from ATP.
3. The elevated cytoplasmic level of cAMP activates *protein kinase A* (Section 10.3). The binding of cAMP to inhibitory regulatory subunits

**FIGURE 21.16 Regulatory cascade for glycogen breakdown.** Glycogen degradation is stimulated by hormone binding to 7TM receptors. Hormone binding initiates a G-protein-dependent signal-transduction pathway that results in the phosphorylation and activation of glycogen phosphorylase.

triggers their dissociation from the catalytic subunits. The free catalytic subunits are now active.

4. Protein kinase A phosphorylates phosphorylase kinase, first on the  $\beta$  subunit and then on the  $\alpha$  subunit, which activates glycogen phosphorylase.

*The cyclic AMP cascade highly amplifies the effects of hormones.* The binding of a small number of hormone molecules to cell-surface receptors leads to the release of a very large number of sugar units. Indeed, much of the stored glycogen would be mobilized within seconds were it not for a counterregulatory system.

The signal-transduction processes in the liver are more complex than those in muscle. Epinephrine can also elicit glycogen degradation in the liver. However, in addition to binding to the  $\beta$ -adrenergic receptor, it binds to the 7TM  $\alpha$ -adrenergic receptor, which then initiates the *phosphoinositide cascade* (Section 14.2) that induces the release of  $\text{Ca}^{2+}$  from endoplasmic reticulum stores. Recall that the  $\delta$  subunit of phosphorylase kinase is the  $\text{Ca}^{2+}$  sensor calmodulin. The binding of  $\text{Ca}^{2+}$  to calmodulin leads to a partial activation of phosphorylase kinase. Stimulation by both glucagon and epinephrine leads to maximal mobilization of liver glycogen.

### Glycogen breakdown must be rapidly turned off when necessary

It is crucial that the high-gain system of glycogen breakdown be terminated quickly to prevent the wasteful depletion of glycogen after energy needs have been met. When glucose needs have been satisfied, phosphorylase kinase and glycogen phosphorylase are dephosphorylated and inactivated. Simultaneously, glycogen synthesis is activated.

The signal-transduction pathway leading to the activation of glycogen phosphorylase is shut down automatically when secretion of the initiating hormone ceases. The inherent GTPase activity of the G protein converts the bound GTP into inactive GDP, and phosphodiesterases always present in the cell convert cyclic AMP into AMP. Protein phosphatase 1 (PP1) removes the phosphoryl groups from phosphorylase kinase, thereby inactivating the enzyme. Finally, PP1 also removes the phosphoryl group from glycogen phosphorylase, converting the enzyme into the usually inactive *b* form.

### The regulation of glycogen phosphorylase became more sophisticated as the enzyme evolved

Analyses of the primary structures of glycogen phosphorylase from human beings, rats, *Dictyostelium* (slime mold), yeast, potatoes, and *E. coli* have enabled inferences to be made about the evolution of this important enzyme. The 16 residues that come into contact with glucose at the active site are identical in nearly all the enzymes. There is more variation but still substantial conservation of the 15 residues at the pyridoxal phosphate-binding site. Likewise, the glycogen-binding site is well conserved in all the enzymes. The high degree of similarity among these three sites shows that the catalytic mechanism has been maintained throughout evolution.

Differences arise, however, when we compare the regulatory sites. The simplest type of regulation would be feedback inhibition by glucose 6-phosphate. Indeed, the glucose 6-phosphate regulatory site is highly conserved among most of the phosphorylases. The crucial amino acid residues that participate in regulation by phosphorylation and nucleotide binding are well conserved only in the mammalian enzymes. Thus, this level of regulation was a later evolutionary acquisition.

## 21.4 Glycogen Is Synthesized and Degraded by Different Pathways

As with glycolysis and gluconeogenesis, biosynthetic and degradative pathways rarely operate by precisely the same reactions in the forward and reverse directions. Glycogen metabolism provided the first known example of this important principle. *Separate pathways afford much greater flexibility, both in energetics and in control.*

Glycogen is synthesized by a pathway that utilizes *uridine diphosphate glucose* (UDP-glucose) as the activated glucose donor.

### UDP-glucose is an activated form of glucose

UDP-glucose, the glucose donor in the biosynthesis of glycogen, is an *activated form of glucose*, just as ATP and acetyl CoA are activated forms of orthophosphate and acetate, respectively. The C-1 carbon atom of the glucosyl unit of UDP-glucose is activated because its hydroxyl group is esterified to the diphosphate moiety of UDP.

UDP-glucose is synthesized from glucose 1-phosphate and uridine triphosphate (UTP) in a reaction catalyzed by *UDP-glucose pyrophosphorylase*. This reaction liberates the outer two phosphoryl residues of UTP as pyrophosphate.

This reaction is readily reversible. However, pyrophosphate is rapidly hydrolyzed *in vivo* to orthophosphate by an inorganic pyrophosphatase. The essentially irreversible hydrolysis of pyrophosphate drives the synthesis of UDP-glucose.

The synthesis of UDP-glucose exemplifies another recurring theme in biochemistry: *Many biosynthetic reactions are driven by the hydrolysis of pyrophosphate.*

### Glycogen synthase catalyzes the transfer of glucose from UDP-glucose to a growing chain

New glucosyl units are added to the nonreducing terminal residues of glycogen. The activated glucosyl unit of UDP-glucose is transferred to the hydroxyl group at C-4 of a terminal residue to form an  $\alpha$ -1,4-glycosidic linkage. UDP is displaced by the terminal hydroxyl group of the growing glycogen molecule. This reaction is catalyzed by *glycogen synthase*, the key regulatory enzyme in glycogen synthesis. Humans have two isozymes of

glycogen synthase: one is specific to the liver while the other is expressed in muscle and other tissues.

Glycogen synthase, a member of the large glycosyltransferase family (Section 11.3), can add glucosyl residues only to a polysaccharide chain already containing at least four residues. Thus, glycogen synthesis requires a *primer*. This priming function is carried out by *glycogenin*, a  $Mn^{2+}$ -requiring glycosyltransferase composed of two identical 37-kDa subunits. Each subunit of glycogenin catalyzes the formation of  $\alpha$ -1,4-glucose polymers, 10 to 20 glucosyl units in length, which are covalently attached to the phenolic hydroxyl group of a specific tyrosine residue in each glycogenin subunit. UDP-glucose is the donor in this autoglycosylation. At this point, glycogen synthase takes over to extend the glycogen molecule. Thus, every glycogen molecule has a glycogenin molecule at its core (Figure 21.1).

 Despite no detectable sequence similarity, structural studies have revealed that glycogen synthase is homologous to glycogen phosphorylase. The binding site for UDP-glucose in glycogen synthase corresponds in position to the pyridoxal phosphate in glycogen phosphorylase.

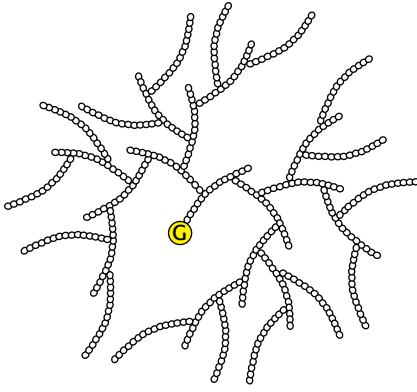

### A branching enzyme forms $\alpha$ -1,6 linkages

Glycogen synthase catalyzes only the synthesis of  $\alpha$ -1,4 linkages. Another enzyme is required to form the  $\alpha$ -1,6 linkages that make glycogen a branched polymer. Branching takes place after a number of glucosyl residues are joined in  $\alpha$ -1,4 linkages by glycogen synthase (Figure 21.17). A branch is created by the breaking of an  $\alpha$ -1,4 link and the formation of an  $\alpha$ -1,6 link. A block of residues, typically 7 in number, is transferred to a more interior site. The *branching enzyme* that catalyzes this reaction requires that the block of 7 or so residues must include the nonreducing

**FIGURE 21.17 Branching reaction.** The branching enzyme removes an oligosaccharide of approximately seven residues from the nonreducing end and creates an internal  $\alpha$ -1,6 linkage.

**FIGURE 21.18** Cross section of a glycogen molecule. The component labeled G is glycogenin.

terminus, and must come from a chain at least 11 residues long. In addition, the new branch point must be at least 4 residues away from a preexisting one.

*Branching is important because it increases the solubility of glycogen.* Furthermore, branching creates a large number of terminal residues, the sites of action of glycogen phosphorylase and synthase (Figure 21.18). Thus, *branching increases the rate of glycogen synthesis and degradation.*

### Glycogen synthase is the key regulatory enzyme in glycogen synthesis

Glycogen synthase, like phosphorylase, exists in two forms: an active non-phosphorylated *a* form and a usually inactive phosphorylated *b* form. Again, like the phosphorylase, the interconversion of the two forms is regulated by covalent modification. However, the key means of regulating glycogen synthase is by allosteric regulation of the phosphorylated form of the enzyme, glycogen synthase *b*. Glucose 6-phosphate is a powerful activator of the enzyme, stabilizing the R state of the enzyme relative to the T state.

The covalent modification of glycogen synthase appears to play more of a fine-tuning role. The synthase is phosphorylated at multiple sites by several protein kinases—notably, *glycogen synthase kinase* (GSK), which is under the control of insulin (p. 635), and *protein kinase A*. The function of the multiple phosphorylation sites is still under investigation. Note that *phosphorylation has opposite effects on the enzymatic activities of glycogen synthase and glycogen phosphorylase.*

### Glycogen is an efficient storage form of glucose

What is the cost of converting glucose 6-phosphate into glycogen and back into glucose 6-phosphate? The pertinent reactions have already been described, except for reaction 5, which is the regeneration of UTP. ATP phosphorylates UDP in a reaction catalyzed by *nucleoside diphosphokinase*.

Thus, 1 molecule of ATP is hydrolyzed to incorporate glucose 6-phosphate into glycogen. The energy yield from the breakdown of glycogen is highly efficient. About 90% of the residues are phosphorolytically cleaved to glucose 1-phosphate, which is converted at no cost into glucose 6-phosphate. The other residues are branch residues, which are hydrolytically cleaved. One molecule of ATP is then used to phosphorylate each of these glucose molecules to glucose 6-phosphate. The complete oxidation of glucose 6-phosphate yields about 31 molecules of ATP, and storage consumes slightly more than 1 molecule of ATP per molecule of glucose 6-phosphate; so *the overall efficiency of storage is nearly 97%.*

## 21.5 Glycogen Breakdown and Synthesis Are Reciprocally Regulated

An important control mechanism prevents glycogen from being synthesized at the same time as it is being broken down. *The same glucagon- and epinephrine-triggered cAMP cascades that initiate glycogen breakdown in the*

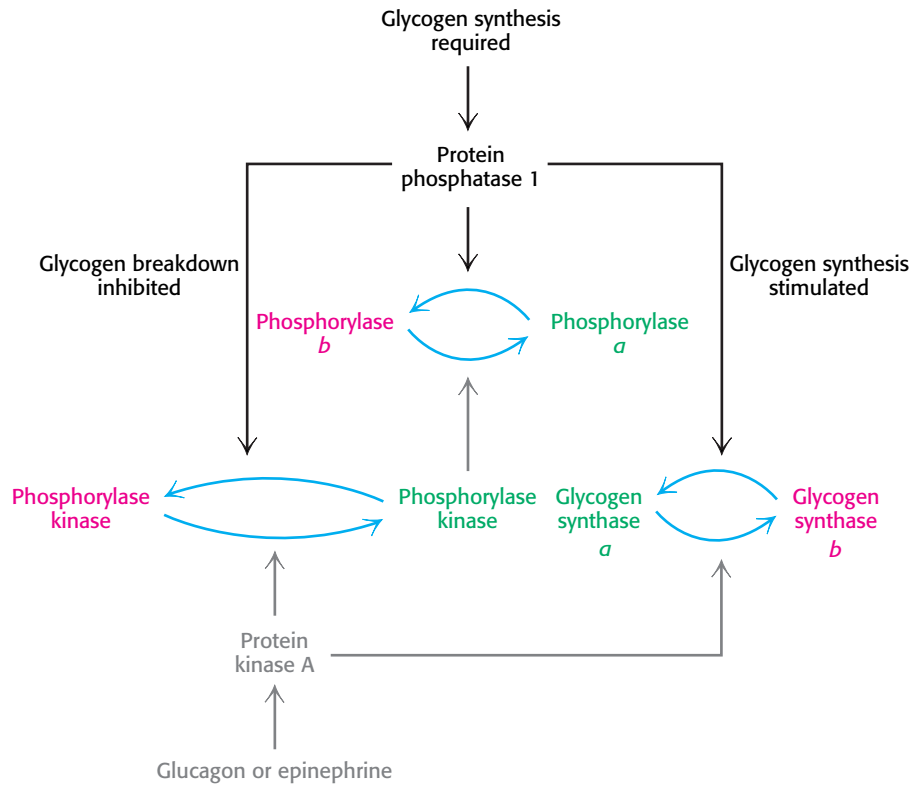

**FIGURE 21.19 Coordinate control of glycogen metabolism.** Glycogen metabolism is regulated, in part, by hormone-triggered cyclic AMP cascades. The sequence of reactions leading to the activation of protein kinase A ultimately activates glycogen degradation. At the same time, protein kinase A along with glycogen synthase kinase inactivates glycogen synthase, shutting down glycogen synthesis.

*liver and muscle, respectively, also shut off glycogen synthesis. Glucagon and epinephrine control both glycogen breakdown and glycogen synthesis through protein kinase A (Figure 21.19). Recall that protein kinase A adds a phosphoryl group to phosphorylase kinase, activating that enzyme and initiating glycogen breakdown. Glycogen synthase kinase and protein kinase A add phosphoryl groups to glycogen synthase, but this phosphorylation leads to a decrease in enzymatic activity. In this way, glycogen breakdown and synthesis are reciprocally regulated. How is the enzymatic activity reversed so that glycogen breakdown halts and glycogen synthesis begins?*

### Protein phosphatase 1 reverses the regulatory effects of kinases on glycogen metabolism

After a bout of exercise, muscle must shift from a glycogen-degrading mode to one of glycogen replenishment. A first step in this metabolic task is to shut down the phosphorylated proteins that stimulate glycogen breakdown. This task is accomplished by *protein phosphatases* that catalyze the hydrolysis of phosphorylated serine and threonine residues in proteins. *Protein phosphatase 1 plays key roles in regulating glycogen metabolism* (Figure 21.20). PP1 inactivates phosphorylase *a* and phosphorylase kinase by dephosphorylating them. PP1 decreases the rate of glycogen breakdown; it reverses the effects of the phosphorylation cascade. Moreover, *PP1 also removes phosphoryl groups from glycogen synthase b to convert it into the more active glycogen synthase a form.* Here, PP1 also accelerates glycogen synthesis. PP1 is yet another molecular device for coordinating carbohydrate storage. Interestingly, recent research suggests that glycogen phosphorylase is also regulated by acetylation (Chapter 10.3). Acetylation not only inhibits the enzyme, but also enhances dephosphorylation by promoting the interaction with PP1. Acetylation is stimulated

AFTER A MEAL OR REST

**FIGURE 21.20 Regulation of glycogen synthesis by protein phosphatase 1.** Protein phosphatase 1 stimulates glycogen synthesis while inhibiting glycogen breakdown. Active enzymes are shown in green and inactive enzymes in red.

by glucose and insulin, but inhibited by glucagon. It is fascinating that glycogen phosphorylase, one of the first allosteric enzymes identified and one of the most studied enzymes, is still revealing secrets.

**FIGURE 21.21 Regulation of protein phosphatase 1 (PP1) in muscle takes place in two steps.** Phosphorylation of  $G_M$  by protein kinase A dissociates the catalytic subunit from its substrates in the glycogen particle. Phosphorylation of the inhibitor subunit by protein kinase A inactivates the catalytic unit of PP1.

The catalytic subunit of PP1 is a 37-kDa single-domain protein. This subunit is usually bound to one of a family of regulatory subunits with masses of approximately 120 kDa. In skeletal muscle and heart, the most prevalent regulatory subunit is called  $G_M$ , whereas in the liver, the most prevalent subunit is  $G_L$ . These regulatory subunits have modular structures with domains that participate in interactions with glycogen, with the catalytic subunit, and with target enzymes. Thus, *these regulatory subunits act as scaffolds, bringing together the phosphatase and its substrates on the glycogen particle.*

DURING EXERCISE OR FASTING

What prevents the phosphatase activity of PP1 from always inhibiting glycogen degradation? When glycogen degradation is called for, epinephrine or glucagon initiate the cAMP cascade that activates protein kinase A (Figure 21.21). Protein kinase A reduces the activity of PP1 by two mechanisms. First, in muscle,  $G_M$  is phosphorylated in the domain responsible for binding the catalytic subunit. The catalytic subunit is released from glycogen and from its substrates and dephosphorylation is greatly reduced. Second, almost all tissues contain small proteins that, when phosphorylated, bind to the catalytic

**FIGURE 21.22 Insulin inactivates glycogen synthase kinase.** Insulin triggers a cascade that leads to the phosphorylation and inactivation of glycogen synthase kinase and prevents the phosphorylation of glycogen synthase. Protein phosphatase 1 (PP1) removes the phosphates from glycogen synthase, thereby activating the enzyme and allowing glycogen synthesis. IRS, insulin-receptor substrate.

subunit of PP1 and inhibit it. Thus, when glycogen degradation is switched on by cAMP, the accompanying phosphorylation of these inhibitors keeps phosphorylase in its active *a* form and glycogen synthase in its inactive *b* form.

### Insulin stimulates glycogen synthesis by inactivating glycogen synthase kinase

After exercise, people often consume carbohydrate-rich foods to restock their glycogen stores. How is glycogen synthesis stimulated? When blood-glucose levels are high, *insulin stimulates the synthesis of glycogen by inactivating glycogen synthase kinase*, one of the enzymes that maintains glycogen synthase in its phosphorylated, inactive state (Figure 21.22). The first step in the action of insulin is its binding to its receptor, a tyrosine kinase receptor in the plasma membrane (Section 14.2). The binding of insulin stimulates the tyrosine kinase activity of the receptor so that it phosphorylates insulin-receptor substrates (IRSs). These phosphorylated proteins trigger signal-transduction pathways that eventually lead to the activation of protein kinases that phosphorylate and inactivate glycogen synthase kinase. The inactive kinase can no longer maintain glycogen synthase in its phosphorylated, inactive state. Protein phosphatase 1 dephosphorylates glycogen synthase, activating it, and restoring glycogen reserves. Recall that insulin increases the amount of glucose in the cell by increasing the number of glucose transporters in the membrane (Section 16.2). The net effect of insulin is thus the replenishment of glycogen stores.

### Glycogen metabolism in the liver regulates the blood-glucose level

After a meal rich in carbohydrates, blood-glucose levels rise, and glycogen synthesis is stepped up in the liver. Although insulin is the primary signal for glycogen synthesis, another is the concentration of glucose in the blood, which normally ranges from about 4.4–6.7 mM. The liver senses the concentration of glucose in the blood and takes up or releases glucose

**FIGURE 21.23 Blood glucose regulates liver-glycogen metabolism.** The infusion of glucose into the bloodstream leads to the inactivation of phosphorylase, followed by the activation of glycogen synthase, in the liver. [Data from W. Stalmans, H. De Wulf, L. Hue, and H.-G. Hers. *Eur. J. Biochem.* 41:117–134, 1974.]

accordingly. The amount of liver phosphorylase *a* decreases rapidly when glucose is infused (Figure 21.23). After a lag period, the amount of glycogen synthase *a* increases, which results in glycogen synthesis. Phosphorylase *a* is the glucose sensor in liver cells, facilitating the switch from degradation to synthesis. How does phosphorylase perform its sensor function?

Phosphorylase *a* and PP1 are localized to the glycogen particle by interactions with the  $G_L$  subunit of PP1. The binding of glucose to phosphorylase *a* shifts its allosteric equilibrium from the active R form to the inactive T form. This conformational change renders the phosphoryl group on serine 14 a substrate for protein phosphatase 1. PP1 binds tightly to phosphorylase *a* only when the phosphorylase is in the R state but is inactive when bound. When glucose induces the transition to the T form, PP1 and the phosphorylase dissociate from each other and the glycogen particle, and PP1 becomes active, converting the phosphorylase *a* form to the *b* form. Recall that the  $R \leftrightarrow T$  transition of muscle phosphorylase *a* is unaffected by glucose and is thus unaffected by the rise in blood-glucose levels (Section 21.2).

How does glucose binding to glycogen phosphorylase stimulate glycogen synthesis? As mentioned above, the conversion of *a* into *b* is accompanied by the release of PP1, which is then free to activate glycogen synthase (Figure 21.24). The removal of the phosphoryl group of inactive glycogen synthase *b* converts it into the active *a* form. What accounts for the lag between termination of glycogen degradation and the beginnings of glycogen synthesis (Figure 21.23)? There are about 10 phosphorylase *a* molecules per molecule of phosphatase. Consequently, the activity of glycogen synthase begins to increase only after most of phosphorylase *a* is converted into *b*. The lag between the decrease in glycogen degradation and the increase in glycogen synthesis prevents the two pathways from operating simultaneously. This remarkable glucose-sensing system depends on three key elements: (1) communication between the allosteric site for glucose and the serine phosphate, (2) the use of PP1 to inactivate phosphorylase and activate glycogen synthase, and (3) the binding of the phosphatase to phosphorylase *a* to prevent the premature activation of glycogen synthase.

Efforts are underway to develop drugs that disrupt the interaction of liver phosphorylase with the  $G_L$  subunit as a treatment for type 2 diabetes (Section 27.2). One experimental drug binds at a unique site on the enzyme that, synergistically with glucose, stabilizes the T state of

**FIGURE 21.24 Glucose regulation of liver-glycogen metabolism.** Glucose binds to and inhibits glycogen phosphorylase *a* in the liver, facilitating the formation of the T state of phosphorylase *a*. The T state of phosphorylase *a* does not bind protein phosphatase 1 (PP1), leading to the dissociation and activation of PP1 from glycogen phosphorylase *a*. The free PP1 dephosphorylates glycogen phosphorylase *a* and glycogen synthase *b*, leading to the inactivation of glycogen breakdown and the activation of glycogen synthesis.

phosphorylase and thereby enhances the transition to glycogen synthesis, as described earlier. Type 2 diabetes is characterized by excess blood glucose. Hence, disrupting the association of phosphorylase with the  $G_L$  would render it a substrate for PP1. Glycogen degradation would cease, and glucose release into the blood would be inhibited.

### A biochemical understanding of glycogen-storage diseases is possible

Edgar von Gierke described the first glycogen-storage disease in 1929. A patient with this disease has a huge abdomen caused by a massive enlargement of the liver. There is a pronounced hypoglycemia between meals. Furthermore, the blood-glucose level does not rise on administration of epinephrine and glucagon. An infant with this glycogen-storage disease may have convulsions because of the low blood-glucose level.

The enzymatic defect in von Gierke disease was elucidated in 1952 by Carl and Gerty Cori. They found that *glucose 6-phosphatase is missing from the liver of a patient with this disease*. This finding was the first demonstration of an inherited deficiency of a liver enzyme. The glycogen in the liver is normal in structure but is present in abnormally large amounts. The absence of glucose 6-phosphatase in the liver causes hypoglycemia because glucose cannot be formed from glucose 6-phosphate. This phosphorylated sugar does not leave the liver, because it cannot cross the plasma membrane. The presence of excess glucose 6-phosphate triggers an increase in glycolysis in the liver, leading to a high level of lactate and pyruvate in the blood. Patients who have von Gierke disease also have an increased dependence on fat metabolism. This disease can also be produced by a mutation in the gene that encodes the *glucose 6-phosphate transporter*. Recall that glucose 6-phosphate must be transported into the lumen of the endoplasmic reticulum to be hydrolyzed by phosphatase (Section 16.3). Mutations in the other three essential proteins of this system can likewise lead to von Gierke disease.

Seven other glycogen-storage diseases have been characterized (Table 21.2). In Pompe disease (type II), lysosomes become engorged with

**TABLE 21.2** Glycogen-storage diseases

Type	Defective enzyme	Organ affected	Glycogen in the affected organ	Clinical features
I Von Gierke	Glucose 6-phosphatase or transport system	Liver and kidney	Increased amount; normal structure.	Massive enlargement of the liver; failure to thrive; severe hypoglycemia, ketosis, hyperuricemia, hyperlipemia.
II Pompe	$\alpha$ -1,4-Glucosidase (lysosomal)	All organs	Massive increase in amount; normal structure.	Cardiorespiratory failure causes death, usually before age 2.
III Cori	$\alpha$ -1,6-Glucosidase (debranching enzyme)	Muscle and liver	Increased amount; short outer branches.	Like type I, but milder course.
IV Andersen	Branching enzyme ( $\alpha$ -1,4 $\rightarrow$ $\alpha$ -1,6)	Liver and spleen	Normal amount; very long outer branches.	Progressive cirrhosis of the liver; liver failure causes death, usually before age 2.
V McArdle	Phosphorylase	Muscle	Moderately increased amount; normal structure.	Limited ability to perform strenuous exercise because of painful muscle cramps; otherwise patient is normal and well developed.
VI Hers	Phosphorylase	Liver	Increased amount.	Like type I, but milder course.
VII	Phosphofructokinase	Muscle	Increased amount; normal structure.	Like type V.
VIII	Phosphorylase kinase	Liver	Increased amount; normal structure.	Mild liver enlargement; mild hypoglycemia.

Note: Types I through VII are inherited as autosomal recessives. Type VIII is sex linked.

**FIGURE 21.25 Electron micrograph of muscle cell from a patient with Pompe disease.** Glycogen-engorged lysosomes are seen throughout the cell, including the myofibrils. As the disease progresses, lysosomes may rupture, releasing large amounts of glycogen into the cytoplasm. Such accumulations of cytoplasmic glycogen are called glycogen lakes. [Reproduced with permission of the author, from Thurberg, B. L. et. al. Characterization of pre- and post-treatment pathology after enzyme replacement for Pompe disease. *Lab. Invest.* 86 (12):1208–1220, 2006.]

glycogen because they lack  $\alpha$ -1,4-glucosidase, a hydrolytic enzyme confined to these organelles (Figure 21.25). Carl and Gerty Cori also elucidated the biochemical defect in another glycogen-storage disease (type III), which cannot be distinguished from von Gierke disease (type I) by physical examination alone. In type III disease, the structure of liver and muscle glycogen is abnormal and the amount is markedly increased. Most striking, the outer branches of the glycogen are very short. *Patients having this type lack the debranching enzyme ( $\alpha$ -1,6-glucosidase),* and so only the outermost branches of glycogen can be effectively utilized. Thus, only a small fraction of this abnormal glycogen is functionally active as an accessible store of glucose.

A defect in glycogen metabolism confined to muscle is found in McArdle disease (type V). *Muscle phosphorylase activity is absent,* and a patient's capacity to perform strenuous exercise is limited because of painful muscle cramps. The patient is otherwise normal and well developed. Thus, effective utilization of muscle glycogen is not essential for life.

## SUMMARY

Glycogen, a readily mobilized fuel store, is a branched polymer of glucose residues. Most of the glucose units in glycogen are linked by  $\alpha$ -1,4-glycosidic bonds. At about every twelfth residue, a branch is created by an  $\alpha$ -1,6-glycosidic bond. Glycogen is present in large amounts in muscle cells and in liver cells, where it is stored in the cytoplasm in the form of hydrated granules.

### 21.1 Glycogen Breakdown Requires the Interplay of Several Enzymes

Most of the glycogen molecule is degraded to glucose 1-phosphate by the action of glycogen phosphorylase, the key enzyme in glycogen breakdown. The glycosidic linkage between C-1 of a terminal residue and C-4 of the adjacent one is split by orthophosphate to give glucose 1-phosphate, which can be reversibly converted into glucose 6-phosphate. Branch points are degraded by the concerted action of an oligosaccharide transferase and an  $\alpha$ -1,6-glucosidase.

### 21.2 Phosphorylase Is Regulated by Allosteric Interactions and Reversible Phosphorylation

Phosphorylase *b*, which is usually inactive, is converted into active phosphorylase *a* by the phosphorylation of a single serine residue in each subunit. This reaction is catalyzed by phosphorylase kinase. The *a* form in the liver is inhibited by glucose. In liver, phosphorylase is activated to liberate glucose for export to other organs, such as skeletal muscle and the brain. The *b* form in muscle can be activated by the binding of AMP, an effect counteracted by ATP and glucose 6-phosphate. In contrast to liver, muscle phosphorylase is activated to generate glucose for use inside the cell as a fuel for contractile activity.

### 21.3 Epinephrine and Glucagon Signal the Need for Glycogen Breakdown

Epinephrine and glucagon stimulate glycogen breakdown through specific 7TM receptors. Muscle is the primary target of epinephrine, whereas the liver is responsive to glucagon. Both signal molecules initiate a kinase cascade that leads to the activation of phosphorylase kinase, which in turn converts glycogen phosphorylase *b* to the phosphorylated *a* form.

### 21.4 Glycogen Is Synthesized and Degraded by Different Pathways

The pathway for glycogen synthesis differs from that for glycogen breakdown. UDP-glucose, the activated intermediate in glycogen synthesis, is formed from glucose 1-phosphate and UTP. Glycogen synthase catalyzes the transfer of glucose from UDP-glucose to the C-4 hydroxyl group of a terminal residue in the growing glycogen molecule. Synthesis is primed by glycogenin, an autoglycosylating protein that contains a covalently attached oligosaccharide unit on a specific tyrosine residue. A branching enzyme converts some of the  $\alpha$ -1,4 linkages into  $\alpha$ -1,6 linkages to increase the number of ends so that glycogen can be made and degraded more rapidly.

### 21.5 Glycogen Breakdown and Synthesis Are Reciprocally Regulated

Glycogen synthesis and degradation are coordinated by several amplifying reaction cascades. Epinephrine and glucagon stimulate glycogen breakdown and inhibit its synthesis by increasing the cytoplasmic level of cyclic AMP, which activates protein kinase A. Protein kinase A activates glycogen breakdown by attaching a phosphate to phosphorylase kinase and inhibits glycogen synthesis by phosphorylating glycogen synthase. Glycogen synthase kinase also inhibits synthesis by phosphorylating the synthase.

The glycogen-mobilizing actions of protein kinase A are reversed by protein phosphatase 1, which is regulated by several hormones. Epinephrine inhibits this phosphatase by blocking its attachment to glycogen molecules and by turning on an inhibitor. Insulin, in contrast, triggers a cascade that phosphorylates and inactivates glycogen synthase kinase. Hence, glycogen synthesis is decreased by epinephrine and increased by insulin. Glycogen synthase and phosphorylase are also regulated by noncovalent allosteric interactions. In fact, phosphorylase is a key part of the glucose-sensing system of liver cells. Glycogen metabolism exemplifies the power and precision of reversible phosphorylation in regulating biological processes.

## KEY TERMS

glycogen phosphorylase (p. 619)	epinephrine (adrenaline) (p. 627)	glycogen synthase (p. 630)
phosphorolysis (p. 619)	glucagon (p. 627)	glycogenin (p. 631)
pyridoxal phosphate (PLP) (p. 620)	protein kinase A (PKA) (p. 628)	glycogen synthase kinase (p. 632)
phosphorylase kinase (p. 626)	uridine diphosphate glucose (UDP-glucose) (p. 630)	protein phosphatase 1 (PP1) (p. 633)
calmodulin (p. 626)		insulin (p. 635)

## PROBLEMS

- Step-by-step degradation.* What are the three steps in glycogen degradation and what enzymes are required?
- Match 'em.* Match each term with its description.
 

(a) Glycogen phosphorylase _____	1. Calcium-binding subunit of phosphorylase kinase	(e) Phosphoglucomutase _____	5. Liberates a free glucose residue
(b) Phosphorolysis _____	2. Activates glycogen phosphorylase	(f) Phosphorylase kinase _____	6. Shifts the location of several glucose residues
(c) Transferase _____	3. Removal of a glucose residue by the addition of phosphate	(g) Protein kinase A _____	7. Stimulates glycogen breakdown in the liver
(d) $\alpha$ -1,6-Glucosidase _____	4. Stimulates glycogen breakdown in muscle	(h) Calmodulin _____	8. Catalyzes phosphorolytic cleavage
		(i) Epinephrine _____	9. Prepares glucose 1-phosphate for glycolysis
		(j) Glucagon _____	10. Phosphorylates phosphorylase kinase

3. *Choice is good.* Glycogen is not as reduced as fatty acids are and consequently not as energy rich. Why do animals store any energy as glycogen? Why not convert all excess fuel into fatty acids?

4. *If a little is good, a lot is better.*  $\alpha$ -Amylose is an unbranched glucose polymer. Why would this polymer not be as effective a storage form of glucose as glycogen?

5. *Telltale products.* A sample of glycogen from a patient with liver disease is incubated with orthophosphate, phosphorylase, the transferase, and the debranching enzyme ( $\alpha$ -1,6-glucosidase). The ratio of glucose 1-phosphate to glucose formed in this mixture is 100. What is the most likely enzymatic deficiency in this patient?

6. *Dare to be different.* Compare the allosteric regulation of phosphorylase in the liver and in muscle, and explain the significance of the difference.

7. *A thumb on the balance.* The reaction catalyzed by phosphorylase is readily reversible in vitro. At pH 6.8, the equilibrium ratio of orthophosphate to glucose 1-phosphate is 3.6. The value of  $\Delta G^{\circ}$  for this reaction is small because a glycosidic bond is replaced by a phosphoryl ester bond that has a nearly equal transfer potential. However, phosphorylase proceeds far in the direction of glycogen breakdown in vivo. Suggest one means by which the reaction can be made irreversible in vivo.

8. *Excessive storage.* Suggest an explanation for the fact that the amount of glycogen in type I glycogen-storage disease (von Gierke disease) is increased.

9. *Recouping an essential phosphoryl.* The phosphoryl group on phosphoglucomutase is slowly lost by hydrolysis. Propose a mechanism that utilizes a known catalytic intermediate for restoring this essential phosphoryl group. How might this phosphoryl donor be formed?

10. *Not all absences are equal.* Hers disease results from an absence of liver glycogen phosphorylase and may result in serious illness. In McArdle disease, muscle glycogen phosphorylase is absent. Although exercise is difficult for patients suffering from McArdle disease, the disease is rarely life threatening. Account for the different manifestations of the absence of glycogen phosphorylase in the two tissues. What does the existence of these two different diseases indicate about the genetic nature of the phosphorylase?

11. *Hydrophobia.* Why is water excluded from the active site of phosphorylase? Predict the effect of a mutation that allows water molecules to enter.

12. *Removing all traces.* In human liver extracts, the catalytic activity of glycogenin was detectable only after treatment with  $\alpha$ -amylase, an enzyme that hydrolyzes

$\alpha$ -1,4-bonds in starch and glycogen. Why was  $\alpha$ -amylase necessary to reveal the glycogenin activity?

13. *Two in one.* A single polypeptide chain houses the transferase and debranching enzyme. Cite a potential advantage of this arrangement.

14. *How did they do that?* A strain of mice has been developed that lack the enzyme phosphorylase kinase. Yet, after strenuous exercise, the glycogen stores of a mouse of this strain are depleted. Explain how this depletion is possible.

15. *An appropriate inhibitor.* What is the rationale for the inhibition of muscle glycogen phosphorylase by glucose 6-phosphate when glucose 1-phosphate is the product of the phosphorylase reaction?

16. *Passing along the information.* Outline the signal-transduction cascade for glycogen degradation in muscle.

17. *Slammin' on the breaks.* There must be a way to shut down glycogen breakdown quickly to prevent the wasteful depletion of glycogen after energy needs have been met. What mechanisms are employed to turn off glycogen breakdown?

18. *Diametrically opposed.* Phosphorylation has opposite effects on glycogen synthesis and breakdown. What is the advantage of its having opposing effects?

19. *Feeling depleted.* Glycogen depletion resulting from intense, extensive exercise can lead to exhaustion and the inability to continue exercising. Some people also experience dizziness, an inability to concentrate, and a loss of muscle control. Account for these symptoms.

20. *Everyone had a job to do.* What accounts for the fact that liver phosphorylase is a glucose sensor, whereas muscle phosphorylase is not?

21. *Yin and Yang.* Match the terms on the left with the descriptions on the right.

- |   |  |
|---|--|
| (a) UDP-glucose _____                   | 1. Glucose 1-phosphate is one of its substrates.                 |
| (b) UDP-glucose pyrophosphorylase _____ | 2. Potent activator of glycogen synthase <i>b</i> .              |
| (c) Glycogen synthase _____             | 3. Glucose sensor in the liver.                                  |
| (d) Glycogenin _____                    | 4. Activated substrate for glycogen synthesis.                   |
| (e) Branching enzyme _____              | 5. Synthesizes $\alpha$ -1,4 linkages between glucose molecules. |
| (f) Glucose 6-phosphate _____           | 6. Leads to the inactivation of glycogen synthase kinase.        |
| (g) Glycogen synthase kinase _____      | 7. Synthesizes $\alpha$ -1,6 linkages between glucose molecules. |

 a \_\_\_\_\_
8. Catalyzes the formation of glycogen synthase *b*.  
 9. Catalyzes the formation of glycogen synthase *a*.  
 10. Provides the primer for glycogen synthesis.

22. *Team effort.* What enzymes are required for the synthesis of a glycogen particle starting from glucose 6-phosphate?

23. *Force it forward.* The following reaction accounts for the synthesis of UDP-glucose. This reaction is readily reversible. How is it made irreversible in vivo?

24. *If you insist.* Why does activation of the phosphorylated *b* form of glycogen synthase by high concentrations of glucose 6-phosphate make good biochemical sense?

25. *An ATP saved is an ATP earned.* The complete oxidation of glucose 6-phosphate derived from free glucose yields 30 molecules ATP, whereas the complete oxidation of glucose 6-phosphate derived from glycogen yields 31 molecules of ATP. Account for this difference.

26. *Dual roles.* Phosphoglucomutase is crucial for glycogen breakdown as well as for glycogen synthesis. Explain the role of this enzyme in each of the two processes.

27. *Working at cross-purposes.* Write a balanced equation showing the effect of simultaneous activation of glycogen phosphorylase and glycogen synthase. Include the reactions catalyzed by phosphoglucomutase and UDP-glucose pyrophosphorylase.

28. *Achieving immortality.* Glycogen synthase requires a primer. A primer was formerly thought to be provided when the existing glycogen granules are divided between the daughter cells produced by cell division. In other words, parts of the original glycogen molecule were simply passed from generation to generation. Would this strategy have been successful in passing glycogen stores from generation to generation? How are new glycogen molecules now known to be synthesized?

29. *Synthesis signal.* How does insulin stimulate glycogen synthesis?

### Mechanism Problem

30. *Family resemblance.* Enzymes of the  $\alpha$ -amylase family (problem 12) catalyze a reaction by forming a covalent intermediate to a conserved aspartate residue. Propose mechanisms for the two enzymes catalyzing steps in glycogen debranching on the basis of their potential membership in the  $\alpha$ -amylase family.

### Chapter Integration Problems

31. *Double activation.* What pathway in addition to the cAMP-induced signal transduction pathway is used in the liver to maximize glycogen breakdown?

32. *Carbohydrate conversion.* Write a balanced equation for the formation of glycogen from galactose.

33. *Working together.* What enzymes are required for the liver to release glucose into the blood when an organism is asleep and fasting?

34. *A shattering experience.* Crystals of phosphorylase *a* grown in the presence of glucose shatter when a substrate such as glucose 1-phosphate is added. Why?

35. *I know I've seen that face before.* UDP-glucose is the activated form of glucose used in glycogen synthesis. However, we have previously met other similar activated forms of carbohydrate in our consideration of metabolism. Where else have we seen UDP-carbohydrate?

36. *Same symptoms, different cause.* Suggest another mutation in glucose metabolism that causes symptoms similar to those of von Gierke disease.

### Data Interpretation Problems

37. *An authentic replica.* Experiments were performed in which serine (S) 14 of glycogen phosphorylase was replaced by glutamate (E). The  $V_{\max}$  of the mutant enzyme was then compared with the wild type phosphorylase in both the *a* and the *b* form.

	$V_{\max}$ $\mu\text{moles of glucose 1-PO}_4 \text{ released min}^{-1} \text{ mg}^{-1}$
Wild type phosphorylase <i>b</i>	$25 \pm 0.4$
Wild type phosphorylase <i>a</i>	$100 \pm 5$
S to E mutant	$60 \pm 3$

(a) Explain the results obtained with the mutant.

(b) Predict the effect of substituting aspartic acid for the serine.

38. *Glycogen isolation 1.* The liver is a major storage site for glycogen. Purified from two samples of human liver, glycogen was either treated or not treated with  $\alpha$ -amylase and subsequently analyzed by SDS-PAGE and western blotting with the use of antibodies to glycogenin. The results are presented in the adjoining illustration on the next page.

(a) Why are no proteins visible in the lanes without amylase treatment?

(b) What is the effect of treating the samples with  $\alpha$ -amylase? Explain the results.

(c) List other proteins that you might expect to be associated with glycogen. Why are other proteins not visible?

39. *Glycogen isolation 2.* The gene for glycogenin was transfected into a cell line that normally stores only small amounts of glycogen. The cells were then manipulated according to the following protocol, and glycogen was isolated and analyzed by SDS-PAGE and western blotting by using an antibody to glycogenin with and without  $\alpha$ -amylase treatment. The results are presented in the adjoining illustration.

[Courtesy of Dr. Peter J. Roach, Indiana University School of Medicine.]

The protocol: Cells cultured in growth medium and 25 mM glucose (lane 1) were switched to medium containing no glucose for 24 hours (lane 2). Glucose-starved cells were refed with medium containing 25 mM glucose for 1 hour (lane 3) or 3 hours (lane 4). Samples (12  $\mu$ g of protein) were either treated or not treated with  $\alpha$ -amylase, as indicated, before being loaded on the gel.

- Why did the western analysis produce a “smear”—that is, the high-molecular-weight staining in lane 1(–)?
- What is the significance of the decrease in high-molecular-weight staining in lane 2(–)?
- What is the significance of the difference between lanes 2(–) and 3(–)?
- Suggest a plausible reason why there is essentially no difference between lanes 3(–) and 4(–).
- Why are the bands at 66 kDa the same in the lanes treated with amylase, despite the fact that the cells were treated differently?

## Fatty Acid Metabolism

Fats provide efficient means for storing energy for later use. (Right) The processes of fatty acid synthesis (preparation for energy storage) and fatty acid degradation (preparation for energy use) are, in many ways, the reverse of each other. (Above) Studies of mice are revealing the interplay between these pathways and the biochemical bases of appetite and weight control. ## OUTLINE

- 22.1 Triacylglycerols Are Highly Concentrated Energy Stores
- 22.2 The Use of Fatty Acids as Fuel Requires Three Stages of Processing
- 22.3 Unsaturated and Odd-Chain Fatty Acids Require Additional Steps for Degradation
- 22.4 Fatty Acids Are Synthesized by Fatty Acid Synthase
- 22.5 The Elongation and Unsaturation of Fatty Acids Are Accomplished by Accessory Enzyme Systems
- 22.6 Acetyl CoA Carboxylase Plays a Key Role in Controlling Fatty Acid Metabolism

We turn now from the metabolism of carbohydrates to that of fatty acids. A fatty acid contains a long hydrocarbon chain and a terminal carboxylate group. Fatty acids have four major physiological roles. First, *fatty acids are fuel molecules*. They are stored as *triacylglycerols* (also called *neutral fats* or *triglycerides*), which are uncharged esters of fatty acids with glycerol. Triacylglycerols are stored in adipose tissue, composed of cells called adipocytes (Figure 22.1). Fatty acids mobilized from triacylglycerols are oxidized to meet the energy needs of a cell or organism. During rest or moderate exercise, such as walking, fatty acids are our primary source of energy. Second, *fatty acids are building blocks of phospholipids and glycolipids*. These amphipathic molecules are important components of biological membranes, as discussed in Chapter 12. Third, many proteins are modified by the *covalent attachment of fatty acids, which targets the proteins to membrane locations* (Section 12.4). Fourth, *fatty acid derivatives serve as hormones and intracellular messengers*. In this chapter, we focus on the degradation and synthesis of fatty acids.

**FIGURE 22.1** Electron micrograph of an adipocyte. A small band of cytoplasm surrounds the large deposit of triacylglycerols. [Biophoto Associates/Photo Researchers.]

## Fatty acid degradation and synthesis mirror each other in their chemical reactions

Fatty acid degradation and synthesis consist of four steps that are the reverse of each other in their basic chemistry. Degradation is an oxidative process that converts a fatty acid into a set of activated acetyl units (acetyl CoA) that can be processed by the citric acid cycle (Figure 22.2). An activated fatty acid is oxidized to introduce a double bond; the double bond is hydrated to introduce a hydroxyl group; the alcohol is oxidized to a ketone; and, finally, the fatty acid is cleaved by coenzyme A to yield acetyl CoA and a fatty acid chain two carbons shorter. If the fatty acid has an even number of carbon atoms and is saturated, the process is simply repeated until the fatty acid is completely converted into acetyl CoA units.

Fatty acid synthesis is essentially the reverse of this process. The process starts with the individual units to be assembled—in this case, with an activated acyl group (most simply, an acetyl unit) and a malonyl unit (Figure 22.2). The malonyl unit condenses with the acetyl unit to form a four-carbon fragment. To produce the required hydrocarbon chain, the carbonyl group is reduced to a methylene group in three steps: a reduction,

**FIGURE 22.2** Steps in fatty acid degradation and synthesis. The two processes are in many ways mirror images of each other.

a dehydration, and another reduction, exactly the opposite of degradation. The product of the reduction is butyryl CoA. Another activated malonyl group condenses with the butyryl unit, and the process is repeated until a  $C_{16}$  or shorter fatty acid is synthesized.

## 22.1 Triacylglycerols Are Highly Concentrated Energy Stores

Triacylglycerols are highly concentrated stores of metabolic energy because they are *reduced* and *anhydrous*. The yield from the complete oxidation of fatty acids is about  $38 \text{ kJ g}^{-1}$  ( $9 \text{ kcal g}^{-1}$ ), in contrast with about  $17 \text{ kJ g}^{-1}$  ( $4 \text{ kcal g}^{-1}$ ) for carbohydrates and proteins. The basis of this large difference in caloric yield is that fatty acids are much more reduced than carbohydrates or proteins. Furthermore, triacylglycerols are nonpolar, and so they are stored in a nearly anhydrous form, whereas much more polar carbohydrates are more highly hydrated. In fact, 1 g of dry glycogen binds about 2 g of water. Consequently, *a gram of nearly anhydrous fat stores 6.75 times as much energy as a gram of hydrated glycogen*, which is likely the reason that triacylglycerols rather than glycogen were selected in evolution as the major energy reservoir. Consider a typical 70-kg man, who has fuel reserves of 420,000 kJ (100,000 kcal) in triacylglycerols, 100,000 kJ (24,000 kcal) in protein (mostly in muscle), 2500 kJ (600 kcal) in glycogen, and 170 kJ (40 kcal) in glucose. Triacylglycerols constitute about 11 kg of his total body weight. If this amount of energy were stored in glycogen, his total body weight would be 64 kg greater. The glycogen and glucose stores provide enough energy to sustain physiological function for about 24 hours, whereas the triacylglycerol stores allow survival for several weeks.

In mammals, the major site of triacylglycerol accumulation is the cytoplasm of *adipose cells* (*fat cells*). This fuel-rich tissue is located throughout the body, notably under the skin (subcutaneous fat) and surrounding the internal organs (visceral fat). Droplets of triacylglycerol coalesce to form a large globule, called a *lipid droplet*, which may occupy most of the cell volume (Figure 22.1). The lipid droplet is surrounded by a monolayer of phospholipids and numerous proteins required for triacylglycerol metabolism. Originally believed to be inert-lipid deposits, lipid droplets are now understood to be dynamic organelles essential for the regulation of lipid metabolism. Adipose cells are specialized for the synthesis and storage of triacylglycerols and for their mobilization into fuel molecules that are transported to other tissues by the blood. Muscle also stores triacylglycerols for its own energy needs. Indeed, triacylglycerols are evident as the “marbling” of expensive cuts of beef.

The utility of triacylglycerols as an energy source is dramatically illustrated by the abilities of migratory birds, which can fly great distances without eating after having stored energy as triacylglycerols. Examples are the American golden plover and the ruby-throated hummingbird. The golden plover flies from Alaska to the southern tip of South America; a large segment of the flight (3800 km, or 2400 miles) is over open ocean, where the birds cannot feed. The ruby-throated hummingbird flies nonstop across the Gulf of Mexico. Fatty acids provide the energy source for both these prodigious feats.

Triacylglycerols fuel the long migration flights of the American golden plover (*Pluvialis dominica*). [Source: Jim Zipp/Science Source.]

### Dietary lipids are digested by pancreatic lipases

Most lipids are ingested in the form of triacylglycerols and must be degraded to fatty acids for absorption across the intestinal epithelium. Intestinal enzymes called *lipases*, secreted by the pancreas, degrade triacylglycerols to

**FIGURE 22.3 Action of pancreatic lipases.** Lipases secreted by the pancreas convert triacylglycerols into fatty acids and monoacylglycerol for absorption into the intestine.

**FIGURE 22.4 Glycocholate.** Bile acids, such as glycocholate, facilitate lipid digestion in the intestine.

free fatty acids and monoacylglycerol (Figure 22.3). Lipids present a special problem because, unlike carbohydrates and proteins, these molecules are not soluble in water. They exit the stomach as an emulsion, particles with a triacylglycerol core surrounded by cholesterol and cholesterol esters. How are the lipids made accessible to the lipases, which are in aqueous solution? First, the particles are coated with *bile acids* (Figure 22.4), amphipathic molecules synthesized from cholesterol in the liver and secreted from the gallbladder. The ester bonds of each lipid are oriented toward the surface of the bile salt-coated particle, rendering the bond more accessible to digestion by lipases in aqueous solution. However, in this form, the particles are still not substrates for digestion. The protein colipase (another pancreatic secretory product) must bind the lipase to the particle to permit lipid degradation. The final digestion products are carried in micelles to the intestinal epithelium where they are transported across the plasma membrane (Figure 22.5). If the production of bile salts is inadequate due to liver disease, large amounts of fats (as much as  $30 \text{ g day}^{-1}$ ) are excreted in the feces. This condition is referred to as *steatorrhea*, after stearic acid, a common fatty acid.

### Dietary lipids are transported in chylomicrons

In the intestinal mucosal cells, the triacylglycerols are resynthesized from fatty acids and monoacylglycerols and then packaged into lipoprotein transport particles called *chylomicrons*, stable particles approximately  $2000 \text{ \AA}$  (200 nm) in diameter (Figure 22.5). These particles are composed mainly of triacylglycerols, with apolipoprotein B-48 (apo B-48) as the main protein component. Protein constituents of lipoprotein particles are called *apolipoproteins*. Chylomicrons also transport fat-soluble vitamins and cholesterol.

The chylomicrons are released into the lymph system and then into the blood. These particles bind to membrane-bound lipases, primarily at adipose tissue and muscle, where the triacylglycerols are once again degraded into

**FIGURE 22.5 Chylomicron formation.** Free fatty acids and monoacylglycerols are absorbed by intestinal epithelial cells. Triacylglycerols are resynthesized and packaged with other lipids and apolipoprotein B-48 to form chylomicrons, which are then released into the lymph system.

free fatty acids and monoacylglycerol for transport into the tissue. The triacylglycerols are then resynthesized inside the cell and stored. In the muscle, they can be oxidized to provide energy.

## 22.2 The Use of Fatty Acids as Fuel Requires Three Stages of Processing

Tissues throughout the body gain access to the lipid energy reserves stored in adipose tissue through three stages of processing. First, the lipids must be mobilized. In this process, triacylglycerols are degraded to fatty acids and glycerol, which are released from the adipose tissue and transported to the energy-requiring tissues. Second, at these tissues, the fatty acids must be activated and transported into mitochondria for degradation. Third, the fatty acids are broken down in a step-by-step fashion into acetyl CoA, which is then processed in the citric acid cycle.

### Triacylglycerols are hydrolyzed by hormone-stimulated lipases

Consider someone who has just awakened from a night's sleep and begins a bout of exercise. Glycogen stores will be low, but lipids are readily available. How are these lipid stores mobilized?

Before fats can be used as fuels, the triacylglycerol storage form must be hydrolyzed to yield isolated fatty acids. This reaction is catalyzed by a hormonally controlled lipase. Under the physiological conditions facing an early-morning runner, glucagon and epinephrine will be present. In adipose tissue, these hormones trigger 7 TM receptors that activate adenylate cyclase (Section 14.1). The increased level of cyclic AMP then stimulates protein kinase A, which phosphorylates two key proteins: *perilipin*, a fat-droplet-associated protein, and hormone-sensitive lipase (Figure 22.6). The phosphorylation of perilipin has two crucial effects. First, it restructures the fat droplet so that the triacylglycerols are more accessible to the mobilization. Second, the phosphorylation of perilipin triggers the release of a coactivator for *adipose triglyceride lipase* (ATGL). Once bound to the coactivator, ATGL initiates the mobilization of triacylglycerols by releasing a fatty acid from triacylglycerol, forming diacylglycerol. Diacylglycerol is converted into a free fatty acid and

**FIGURE 22.6 Mobilization of triacylglycerols.** Triacylglycerols in adipose tissue are converted into free fatty acids in response to hormonal signals. 1. The hormones activate protein kinase A through the cAMP cascade. 2. Protein kinase A phosphorylates perilipin, resulting in the restructuring of the lipid droplet and release of the coactivator of ATGL, thereby activating ATGL. 3. ATGL converts triacylglycerol into diacylglycerol. 4. Hormone-sensitive lipase releases a fatty acid from diacylglycerol, generating monoacylglycerol. 5. Monoacylglycerol lipase completes the mobilization process. Abbreviations: 7TM, seven transmembrane receptor; ATGL, adipose triglyceride lipase; CA, coactivator; HS lipase, hormone-sensitive lipase; MAG lipase, monoacylglycerol lipase; DAG, diacylglycerol; TAG, triacylglycerol.

monoacylglycerol by the hormone-sensitive lipase. Finally, a monoacylglycerol lipase completes the mobilization of fatty acids with the production of a free fatty acid and glycerol. Thus, *epinephrine and glucagon induce lipolysis*. Although their role in muscle is not as firmly established, these hormones probably also regulate the use of triacylglycerol stores in that tissue.

If the coactivator required by ATGL is missing or defective, a rare condition (incidence unknown) called Chanarin-Dorfman syndrome results. Fats accumulate throughout the body because they cannot be released by ATGL. Other symptoms include dry skin (ichthyosis), enlarged liver, muscle weakness, and mild cognitive disability.

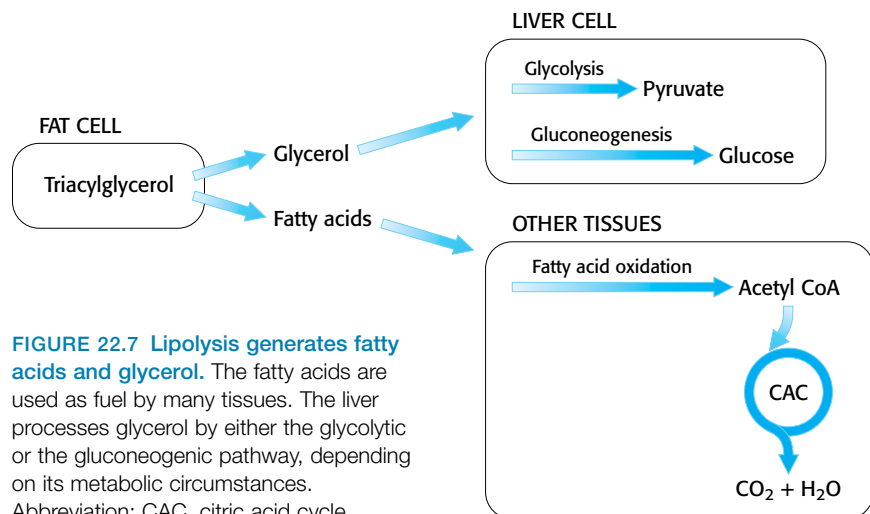

### Free fatty acids and glycerol are released into the blood

Fatty acids are not soluble in aqueous solutions. In order to reach tissues that require fatty acids, the released fatty acids bind to the blood protein albumin, which delivers them to tissues in need of fuel.

Glycerol formed by lipolysis is absorbed by the liver and phosphorylated. It is then oxidized to dihydroxyacetone phosphate, which is isomerized to glyceraldehyde 3-phosphate. This molecule is an intermediate in both the glycolytic and the gluconeogenic pathways.

Hence, glycerol can be converted into pyruvate or glucose in the liver, which contains the appropriate enzymes (Figure 22.7). The reverse process can take place by the reduction of dihydroxyacetone phosphate to glycerol 3-phosphate. Hydrolysis by a phosphatase then gives glycerol. Thus, glycerol and glycolytic intermediates are readily interconvertible.

**FIGURE 22.7 Lipolysis generates fatty acids and glycerol.** The fatty acids are used as fuel by many tissues. The liver processes glycerol by either the glycolytic or the gluconeogenic pathway, depending on its metabolic circumstances. Abbreviation: CAC, citric acid cycle.

### Fatty acids are linked to coenzyme A before they are oxidized

Fatty acids separate from the albumin in the blood stream and diffuse across the cell membrane with the assistance of transport proteins. In the cell, fatty acids are shuttled about in association with fatty-acid-binding-proteins.

Fatty acid oxidation occurs in the mitochondrial matrix, but in order to enter the mitochondria, the fatty acids are first activated through the formation of a thioester linkage to coenzyme A. Adenosine triphosphate (ATP) drives the formation of the thioester linkage between the carboxyl group of a fatty acid and the sulfhydryl group of coenzyme A. This activation reaction takes place on the outer mitochondrial membrane, where it is catalyzed by *acyl CoA synthetase* (also called *fatty acid thiokinase*).

Acyl CoA synthetase accomplishes the activation of a fatty acid in two steps. First, the fatty acid reacts with ATP to form an *acyl adenylate*. In this mixed anhydride, the carboxyl group of a fatty acid is bonded to the phosphoryl group of AMP. The other two phosphoryl groups of the ATP substrate are released as pyrophosphate. In the second step, the sulfhydryl group of coenzyme A attacks the acyl adenylate, which is tightly bound to the enzyme, to form acyl CoA and AMP.

These partial reactions are freely reversible. In fact, the equilibrium constant for the sum of these reactions is close to 1. One high-transfer-potential compound is cleaved (between  $\text{PP}_i$  and AMP) and one high-transfer-potential compound is formed (the thioester acyl CoA). How is the overall reaction driven forward? The answer is that pyrophosphate is rapidly hydrolyzed by a pyrophosphatase. The complete reaction is

This reaction is quite favorable because the equivalent of two molecules of ATP is hydrolyzed, whereas only one high-transfer-potential compound is formed. We see here another example of a recurring theme in biochemistry: *Many biosynthetic reactions are made irreversible by the hydrolysis of inorganic pyrophosphate.*

Another motif recurs in this activation reaction. The enzyme-bound acyl adenylate intermediate is not unique to the synthesis of acyl CoA. *Acyl adenylates are frequently formed when carboxyl groups are activated in biochemical reactions.* Amino acids are activated for protein synthesis by a similar mechanism (Section 30.2), although the enzymes that catalyze this process are not homologous to acyl CoA synthetase. Thus, *activation by adenylation recurs in part because of convergent evolution.*

### Carnitine carries long-chain activated fatty acids into the mitochondrial matrix

Fatty acids are activated on the outer mitochondrial membrane, whereas they are oxidized in the mitochondrial matrix. A special transport

mechanism is needed to carry activated long-chain fatty acids across the inner mitochondrial membrane. These fatty acids must be conjugated to *carnitine*, an alcohol with both a positive and a negative charge (a zwitterion). The acyl group is transferred from the sulfur atom of coenzyme A to the hydroxyl group of carnitine to form *acyl carnitine*. This reaction is catalyzed by *carnitine acyltransferase I*, also called *carnitine palmitoyl transferase I*, which is bound to the outer mitochondrial membrane.

**FIGURE 22.8** Acyl carnitine translocase.

The entry of acyl carnitine into the mitochondrial matrix is mediated by a translocase. Carnitine returns to the cytoplasmic side of the inner mitochondrial membrane in exchange for acyl carnitine.

Acyl carnitine is then shuttled across the inner mitochondrial membrane by a translocase (Figure 22.8). The acyl group is transferred back to coenzyme A on the matrix side of the membrane. This reaction, which is catalyzed by *carnitine acyltransferase II* (*carnitine palmitoyl transferase II*), is simply the reverse of the reaction that takes place in the cytoplasm. The reaction is thermodynamically feasible because of the zwitterionic nature of carnitine. The *O*-acyl link in carnitine has a high group-transfer potential, apparently because, being zwitterions, carnitine and its esters are solvated differently from most other alcohols and their esters. Finally, the translocase returns carnitine to the cytoplasmic side in exchange for an incoming acyl carnitine.

A number of diseases have been traced to a deficiency of carnitine, the transferase, or the translocase. Inability to synthesize carnitine may be a contributing factor to the development of autism in males. The symptoms of carnitine deficiency range from mild muscle cramping to severe weakness and even death. In general, muscle, kidney, and heart are the tissues primarily impaired. Muscle weakness during prolonged exercise is a symptom of a deficiency of carnitine acyltransferases because muscle relies on fatty acids as a long-term source of energy. Medium-chain ( $C_8$ – $C_{10}$ ) fatty acids are oxidized normally in these patients because these fatty acids can enter the mitochondria, to some degree, in the absence of carnitine. These diseases illustrate that *the impaired flow of a metabolite from one compartment of a cell to another can lead to a pathological condition*.

### Acetyl CoA, NADH, and FADH<sub>2</sub> are generated in each round of fatty acid oxidation

A saturated acyl CoA is degraded by a recurring sequence of four reactions: oxidation by flavin adenine dinucleotide (FAD), hydration, oxidation by NAD<sup>+</sup>, and thiolysis by coenzyme A (Figure 22.9). The fatty acid chain is shortened by two carbon atoms as a result of these reactions and FADH<sub>2</sub>, NADH, and acetyl CoA are generated. Because oxidation takes place at the  $\beta$  carbon atom, this series of reactions is called the  $\beta$ -oxidation pathway.

The first reaction in each round of degradation is the *oxidation* of acyl CoA by an *acyl CoA dehydrogenase* to give an enoyl CoA with a *trans* double bond between C-2 and C-3.

As in the dehydrogenation of succinate in the citric acid cycle, FAD rather than NAD<sup>+</sup> is the electron acceptor because the  $\Delta G$  for this reaction is

insufficient to drive the reduction of  $\text{NAD}^+$ . Electrons from the  $\text{FADH}_2$  prosthetic group of the reduced acyl CoA dehydrogenase are transferred to a second flavoprotein called *electron-transferring flavoprotein (ETF)*. In turn, ETF donates electrons to *ETF: ubiquinone reductase*, an iron-sulfur protein. Ubiquinone is thereby reduced to ubiquinol, which delivers its high-potential electrons to the second proton-pumping site of the respiratory chain (Section 18.3). Consequently, 1.5 molecules of ATP are generated per molecule of  $\text{FADH}_2$  formed in this dehydrogenation step, as in the oxidation of succinate to fumarate.

The next step is the *hydration* of the double bond between C-2 and C-3 by *enoyl CoA hydratase*.

The hydration of enoyl CoA is stereospecific. Only the L isomer of 3-hydroxyacyl CoA is formed when the *trans-Δ<sup>2</sup>* double bond is hydrated. The enzyme also hydrates a *cis-Δ<sup>2</sup>* double bond, but the product then is the D isomer. We shall return to this point shortly in considering how unsaturated fatty acids are oxidized.

The hydration of enoyl CoA is a prelude to the second *oxidation* reaction, which converts the hydroxyl group at C-3 into a keto group and generates NADH. This oxidation is catalyzed by *L-3-hydroxyacyl CoA dehydrogenase*, which is specific for the L isomer of the hydroxyacyl substrate.

The preceding reactions have oxidized the methylene group at C-3 to a keto group. The final step is the *cleavage* of 3-ketoacyl CoA by the thiol group of a second molecule of coenzyme A, which yields acetyl CoA and an acyl CoA shortened by two carbon atoms. This thiolytic cleavage is catalyzed by *β-ketothiolase*.

Table 22.1 summarizes the reactions in fatty acid oxidation.

The shortened acyl CoA then undergoes another cycle of oxidation, starting with the reaction catalyzed by acyl CoA dehydrogenase

**FIGURE 22.9** Reaction sequence for the degradation of fatty acids. Fatty acids are degraded by the repetition of a four-reaction sequence consisting of oxidation, hydration, oxidation, and thiolysis.

**TABLE 22.1** Principal reactions in fatty acid oxidation

Step	Reaction	Enzyme
1	$\text{Fatty acid} + \text{CoA} + \text{ATP} \rightleftharpoons \text{acyl CoA} + \text{AMP} + \text{PP}_i$	Acyl CoA synthetase (also called fatty acid thiokinase and fatty acid:CoA ligase)*
2	$\text{Carnitine} + \text{acyl CoA} \rightleftharpoons \text{acyl carnitine} + \text{CoA}$	Carnitine acyltransferase (also called carnitine palmitoyl transferase)
3	$\text{Acyl CoA} + \text{E-FAD} \longrightarrow \text{trans-}\Delta^2\text{-enoyl CoA} + \text{E-FADH}_2$	Acyl CoA dehydrogenases (several isozymes having different chain-length specificity)
4	$\text{trans-}\Delta^2\text{-Enoyl CoA} + \text{H}_2\text{O} \rightleftharpoons \text{L-3-hydroxyacyl CoA}$	Enoyl CoA hydratase (also called crotonase or 3-hydroxyacyl CoA hydrolyase)
5	$\text{L-3-Hydroxyacyl CoA} + \text{NAD}^+ \rightleftharpoons \text{3-ketoacyl CoA} + \text{NADH} + \text{H}^+$	L-3-Hydroxyacyl CoA dehydrogenase
6	$\text{3-Ketoacyl CoA} + \text{CoA} \rightleftharpoons \text{acetyl CoA} + \text{acyl CoA (shortened by C}_2\text{)}$	β-Ketothiolase (also called thiolase)

\*An AMP-forming ligase.

**FIGURE 22.10** First three rounds in the degradation of palmitate. Two-carbon units are sequentially removed from the carboxyl end of the fatty acid.

**FIGURE 22.11** The degradation of a monounsaturated fatty acid. *Cis*- $\Delta^3$ -Enoyl CoA isomerase allows continued  $\beta$ -oxidation of fatty acids with a single double bond.

(Figure 22.10). Fatty acid chains containing from 12 to 18 carbon atoms are oxidized by the long-chain acyl CoA dehydrogenase. The medium-chain acyl CoA dehydrogenase oxidizes fatty acid chains having from 14 to 4 carbons, whereas the short-chain acyl CoA dehydrogenase acts only on 4- and 6-carbon fatty acid chains. In contrast,  $\beta$ -ketothiolase, hydroxyacyl dehydrogenase, and enoyl CoA hydratase act on fatty acid molecules of almost any length.

### The complete oxidation of palmitate yields 106 molecules of ATP

We can now calculate the energy yield derived from the oxidation of a fatty acid. In each reaction cycle, an acyl CoA is shortened by two carbon atoms, and one molecule each of  $\text{FADH}_2$ ,  $\text{NADH}$ , and acetyl CoA are formed.

The degradation of palmitoyl CoA ( $\text{C}_{16}$ -acyl CoA) requires seven reaction cycles. In the seventh cycle, the  $\text{C}_4$ -ketoacyl CoA is thiolized to two molecules of acetyl CoA. Hence, the stoichiometry of the oxidation of palmitoyl CoA is

Approximately 2.5 molecules of ATP are generated when the respiratory chain oxidizes each of these  $\text{NADH}$  molecules, whereas 1.5 molecules of ATP are formed for each  $\text{FADH}_2$  because their electrons enter the chain at the level of ubiquinol. Recall that the oxidation of acetyl CoA by the citric acid cycle yields 10 molecules of ATP. Hence, the number of ATP molecules formed in the oxidation of palmitoyl CoA is 10.5 from the seven  $\text{FADH}_2$ , 17.5 from the seven  $\text{NADH}$ , and 80 from the eight acetyl CoA molecules, which gives a total of 108. The equivalent of 2 molecules of ATP is consumed in the activation of palmitate, in which ATP is split into AMP and 2 molecules of orthophosphate. Thus, *the complete oxidation of a molecule of palmitate yields 106 molecules of ATP.*

## 22.3 Unsaturated and Odd-Chain Fatty Acids Require Additional Steps for Degradation

The  $\beta$ -oxidation pathway accomplishes the complete degradation of saturated fatty acids having an even number of carbon atoms. Most fatty acids have such structures because of their mode of synthesis (to be addressed later in this chapter). However, not all fatty acids are so simple. The oxidation of fatty acids containing double bonds requires additional steps, as does the oxidation of fatty acids containing an odd number of carbon atoms.

### An isomerase and a reductase are required for the oxidation of unsaturated fatty acids

The oxidation of unsaturated fatty acids presents some difficulties, yet many such fatty acids are available in the diet. Most of the reactions are the same as those for saturated fatty acids. In fact, only two additional enzymes—an isomerase and a reductase—are needed to degrade a wide range of unsaturated fatty acids.

Consider the oxidation of palmitoleate (Figure 22.11). This  $\text{C}_{16}$  unsaturated fatty acid, which has one double bond between C-9 and C-10,

FIGURE 22.12 Oxidation of linoleoyl CoA.

The complete oxidation of the diunsaturated fatty acid linoleate is facilitated by the activity of enoyl CoA isomerase and 2,4-dienoyl CoA reductase.

is activated and transported across the inner mitochondrial membrane in the same way as saturated fatty acids are. Palmitoleoyl CoA then undergoes three cycles of degradation, which are carried out by the same enzymes as those in the oxidation of saturated fatty acids. However, the *cis*- $\Delta^3$ -enoyl CoA formed in the third round is not a substrate for acyl CoA dehydrogenase. The presence of a double bond between C-3 and C-4 prevents the formation of another double bond between C-2 and C-3. This impasse is resolved by a new reaction that shifts the position and configuration of the *cis*- $\Delta^3$  double bond. *cis*- $\Delta^3$ -Enoyl CoA isomerase converts this double bond into a *trans*- $\Delta^2$  double bond. The double bond is now between C-2 and C-3. The subsequent reactions are those of the saturated fatty acid oxidation pathway, in which the *trans*- $\Delta^2$ -enoyl CoA is a regular substrate.

Human beings require polyunsaturated fatty acids, which have multiple double bonds, as important precursors for signal molecules, but excess polyunsaturated fatty acids are degraded by  $\beta$  oxidation. However, another problem arises with the oxidation of polyunsaturated fatty acids. Consider linoleate, a  $\text{C}_{18}$  polyunsaturated fatty acid with *cis*- $\Delta^9$  and *cis*- $\Delta^{12}$  double bonds (Figure 22.12). The *cis*- $\Delta^3$  double bond (between carbons 3 and 4) formed after three rounds of  $\beta$ -oxidation is converted into a *trans*- $\Delta^2$  double bond (between carbons 2 and 3) by the aforementioned isomerase. The acyl CoA produced by another round of  $\beta$ -oxidation contains a *cis*- $\Delta^4$  (between carbons 4 and 5) double bond. Dehydrogenation of this species by acyl CoA dehydrogenase yields a 2,4-dienoyl intermediate (double bond between carbons 2 and 3 and carbons 4 and 5), which is not a substrate for the next enzyme in the  $\beta$ -oxidation pathway. This impasse is circumvented by 2,4-dienoyl CoA reductase, an enzyme that uses

NADPH to reduce the 2,4-dienoyl intermediate to *trans*- $\Delta^3$ -enoyl CoA. *cis*- $\Delta^3$ -Enoyl CoA isomerase then converts *trans*- $\Delta^3$ -enoyl CoA into the *trans*- $\Delta^2$  form, a customary intermediate in the  $\beta$ -oxidation pathway. These catalytic strategies are elegant and economical. Only two extra enzymes are needed for the oxidation of *any* polyunsaturated fatty acid. *Odd-numbered double bonds are handled by the isomerase, and even-numbered ones by the reductase and the isomerase.*

### Odd-chain fatty acids yield propionyl CoA in the final thiolysis step

Fatty acids having an odd number of carbon atoms are minor species. They are oxidized in the same way as fatty acids having an even number, except that propionyl CoA and acetyl CoA, rather than two molecules of acetyl CoA, are produced in the final round of degradation. The activated three-carbon unit in propionyl CoA enters the citric acid cycle after it has been converted into succinyl CoA.

The pathway from propionyl CoA to succinyl CoA is especially interesting because it entails a rearrangement that requires *vitamin B<sub>12</sub>* (also known as *cobalamin*). Propionyl CoA is carboxylated at the expense of the hydrolysis of a molecule of ATP to yield the D isomer of methylmalonyl CoA (Figure 22.13). This carboxylation reaction is catalyzed by *propionyl CoA carboxylase*, a biotin enzyme that has a catalytic mechanism like that of the homologous enzyme pyruvate carboxylase (Section 16.3). The D isomer of methylmalonyl CoA is racemized to the L isomer, the substrate for a mutase that converts it into *succinyl CoA* by an *intramolecular rearrangement*. The —CO—S—CoA group migrates from C-2 to a methyl group in exchange for a hydrogen atom. This very unusual isomerization is catalyzed by *methylmalonyl CoA mutase*, which contains a derivative of cobalamin as its coenzyme.

**FIGURE 22.13 Conversion of propionyl CoA into succinyl CoA.** Propionyl CoA, generated from fatty acids with an odd number of carbons as well as some amino acids, is converted into the citric acid cycle intermediate succinyl CoA.

### Vitamin B<sub>12</sub> contains a corrin ring and a cobalt atom

Cobalamin enzymes, which are present in most organisms, catalyze three types of reactions: (1) *intramolecular rearrangements*; (2) *methylations*, as in the synthesis of methionine; and (3) the *reduction of ribonucleotides to deoxyribonucleotides* (Section 25.3). In mammals, only two reactions are known to require coenzyme B<sub>12</sub>. The conversion of L-methylmalonyl CoA into succinyl CoA is one, and the formation of methionine by the methylation of homocysteine is the other (Section 24.2). The latter reaction is especially important because methionine is required for the generation of coenzymes that participate in the synthesis of purines and thymine, which are needed for nucleic acid synthesis.

The core of cobalamin consists of a *corrin ring with a central cobalt atom* (Figure 22.14). The corrin ring, like a porphyrin, has *four pyrrole units*. Two of them are directly bonded to each other, whereas the others are joined by methine bridges, as in porphyrins. The corrin ring is more reduced than that of porphyrins and the substituents are different. A cobalt atom is bonded to the four pyrrole nitrogens. The fifth substituent linked to the cobalt atom is

**FIGURE 22.14** Structure of coenzyme  $B_{12}$ . Coenzyme  $B_{12}$  is a class of molecules that vary, depending on the component designated X in the left-hand structure. 5'-Deoxyadenosylcobalamin is the form of the coenzyme in methylmalonyl mutase. Substitution of methyl and cyano groups for X creates methylcobalamin and, cyanocobalamin, respectively.

a derivative of *dimethylbenzimidazole* that contains ribose 3-phosphate and aminoisopropanol. One of the nitrogen atoms of dimethylbenzimidazole is linked to the cobalt atom. In coenzyme  $B_{12}$ , the sixth substituent linked to the cobalt atom is a 5'-deoxyadenosyl unit or a methyl group. This position can also be occupied by a cyano group. Cyanocobalamin is the form of the coenzyme administered to treat  $B_{12}$  deficiency. In all of these compounds, the cobalt is in the +3 oxidation state.

### Mechanism: Methylmalonyl CoA mutase catalyzes a rearrangement to form succinyl CoA

The rearrangement reactions catalyzed by coenzyme  $B_{12}$  are exchanges of two groups attached to adjacent carbon atoms of the substrate (Figure 22.15). A hydrogen atom migrates from one carbon atom to the next, and an R group (such as the  $-\text{CO}-\text{S}-\text{CoA}$  group of methylmalonyl CoA) concomitantly moves in the reverse direction. The first step in these intramolecular rearrangements is the cleavage of the carbon-cobalt bond of 5'-deoxyadenosylcobalamin to generate the  $\text{Co}^{2+}$  form of the coenzyme and a 5'-deoxyadenosyl radical,  $-\text{CH}_2\cdot$  (Figure 22.16). In this *homolytic cleavage reaction*, one electron of the  $\text{Co}-\text{C}$  bond stays with Co (reducing it from the +3 to the +2 oxidation state), whereas the other electron stays with the carbon atom, generating a free radical. In contrast, nearly all other cleavage reactions in biological systems are *heterolytic*: an electron pair is transferred to one of the two atoms that were bonded together.

What is the role of this very unusual  $-\text{CH}_2\cdot$  radical? This highly reactive species abstracts a hydrogen atom from the substrate to form

**FIGURE 22.15** Rearrangement reaction catalyzed by cobalamin enzymes. The R group can be an amino group, a hydroxyl group, or a substituted carbon.

**FIGURE 22.16** Formation of a 5'-deoxyadenosyl radical. The methylmalonyl CoA mutase reaction begins with the homolytic cleavage of the bond joining  $\text{Co}^{3+}$  of coenzyme  $B_{12}$  to a carbon atom of the ribose of the adenosine moiety of the enzyme. The cleavage generates a 5'-deoxyadenosyl radical and leads to the reduction of  $\text{Co}^{3+}$  to  $\text{Co}^{2+}$ . The letter R represents the 5'-deoxyadenosyl component of the coenzyme, and the green oval represents the remainder of the coenzyme.

**FIGURE 22.17 Formation of succinyl CoA by a rearrangement reaction.** A free radical abstracts a hydrogen atom in the rearrangement of methylmalonyl CoA to succinyl CoA.

5'-deoxyadenosine and a substrate radical (Figure 22.17). This substrate radical spontaneously rearranges: the carbonyl CoA group migrates to the position formerly occupied by H on the neighboring carbon atom to produce a different radical. This product radical abstracts a hydrogen atom from the methyl group of 5'-deoxyadenosine to complete the rearrangement and return the deoxyadenosyl unit to the radical form. *The role of coenzyme B<sub>12</sub> in such intramolecular migrations is to serve as a source of free radicals for the abstraction of hydrogen atoms.*

An essential property of coenzyme B<sub>12</sub> is the weakness of its cobalt–carbon bond, which is readily cleaved to generate a radical. To facilitate the cleavage of this bond, enzymes such as methylmalonyl CoA mutase displace the benzimidazole group from the cobalamin and bind to the cobalt atom through a histidine residue (Figure 22.18). The steric crowding around the cobalt–carbon bond within the corrin ring system contributes to the bond weakness.

### Fatty acids are also oxidized in peroxisomes

Although most fatty acid oxidation takes place in mitochondria, oxidation of long chain and branched fatty acids takes place in cellular organelles

**FIGURE 22.18 Active site of methylmalonyl CoA mutase.** Notice that a histidine residue from the enzyme binds to cobalt in place of benzimidazole. This arrangement of substrate and coenzyme in the active site facilitates the cleavage of the cobalt–carbon bond and the subsequent abstraction of a hydrogen atom from the substrate. [Drawn from 4REQ.pdb.]

called *peroxisomes* (Figure 22.19) (problems 17 and 44). These organelles are small membrane-bounded compartments that are present in the cells of most eukaryotes. Fatty acid oxidation in these organelles, which halts at octanoyl CoA, serves to shorten very long chains ( $C_{26}$ ) to make them better substrates of  $\beta$  oxidation in mitochondria. Peroxisomal oxidation differs from  $\beta$  oxidation in the initial dehydrogenation reaction (Figure 22.20). In peroxisomes, acyl CoA dehydrogenase, a flavoprotein, transfers electrons from the substrate to  $FADH_2$  and then to  $O_2$  to yield  $H_2O_2$  instead of capturing high-energy electrons as  $FADH_2$  for use in the electron-transport chain, as in mitochondrial  $\beta$  oxidation. Peroxisomes contain high concentrations of the enzyme catalase to degrade  $H_2O_2$  into water and  $O_2$ . Subsequent steps are identical with those of their mitochondrial counterparts, although they are carried out by different isoforms of the enzymes.

 Peroxisomes do not function in patients with Zellweger syndrome. Liver, kidney, and muscle abnormalities usually lead to death by age 6. The syndrome is caused by a defect in the import of enzymes into the peroxisomes. Here we see a pathological condition resulting from an inappropriate cellular distribution of enzymes.

**FIGURE 22.19 Electron micrograph of a peroxisome in a liver cell.** A crystal of urate oxidase is present inside the organelle, which is bounded by a single bilayer membrane. The dark granular structures outside the peroxisome are glycogen particles. [Courtesy of Dr. George Palade.]

**FIGURE 22.20 Initiation of peroxisomal fatty acid degradation.** The first dehydrogenation in the degradation of fatty acids in peroxisomes requires a flavoprotein dehydrogenase that transfers electrons from its  $FADH_2$  moiety to  $O_2$  to yield  $H_2O_2$ .

### Ketone bodies are formed from acetyl CoA when fat breakdown predominates

The acetyl CoA formed in fatty acid oxidation enters the citric acid cycle only if fat and carbohydrate degradation are appropriately balanced. Acetyl CoA must combine with oxaloacetate to gain entry to the citric acid cycle. The availability of oxaloacetate, however, depends on an adequate supply of carbohydrate. Recall that oxaloacetate is normally formed from pyruvate, the product of glucose degradation in glycolysis, by pyruvate carboxylase (Section 16.3). If carbohydrate is unavailable or improperly utilized, the concentration of oxaloacetate is lowered and acetyl CoA cannot enter the citric acid cycle. This dependency is the molecular basis of the adage that *fats burn in the flame of carbohydrates*.

In fasting or diabetes, oxaloacetate is consumed to form glucose by the gluconeogenic pathway (Section 16.3) and hence is unavailable for condensation with acetyl CoA. Under these conditions, acetyl CoA is diverted to the formation of acetoacetate and D-3-hydroxybutyrate. Acetoacetate, D-3-hydroxybutyrate, and acetone are often referred to as *ketone bodies*. Abnormally high levels of ketone bodies are present in the blood of untreated diabetics.

Acetoacetate is formed from acetyl CoA in three steps (Figure 22.21). Two molecules of acetyl CoA condense to form acetoacetyl CoA. This reaction, which is catalyzed by thiolase, is the reverse of the thiolysis step in the oxidation of fatty acids. Acetoacetyl CoA then reacts with acetyl

**FIGURE 22.21 Formation of ketone bodies.** The ketone bodies—acetoacetate, D-3-hydroxybutyrate, and acetone—are formed from acetyl CoA primarily in the liver. Enzymes catalyzing these reactions are (1) 3-ketothiolase, (2) hydroxymethylglutaryl CoA synthase, (3) hydroxymethylglutaryl CoA cleavage enzyme, and (4) D-3-hydroxybutyrate dehydrogenase. Acetoacetate spontaneously decarboxylates to form acetone.

CoA and water to give 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) and CoA. This condensation resembles the one catalyzed by citrate synthase (Section 17.2). This reaction, which has a favorable equilibrium owing to the hydrolysis of a thioester linkage, compensates for the unfavorable equilibrium in the formation of acetoacetyl CoA. 3-Hydroxy-3-methylglutaryl CoA is then cleaved to acetyl CoA and acetoacetate. The sum of these reactions is

D-3-Hydroxybutyrate is formed by the reduction of acetoacetate in the mitochondrial matrix by D-3-hydroxybutyrate dehydrogenase. The ratio of hydroxybutyrate to acetoacetate depends on the NADH/NAD<sup>+</sup> ratio inside mitochondria.

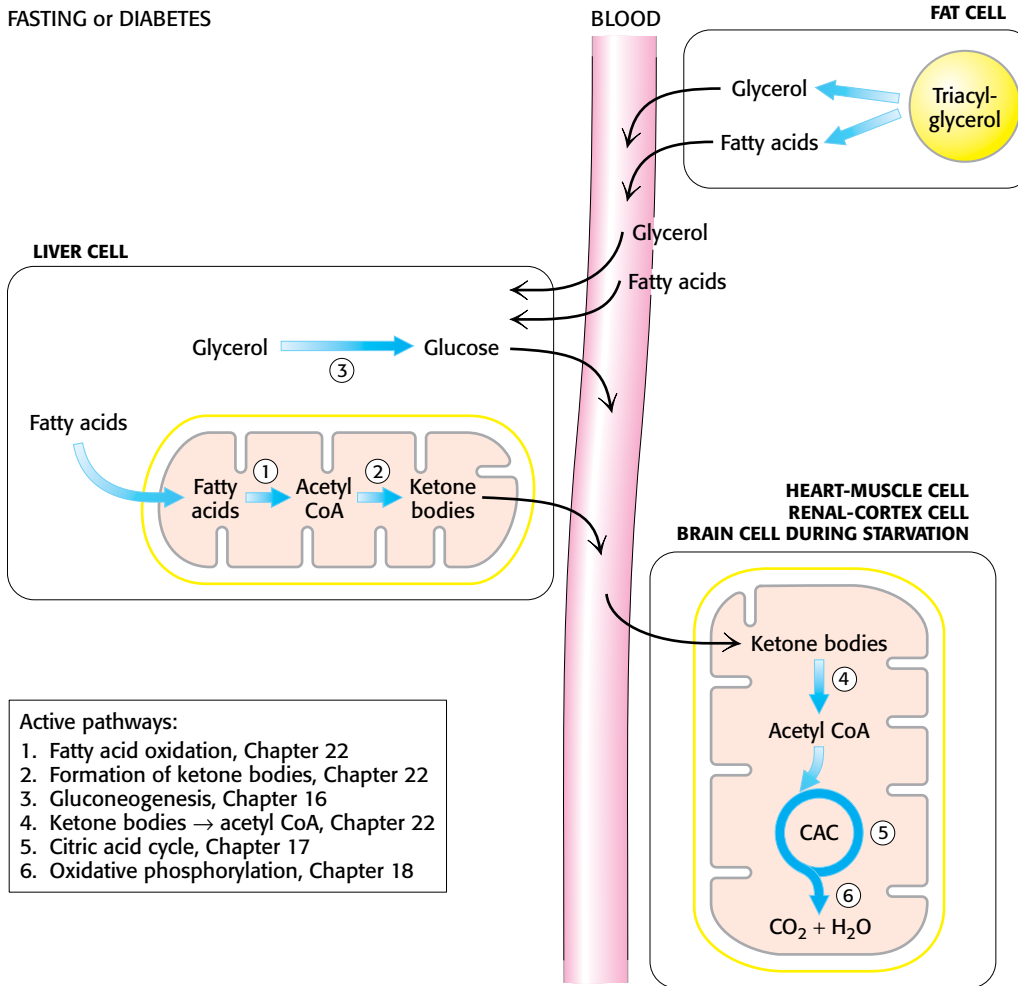

Because it is a β-ketoacid, acetoacetate also undergoes a slow, spontaneous decarboxylation to acetone. The odor of acetone may be detected in the breath of a person who has a high level of acetoacetate in the blood. Under starvation conditions, the acetone may be captured to synthesize glucose.

### Ketone bodies are a major fuel in some tissues

The major site of the production of acetoacetate and 3-hydroxybutyrate is the liver. These molecules diffuse from the liver mitochondria into the blood and are transported to other tissues such as heart and kidney (Figure 22.22). Acetoacetate and 3-hydroxybutyrate are normal fuels of respiration and are quantitatively important as sources of energy. Indeed, heart muscle and the renal cortex use acetoacetate in preference to glucose. In contrast, glucose is the major fuel for the brain and red blood cells in well-nourished people on a balanced diet. However, the brain adapts to the utilization of acetoacetate during starvation and diabetes. In prolonged starvation, 75% of the fuel needs of the brain are met by ketone bodies.

Acetoacetate is converted into acetyl CoA in two steps. First, acetoacetate is activated by the transfer of CoA from succinyl CoA in a reaction catalyzed by a specific CoA transferase. Second, acetoacetyl CoA is cleaved by thiolase to yield two molecules of acetyl CoA, which can then enter the citric acid

FASTING or DIABETES

**FIGURE 22.22 PATHWAY INTEGRATION: Liver supplies ketone bodies to the peripheral tissues.** During fasting or in untreated diabetics, the liver converts fatty acids into ketone bodies, which are a fuel source for a number of tissues. Ketone-body production is especially important during starvation, when ketone bodies are the predominant fuel.

cycle (Figure 22.23). The liver has acetoacetate available to supply to other organs because it lacks this particular CoA transferase. 3-Hydroxybutyrate requires an additional step to yield acetyl CoA. It is first oxidized to produce acetoacetate, which is processed as heretofore described, and NADH for use in oxidative phosphorylation.

**FIGURE 22.23 Utilization of acetoacetate as a fuel.** Acetoacetate can be converted into two molecules of acetyl CoA, which then enter the citric acid cycle.

*Ketone bodies can be regarded as a water-soluble, transportable form of acetyl units. Fatty acids are released by adipose tissue and converted into acetyl units by the liver, which then exports them as acetoacetate. As might be expected, acetoacetate also has a regulatory role. High levels of acetoacetate in the blood signify an abundance of acetyl units and lead to a decrease in the rate of lipolysis in adipose tissue.*

High blood levels of ketone bodies, the result of certain pathological conditions, can be life threatening. The most common of these conditions is diabetic ketosis in patients with insulin-dependent diabetes

**FIGURE 22.24 Diabetic ketosis results when insulin is absent.** In the absence of insulin, fats are released from adipose tissue, and glucose cannot be absorbed by the liver or adipose tissue. The liver degrades the fatty acids by  $\beta$  oxidation but cannot process the acetyl CoA, because of a lack of glucose-derived oxaloacetate (OAA). Excess ketone bodies are formed and released into the blood.

mellitus. These patients are unable to produce insulin. As stated earlier, this hormone, normally released after meals, signals tissues to take up glucose. In addition, it curtails fatty acid mobilization by adipose tissue. The absence of insulin has two major biochemical consequences (Figure 22.24). First, the liver cannot absorb glucose and consequently cannot provide oxaloacetate to process fatty acid-derived acetyl CoA. Second, adipose cells continue to release fatty acids into the blood stream; these fatty acids are then taken up by the liver and converted into ketone bodies. The liver thus produces large amounts of ketone bodies, which are moderately strong acids. The result is severe acidosis. The decrease in pH impairs tissue function, most importantly in the central nervous system.

Interestingly, diets that promote ketone-body formation, called *ketogenic diets*, are frequently used as a therapeutic option for children with drug-resistant epilepsy. Ketogenic diets are rich in fats and low in carbohydrates, with adequate amounts of protein. In essence, the body is forced into starvation mode, where fats and ketone bodies become the main fuel source (Section 27.5). How such diets reduce the seizures suffered by the children is currently unknown.

### Animals cannot convert fatty acids into glucose

A typical human being has far greater fat stores than glycogen stores. However, glycogen is necessary to fuel very active muscle, as well as the brain, which normally uses only glucose as a fuel. When glycogen stores are low, why can't the body make use of fat stores and convert fatty acids into glucose? Because *animals are unable to effect the net synthesis of glucose from fatty acids*. Specifically, acetyl CoA cannot be converted into pyruvate or oxaloacetate in animals. Recall that the reaction that generates acetyl CoA from pyruvate is irreversible (Section 17.1). The two carbon atoms of the acetyl group of acetyl CoA enter the citric acid cycle, but two carbon atoms leave the cycle in the decarboxylations catalyzed by isocitrate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase. Consequently, oxaloacetate is regenerated, but it is not formed *de novo* when the acetyl unit of acetyl CoA is oxidized by the citric acid cycle. In essence, two carbon atoms enter the cycle as an acetyl group, but two carbons leave the cycle as  $\text{CO}_2$  before oxaloacetate is generated. As a result, no net synthesis of oxaloacetate is possible. In contrast, plants have two additional enzymes enabling them to convert the carbon atoms of acetyl CoA into oxaloacetate (Section 17.5).

## Some fatty acids may contribute to the development of pathological conditions

As we will see shortly (Section 22.5), certain polyunsaturated fatty acids are essential for life, serving as precursors to various signal molecules. Vegetable oils, used commonly in food preparation, are rich in polyunsaturated fatty acids. However, polyunsaturated fatty acids are unstable and are readily oxidized. This tendency to become rancid reduces their shelf life and renders them undesirable for cooking. To circumvent this problem, polyunsaturated fatty acids are hydrogenated, converting them to saturated and trans unsaturated fatty acids (popularly known as “trans fat”), a variety of fat that is rare in nature. Epidemiological evidence suggests that consumption of large amounts of saturated fatty acids and trans fat promotes obesity, type 2 diabetes, and atherosclerosis. The mechanism by which these fats exert these effects is under active investigation. Some evidence suggests that they promote an inflammatory response and may mute the action of insulin and other hormones (Section 27.3).

---

## 22.4 Fatty Acids Are Synthesized by Fatty Acid Synthase

Fatty acids are synthesized by a complex of enzymes that together are called *fatty acid synthase*. Because eating a typical Western diet meets our physiological needs for fats and lipids, adult human beings have little need for de novo fatty acid synthesis. However, many tissues, such as liver and adipose tissue, are capable of synthesizing fatty acids, and this synthesis is required under certain physiological conditions. For instance, fatty acid synthesis is necessary during embryonic development and during lactation in mammary glands. Inappropriate fatty acid synthesis in the liver of alcoholics contributes to liver failure.

Acetyl CoA, the end product of fatty acid degradation, is the precursor for virtually all fatty acids. The biochemical challenge is to link the two carbon units together and reduce the carbons to produce palmitate, a C<sub>16</sub> fatty acid. Palmitate then serves as a precursor for the variety of other fatty acids.

### Fatty acids are synthesized and degraded by different pathways

Although fatty acid synthesis is the reversal of the degradative pathway in regard to basic chemical reactions, the synthetic and degradative pathways are different mechanistically, again exemplifying the principle that *synthetic and degradative pathways are almost always distinct*. Some important differences between the pathways are as follows:

1. Synthesis takes place in the *cytoplasm*, in contrast with degradation, which takes place primarily in the mitochondrial matrix.
2. Intermediates in fatty acid synthesis are covalently linked to the sulfhydryl groups of an *acyl carrier protein* (ACP), whereas intermediates in fatty acid breakdown are covalently attached to the sulfhydryl group of coenzyme A.
3. The enzymes of fatty acid synthesis in higher organisms are joined in a *single polypeptide chain* called *fatty acid synthase*. In contrast, the degradative enzymes are not linked covalently.
4. The growing fatty acid chain is elongated by the *sequential addition of two-carbon units* derived from acetyl CoA. The activated donor of two-carbon units in the elongation step is *malonyl ACP*. The elongation reaction is driven by the release of CO<sub>2</sub>.

5. The reductant in fatty acid synthesis is *NADPH*, whereas the oxidants in fatty acid degradation are *NAD<sup>+</sup>* and *FAD*.
6. The isomeric form of the hydroxyacyl intermediate in degradation is L, while the D form is used in synthesis.

### The formation of malonyl CoA is the committed step in fatty acid synthesis

Fatty acid synthesis starts with the carboxylation of acetyl CoA to *malonyl CoA*. This irreversible reaction is the committed step in fatty acid synthesis.

The synthesis of malonyl CoA is catalyzed by the cytoplasmic enzyme *acetyl CoA carboxylase 1*, which contains a biotin prosthetic group. The carboxyl group of biotin is covalently attached to the  $\epsilon$  amino group of a lysine residue, as in pyruvate carboxylase (Figure 16.24) and propionyl CoA carboxylase (p. 654). As with these other enzymes, a carboxybiotin intermediate is formed at the expense of the hydrolysis of a molecule of ATP. The activated  $\text{CO}_2$  group in this intermediate is then transferred to acetyl CoA to form malonyl CoA.

Acetyl CoA carboxylase 2, an isozyme of carboxylase 1 located in the mitochondria, is the essential regulatory enzyme for fatty acid metabolism (Section 22.5).

### Intermediates in fatty acid synthesis are attached to an acyl carrier protein

The intermediates in fatty acid synthesis are linked to an acyl carrier protein. Specifically, they are linked to the sulfhydryl terminus of a phosphopantetheine group. In the degradation of fatty acids, this unit is present as part of coenzyme A, whereas, in their synthesis, it is attached to a serine residue of the acyl carrier protein (Figure 22.25). Thus, ACP, a single polypeptide chain of 77 residues, can be regarded as a giant prosthetic group, a “macro CoA.”

### Fatty acid synthesis consists of a series of condensation, reduction, dehydration, and reduction reactions

The enzyme system that catalyzes the synthesis of saturated long-chain fatty acids from acetyl CoA, malonyl CoA, and *NADPH* is called *fatty acid*

**FIGURE 22.25 Phosphopantetheine.** Both acyl carrier protein and coenzyme A include phosphopantetheine as their reactive units. [Drawn from 1ACP.pdb.]

**TABLE 22.2** Principal reactions in fatty acid synthesis in bacteria

Step	Reaction	Enzyme
1	$\text{Acetyl CoA} + \text{HCO}_3^- + \text{ATP} \longrightarrow \text{malonyl CoA} + \text{ADP} + \text{P}_i + \text{H}^+$	Acetyl CoA carboxylase
2	$\text{Acetyl CoA} + \text{ACP} \rightleftharpoons \text{acetyl ACP} + \text{CoA}$	Acetyl transacylase
3	$\text{Malonyl CoA} + \text{ACP} \rightleftharpoons \text{malonyl ACP} + \text{CoA}$	Malonyl transacylase
4	$\text{Acetyl ACP} + \text{malonyl ACP} \longrightarrow \text{acetoacetyl ACP} + \text{ACP} + \text{CO}_2$	$\beta$ -Ketoacyl synthase
5	$\text{Acetoacetyl ACP} + \text{NADPH} + \text{H}^+ \rightleftharpoons \text{D-3-hydroxybutyryl ACP} + \text{NADP}^+$	$\beta$ -Ketoacyl reductase
6	$\text{D-3-Hydroxybutyryl ACP} \rightleftharpoons \text{crotonyl ACP} + \text{H}_2\text{O}$	3-Hydroxyacyl dehydratase
7	$\text{Crotonyl ACP} + \text{NADPH} + \text{H}^+ \longrightarrow \text{butyryl ACP} + \text{NADP}^+$	Enoyl reductase

*synthase*. The synthase is actually a complex of distinct enzymes. The fatty acid synthase complex in bacteria is readily dissociated into individual enzymes when the cells are broken apart. The availability of these isolated enzymes has helped biochemists elucidate the steps in fatty acid synthesis (Table 22.2). In fact, the reactions leading to fatty acid synthesis in higher organisms are very much like those of bacteria.

The elongation phase of fatty acid synthesis starts with the formation of acetyl ACP and malonyl ACP. *Acetyl transacylase* and *malonyl transacylase* catalyze these reactions.

Malonyl transacylase is highly specific, whereas acetyl transacylase can transfer acyl groups other than the acetyl unit, though at a much slower rate. The synthesis of fatty acids with an odd number of carbon atoms starts with propionyl ACP, which is formed from propionyl CoA by acetyl transacylase.

Acetyl ACP and malonyl ACP react to form acetoacetyl ACP (Figure 22.26). The  *$\beta$ -ketoacyl synthase*, also called the condensing enzyme, catalyzes this condensation reaction.

In the condensation reaction, a four-carbon unit is formed from a two-carbon unit and a three-carbon unit, and  $\text{CO}_2$  is released. Why is the four-carbon unit not formed from two 2-carbon units—say, two molecules of acetyl ACP? The answer is that the equilibrium for the synthesis of acetoacetyl ACP from two molecules of acetyl ACP is highly unfavorable. In contrast, *the equilibrium is favorable if malonyl ACP is a reactant because its decarboxylation contributes a substantial decrease in free energy*. In effect, ATP drives the condensation reaction, though ATP does not directly participate in the condensation reaction. Instead, ATP is used to carboxylate acetyl CoA to malonyl CoA. The free energy thus stored in malonyl CoA is released in the decarboxylation accompanying the formation of acetoacetyl ACP. Although  $\text{HCO}_3^-$  is required for fatty acid synthesis, its carbon atom does not appear in the product. Rather, *all the carbon atoms of fatty acids containing an even number of carbon atoms are derived from acetyl CoA*.

The next three steps in fatty acid synthesis reduce the keto group at C-3 to a methylene group (Figure 22.26). First, acetoacetyl ACP is reduced to D-3-hydroxybutyryl ACP by  $\beta$ -ketoacyl reductase. This reaction differs from the corresponding one in fatty acid degradation in two respects: (1) the D rather than the L isomer is formed; and (2) NADPH is the reducing agent, whereas  $\text{NAD}^+$  is the oxidizing agent in  $\beta$  oxidation. This difference exemplifies the general principle that *NADPH is consumed in biosynthetic reactions, whereas NADH is generated in energy-yielding reactions*. Then, D-3-hydroxybutyryl ACP is *dehydrated* to form crotonyl ACP, which is a

**FIGURE 22.26** The steps of fatty acid synthesis. Fatty acid synthesis begins with the condensation of malonyl ACP and acetyl ACP to form acetoacetyl ACP. Acetoacetyl ACP is then reduced, dehydrated, and reduced again to form butyryl ACP. Another cycle begins with the condensation of butyryl ACP and malonyl ACP. The sequence of reactions is repeated until the final product palmitate is formed.

*trans*- $\Delta^2$ -enoyl ACP by 3-hydroxyacyl dehydratase. The final step in the cycle *reduces* crotonyl ACP to butyryl ACP. NADPH is again the reductant, whereas FAD is the oxidant in the corresponding reaction in  $\beta$  oxidation. The bacterial enzyme that catalyzes this step, *enoyl reductase*, can be inhibited by *triclosan*, a broad-spectrum antibacterial agent that is added to a variety of products such as toothpaste, soaps, and skin creams. These last three reactions—a reduction, a dehydration, and a second reduction—convert acetoacetyl ACP into butyryl ACP, which completes the first elongation cycle.

In the second round of fatty acid synthesis, butyryl ACP condenses with malonyl ACP to form a C<sub>6</sub>- $\beta$ -ketoacyl ACP. This reaction is like the one in the first round, in which acetyl ACP condenses with malonyl ACP to form a C<sub>4</sub>- $\beta$ -ketoacyl ACP. Reduction, dehydration, and a second reduction convert the C<sub>6</sub>- $\beta$ -ketoacyl ACP into a C<sub>6</sub>-acyl ACP, which is ready for a third round of elongation. The elongation cycles continue until C<sub>16</sub>-acyl ACP is formed. This intermediate is a good substrate for a thioesterase that hydrolyzes C<sub>16</sub>-acyl ACP to yield palmitate and ACP. *The thioesterase acts as a ruler to determine fatty acid chain length.* The synthesis of longer-chain fatty acids is discussed in Section 22.6.

### Fatty acids are synthesized by a multifunctional enzyme complex in animals

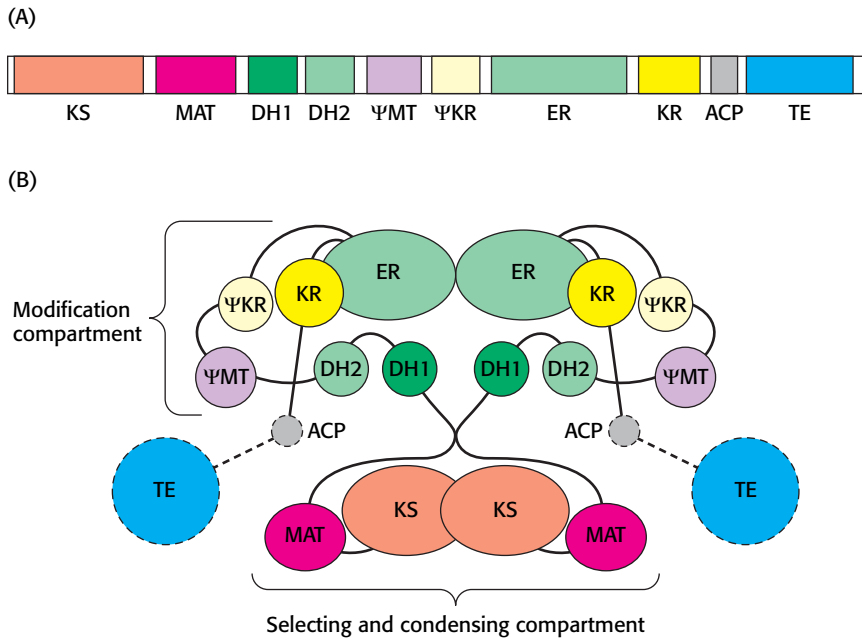

Although the basic biochemical reactions in fatty acid synthesis are very similar in *E. coli* and eukaryotes, the structure of the synthase varies considerably. The component enzymes of animal fatty acid synthases, in contrast with those of *E. coli* and plants, are linked in a large polypeptide chain.

The structure of a large part of the mammalian fatty acid synthase has recently been determined, with the acyl carrier protein and thioesterase remaining to be resolved. The enzyme is a dimer of identical 270-kd subunits. Each chain contains all of the active sites required for activity, as well as an acyl carrier protein tethered to the complex (Figure 22.27A). Despite the fact that each chain possesses all of the enzymes required for fatty acid synthesis, the monomers are not active. A dimer is required.

The two component chains interact such that the enzyme activities are partitioned into two distinct compartments (Figure 22.27B). The selecting and condensing compartment binds the acetyl and malonyl substrates and condenses them to form the growing chain. Interestingly, the mammalian fatty acid synthase has one active site, malonyl/acetyl transacylase, that adds both acetyl CoA and malonyl CoA. In contrast, most other fatty acid synthases have two separate enzyme activities, one for acetyl CoA and one for malonyl CoA. The modification compartment is responsible for the reduction and dehydration activities that result in the saturated fatty acid product.

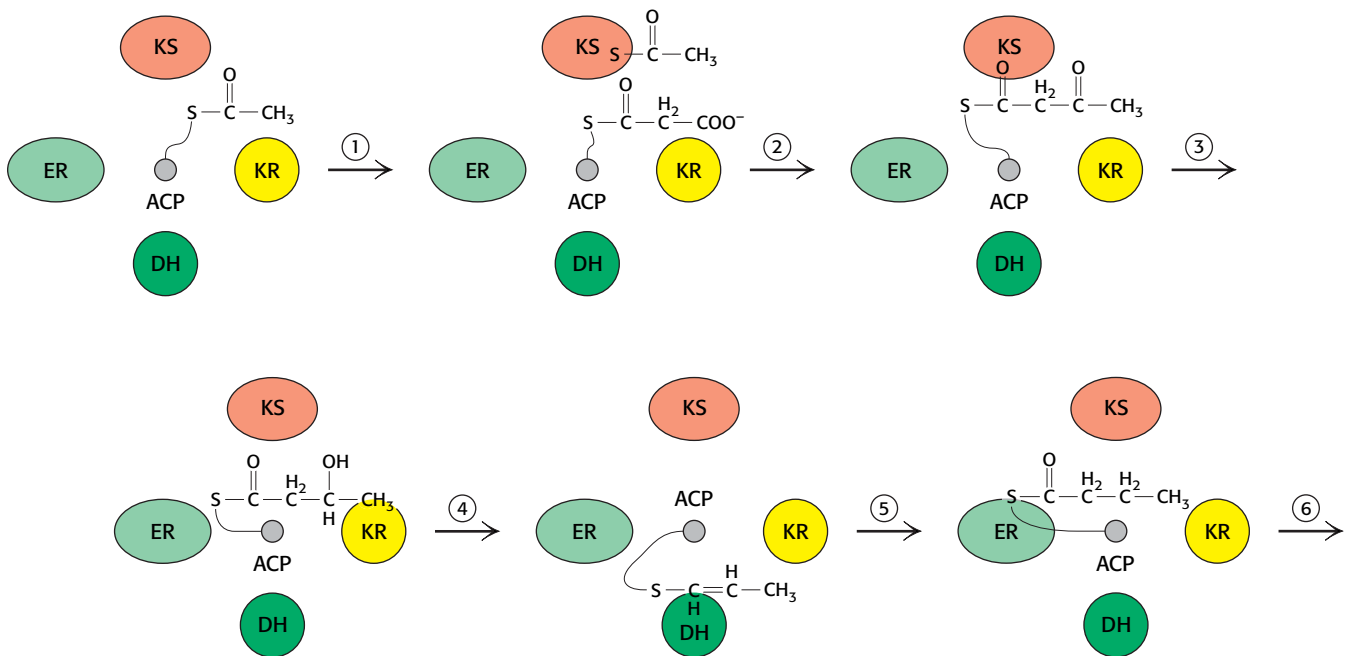

Let us consider one catalytic cycle of the fatty acid synthase complex (Figure 22.28). An elongation cycle begins when malonyl/acetyl transacylase (MAT) moves an acetyl unit from coenzyme A to the acyl carrier protein (ACP).  $\beta$ -Ketosynthase ( $\beta$ -KS) accepts the acetyl unit, which forms a thioester with a cysteine residue at the  $\beta$ -KS active site. The vacant ACP is reloaded by MAT, this time with a malonyl moiety. Malonyl ACP visits the active site of  $\beta$ -KS where the condensation of the two 2-carbon fragments takes place on the ACP with the concomitant release of CO<sub>2</sub>. The selecting and condensing process concludes with the  $\beta$ -ketoacyl product attached to the ACP.

The loaded ACP then sequentially visits the active sites of the modification compartment of the enzyme, where the  $\beta$ -keto group of the substrate is reduced to —OH, dehydrated, and finally reduced to yield the saturated acyl product, still attached to the ACP. With the completion of the modification

**FIGURE 22.27 The structure of the mammalian fatty acid synthase.** (A) The arrangement of the catalytic activities present in a single polypeptide chain. (B) A cartoon of the dimer based on an x-ray crystallographic result. The  $\Psi$ -MT and  $\Psi$ -KR are inactive domains similar to methyl transferase and ketoreductase sequences. Although there are two domains for DH, only one is active. The inactive domains are presented in faded colors. Dotted lines outline domains for which the structure has not yet been determined. Abbreviations: KS, ketosynthase; MAT, malonylacetyl transferase; DH, dehydratase;  $\Psi$ -MT, methyl transferase (inactive);  $\Psi$ -KR, ketoreductase (inactive); ER, enoyl reductase; KR, ketoreductase; ACP, acyl carrier protein; TE, thioesterase.

process, the reduced product is transferred to the  $\beta$ -KS while the ACP accepts another malonyl unit. Condensation takes place and is followed by another modification cycle. The process is repeated until the thioesterase releases the final  $C_{16}$  palmitic acid product.

**FIGURE 22.28 A catalytic cycle of mammalian fatty acid synthase.**

The cycle begins when MAT (not shown) attaches an acetyl unit to ACP. (1) ACP delivers the acetyl unit to KS, and MAT then attaches a malonyl unit to ACP. (2) ACP visits KS again, which condenses the acetyl and malonyl units to form the  $\beta$ -ketoacyl product, attached to the ACP. (3) ACP delivers the  $\beta$ -ketoacyl product to the KR enzyme, which reduces the keto group to an alcohol. (4) The  $\beta$ -hydroxyl product then visits the DH, which introduces a double bond with the loss of water. (5) The enoyl product is delivered to the ER enzyme, where the double bond is reduced. (6) ACP hands the reduced product to KS and is recharged with malonyl CoA by MAT. (7) KS condenses the two molecules on ACP, which is now ready to begin another cycle. See Figure 22.27 for abbreviations.

Many eukaryotic multienzyme complexes are multifunctional proteins in which different enzymes are linked covalently. Multifunctional enzymes such as fatty acid synthase seem likely to have arisen in eukaryotic evolution by fusion of the individual genes of evolutionary ancestors.

### The synthesis of palmitate requires 8 molecules of acetyl CoA, 14 molecules of NADPH, and 7 molecules of ATP

The stoichiometry of the synthesis of palmitate is

The equation for the synthesis of the malonyl CoA used in the preceding reaction is

Hence, the overall stoichiometry for the synthesis of palmitate is

### Citrate carries acetyl groups from mitochondria to the cytoplasm for fatty acid synthesis

Fatty acids are synthesized in the cytoplasm, whereas acetyl CoA is formed from pyruvate in mitochondria. Hence, acetyl CoA must be transferred from mitochondria to the cytoplasm for fatty acid synthesis. Mitochondria, however, are not readily permeable to acetyl CoA. Recall that carnitine carries only long-chain fatty acids. *The barrier to acetyl CoA is bypassed by citrate, which carries acetyl groups across the inner mitochondrial membrane.* Citrate is formed in the mitochondrial matrix by the condensation of acetyl CoA with oxaloacetate (Figure 22.29). When present at high levels, citrate is transported to the cytoplasm, where it is cleaved by *ATP-citrate lyase*.

This reaction occurs in three steps: (1) The formation of a phospho-enzyme with the donation of a phosphoryl group from ATP; (2) binding of citrate and CoA followed by the formation of citroyl CoA and release of the phosphate; (3) cleavage of citroyl CoA to yield acetyl CoA and oxaloacetate. As we will see shortly (Section 22.6), citrate stimulates acetyl CoA carboxylase, the enzyme that regulates fatty acid metabolism. Recall also that the

#### Lyases

Enzymes catalyzing the cleavage of C—C, C—O, or C—N bonds by elimination. A double bond is formed in these reactions.

**FIGURE 22.29 Transfer of acetyl CoA to the cytoplasm.** Acetyl CoA is transferred from mitochondria to the cytoplasm, and the reducing potential of NADH is concomitantly converted into that of NADPH by this series of reactions.

presence of citrate in the cytoplasm inhibits phosphofructokinase, the enzyme that controls the glycolytic pathway.

ATP-citrate lyase is stimulated by insulin, which initiates a signal transduction pathway that ultimately results in the phosphorylation and activation of the lyase by protein kinase B (also called Akt).

### Several sources supply NADPH for fatty acid synthesis

Oxaloacetate formed in the transfer of acetyl groups to the cytoplasm must now be returned to the mitochondria. The inner mitochondrial membrane is impermeable to oxaloacetate. Hence, a series of bypass reactions are needed. These reactions also generate much of the NADPH needed for fatty acid synthesis. First, oxaloacetate is reduced to malate by NADH. This reaction is catalyzed by a *malate dehydrogenase* in the cytoplasm.

Second, malate is oxidatively decarboxylated by an  $\text{NADP}^+$ -linked *malate enzyme* (also called *malic enzyme*).

The pyruvate formed in this reaction readily enters mitochondria, where it is carboxylated to oxaloacetate by pyruvate carboxylase.

The sum of these three reactions is

Thus, *one molecule of NADPH is generated for each molecule of acetyl CoA that is transferred from mitochondria to the cytoplasm.* Hence, eight molecules of NADPH are formed when eight molecules of acetyl CoA are transferred to the cytoplasm for the synthesis of palmitate. *The additional six molecules of NADPH required for this process come from the pentose phosphate pathway* (Section 20.3).

The accumulation of the precursors for fatty acid synthesis is a wonderful example of the coordinated use of multiple pathways. The citric acid cycle, transport of oxaloacetate from the mitochondria, and pentose phosphate pathway provide the carbon atoms and reducing power, whereas glycolysis and oxidative phosphorylation provide the ATP to meet the needs for fatty acid synthesis (Figure 22.30).

### Fatty acid metabolism is altered in tumor cells

 We have previously seen that cancer cells alter glucose metabolism to meet the needs of rapid cell growth. Cancer cells must also increase fatty acid synthesis for use as signal molecules as well as for incorporation into membrane phospholipids. Many of the enzymes of fatty acid synthesis are overexpressed in most human cancers, and this expression is correlated with tumor malignancy. Recall that normal cells do *de novo* fatty acid synthesis, relying instead on dietary intake to meet their fatty needs.

**FIGURE 22.30 PATHWAY INTEGRATION: Fatty acid synthesis.** Fatty acid synthesis requires the cooperation of various metabolic pathways located in different cellular compartments.

The dependence of de novo fatty acid synthesis provides possible therapeutic targets to inhibit cancer cell growth. Inhibition of  $\beta$ -ketoacyl ACP synthase, the enzyme that catalyzes the condensation step of fatty acid synthesis, does indeed inhibit phospholipid synthesis and subsequent cell growth in some cancers, apparently by inducing apoptosis. However, another startling observation was made: *mice treated with inhibitors of the  $\beta$ -ketoacyl ACP synthase showed remarkable weight loss because they ate less.* Thus, fatty acid synthase inhibitors are exciting candidates both as antitumor and as antiobesity drugs.

Acetyl CoA carboxylase is also being investigated as a possible target for inhibiting cancer cell growth. Inhibition of the carboxylase in prostate and breast cancer cell lines induces apoptosis in the cancer cells, and yet is without effect in normal cells (problem 54). Understanding the alteration of fatty acid metabolism in cancer cells is a developing area of research that holds promise of generating new cancer therapies.

## 22.5 The Elongation and Unsaturation of Fatty Acids Are Accomplished by Accessory Enzyme Systems

The major product of the fatty acid synthase is palmitate. In eukaryotes, longer fatty acids are formed by elongation reactions catalyzed by enzymes on the cytoplasmic face of the *endoplasmic reticulum membrane*. These reactions add two-carbon units sequentially to the carboxyl ends of both saturated and unsaturated fatty acyl CoA substrates. Malonyl CoA is the two-carbon donor in the elongation of fatty acyl CoAs. Again, condensation is driven by the decarboxylation of malonyl CoA.

### Membrane-bound enzymes generate unsaturated fatty acids

Endoplasmic reticulum systems also introduce double bonds into long-chain acyl CoAs. For example, in the conversion of stearoyl CoA into oleoyl CoA, a *cis*- $\Delta^9$  double bond is inserted by an oxidase that employs *molecular oxygen* and *NADH* (or *NADPH*).

This reaction is catalyzed by a complex of three membrane-bound proteins: *NADH-cytochrome  $b_5$  reductase*, *cytochrome  $b_5$* , and *stearoyl CoA desaturase* (Figure 22.31). First, electrons are transferred from NADH to the FAD moiety of NADH-cytochrome  $b_5$  reductase. The heme iron atom of cytochrome  $b_5$  is then reduced to the  $\text{Fe}^{2+}$  state. The nonheme iron atom of the desaturase is subsequently converted into the  $\text{Fe}^{2+}$  state, which enables it to interact with  $\text{O}_2$  and the saturated fatty acyl CoA substrate. A double bond is formed and two molecules of  $\text{H}_2\text{O}$  are released. Two electrons come from NADH and two from the single bond of the fatty acyl substrate.

FIGURE 22.31 Electron-transport chain in the desaturation of fatty acids.

A variety of unsaturated fatty acids can be formed from oleate by a combination of elongation and desaturation reactions. For example, oleate can be elongated to a 20:1 *cis*- $\Delta^{11}$  fatty acid. Alternatively, a second double bond can be inserted to yield an 18:2 *cis*- $\Delta^6$ ,  $\Delta^9$  fatty acid. Similarly, palmitate (16:0) can be oxidized to palmitoleate (16:1 *cis*- $\Delta^9$ ), which can then be elongated to *cis*-vaccenate (18:1 *cis*- $\Delta^{11}$ ).

Unsaturated fatty acids in mammals are derived from either palmitoleate (16:1), oleate (18:1), linoleate (18:2), or linolenate (18:3). The number of carbon atoms from the  $\omega$  end of a derived unsaturated fatty acid to the nearest double bond identifies its precursor.

Mammals lack the enzymes to introduce double bonds at carbon atoms beyond C-9 in the fatty acid chain. Hence, mammals cannot synthesize linoleate (18:2 *cis*- $\Delta^9$ ,  $\Delta^{12}$ ) and linolenate (18:3 *cis*- $\Delta^9$ ,  $\Delta^{12}$ ,  $\Delta^{15}$ ). Linoleate and linolenate are the two essential fatty acids. The term *essential* means that they must be supplied in the diet because they are required by an organism and cannot be synthesized by the organism itself. Linoleate and linolenate furnished by the diet are the starting points for the synthesis of a variety of other unsaturated fatty acids.

Precursor	Formula
Linolenate ( $\omega$ -3)	$\text{CH}_3-(\text{CH}_2)_2=\text{CH}-\text{R}$
Linoleate ( $\omega$ -6)	$\text{CH}_3-(\text{CH}_2)_5=\text{CH}-\text{R}$
Palmitoleate ( $\omega$ -7)	$\text{CH}_3-(\text{CH}_2)_6=\text{CH}-\text{R}$
Oleate ( $\omega$ -9)	$\text{CH}_3-(\text{CH}_2)_8=\text{CH}-\text{R}$

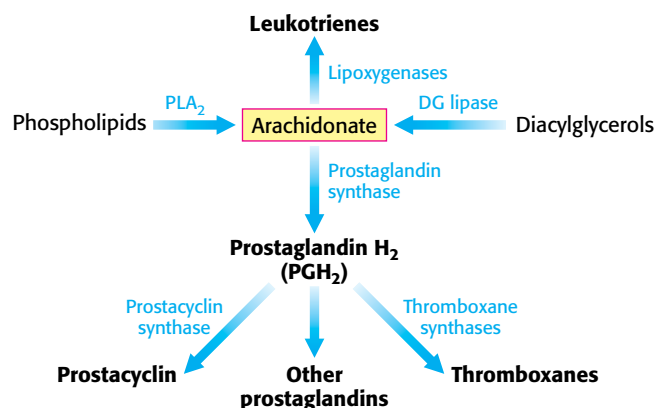

### Eicosanoid hormones are derived from polyunsaturated fatty acids

*Arachidonate*, a 20:4 fatty acid derived from linoleate, is the major precursor of several classes of signal molecules: prostaglandins, prostacyclins, thromboxanes, and leukotrienes (Figure 22.32).

A *prostaglandin* is a 20-carbon fatty acid containing a 5-carbon ring (Figure 22.33). This basic compound is modified by reductases and isomerases to yield nine major classes of prostaglandins, designated PGA through PGI<sub>2</sub>; a subscript denotes the number of carbon-carbon double bonds outside the ring. Prostaglandins with two double bonds, such as PGE<sub>2</sub>, are derived from arachidonate; the other two double bonds of this precursor are lost in forming a 5-membered ring. *Prostacyclin* and *thromboxanes* are related compounds that arise from a nascent prostaglandin. They are generated by *prostacyclin synthase* and *thromboxane synthase*, respectively. Alternatively, arachidonate can be converted into *leukotrienes* by the action of *lipoxygenase*. Leukotrienes, first found in leukocytes, contain three conjugated double bonds—hence the name. Prostaglandins, prostacyclin, thromboxanes, and leukotrienes are called *eicosanoids* (from the Greek *eikosi*, “twenty”) because they contain 20 carbon atoms.

Prostaglandins and other eicosanoids are *local hormones* because they are short-lived. They alter the activities both of the cells in which they are synthesized and of adjoining cells by binding to 7TM receptors. Their effects may vary from one cell type to another, in contrast with the more-uniform actions of global hormones such as insulin and glucagon. Prostaglandins stimulate inflammation, regulate blood flow to particular organs, control ion transport across membranes, modulate synaptic transmission, and induce sleep.

 Recall that aspirin blocks access to the active site of the enzyme that converts arachidonate into prostaglandin H<sub>2</sub> (Section 12.3). Because arachidonate is the precursor of other prostaglandins, prostacyclin, and thromboxanes, blocking this step interferes with many signaling pathways. Aspirin's ability to obstruct these pathways accounts for its wide-ranging effects on inflammation, fever, pain, and blood clotting.

**FIGURE 22.32 Arachidonate is the major precursor of eicosanoid hormones.** Prostaglandin synthase catalyzes the first step in a pathway leading to prostaglandins, prostacyclins, and thromboxanes. Lipoxygenase catalyzes the initial step in a pathway leading to leukotrienes.

FIGURE 22.33 Structures of several eicosanoids.

### Variations on a theme: Polyketide and nonribosomal peptide synthetases resemble fatty acid synthase

 The mammalian multifunctional fatty acid synthase is a member of a large family of complex enzymes termed *megasynthases* that participate in step-by-step synthetic pathways. Two important classes of compounds that are synthesized by such enzymes are the *polyketides* and the *nonribosomal peptides*. These classes of compounds provide a variety of useful drugs, including antibiotics, immunosuppressants, antifungal agents and anticancer drugs. The antibiotic erythromycin is an example of a polyketide, whereas penicillin (Section 8.5) is a nonribosomal peptide.

Research is underway to learn how to manipulate the pathways and the enzymes of polyketide and nonribosomal peptide synthesis in order to generate new therapeutics.

## 22.6 Acetyl CoA Carboxylase Plays a Key Role in Controlling Fatty Acid Metabolism

Fatty acid metabolism is stringently controlled so that synthesis and degradation are highly responsive to physiological needs. Fatty acid synthesis is maximal when carbohydrates and energy are plentiful and when fatty acids are

scarce. *Acetyl CoA carboxylase 1 and 2 play essential roles in regulating fatty acid synthesis and degradation.* Recall that this enzyme catalyzes the committed step in fatty acid synthesis: the production of malonyl CoA (the activated two-carbon donor). This important enzyme is subject to both local and hormonal regulation. We will examine each of these levels of regulation in turn.

### Acetyl CoA carboxylase is regulated by conditions in the cell

Acetyl CoA carboxylase responds to changes in its immediate environment. *Acetyl CoA carboxylase is switched off by phosphorylation and activated by dephosphorylation* (Figure 22.34). *AMP-activated protein kinase (AMPK)* converts the carboxylase into an inactive form by modifying three serine residues. AMPK is essentially a fuel gauge; it is activated by AMP and inhibited by ATP.

The carboxylase is also allosterically stimulated by citrate. The level of citrate is high when both acetyl CoA and ATP are abundant, signifying that raw materials and energy are available for fatty acid synthesis. Citrate acts in an unusual manner on inactive acetyl CoA carboxylase, which exists as isolated inactive dimers. Citrate facilitates the polymerization of the inactive dimers into active filaments (Figure 22.35). However, polymerization by citrate alone requires supraphysiological concentrations. In the cell, citrate-induced polymerization is facilitated by the protein MIG12, which greatly reduces the amount of citrate required. Polymerization can partly reverse the inhibition produced by phosphorylation (Figure 22.36). The stimulatory effect of citrate on the carboxylase is counteracted by *palmitoyl CoA*, which is abundant when there is an excess of fatty acids. Palmitoyl CoA causes the filaments to disassemble into the inactive subunits. Palmitoyl CoA also inhibits the translocase that transports citrate from mitochondria to the cytoplasm, as well as glucose 6-phosphate dehydrogenase, which generates NADPH in the pentose phosphate pathway.

The isozyme acetyl CoA carboxylase 2, located in the mitochondria, plays a role in the regulation of fatty acid degradation. Malonyl CoA, the product of the carboxylase reaction, is present at a high level when fuel molecules are abundant. *Malonyl CoA inhibits carnitine acyltransferase I, preventing the entry of fatty acyl CoAs into the mitochondrial matrix in times of plenty.* Malonyl CoA is an especially effective inhibitor of carnitine acyltransferase I in heart and muscle, tissues that have little fatty acid synthesis capacity of their own. In these tissues, acetyl CoA carboxylase may be a purely regulatory enzyme.

### Acetyl CoA carboxylase is regulated by a variety of hormones

Acetyl CoA carboxylase is controlled by the hormones glucagon, epinephrine, and insulin, which denote the overall energy status of the organism. *Insulin stimulates fatty acid synthesis by activating the carboxylase, whereas glucagon and epinephrine have the reverse effect.*

**Regulation by glucagon and epinephrine.** Consider, again, a person who has just awakened from a night's sleep and begins a bout of exercise. As mentioned, glycogen stores will be low, but lipids are readily available for mobilization.

As stated earlier, the hormones glucagon and epinephrine, present under conditions of fasting and exercise, will stimulate the release of fatty acids from triacylglycerols in fat cells, which will be released into the blood, and probably from muscle cells, where they will be used immediately as fuel. These same hormones will inhibit fatty acid synthesis by inhibiting

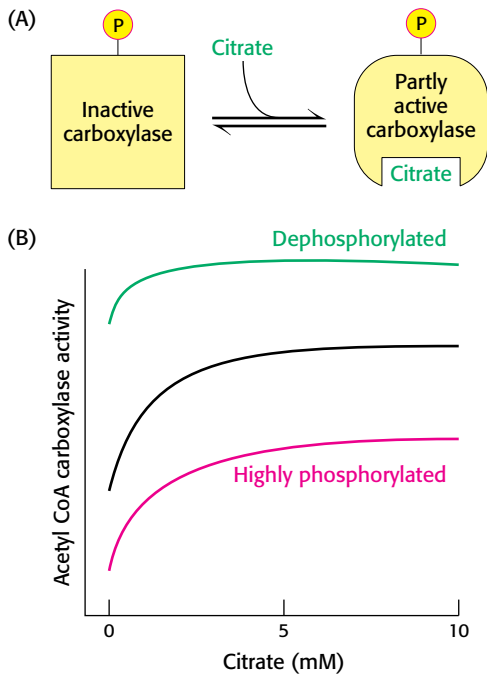

**FIGURE 22.34 Control of acetyl CoA carboxylase.** Acetyl CoA carboxylase is inhibited by phosphorylation.

**FIGURE 22.35 Filaments of acetyl CoA carboxylase.** The electron micrograph shows the enzymatically active filamentous form of acetyl CoA carboxylase from chicken liver. The inactive form is a dimer of 265-kDa subunits. [Courtesy of Dr. M. Daniel Lane.]

**FIGURE 22.36** Dependence of the catalytic activity of acetyl CoA carboxylase on the concentration of citrate. (A) Citrate can partly activate the phosphorylated carboxylase. (B) The dephosphorylated form of the carboxylase is highly active even when citrate is absent. Citrate partly overcomes the inhibition produced by phosphorylation. [Information from G. M. Mabrouk, I. M. Helmy, K. G. Thampy, and S. J. Wakil. *J. Biol. Chem.* 265:6330–6338, 1990.]

acetyl CoA carboxylase. Although the exact mechanism by which these hormones exert their effects is not known, the net result is to augment the inhibition by the AMP-activated kinase. This result makes sound physiological sense: when the energy level of the cell is low, as signified by a high concentration of AMP, and the energy level of the organism is low, as signaled by glucagon, fats should not be synthesized. Epinephrine, which signals the need for immediate energy, enhances this effect. Hence, *these catabolic hormones switch off fatty acid synthesis by keeping the carboxylase in the inactive phosphorylated state.*

**Regulation by insulin.** Now consider the situation after the exercise has ended and the runner has had a meal. In this case, the hormone insulin inhibits the mobilization of fatty acids and stimulates their accumulation as triacylglycerols by muscle and adipose tissue. Insulin also stimulates fatty acid synthesis by activating acetyl CoA carboxylase. Insulin activates the carboxylase by enhancing the phosphorylation of AMPK by protein kinase B, which inhibits AMPK, as well as by stimulating the activity of a protein phosphatase that dephosphorylates and activates acetyl CoA carboxylase. Thus, the signal molecules glucagon, epinephrine, and insulin act in concert on triacylglycerol metabolism and acetyl CoA carboxylase to carefully regulate the utilization and storage of fatty acids.

**Response to diet.** *Long-term control is mediated by changes in the rates of synthesis and degradation of the enzymes participating in fatty acid synthesis.* Animals that have fasted and are then fed high-carbohydrate, low-fat diets show marked increases in their amounts of acetyl CoA carboxylase and fatty acid synthase within a few days. This type of regulation is known as *adaptive control*. This regulation, which is mediated both by insulin and by glucose, is at the level of gene transcription.

## SUMMARY

### 22.1 Triacylglycerols Are Highly Concentrated Energy Stores

Fatty acids are physiologically important as (1) fuel molecules, (2) components of phospholipids and glycolipids, (3) hydrophobic modifiers of proteins, and (4) hormones and intracellular messengers. They are stored in adipose tissue as triacylglycerols (neutral fat).

### 22.2 The Use of Fatty Acids as Fuel Requires Three Stages of Processing

Triacylglycerols can be mobilized by the hydrolytic action of lipases that are under hormonal control. Glucagon and epinephrine stimulate triacylglycerol breakdown by activating the lipase. Insulin, in contrast, inhibits lipolysis. Fatty acids are activated to acyl CoAs, transported across the inner mitochondrial membrane by carnitine, and degraded in the mitochondrial matrix by a recurring sequence of four reactions: oxidation by FAD, hydration, oxidation by  $\text{NAD}^+$ , and thiolysis by coenzyme A. The  $\text{FADH}_2$  and  $\text{NADH}$  formed in the oxidation steps transfer their electrons to  $\text{O}_2$  by means of the respiratory chain, whereas the acetyl CoA formed in the thiolysis step normally enters the citric acid cycle by condensing with oxaloacetate.

### 22.3 Unsaturated and Odd-Chain Fatty Acids Require Additional Steps for Degradation

Fatty acids that contain double bonds or odd numbers of carbon atoms require ancillary steps to be degraded. An isomerase and a reductase are required for the oxidation of unsaturated fatty acids, whereas propionyl

CoA derived from chains with odd numbers of carbon atoms requires a vitamin B<sub>12</sub>-dependent enzyme to be converted into succinyl CoA. Ketone bodies, formed from acetyl CoA, are an important fuel source for some tissues. Mammals are unable to convert fatty acids into glucose, because they lack a pathway for the net production of oxaloacetate, pyruvate, or other gluconeogenic intermediates from acetyl CoA.

#### 22.4 Fatty Acids Are Synthesized by Fatty Acid Synthase

Fatty acids are synthesized in the cytoplasm by a different pathway from that of  $\beta$  oxidation. Fatty acid synthase is the enzyme complex responsible for fatty acid synthesis. Synthesis starts with the carboxylation of acetyl CoA to malonyl CoA, the committed step. This ATP-driven reaction is catalyzed by acetyl CoA carboxylase, a biotin enzyme. The intermediates in fatty acid synthesis are linked to an acyl carrier protein. Acetyl ACP is formed from acetyl CoA, and malonyl ACP is formed from malonyl CoA. Acetyl ACP and malonyl ACP condense to form acetoacetyl ACP, a reaction driven by the release of CO<sub>2</sub> from the activated malonyl unit. A reduction, a dehydration, and a second reduction follow. NADPH is the reductant in these steps. The butyryl ACP formed in this way is ready for a second round of elongation, starting with the addition of a two-carbon unit from malonyl ACP. Seven rounds of elongation yield palmitoyl ACP, which is hydrolyzed to palmitate. In higher organisms, the enzymes catalyzing fatty acid synthesis are covalently linked in a multifunctional enzyme complex. A reaction cycle based on the formation and cleavage of citrate carries acetyl groups from mitochondria to the cytoplasm. NADPH needed for synthesis is generated in the transfer of reducing equivalents from mitochondria by the combined action of cytoplasmic malate dehydrogenase and malic enzyme and by the pentose phosphate pathway.

#### 22.5 The Elongation and Unsaturation of Fatty Acids Are Accomplished by Accessory Enzyme Systems

Fatty acids are elongated and desaturated by enzyme systems in the endoplasmic reticulum membrane. Desaturation requires NADH and O<sub>2</sub> and is carried out by a complex consisting of a flavoprotein, a cytochrome, and a nonheme iron protein. Mammals lack the enzymes to introduce double bonds distal to C-9, and so they require linoleate and linolenate in their diets.

Arachidonate, an essential precursor of prostaglandins and other signal molecules, is derived from linoleate. This 20:4 polyunsaturated fatty acid is the precursor of several classes of signal molecules—prostaglandins, prostacyclins, thromboxanes, and leukotrienes—that act as messengers and local hormones because of their transience. They are called eicosanoids because they contain 20 carbon atoms. Aspirin (acetylsalicylate), an anti-inflammatory and antithrombotic drug, irreversibly blocks the synthesis of these eicosanoids.

#### 22.6 Acetyl CoA Carboxylase Plays a Key Role in Controlling Fatty Acid Metabolism

Fatty acid synthesis and degradation are reciprocally regulated so that both are not simultaneously active. Acetyl CoA carboxylase, the essential control site, is phosphorylated and inactivated by AMP-activated kinase. The phosphorylation is reversed by a protein phosphatase. Citrate, which signals an abundance of building blocks and energy, partly reverses the inhibition by phosphorylation. Carboxylase activity is stimulated by insulin and inhibited by glucagon and epinephrine. In times of plenty, fatty acyl CoAs do not enter the mitochondrial matrix, because malonyl CoA inhibits carnitine acyltransferase I.

## KEY TERMS

triacylglycerol (neutral fat, triglyceride) (p. 643)	peroxisome (p. 656)	arachidonate (p. 669)
lipid droplet (p. 645)	ketone body (p. 657)	prostaglandin (p. 669)
acyl adenylate (p. 649)	acyl carrier protein (ACP) (p. 661)	eicosanoid (p. 669)
carnitine (p. 649)	fatty acid synthase (p. 661)	polyketide (p. 670)
$\beta$ -oxidation pathway (p. 650)	malonyl CoA (p. 661)	AMP-activated protein kinase (AMPK) (p. 671)
vitamin B <sub>12</sub> (cobalamin) (p. 654)	acetyl CoA carboxylase (p. 662)	
	ATP-citrate lyase (p. 666)	

## PROBLEMS

1. *Match'em.* Match each term with its description.

- |                                       |  |
|---------------------------------------|--|
| (a) Triacylglycerol _____             | 1. The enzyme that initiates lipid degradation   |
| (b) Perilipin _____                   | 2. Activates fatty acids for degradation   |
| (c) Adipose triglyceride lipase _____ | 3. Converts a <i>cis</i> - $\Delta^3$ double bond into a <i>trans</i> - $\Delta^2$ double bond |
| (d) Glucagon _____                    | 4. Reduces 2,4-dienoyl intermediate to <i>trans</i> - $\Delta^3$ -enoyl CoA                    |
| (e) Acyl CoA synthetase _____         | 5. Storage form of fats  |
| (f) Carnitine _____                   | 6. Required for entry into mitochondria  |
| (g) $\beta$ -Oxidation pathway _____  | 7. Requires vitamin B <sub>12</sub>  |
| (h) Enoyl CoA isomerase _____         | 8. Acetoacetate  |
| (i) 2,4-Dienoyl CoA reductase _____   | 9. Means by which fatty acids are degraded   |
| (j) Methylmalonyl CoA mutase _____    | 10. Stimulates lipolysis   |
| (k) Ketone body _____                 | 11. Lipid-droplet-associated protein   |

2. *After lipolysis.* Write a balanced equation for the conversion of glycerol into pyruvate. Which enzymes are required in addition to those of the glycolytic pathway?

3. *Forms of energy.* The partial reactions leading to the synthesis of acyl CoA (equations 1 and 2, p. 649) are freely reversible. The equilibrium constant for the sum of these reactions is close to 1, meaning that the energy levels of the reactants and products are about equal, even though a molecule of ATP has been hydrolyzed. Explain why these reactions are readily reversible.

4. *Activation fee.* The reaction for the activation of fatty acids before degradation is

This reaction is quite favorable because the equivalent of two molecules of ATP is hydrolyzed. Explain why, from a biochemical bookkeeping point of view, the equivalent of two molecules of ATP is used despite the fact that the left side of the equation has only one molecule of ATP.

5. *Proper sequence.* Place the following list of reactions or relevant locations in the  $\beta$  oxidation of fatty acids in the proper order.

- Reaction with carnitine
- Fatty acid in the cytoplasm
- Activation of fatty acid by joining to CoA
- Hydration
- NAD<sup>+</sup>-linked oxidation
- Thiolysis
- Acyl CoA in mitochondrion
- FAD-linked oxidation.

6. *Remembrance of reactions past.* We have encountered reactions similar to the oxidation, hydration, and oxidation reactions of fatty acid degradation earlier in our study of biochemistry. What other pathway employs this set of reactions?

7. *A phantom acetyl CoA?* In the equation for fatty acid degradation shown here, only seven molecules of CoA are required to yield eight molecules of acetyl CoA. How is this difference possible?

8. *Comparing yields.* Compare the ATP yields from palmitic acid and palmitoleic acid.

9. *Counting ATPs 1.* What is the ATP yield for the complete oxidation of C<sub>17</sub> (heptadecanoic) fatty acid? Assume that the propionyl CoA ultimately yields oxaloacetate in the citric acid cycle.

10. *Sweet temptation.* Stearic acid is a  $C_{18}$  fatty acid component of chocolate. Suppose you had a depressing day and decided to settle matters by gorging on chocolate. How much ATP would you derive from the complete oxidation of stearic acid to  $CO_2$ ?

11. *The best storage form.* Compare the ATP yield from the complete oxidation of glucose, a six-carbon carbohydrate, and hexanoic acid, a six-carbon fatty acid. Hexanoic acid is also called *caproic acid* and is responsible for the "aroma" of goats. Why are fats better fuels than carbohydrates?

12. *From fatty acid to ketone body.* Write a balanced equation for the conversion of stearate into acetoacetate.

13. *Generous, but not to a fault.* Liver is the primary site of ketone-body synthesis. However, ketone bodies are not used by the liver but are released for other tissues to use. The liver does gain energy in the process of synthesizing and releasing ketone bodies. Calculate the number of molecules of ATP generated by the liver in the conversion of palmitate, a  $C_{16}$  fatty acid, into acetoacetate.

14. *Counting ATPs 2.* How much energy is attained with the complete oxidation of the ketone body D-3-hydroxybutyrate?

15. *Another view.* Why might someone argue that the answer to problem 14 is wrong?

16. *An accurate adage.* An old biochemistry adage is that *fats burn in the flame of carbohydrates*. What is the molecular basis of this adage?

17. *Refsum disease.* Phytanic acid is a branched-chain fatty acid component of chlorophyll and is a significant component of milk. In susceptible people, phytanic acid can accumulate, leading to neurological problems. This syndrome is called Refsum disease or phytanic acid storage disease.

(a) Why does phytanic acid accumulate?

(b) What enzyme activity would you invent to prevent its accumulation?

18. *A hot diet.* Tritium is a radioactive isotope of hydrogen and can be readily detected. A fully tritiated, six-carbon saturated fatty acid is administered to a rat, and a muscle biopsy of the rat is taken by concerned, sensitive, and discrete technical assistants. These assistants carefully isolate all of the acetyl CoA generated from the  $\beta$  oxidation of the radioactive fatty acid and remove the CoA to form acetate. What will be the overall tritium-to-carbon ratio of the isolated acetate?

19. *Finding triacylglycerols in all the wrong places.* Insulin-dependent diabetes is often accompanied by high levels of triacylglycerols in the blood. Suggest a biochemical explanation.

20. *Match 'em.* Match the terms with the descriptions.

- |  |   |
|--|---|
| (a) ATP-citrate lyase _____            | 1. Helps to generate NADPH from NADH                    |
| (b) Malic enzyme _____                 | 2. Inactivates acetyl CoA carboxylase                   |
| (c) Malonyl CoA _____                  | 3. Molecule on which fatty acids are synthesized        |
| (d) Acetyl CoA carboxylase _____       | 4. A precursor of prostaglandins                        |
| (e) Acyl carrier protein _____         | 5. Activated acetyl CoA                                 |
| (f) $\beta$ -Ketoacyl synthase _____   | 6. The end product of fatty acid synthase               |
| (g) Palmitate _____                    | 7. Fatty acids containing 20 carbon atoms               |
| (h) Eicosanoids _____                  | 8. Catalyzes the committed step in fatty acid synthesis |
| (i) Arachidonate _____                 | 9. Catalyzes the reaction of acetyl ACP and malonyl ACP |
| (j) AMP-activated protein kinase _____ | 10. Generates cytoplasmic acetyl CoA                    |

21. *Counterpoint.* Compare and contrast fatty acid oxidation and synthesis with respect to

- site of the process
- acyl carrier
- reductants and oxidants

22. *The fizz in fatty acid synthesis.* During the initial in vitro studies on fatty acid synthesis, experiments were performed to determine which buffer would result in optimal activity. Bicarbonate buffer proved far superior to phosphate buffer. The researchers could not initially account for this result. From your perspective of many decades later, explain why the result is not surprising.

23. *A supple synthesis.* Myristate, a saturated  $C_{14}$  fatty acid, is used as an emollient for cosmetics and topical medicinal preparations. Write a balanced equation for the synthesis of myristate.

24. *The cost of cleanliness.* Lauric acid is a 12-carbon fatty acid with no double bonds. The sodium salt of lauric acid (sodium laurate) is a common detergent used in a variety of products, including laundry detergent, shampoo, and toothpaste. How many molecules of ATP and NADPH are required to synthesize lauric acid?

25. *Proper organization.* Arrange the following steps in fatty acid synthesis in their proper order.

- (a) Dehydration (d) Reduction of a carbonyl group  
 (b) Condensation (e) Formation of malonyl ACP  
 (c) Release of a C<sub>16</sub> fatty acid

26. *No access to assets.* What would be the effect on fatty acid synthesis of a mutation in ATP-citrate lyase that reduces the enzyme's activity? Explain.

27. *The truth and nothing but.* True or False. If false, explain.

- (a) Biotin is required for fatty acid synthase activity.  
 (b) The condensation reaction in fatty acid synthesis is powered by the decarboxylation of malonyl CoA.  
 (c) Fatty acid synthesis does not depend on ATP.  
 (d) Palmitate is the end product of fatty acid synthase.  
 (e) All of the enzyme activities required for fatty acid synthesis in mammals are contained in a single polypeptide chain.  
 (f) Fatty acid synthase in mammals is active as a monomer.  
 (g) The fatty acid arachidonate is a precursor for signal molecules.  
 (h) Acetyl CoA carboxylase is inhibited by citrate.

28. *Odd fat out.* Suggest how fatty acids with odd numbers of carbons are synthesized.

29. *Labels.* Suppose that you had an in vitro fatty acid-synthesizing system that had all of the enzymes and cofactors required for fatty acid synthesis except for acetyl CoA. To this system, you added acetyl CoA that contained radioactive hydrogen (<sup>3</sup>H, tritium) and carbon 14 (<sup>14</sup>C) as shown here.

The ratio of <sup>3</sup>H/<sup>14</sup>C is 3. What would the <sup>3</sup>H/<sup>14</sup>C ratio be after the synthesis of palmitic acid (C<sub>16</sub>) with the use of the radioactive acetyl CoA?

30. *A tight embrace.* Avidin, a glycoprotein found in eggs, has a high affinity for biotin. Avidin can bind biotin and prevent its use by the body. How might a diet rich in raw eggs affect fatty acid synthesis? What will be the effect on fatty acid synthesis of a diet rich in cooked eggs? Explain.

31. *Alpha or omega?* Only one acetyl CoA molecule is used directly in fatty acid synthesis. Identify the carbon atoms in palmitic acid that were donated by acetyl CoA.

32. *Now you see it, now you don't.* Although HCO<sub>3</sub><sup>-</sup> is required for fatty acid synthesis, its carbon atom does not appear in the product. Explain how this omission is possible.

33. *It is all about communication.* Why is citrate an appropriate inhibitor of phosphofructokinase?

34. *Tracing carbon atoms.* Consider a cell extract that actively synthesizes palmitate. Suppose that a fatty acid synthase in this preparation forms one molecule of palmitate in about 5 minutes. A large amount of malonyl CoA labeled with <sup>14</sup>C in each carbon atom of its malonyl unit is suddenly added to this system, and fatty acid synthesis is stopped a minute later by altering the pH. The fatty acids are analyzed for radioactivity. Which carbon atom of the palmitate formed by this system is more radioactive—C-1 or C-14?

35. *An unaccepting mutant.* The serine residues in acetyl CoA carboxylase that are the target of the AMP-activated protein kinase are mutated to alanine. What is a likely consequence of this mutation?

36. *Sources.* For each of the following unsaturated fatty acids, indicate whether the biosynthetic precursor in animals is palmitoleate, oleate, linoleate, or linolenate.

- (a) 18:1 *cis*-Δ<sup>11</sup> (d) 20:3 *cis*-Δ<sup>5</sup>, Δ<sup>8</sup>, Δ<sup>11</sup>  
 (b) 18:3 *cis*-Δ<sup>6</sup>, Δ<sup>9</sup>, Δ<sup>12</sup> (e) 22:1 *cis*-Δ<sup>13</sup>  
 (c) 20:2 *cis*-Δ<sup>11</sup>, Δ<sup>14</sup> (f) 22:6 *cis*-Δ<sup>4</sup>, Δ<sup>7</sup>, Δ<sup>10</sup>, Δ<sup>13</sup>, Δ<sup>16</sup>, Δ<sup>19</sup>

37. *Driven by decarboxylation.* What is the role of decarboxylation in fatty acid synthesis? Name another key reaction in a metabolic pathway that employs this mechanistic motif.

38. *Kinase surfeit.* Suppose that a promoter mutation leads to the overproduction of protein kinase A in adipose cells. How might fatty acid metabolism be altered by this mutation?

39. *Blocked assets.* The presence of a fuel molecule in the cytoplasm does not ensure that the fuel molecule can be effectively used. Give two examples of how impaired transport of metabolites between compartments leads to disease.

40. *Elegant inversion.* Peroxisomes have an alternative pathway for oxidizing polyunsaturated fatty acids. They contain a hydratase that converts D-3-hydroxyacyl CoA into *trans*-Δ<sup>2</sup>-enoyl CoA. How can this enzyme be used to oxidize CoAs containing a *cis* double bond at an even-numbered carbon atom (e.g., the *cis*-Δ<sup>12</sup> double bond of linoleate)?

41. *Arm in arm.* Many eukaryotic enzymes, such as fatty acid synthase, are multifunctional proteins with multiple active sites covalently linked. What is the advantage of this arrangement?

42. *Covalent catastrophe.* What is a potential disadvantage of having many catalytic sites together on one very long polypeptide chain?

43. *Missing acyl CoA dehydrogenases.* A number of genetic deficiencies in acyl CoA dehydrogenases have been described. This deficiency presents early in life after a period of fasting. Symptoms include vomiting, lethargy, and sometimes coma. Not only are blood levels of glucose low (hypoglycemia), but starvation-induced ketosis is absent. Provide a biochemical explanation for these last two observations.

44. *Effects of clofibrate.* High blood levels of triacylglycerides are associated with heart attacks and strokes. Clofibrate, a drug that increases the activity of peroxisomes, is sometimes used to treat patients with such a condition. What is the biochemical basis for this treatment?

45. *A different kind of enzyme.* Figure 22.36 shows the response of acetyl CoA carboxylase to varying amounts of citrate. Explain this effect in light of the allosteric effects that citrate has on the enzyme. Predict the effects of increasing concentrations of palmitoyl CoA.

### Mechanism Problems

46. *Variation on a theme.* Thiolase is homologous in structure to the condensing enzyme. On the basis of this observation, propose a mechanism for the cleavage of 3-ketoacyl CoA by CoA.

47. *Two plus three to make four.* Propose a reaction mechanism for the condensation of an acetyl unit with a malonyl unit to form an acetoacetyl unit in fatty acid synthesis.

### Chapter Integration Problems

48. *Ill-advised diet.* Suppose that, for some bizarre reason, you decided to exist on a diet of whale and seal blubber, exclusively.

(a) How would lack of carbohydrates affect your ability to utilize fats?

(b) What would your breath smell like?

(c) One of your best friends, after trying unsuccessfully to convince you to abandon this diet, makes you promise to consume a healthy dose of odd-chain fatty acids. Does your friend have your best interests at heart? Explain.

49. *Fats to glycogen.* An animal is fed stearic acid that is radioactively labeled with [ $^{14}\text{C}$ ]carbon. A liver biopsy reveals the presence of  $^{14}\text{C}$ -labeled glycogen. How is this finding possible in light of the fact that animals cannot convert fats into carbohydrates?

50. *Enzyme deficit.* Pyruvate dehydrogenase deficiency, a severe condition with a poor prognosis, results in neurological dysfunction and unremitting lactic acidosis. One treatment is placing the patients on a low carbohydrate/high fat diet.

(a) Explain why the deficiency would be characterized by neurological dysfunction.

(b) Why does lactic acidosis result?

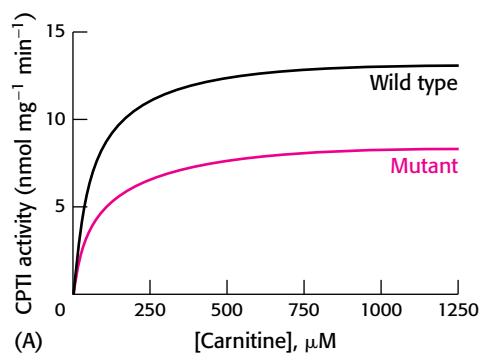

(c) Explain the rationale for the low carbohydrate/high fat diet.

51. *Right enzymes. Wrong location.* Zellweger syndrome is caused by a defect in enzyme importation into the peroxisomes. What disease of carbohydrate metabolism is caused by inappropriate cellular distribution of enzymes?

### Data Interpretation Problem

52. *Mutant enzyme.* Carnitine palmitoyl transferase I (CPTI) catalyzes the conversion of long-chain acyl CoA into acyl carnitine, a prerequisite for transport into mitochondria and subsequent degradation. A mutant enzyme was constructed with a single amino acid change at position 3 of glutamic acid for alanine. Graphs A through C show data from studies performed to identify the effect of the mutation.

(a) What is the effect of the mutation on enzyme activity when the concentration of carnitine is varied (Graph A)? What are the  $K_M$  and  $V_{max}$  values for the wild-type and mutant enzymes?

(b) What is the effect when the experiment is repeated with varying concentrations of palmitoyl CoA (Graph B)? What are the  $K_M$  and  $V_{max}$  values for the wild-type and mutant enzymes?

(c) Graph C shows the inhibitory effect of malonyl CoA on the wild-type and mutant enzymes. Which enzyme is more sensitive to malonyl CoA inhibition?

(d) Suppose that the concentration of palmitoyl CoA = 100  $\mu\text{M}$ , that of carnitine = 100  $\mu\text{M}$ , and that of malonyl CoA = 10  $\mu\text{M}$ . Under these conditions, what is the most prominent effect of the mutation on the properties of the enzyme?

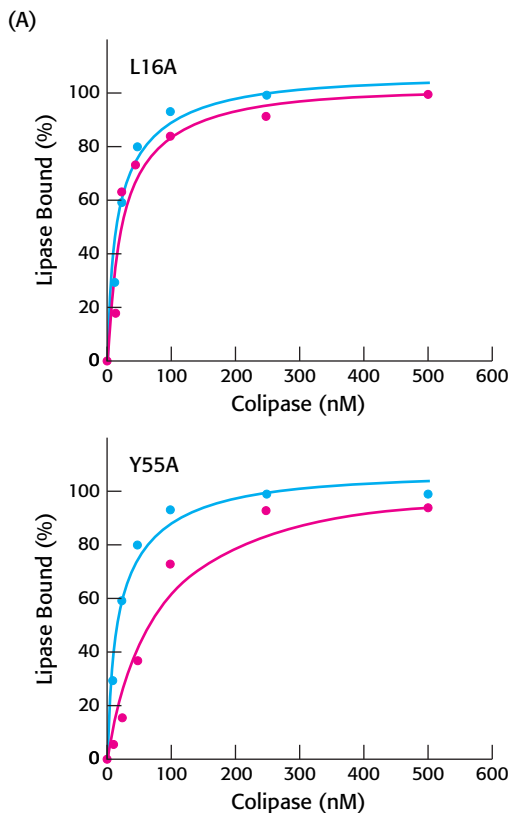

(e) What can you conclude about the role of glutamate 3 in CPTI function?

[Data from J. Shi, H. Zhu, D. N. Arvidson, and G. J. Woldegiorgis. *J. Biol. Chem.* 274:9421–9426, 1999.]

53. *Partners.* Colipase binds to lipid particles in the intestine and facilitates the subsequent binding and activation of pancreatic lipase. The lipase then hydrolyzes the lipids so that they can be absorbed by intestinal cells. Experiments were undertaken using site-directed mutagenesis (Section 5.2) to determine which amino acids in the colipase facilitated lipase binding and which activated the lipase. A portion of these experiments is presented below.

Figure A shows the results of two different amino acid substitutions on the ability of colipase to facilitate the binding of lipase to the lipid particles. In both panels, the blue circles show the control (no amino acid changes) data and the red circles the data with the altered amino acid. The first letter represents the normal amino acid, the number its position in the amino acid sequence, and the second letter the replacement amino acid.

(a) What is the amino acid alteration in the upper panel?

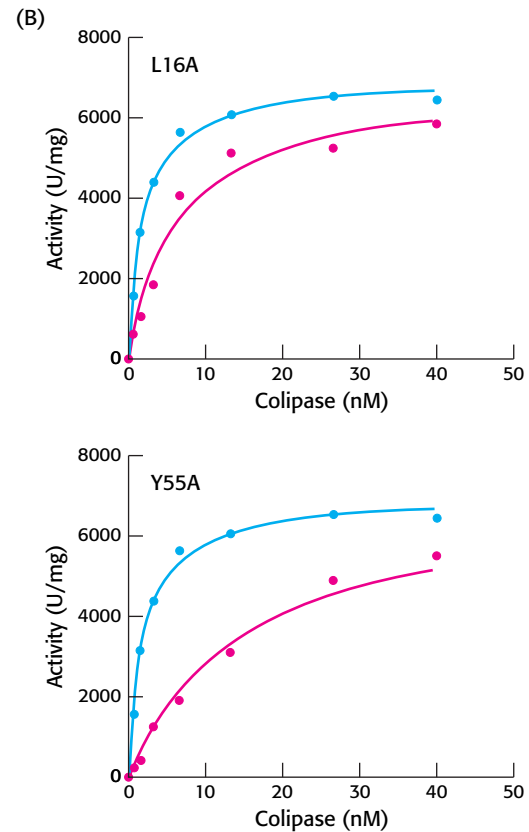

(b) How does this mutation change the ability of colipase to bind the lipase to the lipid particle?

(c) What is the amino acid substitution in the lower panel?

(d) What is the effect of this substitution on the ability of the colipase to bind the lipase to the lipid particle?

Next, the activity of the bound lipase was examined, as shown in Figure B.

[Data from: Ross, L. E., Xiao, X., and Lowe, M. E. 2013. Identification of amino acids in human colipase that mediate adsorption to lipid emulsions and mixed micelles. *Biochim. Biophys. Acta* 1831: 1052–1059.]

(e) What was the effect of the L16A mutation on lipase activity?

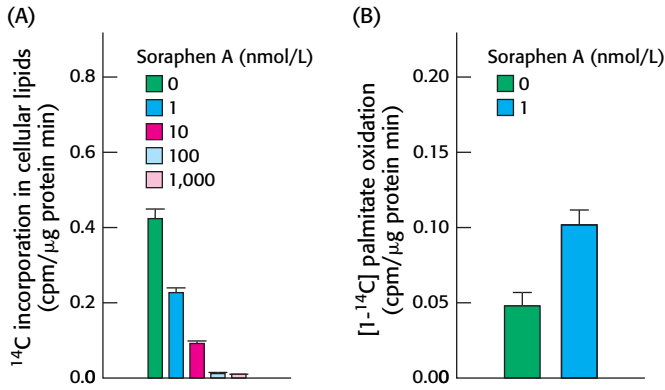

(f) What does this suggest about the lipase binding and activation properties of the colipase?

(g) What was the effect of the Y55A mutation on lipase activity?

54. *Nip it in the bud.* Soraphen A is a natural antifungal agent isolated from a myxobacterium. Soraphen A is also a potent inhibitor of acetyl CoA carboxylase, the regulatory enzyme that initiates fatty acid synthesis. As discussed earlier (p. 667), cancer cells must produce large amount of fatty acids to generate phospholipids for membrane synthesis. Thus, acetyl CoA carboxylase might be a target for anti-cancer drugs.

Following are the results of experiments testing this hypothesis on a cancer line.

Figure A shows the effect of various amounts of soraphen A on fatty acid synthesis as measured by the incorporation of radioactive acetate ( $^{14}\text{C}$ ) into fatty acids.

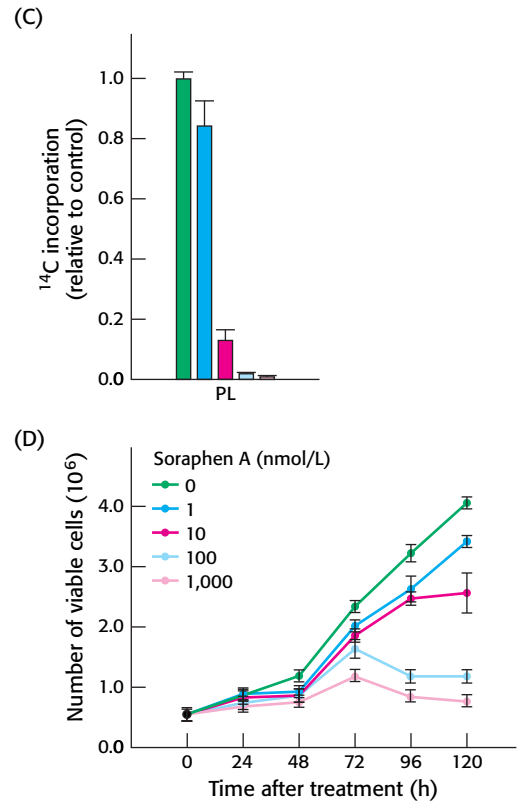

(a) How did soraphen A alter fatty acid synthesis? How was synthesis affected by increasing concentrations of soraphen A?

Figure B shows the results obtained when fatty acid oxidation was measured, as the release of radioactive  $\text{CO}_2$  from added radioactive ( $^{14}\text{C}$ ) palmitate, in the presence of soraphen A.

(b) How did soraphen A alter fatty acid oxidation?

(c) Explain the results obtained in B in light of the fact that soraphen A inhibits acetyl CoA carboxylase.

More experiments were undertaken to assess whether carboxylase inhibition did indeed prevent phospholipid synthesis. Again, cells were grown in the presence of radioactive acetate and phospholipids were subsequently isolated and the amount of  $^{14}\text{C}$  incorporated into the phospholipid was determined. The effect of soraphen A on phospholipid synthesis is shown in Figure C.

[Data from: Beckers, A., Organe, S., Timmermans, L., Scheys, K., Peeters, A., Brusselmans, K., Verhoeven, G., and Swinnen, J. V. 2007. Chemical inhibition of acetyl-CoA carboxylase induces growth arrest and cytotoxicity selectively in cancer cells. *Cancer Res.* 67: 8180–8187.]

(d) Did the inhibition of carboxylase by the drug alter phospholipid synthesis?

(e) How might phospholipid synthesis affect cell viability?

Finally, as shown in Figure D, experiments were performed to determine if the drug inhibits cancer growth in vitro by determining the number of cancer cells surviving upon exposure to soraphen A.

(f) How did soraphen A affect cancer cell viability?

# Protein Turnover and Amino Acid Catabolism

This fourteenth-century hand-colored woodcut from Germany depicts a wheel that classifies urine samples according to their color and consistency. In the middle of the wheel, a doctor inspects a patient's urine by sight, smell, and taste. The vials on the wheel aided physicians in diagnosing diseases. A key component of urine is urea, which is formed from the amino groups released during the metabolism of amino acids. [(Left) Rosenwald Collection. Rare Book and Special Collections Division, Library of Congress (128.2).]

The digestion of dietary proteins in the intestine and the degradation of proteins within the cell provide a steady supply of amino acids to the cell. Many cellular proteins are constantly degraded and resynthesized in response to changing metabolic demands. Others are misfolded or become damaged and they, too, must be degraded. Unneeded or damaged proteins are marked for destruction by the covalent attachment of chains of a small protein called *ubiquitin* and then degraded by a large, ATP-dependent complex called the *proteasome*. The primary use of amino acids provided through degradation or digestion is as building blocks for the synthesis of proteins and other nitrogenous compounds such as nucleotide bases.

Amino acids in excess of those needed for biosynthesis can neither be stored, in contrast with fatty acids and glucose, nor excreted. Rather, surplus amino acids are used as metabolic fuel. The  $\alpha$ -amino group is removed, and the resulting carbon skeleton is converted into a major metabolic intermediate. Most of the amino groups harvested from surplus amino acids are converted into urea through the *urea cycle*, and their carbon skeletons are transformed into acetyl CoA, acetoacetyl CoA, pyruvate, or one of the intermediates of the citric acid cycle. The carbon skeletons are converted into glucose, glycogen, and fats.

## OUTLINE

- 23.1 Proteins Are Degraded to Amino Acids
- 23.2 Protein Turnover Is Tightly Regulated
- 23.3 The First Step in Amino Acid Degradation Is the Removal of Nitrogen
- 23.4 Ammonium Ion Is Converted into Urea in Most Terrestrial Vertebrates
- 23.5 Carbon Atoms of Degraded Amino Acids Emerge as Major Metabolic Intermediates
- 23.6 Inborn Errors of Metabolism Can Disrupt Amino Acid Degradation

Several coenzymes play key roles in amino acid degradation; foremost among them is *pyridoxal phosphate*. This coenzyme forms Schiff-base intermediates, which are a type of aldimine, that allow  $\alpha$ -amino groups to be shuttled between amino acids and ketoacids. We will consider several genetic errors of amino acid degradation that lead to brain damage and mental retardation unless remedial action is initiated soon after birth. The study of amino acid metabolism is especially rewarding because it is rich in connections between basic biochemistry and clinical medicine.

## 23.1 Proteins Are Degraded to Amino Acids

Dietary protein is a vital source of amino acids. Especially important dietary proteins are those containing the essential amino acids—amino acids that cannot be synthesized and must be acquired in the diet (Table 23.1). Proteins ingested in the diet are digested into amino acids or small peptides that can be absorbed by the intestine and transported in the blood. Another crucial source of amino acids is the degradation of cellular proteins.

### The digestion of dietary proteins begins in the stomach and is completed in the intestine

 Protein digestion begins in the stomach, where the acidic environment denatures proteins into random coils. Denatured proteins are more accessible as substrates for proteolysis than are native proteins. The primary proteolytic enzyme of the stomach is *pepsin*, a nonspecific protease that, remarkably, is maximally active at pH 2. Thus, pepsin can function in the highly acidic environment of the stomach that disables other proteins.

The partly digested proteins then move from the acidic environment of the stomach to the beginning of the small intestine. The low pH of the food as well as the polypeptide products of pepsin digestion stimulate the release of hormones that promote the secretion from the pancreas of sodium bicarbonate ( $\text{NaHCO}_3$ ), which neutralizes the pH of the food, and a variety of pancreatic proteolytic enzymes. Recall that these enzymes are secreted as inactive zymogens that are then converted into active enzymes (Sections 9.1 and 10.4). The battery of enzymes displays a wide array of specificity, and so the substrates are degraded into free amino acids as well as di- and tripeptides. Digestion is further enhanced by proteolytic enzymes, such as aminopeptidase N, that are located in the plasma membrane of the intestinal cells. Aminopeptidases digest proteins from the amino-terminal end. Single amino acids, as well as di- and tripeptides, are transported into the intestinal cells.

At least seven different transporters exist, each specific to a different group of amino acids. A number of inherited disorders result from mutations in these transporters. For example, Hartnup disease, a rare disorder characterized by rashes, ataxia (lack of muscle control), delayed mental development, and diarrhea, results from a defect in the transporter for tryptophan and other nonpolar amino acids. The absorbed amino acids are subsequently released into the blood by a number of  $\text{Na}^+$ -amino acid antiporters for use by other tissues (Figure 23.1).

### Cellular proteins are degraded at different rates

*Protein turnover*—the degradation and resynthesis of proteins—takes place constantly in cells. Although some proteins are very stable, many proteins are short lived, particularly those that participate in metabolic regulation. These proteins can be quickly degraded to activate or shut down a signaling

**FIGURE 23.1 Digestion and absorption of proteins.** Protein digestion is primarily a result of the activity of enzymes secreted by the pancreas. Aminopeptidases associated with the intestinal epithelium further digest proteins. The amino acids and di- and tripeptides are absorbed into the intestinal cells by specific transporters (green and orange ovals). Free amino acids are then released into the blood by transporters (red oval) for use by other tissues.

pathway. In addition, cells must eliminate damaged proteins. A significant proportion of newly synthesized protein molecules are defective because of errors in translation or misfolding. Even proteins that are normal when first synthesized may undergo oxidative damage or be altered in other ways with the passage of time. These proteins must be removed before they accumulate and aggregate. Indeed, a number of pathological conditions, such as certain forms of Parkinson disease and Huntington disease, are associated with protein aggregation.

The half-lives of proteins range over several orders of magnitude. Ornithine decarboxylase, at approximately 11 minutes, has one of the shortest half-lives of any mammalian protein. This enzyme participates in the synthesis of polyamines, which are cellular cations essential for growth and differentiation. The life of hemoglobin, however, is limited only by the life of the red blood cell, and the lens protein crystallin is limited by the life of the organism.

**FIGURE 23.2 Structure of ubiquitin.** Notice that ubiquitin has an extended carboxyl terminus, which is activated and linked to proteins targeted for destruction. Lysine residues, including lysine 48, the major site for linking additional ubiquitin molecules, are shown as ball-and-stick models. [Drawn from 1UBI.pdb.]

## 23.2 Protein Turnover Is Tightly Regulated

How can a cell distinguish proteins that should be degraded? *Ubiquitin* (Ub), a small (76 amino acids) protein present in all eukaryotic cells, is a tag that marks proteins for destruction (Figure 23.2). Ubiquitin is the cellular equivalent of the “black spot” of Robert Louis Stevenson’s *Treasure Island*—the signal for death.

### Ubiquitin tags proteins for destruction

Ubiquitin is highly conserved in eukaryotes: yeast and human ubiquitin differ at only 3 of 76 residues. The carboxyl-terminal glycine residue of ubiquitin becomes covalently attached to the  $\epsilon$ -amino groups of several lysine residues on a protein destined to be degraded. The energy for the formation of these *isopeptide bonds* (*iso* because  $\epsilon$ - rather than  $\alpha$ -amino groups are targeted) comes from ATP hydrolysis.

Three enzymes participate in the attachment of ubiquitin to a protein (Figure 23.3): ubiquitin-activating enzyme, or E1; ubiquitin-conjugating enzyme, or E2; and ubiquitin–protein ligase, or E3. First, the C-terminal carboxylate group of ubiquitin becomes linked to a sulfhydryl group of E1 by a thioester bond. This ATP-driven reaction is reminiscent of fatty acid activation (Section 22.2). In this reaction, an acyl adenylate is formed at the

**FIGURE 23.3 Ubiquitin conjugation.** The ubiquitin-activating enzyme E1 adenylates ubiquitin (Ub) (1) and transfers the ubiquitin to one of its own cysteine residues (2). Ubiquitin is then transferred to a cysteine residue in the ubiquitin-conjugating enzyme E2 by the E2 enzyme. (3). Finally, the ubiquitin–protein ligase E3 transfers the ubiquitin to a lysine residue on the target protein (4a and 4b).

C-terminal carboxylate of ubiquitin with the release of pyrophosphate, and the ubiquitin is subsequently transferred to a sulfhydryl group of a key cysteine residue in E1. The activated ubiquitin is then shuttled to a sulfhydryl group of E2, a reaction catalyzed by E2 itself. Finally, E3 catalyzes the transfer of ubiquitin from E2 to an  $\epsilon$ -amino group on the target protein. The ubiquitination reaction is processive: E3 remains bound to the target proteins and generates a chain of ubiquitin molecules by linking the  $\epsilon$ -amino group of lysine residue 48 of one ubiquitin molecule to the terminal carboxylate of another. A chain of four or more ubiquitin molecules is especially effective in signaling the need for degradation (Figure 23.4).

**FIGURE 23.4 Structure of tetraubiquitin.**

Four ubiquitin molecules are linked by isopeptide bonds. Notice that each isopeptide bond is formed by the linkage of the carboxylate group at the end of the extended C terminus with the  $\epsilon$ -amino group of a lysine residue. Dashed lines indicate the positions of the extended C-termini that were not observed in the crystal structure. This unit is the primary signal for degradation when linked to a target protein. [Drawn from 1TBE. pdb.]

What determines whether a protein becomes ubiquitinated? A specific sequence of amino acids, termed a *degron*, indicates that a protein should be degraded. One such signal appears to be quite simple. *The half-life of a cytoplasmic protein is determined to a large extent by its amino-terminal residue* (Table 23.2). This dependency is referred to as the *N-terminal rule* or the *N-terminal degron*. A yeast protein with methionine at its N terminus typically has a half-life of more than 20 hours, whereas one with arginine at this position has a half-life of about 2 minutes. A highly destabilizing N-terminal residue such as arginine or leucine favors rapid ubiquitination, whereas a stabilizing residue such as methionine or proline does not. Why is the N-terminal rule only *apparently* simple? Sometimes the N-terminal degron is exposed only after the protein is proteolytically cleaved. Such degrons are called *pro-N-terminal degrons*, in analogy to proenzymes (Section 10.4), because the protein must be cleaved to expose the signal. In other cases, the destabilizing amino acid is added to the protein after the protein is synthesized. Other modifications, notably N-terminal acetylation, can also activate a degron. Additional degrons thought to identify proteins for degradation include *cyclin destruction boxes*, which are amino acid sequences that mark cell-cycle proteins for destruction, and *PEST sequences*, which contain the amino acid sequence proline (P, single-letter abbreviation), glutamic acid (E), serine (S), and threonine (T).

E3 enzymes are the readers of N-terminal residues. Although most eukaryotes have only one or a small number of distinct E1 enzymes, all eukaryotes have many distinct E2 and E3 enzymes. Moreover, there appears to be only a single family of evolutionarily related E2 proteins but three distinct families of E3 proteins, all together consisting of

hundreds of members. Indeed, the E3 family is one of the largest gene families in human beings. The diversity of target proteins that must be tagged for destruction requires a large number of E3 proteins as readers.

 Three examples demonstrate the importance of E3 proteins to normal cell function. Proteins that are not broken down owing to a defective E3 may accumulate to create a disease of protein aggregation such as juvenile or early-onset Parkinson disease. A defect in another member of the E3 family causes Angelman syndrome, a severe neurological disorder characterized by mental retardation, absence of speech, uncoordinated movement, and hyperactivity. Conversely, uncontrolled protein turnover also can create dangerous pathological conditions. For example, human papillomavirus (HPV) encodes a protein that activates a specific E3 enzyme. The enzyme ubiquitinates the tumor suppressor p53 and other proteins that control DNA repair, which are then destroyed. The activation of this E3 enzyme is observed in more than 90% of cervical carcinomas. Thus, the inappropriate marking of key regulatory proteins for destruction can trigger further events, leading to tumor formation.

It is important to note that the role of ubiquitin is much broader than merely marking proteins for destruction. Although we have focused on protein degradation, monoubiquitination also regulates proteins involved in DNA repair, chromatin remodeling, and protein kinase activation, among other biochemical processes.

### The proteasome digests the ubiquitin-tagged proteins

If ubiquitin is the mark of death, what is the executioner? A large protease complex called the proteasome or the 26S proteasome digests the ubiquitinated proteins. This ATP-driven multisubunit protease spares ubiquitin, which is then recycled. The 26S proteasome is a complex of two components: a 20S catalytic unit and a 19S regulatory unit.

The 20S unit is composed of 28 subunits, encoded by 14 genes, arranged into 4 heteroheptameric rings stacked to form a structure resembling a barrel (Figure 23.5). The outer two rings of the barrel are made up of  $\alpha$ -type subunits and the inner two rings of  $\beta$ -type subunits. The 20S catalytic core is a sealed barrel. Access to its interior is controlled by a 19S regulatory unit, itself a 700-kDa complex made up of 19 subunits. Two such 19S complexes bind to the 20S proteasome core, one at each end, to form the complete 26S proteasome (Figure 23.6). The 19S regulatory unit has three functions. First, components of the 19S unit are ubiquitin receptors that bind specifically to polyubiquitin chains, thereby ensuring that only ubiquitinated proteins are degraded. Second, an isopeptidase in the 19S unit cleaves off intact ubiquitin molecules from the proteins so that they can be reused. Finally, the doomed protein is unfolded and directed into the catalytic core. Key components of the 19S complex are six ATPases of a type called the AAA class (ATPase associated with various cellular activities). ATP hydrolysis assists the 19S complex to unfold the substrate and induce conformational changes in the 20S catalytic core so that the substrate can be passed into the center of the complex.

The proteolytic active sites are sequestered in the interior of the barrel to protect potential substrates until they are directed into the barrel. There are three types of active sites in the  $\beta$  subunits, each with a different specificity,

**TABLE 23.2** Dependence of the half-lives of cytoplasmic yeast proteins on the identity of their amino-terminal residues

Highly stabilizing residues ( $t_{1/2} > 20$ hours)			
Ala	Cys	Gly	Met
Pro	Ser	Thr	Val
Intrinsically destabilizing residues ( $t_{1/2} = 2$ to 30 minutes)			
Arg	His	Ile	Leu
Lys	Phe	Trp	Tyr
Destabilizing residues after chemical modification ( $t_{1/2} = 3$ to 30 minutes)			
Asn	Asp	Gln	Glu

**FIGURE 23.5** 20S proteasome. The 20S proteasome comprises 28 homologous subunits ( $\alpha$ -type, red;  $\beta$ -type, blue), arranged in four rings of 7 subunits each. Some of the  $\beta$ -type subunits (right) include protease active sites at their amino termini. [Subunit drawn from 1RYP.pdb.]

**FIGURE 23.6** 26S proteasome. A 19S regulatory subunit is attached to each end of the 20S catalytic unit. [From W. Baumeister, J. Walz, F. Zuhl, and E. Seemuller. *Cell* 92(1998):367–380; courtesy of Dr. Wolfgang Baumeister.]

**FIGURE 23.7 The proteasome and other proteases generate free amino acids.**

Ubiquitinated proteins are processed to peptide fragments from which the ubiquitin is subsequently removed and recycled. The peptide fragments are further digested to yield free amino acids, which can be used for biosynthetic reactions, most notably protein synthesis. Alternatively, the amino group can be removed and processed to urea (p. 693) and the carbon skeleton can be used to synthesize carbohydrate or fats or used directly as a fuel for cellular respiration.

**Archaeal proteasome Eukaryotic proteasome**

**FIGURE 23.8 Proteasome evolution.** The archaeal proteasome consists of 14 identical  $\alpha$  subunits and 14 identical  $\beta$  subunits. In the eukaryotic proteasome, gene duplication and specialization has led to 7 distinct subunits of each type. The overall architecture of the proteasome is conserved.

but all employ an N-terminal threonine. The hydroxyl group of the threonine residue is converted into a nucleophile that attacks the carbonyl groups of peptide bonds to form acyl-enzyme intermediates. Substrates are degraded in a processive manner without the release of degradation intermediates, until the substrate is reduced to peptides ranging in length from seven to nine residues. These peptide products are released from the proteasome and further degraded by other cellular proteases to yield individual amino acids. Thus, the ubiquitination pathway and the proteasome cooperate to degrade unwanted proteins. Figure 23.7 presents an overview of the fates of amino acids following proteasomal digestion.

**The ubiquitin pathway and the proteasome have prokaryotic counterparts**

Both the ubiquitin pathway and the proteasome appear to be present in all eukaryotes. Homologs of the proteasome are also found in some prokaryotes. The proteasomes of some archaea are quite similar in overall structure to their eukaryotic counterparts and similarly have 28 subunits (Figure 23.8). In the archaeal proteasome, however, all  $\alpha$  outer-ring subunits and all  $\beta$  inner-ring subunits are identical; in eukaryotes, each  $\alpha$  or  $\beta$  subunit is one of seven different isoforms. This specialization provides distinct substrate specificity.

## Protein degradation can be used to regulate biological function

 Table 23.3 lists a number of physiological processes that are controlled at least in part by protein degradation through the ubiquitin–proteasome pathway. In each case, the proteins being degraded are regulatory proteins. Consider, for example, control of the inflammatory response. A transcription factor called *NF-κB* (NF for nuclear factor) initiates the expression of a number of the genes that take part in this response. This factor is itself activated by the degradation of an attached inhibitory protein, *I-κB* (I for inhibitor). In response to inflammatory signals that bind to membrane-bound receptors, *I-κB* is phosphorylated at two serine residues, creating an E3 binding site. The binding of E3 leads to the ubiquitination and degradation of *I-κB*, unleashing *NF-κB*. The liberated transcription factor migrates from the cytoplasm to the nucleus to stimulate the transcription of the target genes. The *NF-κB*–*I-κB* system illustrates the interplay of several key regulatory motifs: receptor-mediated signal transduction, phosphorylation, compartmentalization, controlled and specific degradation, and selective gene expression. The importance of the ubiquitin–proteasome system for the regulation of gene expression is highlighted by the use of bortezomib (Velcade), a potent inhibitor of the proteasome, as a therapy for multiple myeloma. Bortezomib is a dipeptidyl boronic acid inhibitor of the proteasome.

 The evolutionary studies of proteasomes described previously have also yielded potential clinical benefits. The bacterial pathogen *Mycobacterium tuberculosis*, the cause of tuberculosis, harbors a proteasome that is very similar to the human counterpart. Nevertheless, recent work has shown that it is possible to exploit the differences between the human and the bacterial proteasomes to develop specific inhibitors of the *M. tuberculosis* complex. Oxathiazol-2-one compounds such as HT1171 are suicide inhibitors (Section 8.5) of the proteolytic activity of the *M. tuberculosis* proteasome, but have no effect on the proteasomes of the human host. This is especially exciting because these drugs kill the nonreplicating form of *M. tuberculosis*, and thus may not require the prolonged treatment required with conventional drugs, thereby reducing the likelihood of drug resistance due to interruption of the treatment regime.

## 23.3 The First Step in Amino Acid Degradation Is the Removal of Nitrogen

What is the fate of amino acids released on protein digestion or turnover? The first call is for use as building blocks for biosynthetic reactions. However, any not needed as building blocks are degraded to compounds able to enter the metabolic mainstream. The amino group is first removed, and then the remaining carbon skeleton is metabolized to glucose, one of several citric acid cycle intermediates, or to acetyl CoA. The major site of amino acid degradation in mammals is the liver, although muscles readily degrade the branched-chain amino acids (Leu, Ile, and Val). The fate of the  $\alpha$ -amino group will be considered first, followed by that of the carbon skeleton (Section 23.5).

### Alpha-amino groups are converted into ammonium ions by the oxidative deamination of glutamate

The  $\alpha$ -amino group of many amino acids is transferred to  $\alpha$ -ketoglutarate to form *glutamate*, which is then oxidatively deaminated to yield ammonium ion ( $\text{NH}_4^+$ ).

*Aminotransferases* catalyze the transfer of an  $\alpha$ -amino group from an  $\alpha$ -amino acid to an  $\alpha$ -ketoacid. These enzymes, also called *transaminases*, generally funnel  $\alpha$ -amino groups from a variety of amino acids to  $\alpha$ -ketoglutarate for conversion into  $\text{NH}_4^+$ .

*Aspartate aminotransferase*, one of the most important of these enzymes, catalyzes the transfer of the amino group of aspartate to  $\alpha$ -ketoglutarate.

*Alanine aminotransferase* catalyzes the transfer of the amino group of alanine to  $\alpha$ -ketoglutarate.

Transamination reactions are reversible and can thus be used to synthesize amino acids from  $\alpha$ -ketoacids, as we shall see in Chapter 24.

The nitrogen atom in glutamate is converted into free ammonium ion by oxidative deamination, a reaction catalyzed by *glutamate dehydrogenase*. This enzyme is unusual in being able to utilize either  $\text{NAD}^+$  or  $\text{NADP}^+$ , at least in some species. The reaction proceeds by dehydrogenation of the C—N bond, followed by hydrolysis of the resulting ketimine.

This reaction equilibrium constant is close to 1 in the liver, so the direction of the reaction is determined by the concentrations of reactants and products. Normally, the reaction is driven forward by the rapid removal of ammonium ion. Glutamate dehydrogenase, essentially a liver-specific enzyme, is located in mitochondria, as are some of the other enzymes required for the production of urea. This compartmentalization sequesters free ammonium ion, which is toxic.

In mammals, but not in other organisms, glutamate dehydrogenase is allosterically inhibited by GTP and stimulated by ADP. These nucleotides exert their regulatory effects in a unique manner. An *abortive complex* is formed on the enzyme when a product is replaced by substrate before the reaction is complete. For instance, the enzyme bound to glutamate and  $\text{NAD(P)H}$  is an abortive complex. GTP facilitates the formation of such complexes while ADP destabilizes the complexes.

The sum of the reactions catalyzed by aminotransferases and glutamate dehydrogenase is

In most terrestrial vertebrates,  $\text{NH}_4^+$  is converted into urea, which is excreted.

### Mechanism: Pyridoxal phosphate forms Schiff-base intermediates in aminotransferases

All aminotransferases contain the prosthetic group *pyridoxal phosphate* (PLP), which is derived from *pyridoxine* (vitamin  $\text{B}_6$ ). Pyridoxal phosphate includes a pyridine ring that is slightly basic to which is attached an OH group that is slightly acidic. Thus, pyridoxal phosphate derivatives can form a stable tautomeric form in which the pyridine nitrogen atom is protonated and, hence, positively charged, while the OH group loses a proton and hence is negatively charged, forming a phenolate.

The most important functional group on PLP is the aldehyde. This group forms covalent Schiff-base intermediates with amino acid substrates. Indeed, even in the absence of substrate, the aldehyde group of PLP usually forms a Schiff-base linkage with the  $\epsilon$ -amino group of a specific lysine residue at the enzyme's active site. A new Schiff-base linkage is formed on addition of an amino acid substrate.

The  $\alpha$ -amino group of the amino acid substrate displaces the  $\epsilon$ -amino group of the active-site lysine residue. In other words, an internal aldimine becomes an external aldimine. The amino acid-PLP Schiff base that is formed remains tightly bound to the enzyme by multiple noncovalent interactions. The Schiff-base linkage often accepts a proton at the N, with the positive charge stabilized by interaction with the negatively charged phenolate group of PLP.

**FIGURE 23.9 Transamination mechanism.** (1) The external aldimine loses a proton to form a quinonoid intermediate. (2) Reprotonation of this intermediate at the aldehyde carbon atom yields a ketimine. (3) This intermediate is hydrolyzed to generate the α-ketoacid product and pyridoxamine phosphate.

The Schiff base between the amino acid substrate and PLP, the external *aldimine*, loses a proton from the α-carbon atom of the amino acid to form a *quinonoid* intermediate (Figure 23.9). Reprotonation of this intermediate at the aldehyde carbon atom yields a *ketimine*. The ketimine is then hydrolyzed to an α-ketoacid and *pyridoxamine phosphate* (PMP). These steps constitute half of the transamination reaction.

The second half takes place by the reverse of the preceding pathway. A second α-ketoacid reacts with the enzyme–pyridoxamine phosphate complex (E-PMP) to yield a second amino acid and regenerate the enzyme–pyridoxal phosphate complex (E-PLP).

The sum of these partial reactions is

### Aspartate aminotransferase is an archetypal pyridoxal-dependent transaminase

The mitochondrial enzyme aspartate aminotransferase provides an especially well studied example of PLP as a coenzyme for transamination reactions (Figure 23.10). X-ray crystallographic studies provided detailed views of how PLP and substrates are bound and confirmed much of the proposed catalytic mechanism. Each of the identical 45-kDa subunits of this dimer

**FIGURE 23.10 Aspartate aminotransferase.** The active site of this prototypical PLP-dependent enzyme includes pyridoxal phosphate attached to the enzyme by a Schiff-base linkage with lysine 258. An arginine residue in the active site helps orient substrates by binding to their α-carboxylate groups. Only one of the enzyme's two subunits is shown. [Drawn from 1AAW.pdb.]

consists of a large domain and a small one. PLP is bound to the large domain, in a pocket near the domain interface. In the absence of substrate, the aldehyde group of PLP is in a Schiff-base linkage with lysine 258, as expected. Adjacent to the coenzyme's binding site is a conserved arginine residue that interacts with the  $\alpha$ -carboxylate group of the amino acid substrate, helping to orient the substrate appropriately in the active site. A base is necessary to remove a proton from the  $\alpha$ -carbon group of the amino acid and to transfer it to the aldehyde carbon atom of PLP (Figure 23.9, steps 1 and 2). The lysine amino group that was initially in Schiff-base linkage with PLP appears to serve as the proton donor and acceptor.

### Blood levels of aminotransferases serve a diagnostic function

 The presence of alanine and aspartate aminotransferase in the blood is an indication of liver damage. Liver damage can occur for a number of reasons, including viral hepatitis, long-term excessive alcohol consumption, and reaction to drugs such as acetaminophen (Section 36.1). Under these conditions, liver cell membranes are damaged and some cellular proteins, including the aminotransferases, leak into the blood. Normal blood values for alanine and aspartate aminotransferase activity are 5–30 units/l and 40–125 units/l, respectively. Depending on the extent of liver damage, the values will reach 200–300 units/l.

### Pyridoxal phosphate enzymes catalyze a wide array of reactions

Transamination is just one of a wide range of amino acid transformations that are catalyzed by PLP enzymes. The other reactions catalyzed by PLP enzymes at the  $\alpha$ -carbon atom of amino acids are decarboxylations, deaminations, racemizations, and aldol cleavages (Figure 23.11). In addition, PLP enzymes catalyze elimination and replacement reactions at the  $\beta$ -carbon atom (e.g., tryptophan synthetase in the synthesis of tryptophan) and the  $\gamma$ -carbon atom (e.g., cystathionine  $\beta$ -synthase in the synthesis of cysteine) of amino acid substrates. Three common features of PLP catalysis underlie these diverse reactions.

1. A Schiff base is formed by the amino acid substrate (the amine component) and PLP (the carbonyl component).
2. The protonated form of PLP acts as an *electron sink* to stabilize catalytic intermediates that are negatively charged. Electrons from these intermediates are attracted to the positive charge on the ring nitrogen atom. In other words, PLP is an *electrophilic catalyst*.
3. The product Schiff base is cleaved at the completion of the reaction.

How does an enzyme selectively break a particular one of three bonds at the  $\alpha$ -carbon atom of an amino acid substrate? An important principle is that *the bond being broken must be perpendicular to the  $\pi$  orbitals of the electron sink* (Figure 23.12). An aminotransferase, for example, binds the amino acid substrate so that the  $C_{\alpha}$ —H bond is perpendicular to the PLP ring

**FIGURE 23.11 Bond cleavage by PLP enzymes.** Pyridoxal phosphate enzymes labilize one of three bonds at the  $\alpha$ -carbon atom of an amino acid substrate. For example, bond *a* is labilized by aminotransferases, bond *b* by decarboxylases, and bond *c* by aldolases (such as threonine aldolases). PLP enzymes also catalyze reactions at the  $\beta$ - and  $\gamma$ -carbon atoms of amino acids.

**FIGURE 23.12 Stereoelectronic effects.** The orientation about the  $N-C_{\alpha}$  bond determines the most favored reaction catalyzed by a pyridoxal phosphate enzyme. The bond that is most nearly perpendicular to the plane of delocalized  $\pi$  orbitals (represented by dashed lines) of the pyridoxal phosphate electron sink is most easily cleaved.

**FIGURE 23.13 Reaction choice.** In aspartate aminotransferase, the  $C_{\alpha}$ -H bond is most nearly perpendicular to the  $\pi$ -orbital system and is cleaved. In serine hydroxymethyltransferase, a small rotation about the  $N-C_{\alpha}$  bond places the  $C_{\alpha}-C_{\beta}$  bond perpendicular to the  $\pi$  system, favoring its cleavage.

(Figure 23.13). In serine hydroxymethyltransferase, the enzyme that converts serine into glycine, the  $N-C_{\alpha}$  bond is rotated so that the  $C_{\alpha}-C_{\beta}$  bond is most nearly perpendicular to the plane of the PLP ring, favoring its cleavage. This means of choosing one of several possible catalytic outcomes is called *stereoelectronic control*.

 Many of the PLP enzymes that catalyze amino acid transformations, such as serine hydroxymethyltransferase, have a similar structure and are clearly related by divergent evolution. Others, such as tryptophan synthetase, have quite different overall structures. Nonetheless, the active sites of these enzymes are remarkably similar to that of aspartate aminotransferase, revealing the effects of convergent evolution.

### Serine and threonine can be directly deaminated

The  $\alpha$ -amino groups of serine and threonine can be directly converted into  $NH_4^+$  without first being transferred to  $\alpha$ -ketoglutarate. These direct deaminations are catalyzed by *serine dehydratase* and *threonine dehydratase*, in which PLP is the prosthetic group.

These enzymes are called *dehydratases* because *dehydration precedes deamination*. Serine loses a hydrogen ion from its  $\alpha$ -carbon atom and a hydroxide ion group from its  $\beta$ -carbon atom to yield aminoacrylate. This unstable compound reacts with  $H_2O$  to give pyruvate and  $NH_4^+$ . Thus, the presence of a hydroxyl group attached to the  $\beta$ -carbon atom in each of these amino acids permits the direct deamination.

### Peripheral tissues transport nitrogen to the liver

Although most amino acid degradation takes place in the liver, other tissues can degrade amino acids. For instance, muscle uses branched-chain amino acids as a source of fuel during prolonged exercise and fasting. How is the nitrogen processed in these other tissues? As in the liver, the first step is the removal of the nitrogen from the amino acid. However, muscle lacks the enzymes of the urea cycle, and so the nitrogen must be released in a non-toxic form that can be absorbed by the liver and converted into urea.

Nitrogen is transported from muscle to the liver in two principal transport forms. Glutamate is formed by transamination reactions, but the nitrogen is then transferred to pyruvate to form alanine, which is released into

**FIGURE 23.14 PATHWAY INTEGRATION: The glucose–alanine cycle.** During prolonged exercise and fasting, muscle uses branched-chain amino acids as fuel. The nitrogen removed is transferred (through glutamate) to alanine, which is released into the blood stream. In the liver, alanine is taken up and converted into pyruvate for the subsequent synthesis of glucose.

the blood (Figure 23.14). The liver takes up the alanine and converts it back into pyruvate by transamination. The pyruvate can be used for gluconeogenesis and the amino group eventually appears as urea. This transport is referred to as the *glucose–alanine cycle*. It is reminiscent of the Cori cycle discussed earlier (Figure 16.33). However, in contrast with the Cori cycle, pyruvate is not reduced to lactate by NADH, and thus more high-energy electrons are available for oxidative phosphorylation in the muscle.

Glutamine is also a key transport form of nitrogen. Glutamine synthetase catalyzes the synthesis of glutamine from glutamate and  $\text{NH}_4^+$  in an ATP-dependent reaction:

The nitrogens of glutamine can be converted into urea in the liver.

## 23.4 Ammonium Ion Is Converted into Urea in Most Terrestrial Vertebrates

Some of the  $\text{NH}_4^+$  formed in the breakdown of amino acids is consumed in the biosynthesis of nitrogen compounds. In most terrestrial vertebrates, the excess  $\text{NH}_4^+$  is converted into *urea* and then excreted. Such organisms are referred to as *ureotelic*.

In terrestrial vertebrates, urea is synthesized by the *urea cycle* (Figure 23.15). One of the nitrogen atoms of urea is transferred from an amino acid, aspartate. The other nitrogen atom is derived directly from free  $\text{NH}_4^+$ , and the carbon atom comes from  $\text{HCO}_3^-$  (derived by the hydration of  $\text{CO}_2$ ; Section 9.2).

### The urea cycle begins with the formation of carbamoyl phosphate

The urea cycle begins with the coupling of free  $\text{NH}_3$  with  $\text{HCO}_3^-$  to form carbamoyl phosphate, the committed reaction of the urea cycle, which is catalyzed by *carbamoyl phosphate*

**FIGURE 23.15 The urea cycle.**

*synthetase I*. Carbamoyl phosphate is a simple molecule, but its synthesis is complex, requiring three steps.

Note that  $\text{NH}_3$ , because it is a strong base, normally exists as  $\text{NH}_4^+$  in aqueous solution. However, carbamoyl phosphate synthetase uses only  $\text{NH}_3$  as a substrate. The reaction begins with the phosphorylation of  $\text{HCO}_3^-$  to form carboxyphosphate, which then reacts with  $\text{NH}_3$  to form carbamic acid. Finally, a second molecule of ATP phosphorylates carbamic acid to form carbamoyl phosphate. The structure and mechanism of the enzyme that catalyzes these reactions will be presented in Chapter 25. The consumption of two molecules of ATP makes this synthesis of carbamoyl phosphate essentially irreversible.

### Carbamoyl phosphate synthetase is the key regulatory enzyme for urea synthesis

Carbamoyl phosphate synthetase is regulated both allosterically and by covalent modification so that it is maximally active when amino acids are being metabolized for fuel use. The allosteric regulator *N-acetylglutamate* (NAG) is required for synthetase activity. This molecule is synthesized by *N-acetylglutamate synthase*.

*N*-acetylglutamate synthase is itself activated by arginine. Thus, NAG is synthesized when amino acids, as represented by arginine and glutamate, are readily available, and carbamoyl phosphate synthetase is then activated to process the generated ammonia. When ammonia is not being generated, the synthetase is inhibited by acetylation. A rise in the mitochondrial  $\text{NAD}^+$ , indicative of an energy-poor state, stimulates a deacetylase that removes the acetyl group, activating the synthetase and readying the enzyme for processing ammonia from protein degradation. The control of the acetylation of the synthetase is not yet clear.

### Carbamoyl phosphate reacts with ornithine to begin the urea cycle

The carbamoyl group of carbamoyl phosphate has a high transfer potential because of its anhydride linkage. The carbamoyl group is transferred to *ornithine* to form *citrulline*, in a reaction catalyzed by *ornithine transcarbamoylase*.

Ornithine and citrulline are amino acids, but they are not used as building blocks of proteins. The formation of  $\text{NH}_4^+$  by glutamate dehydrogenase, its incorporation into carbamoyl phosphate as  $\text{NH}_3$ , and the subsequent synthesis of citrulline take place in the mitochondrial matrix. In contrast, the next three reactions of the urea cycle, which lead to the formation of urea, take place in the cytoplasm.

Citrulline is transported to the cytoplasm, where it condenses with aspartate, the donor of the second amino group of urea. This synthesis of *argininosuccinate*, catalyzed by *argininosuccinate synthetase*, is driven by the cleavage of ATP into AMP and pyrophosphate and by the subsequent hydrolysis of pyrophosphate.

*Argininosuccinase* (also called argininosuccinate lyase) cleaves argininosuccinate into *arginine* and *fumarate*. Thus, the carbon skeleton of aspartate is preserved in the form of fumarate.

Finally, arginine is hydrolyzed to generate urea and ornithine in a reaction catalyzed by *arginase*. Ornithine is then transported back into the mitochondrion to begin another cycle. The urea is excreted. Indeed, human beings excrete about 10 kg (22 pounds) of urea per year.

In ancient Rome, urine was a valuable commodity. Vessels were placed on street corners for passersby to urinate into. Bacteria would degrade the urea, releasing ammonium ion, which would act as a bleach to brighten togas.

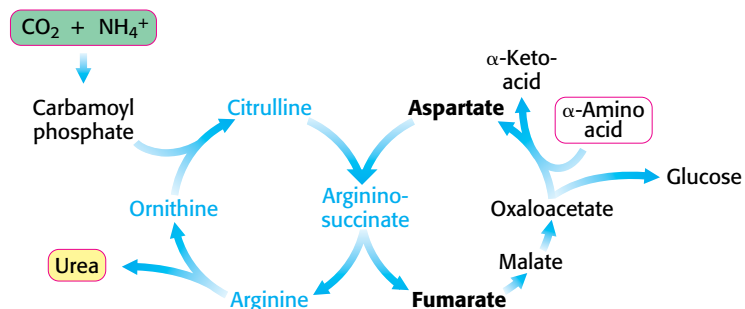

### The urea cycle is linked to gluconeogenesis

The stoichiometry of urea synthesis is

Pyrophosphate is rapidly hydrolyzed, and so the equivalent of four molecules of ATP are consumed in these reactions to synthesize one molecule of urea. The synthesis of fumarate by the urea cycle is important because it is a precursor for glucose synthesis (Figure 23.16). Fumarate is hydrated to malate, which is in turn oxidized to oxaloacetate. Oxaloacetate can be converted into glucose by gluconeogenesis or transaminated to aspartate.

**FIGURE 23.16 Metabolic integration of nitrogen metabolism.** The urea cycle, gluconeogenesis, and the transamination of oxaloacetate are linked by fumarate and aspartate.

### Urea-cycle enzymes are evolutionarily related to enzymes in other metabolic pathways

 Carbamoyl phosphate synthetase generates carbamoyl phosphate for both the urea cycle and the first step in pyrimidine biosynthesis (Section 25.1). In mammals, two distinct isozymes of the enzyme are present. Carbamoyl phosphate synthetase II, used in pyrimidine biosynthesis, differs in two important ways from its urea-cycle counterpart. First, this enzyme utilizes glutamine as a nitrogen source rather than  $\text{NH}_3$ . The side-chain amide of glutamine is hydrolyzed within one domain of the enzyme, and the ammonia generated moves through a tunnel in the enzyme to a second active site, where it reacts with carboxyphosphate. Second, this enzyme is part of a large complex that catalyzes several steps in pyrimidine biosynthesis (Section 25.1). Interestingly, the domain in which glutamine hydrolysis takes place is largely preserved in the urea-cycle enzyme, although that domain is catalytically inactive. This site binds *N*-acetylglutamate, an allosteric activator of the enzyme. *A catalytic site in one isozyme has been adapted to act as an allosteric site in another isozyme having a different physiological role.*

Can we find homologs for the other enzymes in the urea cycle? Ornithine transcarbamoylase is homologous to aspartate transcarbamoylase, which catalyzes the first step in pyrimidine biosynthesis, and the structures of their catalytic subunits are quite similar (Figure 23.17). Thus, two consecutive steps in the pyrimidine biosynthetic pathway were adapted for urea synthesis. The next step in the urea cycle is the addition of aspartate to citrulline to form argininosuccinate, and the subsequent step is the removal of fumarate. These two steps together accomplish the net addition of an amino group to citrulline to form arginine. Remarkably, these steps are analogous to two consecutive steps in the purine biosynthetic pathway (Section 25.2).

**FIGURE 23.17 Homologous enzymes.** The structure of the catalytic subunit of ornithine transcarbamoylase (blue) is quite similar to that of the catalytic subunit of aspartate transcarbamoylase (red), indicating that these two enzymes are homologs. [Drawn from 1AKM.pdb and 1RAI.pdb.]

The enzymes that catalyze these steps are homologous to argininosuccinate synthetase and argininosuccinase, respectively. Thus, four of the five enzymes in the urea cycle were adapted from enzymes taking part in nucleotide biosynthesis. The remaining enzyme, arginase, appears to be an ancient enzyme found in all domains of life.

### Inherited defects of the urea cycle cause hyperammonemia and can lead to brain damage

 The synthesis of urea in the liver is the major route for the removal of  $\text{NH}_4^+$ . Urea cycle disorders occur with a prevalence of about 1 in 15,000. A blockage of carbamoyl phosphate synthesis or of any of the four steps of the urea cycle has devastating consequences because there is no alternative pathway for the synthesis of urea. *All defects in the urea cycle lead to an elevated level of  $\text{NH}_4^+$  in the blood (hyperammonemia).* Some of these genetic defects become evident a day or two after birth, when the afflicted infant becomes lethargic and vomits periodically. Coma and irreversible brain damage may soon follow, a condition called *hepatic encephalopathy*. Why are high levels of  $\text{NH}_4^+$  toxic? The answer to this question is not yet known. Recent work, however, suggests that  $\text{NH}_4^+$  may inappropriately activate a sodium-potassium-chloride cotransporter. This activation disrupts the osmotic balance of the nerve cell, causing swelling that damages the cell and results in neurological disorders.

Ingenious strategies for coping with deficiencies in urea synthesis have been devised on the basis of a thorough understanding of the underlying biochemistry. Consider, for example, *argininosuccinase deficiency*. This defect can be partly bypassed by *providing a surplus of arginine in the diet and restricting the total protein intake*. In the liver, arginine is split into urea and ornithine, which then reacts with carbamoyl phosphate to form citrulline (Figure 23.18). This urea-cycle intermediate condenses with aspartate to yield argininosuccinate, which is then excreted. Note that two nitrogen atoms—one from carbamoyl phosphate and the other from aspartate—are eliminated from the body per molecule of arginine provided in the diet. In essence, *argininosuccinate substitutes for urea in carrying nitrogen out of the body*.

The treatment of *carbamoyl phosphate synthetase deficiency* or *ornithine transcarbamoylase deficiency* illustrates a different strategy for circumventing a metabolic block. Citrulline and argininosuccinate cannot be used to dispose of nitrogen atoms because their formation is impaired. Under these conditions, excess nitrogen accumulates in glycine and glutamine. The challenge then is to rid the body of the nitrogen accumulating in these two amino acids. That goal is accomplished by supplementing a protein-restricted diet with *large amounts of benzoate and phenylacetate*. Benzoate is activated to benzoyl CoA, which reacts with glycine to form hippurate, which is excreted (Figure 23.19). Likewise, phenylacetate is activated to phenylacetyl CoA, which reacts with glutamine to form phenylacetylglutamine, which is also excreted. These conjugates substitute for urea in the

**FIGURE 23.18 Treatment of argininosuccinase deficiency.**

Argininosuccinase deficiency can be managed by supplementing the diet with arginine. Nitrogen is excreted in the form of argininosuccinate.

**FIGURE 23.19 Treatment of carbamoyl phosphate synthetase and ornithine transcarbamoylase deficiencies.** Both deficiencies can be treated by supplementing the diet with benzoate and phenylacetate. Nitrogen is excreted in the form of hippurate and phenylacetylglutamine.

disposal of nitrogen. Thus, *latent biochemical pathways can be activated to partly bypass a genetic defect.*

### Urea is not the only means of disposing of excess nitrogen

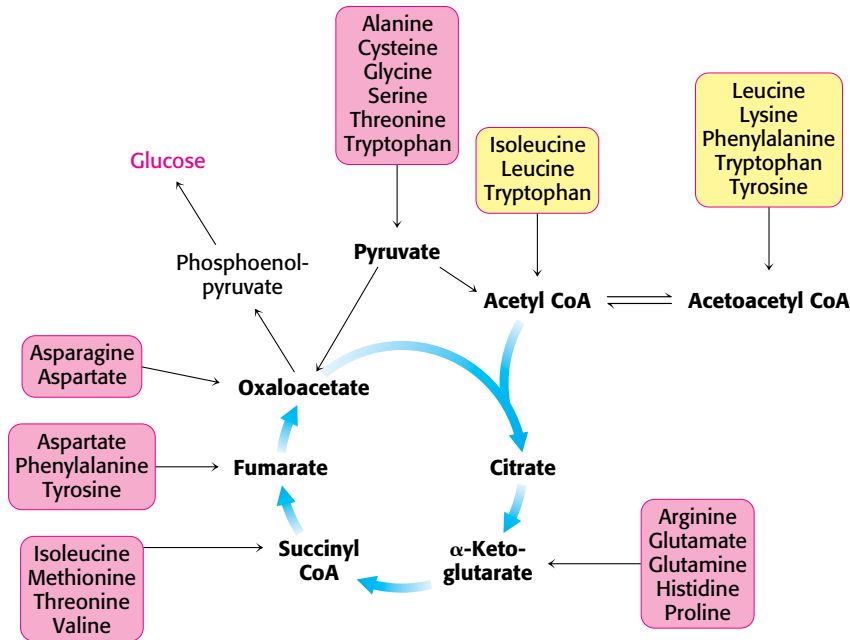

As stated earlier, most terrestrial vertebrates are ureotelic; they excrete excess nitrogen as urea. However, urea is not the only excretable form of nitrogen. *Ammoniotelic organisms, such as aquatic vertebrates and invertebrates, release nitrogen as  $\text{NH}_4^+$  and rely on the aqueous environment to dilute this toxic substance.* Interestingly, lungfish, which are normally ammoniotelic, become ureotelic in time of drought, when they live out of the water.

Both ureotelic and ammoniotelic organisms depend on sufficient water, to varying degrees, for nitrogen excretion. *In contrast, uricotelic organisms, such as birds and reptiles, secrete nitrogen as the purine uric acid.* Uric acid is secreted as an almost solid slurry requiring little water. The secretion of uric acid also has the advantage of removing four atoms of nitrogen per molecule. The pathway for nitrogen excretion developed in the course of evolution clearly depends on the habitat of the organism.

## 23.5 Carbon Atoms of Degraded Amino Acids Emerge as Major Metabolic Intermediates

We now turn to the fates of the carbon skeletons of amino acids after the removal of the  $\alpha$ -amino group. *The strategy of amino acid degradation is to transform the carbon skeletons into major metabolic intermediates that can be converted into glucose or oxidized by the citric acid cycle.* The conversion pathways range from extremely simple to quite complex. The carbon skeletons of the diverse set of 20 fundamental amino acids are funneled into only seven molecules: *pyruvate, acetyl CoA, acetoacetyl CoA,  $\alpha$ -ketoglutarate, succinyl CoA, fumarate, and oxaloacetate.* We see here an example of the remarkable economy of metabolic conversions.

Amino acids that are degraded to acetyl CoA or acetoacetyl CoA are termed *ketogenic* amino acids because they can give rise to ketone bodies or fatty acids. Amino acids that are degraded to pyruvate,  $\alpha$ -ketoglutarate, succinyl CoA, fumarate, or oxaloacetate are termed *glucogenic* amino acids. Oxaloacetate, generated from pyruvate and other citric acid cycle intermediates, can be converted into phosphoenolpyruvate and then into glucose (Section 16.3). Recall that mammals lack a pathway for the net synthesis of glucose from acetyl CoA or acetoacetyl CoA.

**FIGURE 23.20 Fates of the carbon skeletons of amino acids.** Glucogenic amino acids are shaded red, and ketogenic amino acids are shaded yellow. Several amino acids are both glucogenic and ketogenic.

Of the basic set of 20 amino acids, only leucine and lysine are solely ketogenic (Figure 23.20). Isoleucine, phenylalanine, tryptophan, and tyrosine are both ketogenic and glucogenic. Some of their carbon atoms emerge in acetyl CoA or acetoacetyl CoA, whereas others appear in potential precursors of glucose. The other 14 amino acids are classed as solely glucogenic. We will identify the degradation pathways by the entry point into metabolism.

### Pyruvate is an entry point into metabolism for a number of amino acids

Pyruvate is the entry point of the three-carbon amino acids—alanine, serine, and cysteine—into the metabolic mainstream (Figure 23.21). The transamination of alanine directly yields pyruvate.

**FIGURE 23.21 Pyruvate formation from amino acids.** Pyruvate is the point of entry for alanine, serine, cysteine, glycine, threonine, and tryptophan.

As mentioned earlier in the chapter, glutamate is then oxidatively deaminated, yielding  $\text{NH}_4^+$  and regenerating  $\alpha$ -ketoglutarate. The sum of these reactions is

Another simple reaction in the degradation of amino acids is the *deamination of serine to pyruvate* by *serine dehydratase* (p. 692).

Cysteine can be converted into pyruvate by several pathways, with its sulfur atom emerging in  $\text{H}_2\text{S}$ ,  $\text{SCN}^-$ , or  $\text{SO}_3^{2-}$ .

The carbon atoms of three other amino acids can be converted into pyruvate. *Glycine* can be converted into serine by the enzymatic addition of a hydroxymethyl group or it can be cleaved to give  $\text{CO}_2$ ,  $\text{NH}_4^+$ , and an activated one-carbon unit. *Threonine* can give rise to pyruvate through the intermediate 2-amino-3-ketobutyrate. Three carbon atoms of *tryptophan* can emerge in alanine, which can be converted into pyruvate.

### Oxaloacetate is an entry point into metabolism for aspartate and asparagine

Aspartate and asparagine are converted into oxaloacetate, a citric acid cycle intermediate. *Aspartate*, a four-carbon amino acid, is directly *transaminated to oxaloacetate*.

*Asparagine* is hydrolyzed by *asparaginase* to  $\text{NH}_4^+$  and aspartate, which is then transaminated.

Recall that aspartate can also be converted into *fumarate* by the urea cycle (Figure 23.16). Fumarate is a point of entry for half the carbon atoms of tyrosine and phenylalanine, as will be discussed shortly.

**FIGURE 23.22  $\alpha$ -Ketoglutarate formation from amino acids.**  $\alpha$ -Ketoglutarate is the point of entry of several five-carbon amino acids that are first converted into glutamate.

### Alpha-ketoglutarate is an entry point into metabolism for five-carbon amino acids

The carbon skeletons of several five-carbon amino acids enter the citric acid cycle at  $\alpha$ -ketoglutarate. These amino acids are first converted into *glutamate*, which is then oxidatively deaminated by glutamate dehydrogenase to yield  $\alpha$ -ketoglutarate (Figure 23.22).

*Histidine* is converted into 4-imidazolone 5-propionate (Figure 23.23). The amide bond in the ring of this intermediate is hydrolyzed to the *N*-formimino derivative of glutamate, which is then converted into glutamate by the transfer of its formimino group to tetrahydrofolate, a carrier of activated one-carbon units (Figure 24.9).

**FIGURE 23.23 Histidine degradation.** Conversion of histidine into glutamate.

**FIGURE 23.24 Proline and arginine degradation.** Conversion of proline and arginine into glutamate.

Glutamine is hydrolyzed to glutamate and  $\text{NH}_4^+$  by *glutaminase*. Proline and arginine are each converted into glutamate  $\gamma$ -semialdehyde, which is then oxidized to glutamate (Figure 23.24).

### Succinyl coenzyme A is a point of entry for several nonpolar amino acids

Succinyl CoA is a point of entry for some of the carbon atoms of methionine, isoleucine, and valine. Propionyl CoA and then methylmalonyl CoA are intermediates in the breakdown of these three nonpolar amino acids (Figure 23.25). This pathway from propionyl CoA to succinyl CoA is also used in the oxidation of fatty acids that have an odd number of carbon atoms. The mechanism for the interconversion of propionyl CoA and methylmalonyl CoA was presented in Section 22.3.

**FIGURE 23.25 Succinyl CoA formation.** Conversion of methionine, isoleucine, and valine into succinyl CoA.

### Methionine degradation requires the formation of a key methyl donor, S-adenosylmethionine

Methionine is converted into succinyl CoA in nine steps (Figure 23.26). The first step is the adenylation of methionine to form *S-adenosylmethionine* (SAM), a common methyl donor in the cell (Section 24.2). Loss of the methyl and adenosyl groups yields homocysteine, which is eventually processed to  $\alpha$ -ketobutyrate. This  $\alpha$ -ketoacid is oxidatively decarboxylated by the  $\alpha$ -ketoacid dehydrogenase complex to *propionyl CoA*, which is processed to *succinyl CoA*, as described in Section 22.3.

### The branched-chain amino acids yield acetyl CoA, acetoacetate, or propionyl CoA

The branched-chain amino acids are degraded by reactions that we have already encountered in the citric acid cycle and fatty acid oxidation. Leucine is transaminated to the corresponding  $\alpha$ -ketoacid,  $\alpha$ -ketoisocaproate.

**FIGURE 23.26 Methionine metabolism.**

The pathway for the conversion of methionine into succinyl CoA. S-Adenosylmethionine, formed along this pathway, is an important methyl donor.

This  $\alpha$ -ketoacid is *oxidatively decarboxylated to isovaleryl CoA* by the *branched-chain  $\alpha$ -ketoacid dehydrogenase complex*.

The  $\alpha$ -ketoacids of valine and isoleucine, the other two branched-chain aliphatic amino acids, also are substrates (as is  $\alpha$ -ketobutyrate derived from methionine). The oxidative decarboxylation of these  $\alpha$ -ketoacids is analogous to that of pyruvate to acetyl CoA and of  $\alpha$ -ketoglutarate to succinyl CoA. The branched-chain  $\alpha$ -ketoacid dehydrogenase, a multienzyme complex, is a homolog of pyruvate dehydrogenase (Section 17.1) and  $\alpha$ -ketoglutarate dehydrogenase (Section 17.2). Indeed, the E3 components of these enzymes, which regenerate the oxidized form of lipoamide, are identical.

The isovaleryl CoA derived from leucine is *dehydrogenated* to yield  $\beta$ -methylcrotonyl CoA. This oxidation is catalyzed by *isovaleryl CoA dehydrogenase*. The hydrogen acceptor is FAD, as in the analogous reaction in fatty acid oxidation that is catalyzed by acyl CoA dehydrogenase.  $\beta$ -Methylglutaconyl CoA is then formed by the *carboxylation* of  $\beta$ -methylcrotonyl CoA at the expense of the hydrolysis of a molecule of ATP. As might be expected, the carboxylation mechanism of  $\beta$ -methylcrotonyl CoA carboxylase is similar to that of pyruvate carboxylase and acetyl CoA carboxylase.

$\beta$ -Methylglutaconyl CoA is then *hydrated* to form *3-hydroxy-3-methylglutaryl CoA*, which is cleaved into *acetyl CoA* and *acetoacetate*. This reaction has already been discussed in regard to the formation of ketone bodies from fatty acids (Section 22.3).

The degradative pathways of valine and isoleucine resemble that of leucine. After transamination and oxidative decarboxylation to yield a CoA derivative, the subsequent reactions are like those of fatty acid oxidation. Isoleucine yields acetyl CoA and propionyl CoA, whereas valine yields  $CO_2$  and propionyl CoA. The degradation of leucine, valine, and isoleucine validate a point made earlier (Chapter 15): the number of reactions in metabolism is large, but the number of *kinds* of reactions is relatively small. The degradation of leucine, valine, and isoleucine provides a striking illustration of the underlying simplicity and elegance of metabolism.

### Oxygenases are required for the degradation of aromatic amino acids

The degradation of the aromatic amino acids yields the common intermediates acetoacetate, fumarate, and pyruvate. The degradation pathway is not as straightforward as that of the amino acids previously discussed. For the aromatic amino acids, *molecular oxygen is used to break the aromatic ring*.

The degradation of phenylalanine begins with its hydroxylation to tyrosine, a reaction catalyzed by *phenylalanine hydroxylase*. This enzyme is called a *monooxygenase* (or *mixed-function oxygenase*) because *one atom of  $O_2$  appears in the product and the other in  $H_2O$* .

The reductant here is *tetrahydrobiopterin*, an electron carrier that has not been previously discussed and is derived from the cofactor *biopterin*. Because biopterin is synthesized in the body, it is not a vitamin. The quinonoid form of dihydrobiopterin is produced in the hydroxylation of phenylalanine. It is reduced back to tetrahydrobiopterin by NADPH in a reaction catalyzed by *dihydropteridine reductase*.

**FIGURE 23.27 Phenylalanine and tyrosine degradation.** The pathway for the conversion of phenylalanine into acetoacetate and fumarate.

The sum of the reactions catalyzed by phenylalanine hydroxylase and dihydropteridine reductase is

Note that these reactions can also be used to synthesize tyrosine from phenylalanine.

The next step in the degradation of phenylalanine and tyrosine is the transamination of tyrosine to *p*-hydroxyphenylpyruvate (Figure 23.27). This  $\alpha$ -ketoacid then reacts with  $\text{O}_2$  to form *homogentisate*. The enzyme catalyzing this complex reaction, *p*-hydroxyphenylpyruvate hydroxylase, is called a *dioxygenase* because *both atoms of  $\text{O}_2$*  become incorporated into the product, one on the ring and one in the carboxyl group. The aromatic ring of *homogentisate* is then cleaved by  $\text{O}_2$ , which yields 4-maleylacetoacetate. This reaction is catalyzed by *homogentisate oxidase*, another dioxygenase. 4-Maleylacetoacetate is then isomerized to 4-fumarylacetoacetate by an enzyme that uses glutathione as a cofactor. Finally, 4-fumarylacetoacetate is hydrolyzed to *fumarate* and *acetoacetate*.

Tryptophan degradation requires several oxygenases (Figure 23.28). Tryptophan 2,3-dioxygenase cleaves the pyrrole ring, and kynureinase 3-monooxygenase hydroxylates the remaining benzene ring, a reaction similar to the hydroxylation of phenylalanine to form tyrosine. Alanine is removed and the 3-hydroxyanthranilate is cleaved by another dioxygenase and

**FIGURE 23.28 Tryptophan degradation.**

The pathway for the conversion of tryptophan into alanine and acetoacetate.

subsequently processed to acetoacetyl CoA. Nearly all cleavages of aromatic rings in biological systems are catalyzed by dioxygenases. The active sites of these enzymes contain iron that is not part of heme or an iron–sulfur cluster.

## 23.6 Inborn Errors of Metabolism Can Disrupt Amino Acid Degradation

 Errors in amino acid metabolism provided some of the first examples of biochemical defects linked to pathological conditions. For instance, *alcaptonuria*, an inherited metabolic disorder caused by the absence of homogentisate oxidase, was described in 1902. Homogentisate, a normal intermediate in the degradation of phenylalanine and tyrosine (Figure 23.27), accumulates in *alcaptonuria* because its degradation is blocked. Homogentisate is excreted in the urine, which turns dark on standing as homogentisate is oxidized and polymerized to a melanin-like substance.

Although *alcaptonuria* is a relatively harmless condition, such is not the case with other errors in amino acid metabolism. In *maple syrup urine disease*, the oxidative decarboxylation of  $\alpha$ -ketoacids derived from valine, isoleucine, and leucine is blocked because the branched-chain dehydrogenase is missing or defective. Hence, the levels of these  $\alpha$ -ketoacids and the branched-chain amino acids that give rise to them are markedly elevated in both blood and urine. The urine of patients has the odor of maple syrup—hence the name of the disease (also called *branched-chain ketoaciduria*). Maple syrup urine disease usually leads to mental and physical retardation unless the patient is placed on a diet low in valine, isoleucine, and leucine early in life. The disease can be readily detected in newborns by screening urine samples with 2,4-dinitrophenylhydrazine, which reacts with  $\alpha$ -ketoacids to form 2,4-dinitrophenylhydrazone derivatives. A definitive diagnosis can be made by mass spectrometry. Table 23.4 lists some other diseases of amino acid metabolism.

**TABLE 23.4** Inborn errors of amino acid metabolism

Disease	Enzyme deficiency	Symptoms
Citrullinemia	Arginosuccinate lyase	Lethargy, seizures, reduced muscle tension
Tyrosinemia	Various enzymes of tyrosine degradation	Weakness, liver damage, mental retardation
Albinism	Tyrosinase	Absence of pigmentation
Homocystinuria	Cystathionine $\beta$ -synthase	Scoliosis, muscle weakness, mental retardation, thin blond hair
Hyperlysinemia	$\alpha$ -Amino adipic semialdehyde dehydrogenase	Seizures, mental retardation, lack of muscle tone, ataxia

### Phenylketonuria is one of the most common metabolic disorders

*Phenylketonuria* is perhaps the best known of the diseases of amino acid metabolism. Phenylketonuria, which occurs with a prevalence of 1 in 10,000 births, is caused by an *absence or deficiency of phenylalanine hydroxylase* or, more rarely, of its tetrahydrobiopterin cofactor. *Phenylalanine accumulates in all body fluids because it cannot be converted into tyrosine.* Normally, three-quarters of phenylalanine molecules are converted into tyrosine, and the other quarter become incorporated into proteins. Because the major outflow pathway is blocked in phenylketonuria, the blood level of phenylalanine is typically at least 20-fold as high as in normal people. Minor fates of phenylalanine in normal people, such as the formation of phenylpyruvate, become major fates in phenylketonurics. Indeed, the initial description of phenylketonuria in 1934 was made by observing the reaction of phenylpyruvate in the urine of phenylketonurics with  $\text{FeCl}_3$ , which turns the urine olive green.

*Almost all untreated phenylketonurics are severely mentally retarded.* The brain weight of these people is below normal, myelination of their nerves is defective, and their reflexes are hyperactive. The life expectancy of untreated phenylketonurics is drastically shortened. Half die by age 20 and three-quarters by age 30. Phenylketonurics appear normal at birth but are severely defective by age 1 if untreated. The therapy for phenylketonuria is a *low-phenylalanine diet* supplemented with tyrosine, because tyrosine is normally synthesized from phenylalanine. The aim is to provide just enough phenylalanine to meet the needs for growth and replacement. Proteins that have a low content of phenylalanine, such as casein from milk, are hydrolyzed and phenylalanine is removed by adsorption. A low-phenylalanine diet must be started very soon after birth to prevent irreversible brain damage. In one study, the average IQ of phenylketonurics treated within a few weeks after birth was 93; a control group treated starting at age 1 had an average IQ of 53.

Early diagnosis of phenylketonuria is essential and has been accomplished by mass screening programs of all babies born in the United States and Canada. The phenylalanine level in the blood is the preferred diagnostic criterion because it is more sensitive and reliable than the  $\text{FeCl}_3$  test. Prenatal diagnosis of phenylketonuria with DNA probes has become feasible because the gene has been cloned and the exact locations of many mutations have been discovered in the protein.

### Determining the basis of the neurological symptoms of phenylketonuria is an active area of research

The biochemical basis of retardation is not firmly established, but one hypothesis suggests that the lack of hydroxylase reduces the amount of tyrosine, an important precursor to neurotransmitters such as dopamine. Moreover, high concentrations of phenylalanine prevent amino acid transport of any tyrosine present as well as tryptophan, a precursor to the neurotransmitter serotonin, into the brain. Because all three of the amino acids are transported by the same carrier, phenylalanine will saturate the carrier, preventing access to tyrosine and tryptophan. Finally, high blood levels of phenylalanine result in higher levels of phenylalanine in the brain, and evidence suggests this elevated concentration inhibits glycolysis at pyruvate kinase, disrupts myelination of nerve fibers and reduces the synthesis of several neurotransmitters.

### 23.1 Proteins Are Degraded to Amino Acids

Dietary protein is digested in the intestine, producing amino acids that are transported throughout the body. Cellular proteins are degraded at widely variable rates, ranging from minutes to the life of the organism.

### 23.2 Protein Turnover Is Tightly Regulated

The turnover of cellular proteins is a regulated process requiring complex enzyme systems. Proteins to be degraded are conjugated with ubiquitin, a small conserved protein, in a reaction driven by ATP hydrolysis. The ubiquitin-conjugating system is composed of three distinct enzymes. A large, barrel-shaped complex called the proteasome digests the ubiquitinated proteins. The proteasome also requires ATP hydrolysis to function. The resulting amino acids provide a source of precursors for protein, nucleotide bases, and other nitrogenous compounds.

### 23.3 The First Step in Amino Acid Degradation Is the Removal of Nitrogen

Surplus amino acids are used as building blocks and as metabolic fuel. The first step in their degradation is the removal of their  $\alpha$ -amino groups by transamination to  $\alpha$ -ketoacids. Pyridoxal phosphate is the coenzyme in all aminotransferases and in many other enzymes catalyzing amino acid transformations. The  $\alpha$ -amino group funnels into  $\alpha$ -ketoglutarate to form glutamate, which is then oxidatively deaminated by glutamate dehydrogenase to give  $\text{NH}_4^+$  and  $\alpha$ -ketoglutarate.  $\text{NAD}^+$  or  $\text{NADP}^+$  is the electron acceptor in this reaction.

### 23.4 Ammonium Ion Is Converted into Urea in Most Terrestrial Vertebrates

The first step in the synthesis of urea is the formation of carbamoyl phosphate, which is synthesized from  $\text{HCO}_3^-$ ,  $\text{NH}_3$ , and two molecules of ATP by carbamoyl phosphate synthetase. Ornithine is then carbamoylated to citrulline by ornithine transcarbamoylase. These two reactions take place in mitochondria. Citrulline leaves the mitochondrion and condenses with aspartate to form argininosuccinate, which is cleaved into arginine and fumarate. The other nitrogen atom of urea comes from aspartate. Urea is formed by the hydrolysis of arginine, which also regenerates ornithine.

### 23.5 Carbon Atoms of Degraded Amino Acids Emerge as Major Metabolic Intermediates

The carbon atoms of degraded amino acids are converted into pyruvate, acetyl CoA, acetoacetate, or an intermediate of the citric acid cycle. Most amino acids are solely glucogenic, two are solely ketogenic, and a few are both ketogenic and glucogenic. Alanine, serine, cysteine, glycine, threonine, and tryptophan are degraded to pyruvate. Asparagine and aspartate are converted into oxaloacetate.  $\alpha$ -Ketoglutarate is the point of entry for glutamate and four amino acids (glutamine, histidine, proline, and arginine) that can be converted into glutamate. Succinyl CoA is the point of entry for some of the carbon atoms of three amino acids (methionine, isoleucine, and valine) that are degraded through the intermediate methylmalonyl CoA. Leucine is degraded to acetoacetate and acetyl CoA. The breakdown of valine and isoleucine is like that of leucine. Their  $\alpha$ -ketoacid derivatives are oxidatively decarboxylated by the branched-chain  $\alpha$ -ketoacid dehydrogenase.

The rings of aromatic amino acids are degraded by oxygenases. Phenylalanine hydroxylase, a monooxygenase, uses tetrahydrobiopterin as the reductant. One of the oxygen atoms of  $O_2$  emerges in tyrosine and the other in water. Subsequent steps in the degradation of these aromatic amino acids are catalyzed by dioxygenases, which catalyze the insertion of both atoms of  $O_2$  into organic products. Four of the carbon atoms of phenylalanine and tyrosine are converted into fumarate, and four emerge in acetoacetate.

### 23.6 Inborn Errors of Metabolism Can Disrupt Amino Acid Degradation

Errors in amino acid metabolism were sources of some of the first insights into the correlation between pathology and biochemistry. Phenylketonuria is the best known of the many hereditary errors of amino acid metabolism. This condition results from the accumulation of high levels of phenylalanine in the body fluids. This accumulation leads to mental retardation unless the afflicted are placed on low-phenylalanine diets immediately after birth.

## KEY TERMS

ubiquitin (p. 683)	pyridoxal phosphate (PLP) (p. 689)	<i>N</i> -acetylglutamate (p. 694)
degron (p. 684)	pyridoxamine phosphate (PMP) (p. 690)	ketogenic amino acid (p. 698)
proteasome (p. 685)	glucose–alanine cycle (p. 693)	glucogenic amino acid (p. 698)
aminotransferase (transaminase) (p. 688)	urea cycle (p. 693)	biopterin (p. 703)
glutamate dehydrogenase (p. 688)	carbamoyl phosphate synthetase (p. 693)	phenylketonuria (p. 706)

## PROBLEMS

- Getting exposure.* Proteins are denatured by acid in the stomach. This denaturation makes them better substrates for proteolysis. Explain why this is the case.
- Targeting for destruction.* What are the steps required to attach ubiquitin to a target protein?
- Not the dating service.* Match the description on the right with the term on the left.
 

(a) Pepsin _____	1. Requires an adenylate intermediate
(b) N-terminal rule _____	2. Marks a protein for destruction
(c) Ubiquitin _____	3. 19S regulatory subunit
(d) PEST sequence _____	4. Determines half-life of a protein
(e) Threonine nucleophiles _____	5. 20S core
(f) ATP-dependent protein unfolding _____	6. Substrate for ligase
(g) Proteasome _____	7. Stomach proteolytic enzyme
(h) Ubiquitin-activating enzyme _____	8. Recognizes protein to be degraded
(i) Ubiquitin-conjugating enzyme _____	9. Protein degrading machine
(j) Ubiquitin-ligase _____	10. Pro-Glu-Ser-Thr
- Wasted energy?* Protein hydrolysis is an exergonic process, yet the 26S proteasome is dependent on ATP hydrolysis for activity.
  - Explain why ATP hydrolysis is required by the 26S proteasome.
  - Small peptides can be hydrolyzed without the expenditure of ATP. How does this information concur with your answer to part *a*?
- Keto counterparts.* Name the  $\alpha$ -ketoacid that is formed by the transamination of each of the following amino acids:
 

(a) Alanine	(d) Leucine
(b) Aspartate	(e) Phenylalanine
(c) Glutamate	(f) Tyrosine
- A versatile building block.*
  - Write a balanced equation for the conversion of aspartate into glucose through the intermediate oxaloacetate. Which coenzymes participate in this transformation? (b) Write a balanced equation for the conversion of aspartate into oxaloacetate through the intermediate fumarate.
- The benefits of specialization.* The archaeal proteasome contains 14 identical active  $\beta$  subunits, whereas the eukaryotic proteasome has 7 distinct  $\beta$  subunits. What are the potential benefits of having several distinct active subunits?
- Propose a structure.* The 19S subunit of the proteasome contains six subunits that are members of the AAA ATPase family. Other members of this large family are associated into homohexamers with sixfold symmetry. Propose a

structure for the AAA ATPases within the 19S proteasome. How might you test and refine your prediction?

9. *Effective electron sinks.* Pyridoxal phosphate stabilizes carbanionic intermediates by serving as an electron sink. Which other prosthetic group catalyzes reactions in this way?

10. *Cooperation.* How do aminotransferases and glutamate dehydrogenase cooperate in the metabolism of the amino group of amino acids?

11. *Taking away the nitrogen.* What amino acids yield citric acid cycle components and glycolysis intermediates when deaminated?

12. *One reaction only.* What amino acids can be deaminated directly?

13. *Useful products.* What are the common features of the breakdown products of the carbon skeletons of amino acids?

14. *Helping hand.* Propose a role for the positively charged guanidinium nitrogen atom in the cleavage of argininosuccinate into arginine and fumarate.

15. *Nitrogen sources.* What are the immediate biochemical sources for the two nitrogen atoms in urea?

16. *Counterparts.* Match the biochemical on the right with the property on the left.

- |                                 |                        |
|---------------------------------|------------------------|
| (a) Formed from $\text{NH}_4^+$ | 1. Aspartate           |
| _____                           | 2. Urea                |
| (b) Hydrolyzed to yield urea    | 3. Ornithine           |
| _____                           | 4. Carbamoyl phosphate |
| (c) A second source of nitrogen | 5. Arginine            |

| (d) Reacts with aspartate       | 7. Argininosuccinate   |
| _____                           |                        |
| (e) Cleavage yields fumarate    |                        |
| _____                           |                        |
| (f) Accepts the first nitrogen  |                        |
| _____                           |                        |
| (g) Final product               |                        |
| _____                           |                        |

17. *Line up.* Identify structures A–D, and place them in the order that they appear in the urea cycle.

18. *Completing the cycle.* Four high-transfer-potential phosphoryl groups are consumed in the synthesis of urea according to the stoichiometry given on page 696. In this reaction, aspartate is converted into fumarate. Suppose that fumarate is converted into oxaloacetate. What is the resulting stoichiometry of urea synthesis? How many high-transfer-potential phosphoryl groups are spent?

19. *A good bet.* A friend bets you a bazillion dollars that you can't prove that the urea cycle is linked to the citric acid cycle and other metabolic pathways. Can you collect?

20. *Inhibitor design.* Compound A has been synthesized as a potential inhibitor of a urea-cycle enzyme. Which enzyme do you think compound A might inhibit? Explain your answer.

21. *Ammonia toxicity.* Glutamate is an important neurotransmitter whose levels must be carefully regulated in the brain. Explain how a high concentration of ammonia might disrupt this regulation. How might a high concentration of ammonia alter the citric acid cycle?

22. *A precise diagnosis.* The urine of an infant gives a positive reaction with 2,4-dinitrophenylhydrazine. Mass spectrometry shows abnormally high blood levels of pyruvate,  $\alpha$ -ketoglutarate, and the  $\alpha$ -ketoacids of valine, isoleucine, and leucine. Identify a likely molecular defect and propose a definitive test of your diagnosis.

23. *Therapeutic design.* How would you treat an infant who is deficient in argininosuccinate synthetase? Which molecules would carry nitrogen out of the body?

24. *Damaged liver.* As we will see later (Chapter 27), liver damage (cirrhosis) often results in ammonia poisoning. Explain why this is the case.

25. *Argininosuccinic aciduria*. Argininosuccinic aciduria is a condition that results when the urea-cycle enzyme argininosuccinase is deficient. Argininosuccinate is present in the blood and urine. Suggest how this condition might be treated while still removing nitrogen from the body.

26. *Sweet hazard*. Why should phenylketonurics avoid using aspartame, an artificial sweetener? (Hint: Aspartame is L-aspartyl-L-phenylalanine methyl ester.)

27. *Déjà vu*. N-Acetylglutamate is required as a cofactor in the synthesis of carbamoyl phosphate. How is N-acetylglutamate synthesized from glutamate?

28. *Negative nitrogen balance*. A deficiency of even one amino acid results in a negative nitrogen balance. In this state, more protein is degraded than is synthesized, and so more nitrogen is excreted than is ingested. Why would protein be degraded if one amino acid were missing?

29. *Precursors*. Differentiate between ketogenic amino acids and glucogenic amino acids.

30. *A slight of hand*. The end products of tryptophan degradation are acetyl CoA and acetoacetyl CoA, yet tryptophan is a gluconeogenic amino acid in animals. Explain.

31. *Closely related*. Pyruvate dehydrogenase complex and  $\alpha$ -ketoglutarate dehydrogenase complex are huge enzymes consisting of three discrete enzymatic activities. Which amino acids require a related enzyme complex, and what is the name of the enzyme?

32. *Supply lines*. The carbon skeletons of the 20 common amino acids can be degraded into a limited number of end products. What are the end products and in what metabolic pathway are they commonly found?

### Mechanism Problems

33. *Serine dehydratase*. Write out a complete mechanism for the conversion of serine into aminoacrylate catalyzed by serine dehydratase.

34. *Serine racemase*. The nervous system contains a substantial amount of D-serine, which is generated from L-serine by serine racemase, a PLP-dependent enzyme. Propose a mechanism for this reaction. What is the equilibrium constant for the reaction L-serine  $\rightleftharpoons$  D-serine?

### Chapter Integration Problems

35. *Multiple substrates*. In Chapter 8, we learned that there are two types of bisubstrate reactions, sequential and double-displacement. Which type characterizes the action of aminotransferases? Explain your answer.

36. *Double duty*. Degradation signals are commonly located in protein regions that also facilitate protein–protein interactions. Explain why this coexistence of two functions in the same domain might be useful.

37. *Fuel choice*. Within a few days after a fast begins, nitrogen excretion accelerates to a higher-than-normal level. After a few weeks, the rate of nitrogen excretion falls to a lower level and continues at this low rate. However, after the fat stores have been depleted, nitrogen excretion rises to a high level.

(a) What events trigger the initial surge of nitrogen excretion?

(b) Why does nitrogen excretion fall after several weeks of fasting?

(c) Explain the increase in nitrogen excretion when the lipid stores have been depleted.

38. *A serious situation*. Pyruvate carboxylase deficiency is a fatal disorder. Patients with pyruvate carboxylase deficiency sometimes display some or all of the following symptoms: lactic acidosis, hyperammonemia (excess  $\text{NH}_4^+$  in the blood), hypoglycemia, and demyelination of the regions of the brain due to insufficient lipid synthesis. Provide a possible biochemical rationale for each of these observations.

39. *Isoleucine degradation*. Isoleucine is degraded to acetyl CoA and succinyl CoA. Suggest a plausible reaction sequence, based on reactions discussed in the text, for this degradation pathway.

40. *Many roles*. Pyridoxal phosphate is an important coenzyme in transamination reactions. We have seen this coenzyme before, in glycogen metabolism. Which enzyme in glycogen metabolism requires pyridoxal phosphate and what role does the coenzyme play in this enzyme?

41. *Enough cycles to have a race*. The glucose–alanine cycle is reminiscent of the Cori cycle, but the glucose–alanine cycle can be said to be more energy efficient. Explain why this is so.

### Data Interpretation Problem

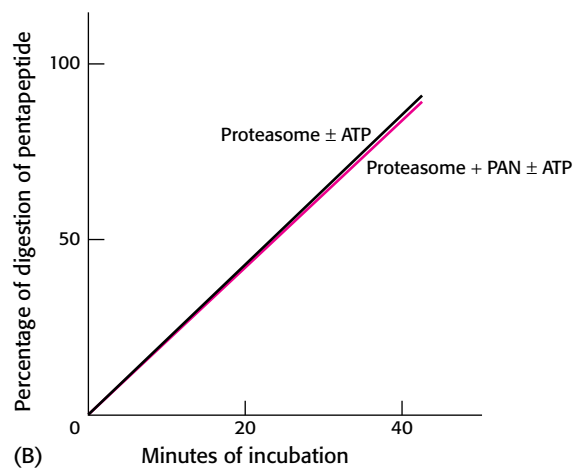

42. *Another helping hand*. In eukaryotes, the 20S proteasome component in conjunction with the 19S component degrades ubiquitinated proteins with the hydrolysis of a molecule of ATP. Archaea lack ubiquitin and the 26S proteasome but do contain a 20S proteasome. Some archaea also contain an ATPase that is homologous to the ATPases of the eukaryotic 19S component. This archaeal ATPase activity was isolated as a 650-kDa complex (called PAN) from the archaeon *Thermoplasma*, and experiments were performed to determine if PAN could enhance the activity of the 20S proteasome from *Thermoplasma* as well as other 20S proteasomes.

Protein degradation was measured as a function of time and in the presence of various combinations of components. Graph A shows the results.

- What is the effect of PAN on archaeal proteasome activity in the absence of nucleotides?
- What is the nucleotide requirement for protein digestion?
- What evidence suggests that ATP hydrolysis, and not just the presence of ATP, is required for digestion?

A similar experiment was performed with a small peptide as a substrate for the proteasome instead of a protein. The results obtained are shown in graph B.

- How do the requirements for peptide digestion differ from those of protein digestion?
- Suggest some reasons for the difference.

The ability of PAN from the archaeon *Thermoplasma* to support protein degradation by the 20S proteasomes from the archaeon *Methanosarcina* and rabbit muscle was then examined.

Percentage of digestion of protein substrate  
(20S proteasome source)

Additions	<i>Thermoplasma</i>	<i>Methanosarcina</i>	Rabbit muscle
None	11	10	10
PAN	8	8	8
PAN + ATP	100	40	30
PAN + ADP	12	9	10

[Data from P. Zwickl, D. Ng, K. M. Woo, H.-P. Klenk, and A. L. Goldberg. An archaeobacterial ATPase, homologous to ATPase in the eukaryotic 26S proteasome, activates protein breakdown by 20S proteasomes. *J. Biol. Chem.* 274(1999): 26008–26014.]

- Can the *Thermoplasma* PAN augment protein digestion by the proteasomes from other organisms?
- What is the significance of the stimulation of rabbit muscle proteasome by *Thermoplasma* PAN?

## The Biosynthesis of Amino Acids

Nitrogen is a key component of amino acids. The atmosphere is rich in nitrogen gas ( $N_2$ ), a very unreactive molecule. Certain organisms, such as bacteria that live in the root nodules of yellow clover, can convert nitrogen gas into ammonia ( $NH_3$ ), which can then be used to synthesize, first, glutamate and then other amino acids. [(Left) Hugh Spencer/Science Source.]

The assembly of biological molecules, including proteins and nucleic acids, requires the generation of appropriate starting materials. We have already considered the assembly of carbohydrates in discussions of the Calvin cycle and the pentose phosphate pathway (Chapter 20). The present chapter and the next two examine the assembly of the other important building blocks—namely, amino acids, nucleotides, and lipids.

The pathways for the biosynthesis of these molecules are extremely ancient, going back to the last common ancestor of all living things. Indeed, these pathways probably predate many of the pathways of energy transduction discussed in Part II and may have provided key selective advantages in early evolution. Many of the intermediates in energy-yielding pathways play a role in biosynthesis as well. These common intermediates allow efficient interplay between energy-yielding (catabolic) and energy-requiring biosynthetic (anabolic) pathways. Thus, cells are able to balance the degradation of compounds for energy mobilization and the synthesis of starting materials for macromolecular construction.

We begin our consideration of biosynthesis with amino acids—the building blocks of proteins and the nitrogen source for many other important molecules, including nucleotides, neurotransmitters, and prosthetic groups such as porphyrins. Amino acid biosynthesis is intimately connected with nutrition because many higher organisms, including human beings,

have lost the ability to synthesize some amino acids and must therefore obtain adequate quantities of these essential amino acids in their diets. Furthermore, because some amino acid biosynthetic enzymes are absent in mammals but present in plants and microorganisms, they are useful targets for herbicides and antibiotics.

### Amino acid synthesis requires solutions to three key biochemical problems

Nitrogen is an essential component of amino acids. Earth has an abundant supply of nitrogen, but it is primarily in the form of atmospheric nitrogen gas ( $N_2$ ), a remarkably inert molecule. Thus, a fundamental problem for biological systems is to obtain nitrogen in a more usable form. This problem is solved by certain microorganisms capable of reducing the inert  $N \equiv N$  molecule of nitrogen gas to two molecules of ammonia in one of the most amazing reactions in biochemistry. Nitrogen in the form of ammonia is the source of nitrogen for all the amino acids. The carbon backbones come from the glycolytic pathway, the pentose phosphate pathway, or the citric acid cycle.

In amino acid production, we encounter an important problem in biosynthesis—namely, stereochemical control. Because all amino acids except glycine are chiral, biosynthetic pathways must generate the correct isomer with high fidelity. In each of the 19 pathways for the generation of chiral amino acids, the stereochemistry at the  $\alpha$ -carbon atom is established by a transamination reaction that includes pyridoxal phosphate (PLP). Almost all the aminotransferases that catalyze these reactions descend from a common ancestor, illustrating once again that effective solutions to biochemical problems are retained throughout evolution.

Biosynthetic pathways are often highly regulated such that building blocks are synthesized only when supplies are low. Very often, a high concentration of the final product of a pathway inhibits the activity of allosteric enzymes that function early in the pathway to control the committed step. These enzymes are similar in functional properties to aspartate transcarbamoylase and its regulators (Section 10.1). Feedback and allosteric mechanisms ensure that all 20 amino acids are maintained in sufficient amounts for protein synthesis and other processes.

---

## 24.1 Nitrogen Fixation: Microorganisms Use ATP and a Powerful Reductant to Reduce Atmospheric Nitrogen to Ammonia

The nitrogen in amino acids, purines, pyrimidines, and other biomolecules ultimately comes from atmospheric nitrogen,  $N_2$ . The biosynthetic process starts with the reduction of  $N_2$  to  $NH_3$  (ammonia), a process called *nitrogen fixation*. The extremely strong  $N \equiv N$  bond, which has a bond energy of  $940 \text{ kJ mol}^{-1}$  ( $225 \text{ kcal mol}^{-1}$ ), is highly resistant to chemical attack. Indeed, Antoine Lavoisier named nitrogen gas “azote,” from Greek words meaning “without life,” because it is so unreactive. Nevertheless, the conversion of nitrogen and hydrogen to form ammonia is thermodynamically favorable; the reaction is difficult kinetically because of the activation energy required to form intermediates along the reaction pathway.

Although higher organisms are unable to fix nitrogen, this conversion is carried out by some bacteria and archaea. Symbiotic *Rhizobium* bacteria invade the roots of leguminous plants and form root nodules in which they

fix nitrogen, supplying both the bacteria and the plants. The importance of nitrogen fixation by *diazotrophic* (nitrogen-fixing) microorganisms to the metabolism of all higher eukaryotes cannot be overstated: the amount of  $N_2$  fixed by these species has been estimated to be  $10^{11}$  kilograms per year, about 60% of Earth's newly fixed nitrogen. Lightning and ultraviolet radiation fix another 15%; the other 25% is fixed by industrial processes. The industrial process for nitrogen fixation devised by Fritz Haber in 1910 is still being used in fertilizer factories.

The fixation of  $N_2$  is typically carried out by mixing with  $H_2$  gas over an iron catalyst at about  $500^\circ\text{C}$  and a pressure of 300 atmospheres.

To meet the kinetic challenge, the biological process of nitrogen fixation requires a complex enzyme with multiple redox centers. The *nitrogenase complex*, which carries out this fundamental transformation, consists of two proteins: a *reductase* (also called the iron protein or Fe protein), which provides electrons with high reducing power, and *nitrogenase* (also called the molybdenum–iron protein or MoFe protein), which uses these electrons to reduce  $N_2$  to  $NH_3$ . The transfer of electrons from the reductase to the nitrogenase component is coupled to the hydrolysis of ATP by the reductase (Figure 24.1).

In principle, the reduction of  $N_2$  to  $NH_3$  is a six-electron process.

However, the biological reaction always generates at least 1 mol of  $H_2$  in addition to 2 mol of  $NH_3$  for each mol of  $N \equiv N$ . Hence, an input of two additional electrons is required.

In most nitrogen-fixing microorganisms, the eight high-potential electrons come from reduced ferredoxin, generated by oxidative processes. Two molecules of ATP are hydrolyzed for each electron transferred. Thus, at least 16 molecules of ATP are hydrolyzed for each molecule of  $N_2$  reduced.

Note that  $O_2$  is required for oxidative phosphorylation to generate the ATP necessary for nitrogen fixation. However, the nitrogenase complex is exquisitely sensitive to inactivation by  $O_2$ . To allow ATP synthesis and nitrogenase to function simultaneously, leguminous plants maintain a very low concentration of free  $O_2$  in their root nodules, the location of the nitrogenase. This is accomplished by binding  $O_2$  to *leghemoglobin*, a homolog of hemoglobin (Section 6.3).

### The iron–molybdenum cofactor of nitrogenase binds and reduces atmospheric nitrogen

Both the reductase and the nitrogenase components of the complex are *iron–sulfur proteins*, in which iron is bonded to the sulfur atom of a cysteine residue and to inorganic sulfide. Recall that iron–sulfur clusters act as electron carriers (Section 18.3). The *reductase* is a dimer of identical 30-kDa subunits bridged by a 4Fe–4S cluster (Figure 24.2).

**FIGURE 24.1 Nitrogen fixation.** Electrons flow from ferredoxin to the reductase (iron protein, or Fe protein) to nitrogenase (molybdenum–iron protein, or MoFe protein) to reduce nitrogen to ammonia. ATP hydrolysis within the reductase drives conformational changes necessary for the efficient transfer of electrons.

**FIGURE 24.2 Fe Protein.** This protein is a dimer composed of two polypeptide chains linked by a 4Fe–4S cluster. Notice that each monomer is a member of the P-loop NTPase family and contains an ATP-binding site. [Drawn from 1N2C.pdb.]

The role of the reductase is to transfer electrons from a suitable donor, such as reduced ferredoxin, to the nitrogenase component. The 4Fe–4S cluster carries the electrons, one at a time, to nitrogenase. The binding and hydrolysis of ATP triggers a conformational change that moves the reductase closer to the nitrogenase component, whence it is able to transfer its electron to the center of nitrogen reduction. The structure of the ATP-binding region reveals it to be a member of the P-loop NTPase family (Section 9.4) that is clearly related to the nucleotide-binding regions found in G proteins and related proteins. Thus, we see another example of how this domain has been recruited in evolution because of its ability to couple nucleoside triphosphate hydrolysis to conformational changes.

The nitrogenase component is an  $\alpha_2\beta_2$  tetramer (240 kDa), in which the  $\alpha$  and  $\beta$  subunits are homologous to each other and structurally quite similar (Figure 24.3). The nitrogenase requires the FeMo cofactor, which consists of  $[\text{Fe}_4\text{-S}_3]$  and  $[\text{Mo-Fe}_3\text{-S}_3]$  subclusters joined by three disulfide bonds. A carbon atom (the interstitial carbon), donated by *S*-adenosylmethionine (p. 724), sits at the interstices of the iron atoms of the FeMo cofactor. The FeMo cofactor is also coordinated to a homocitrate moiety and to the  $\alpha$  subunit through one histidine residue and one cysteinate residue.

Electrons from the reductase enter at the *P clusters*, which are located at the  $\alpha$ – $\beta$  interface. The role of the P clusters is to store electrons until they can be used productively to reduce nitrogen at the FeMo cofactor. *The FeMo cofactor is the site of nitrogen fixation.* One face of the FeMo cofactor is likely to be the site of nitrogen reduction. The electron-transfer reactions from the P cluster take place in concert with the binding of hydrogen ions to nitrogen as it is reduced. Further studies are under way to elucidate the mechanism of this remarkable reaction.

**FIGURE 24.3 MoFe protein.** This protein is a heterotetramer composed of two  $\alpha$  subunits (red) and two  $\beta$  subunits (blue). Notice that the protein contains two copies each of two types of clusters: P clusters and FeMo cofactors. Each P cluster contains eight iron atoms (green) and seven sulfides linked to the protein by six cysteinate residues. Each FeMo cofactor contains one molybdenum atom, seven iron atoms, nine sulfides, the interstitial carbon atom, and a homocitrate, and is linked to the protein by one cysteinate residue and one histidine residue. [Drawn from 1M1N.pdb.]

### Ammonium ion is assimilated into an amino acid through glutamate and glutamine

The next step in the assimilation of nitrogen into biomolecules is the entry of  $\text{NH}_4^+$  into amino acids. The amino acids *glutamate* and *glutamine* play pivotal roles in this regard, acting as nitrogen donors for most amino acids. The  $\alpha$ -amino group of most amino acids comes from the  $\alpha$ -amino group of glutamate by transamination (Section 23.3). Glutamine, the other major nitrogen donor, contributes its side-chain nitrogen atom in the biosynthesis of a wide range of important compounds, including the amino acids tryptophan and histidine.

Glutamate is synthesized from  $\text{NH}_4^+$  and  $\alpha$ -ketoglutarate, a citric acid cycle intermediate, by the action of *glutamate dehydrogenase*. We have already encountered this enzyme in the degradation of amino acids (Section 23.3). Recall that  $\text{NAD}^+$  is the oxidant in catabolism, whereas  $\text{NADPH}$  is the reductant in biosyntheses. Glutamate dehydrogenase is unusual in that it does not discriminate between  $\text{NADH}$  and  $\text{NADPH}$ , at least in some species.

The reaction proceeds in two steps. First, a Schiff base forms between ammonia and  $\alpha$ -ketoglutarate. The formation of a Schiff base between an amine and a carbonyl compound is a key reaction that takes place at many stages of amino acid biosynthesis and degradation.

Schiff bases are easily protonated. In the second step, the protonated Schiff base is reduced by the transfer of a hydride ion from  $\text{NAD(P)H}$  to form glutamate.

This reaction is crucial because it establishes the stereochemistry of the  $\alpha$ -carbon atom (*S* absolute configuration) in glutamate. The enzyme binds the  $\alpha$ -ketoglutarate substrate in such a way that hydride transferred from  $\text{NAD(P)H}$  is added to form the *L* isomer of glutamate (Figure 24.4). As we shall see, this stereochemistry is established for other amino acids by transamination reactions that rely on pyridoxal phosphate.

A second ammonium ion is incorporated into glutamate to form glutamine by the action of *glutamine synthetase*. This amidation is driven by the hydrolysis of ATP. ATP participates directly in the reaction by phosphorylating the

**FIGURE 24.4 Establishment of chirality.** In the active site of glutamate dehydrogenase, hydride transfer (green) from NAD(P)H to a specific face of the achiral protonated Schiff base of  $\alpha$ -ketoglutarate establishes the L configuration of glutamate.

side chain of glutamate to form an acylphosphate intermediate, which then reacts with ammonia to form glutamine.

A high-affinity ammonia-binding site is formed in the enzyme only after the formation of the acylphosphate intermediate. A specific site for ammonia binding is required to prevent attack by water from hydrolyzing the intermediate and wasting a molecule of ATP. The regulation of glutamine synthetase plays a critical role in controlling nitrogen metabolism (Section 24.3).

Glutamate dehydrogenase and glutamine synthetase are present in all organisms. Most prokaryotes also contain an evolutionarily unrelated enzyme, *glutamate synthase*, which catalyzes the reductive amination of  $\alpha$ -ketoglutarate to glutamate. Glutamine is the nitrogen donor.

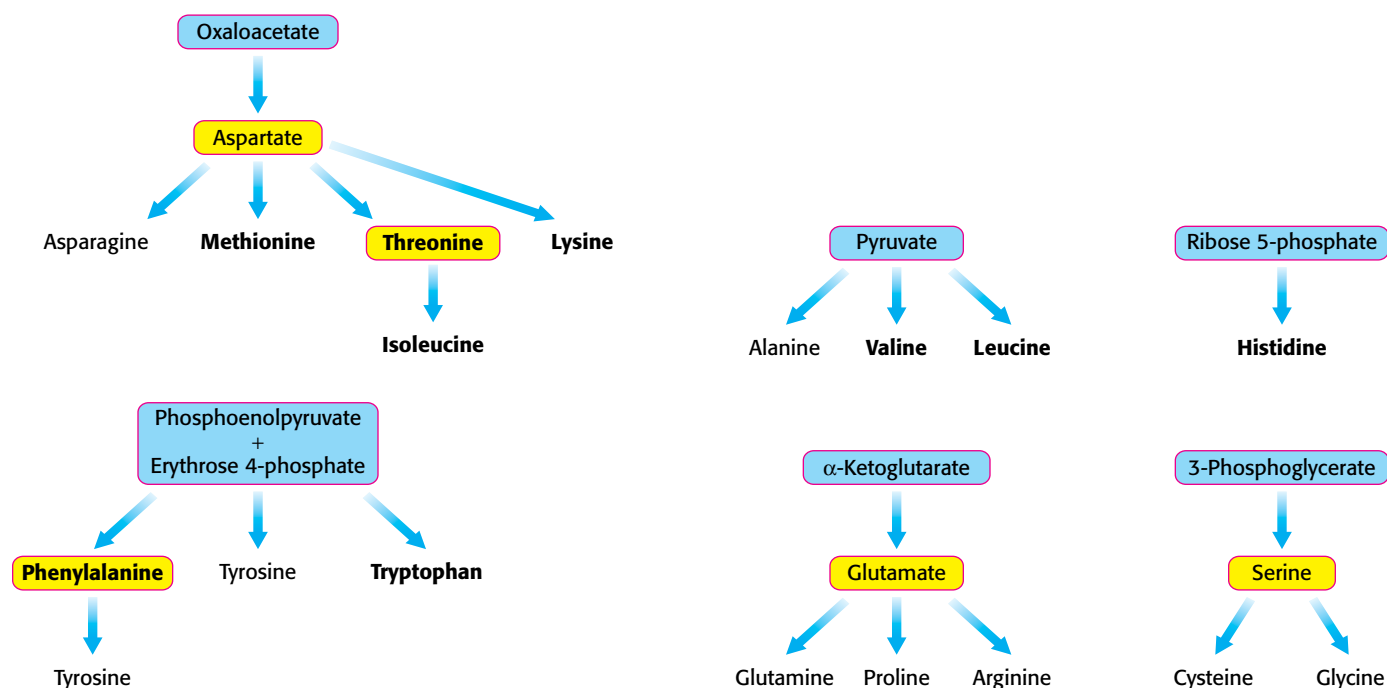

The side-chain amide of glutamine is hydrolyzed to generate ammonia within the enzyme, a recurring theme throughout nitrogen metabolism. When  $\text{NH}_4^+$  is limiting, most of the glutamate is made by the sequential action of *glutamine synthetase* and *glutamate synthase*. The sum of these reactions is

Note that this stoichiometry differs from that of the glutamate dehydrogenase reaction in that ATP is hydrolyzed. Why do prokaryotes sometimes use this more expensive pathway? The answer is that the value of  $K_M$  of glutamate dehydrogenase for  $\text{NH}_4^+$  is high ( $\sim 1$  mM), and so this enzyme is not saturated when  $\text{NH}_4^+$  is limiting. In contrast, glutamine synthetase has very low  $K_M$  for  $\text{NH}_4^+$ . Thus, ATP hydrolysis is required to capture ammonia when it is scarce.

## 24.2 Amino Acids Are Made from Intermediates of the Citric Acid Cycle and Other Major Pathways

Thus far, we have considered the conversion of  $N_2$  into  $NH_4^+$  and the assimilation of  $NH_4^+$  into glutamate and glutamine. We turn now to the biosynthesis of the other amino acids, the majority of which obtain their nitrogen from glutamate or glutamine. The pathways for the biosynthesis of amino acids are diverse. However, they have an important common feature: *their carbon skeletons come from intermediates of glycolysis, the pentose phosphate pathway, or the citric acid cycle.* On the basis of these starting materials, amino acids can be grouped into six biosynthetic families (Figure 24.5).

**FIGURE 24.5** Biosynthetic families of amino acids in bacteria and plants. Major metabolic precursors are shaded blue. Amino acids that give rise to other amino acids are shaded yellow. Essential amino acids are in boldface type.

### Human beings can synthesize some amino acids but must obtain others from their diet

Most microorganisms, such as *E. coli*, can synthesize the entire basic set of 20 amino acids, whereas human beings cannot make 9 of them. The amino acids that *must* be supplied in the diet are called *essential amino acids*, whereas the others, which can be synthesized if dietary content is insufficient, are termed *nonessential amino acids* (Table 24.1). These designations refer to the needs of an organism under a particular set of conditions. For example, enough arginine is synthesized by the urea cycle to meet the needs of an adult, but perhaps not those of a growing child. A deficiency of even one amino acid results in a *negative nitrogen balance*. In this state, more protein is degraded than is synthesized, and so more nitrogen is excreted than is ingested.

The nonessential amino acids are synthesized by quite simple reactions, whereas the pathways for the formation of the essential amino acids are quite complex. For example, the nonessential amino acids *alanine* and *aspartate* are synthesized in a single step from pyruvate and oxaloacetate, respectively. In contrast, the pathways for the essential amino acids require

**TABLE 24.1** Basic set of 20 amino acids

Nonessential	Essential
Alanine	Histidine
Arginine	Isoleucine
Asparagine	Leucine
Aspartate	Lysine
Cysteine	Methionine
Glutamate	Phenylalanine
Glutamine	Threonine
Glycine	Tryptophan
Proline	Valine
Serine	
Tyrosine	

**FIGURE 24.6 Essential and nonessential amino acids.** Some amino acids are nonessential to human beings because they can be biosynthesized in a small number of steps. Those amino acids requiring a large number of steps for their synthesis are essential in the diet because some of the enzymes for these steps have been lost in the course of evolution.

**FIGURE 24.7 Amino acid biosynthesis by transamination.** (1) Within an aminotransferase, the internal aldimine is converted into pyridoxamine phosphate (PMP) by reaction with glutamate in a multistep process not shown. (2) PMP then reacts with an  $\alpha$ -ketoacid to generate a ketimine. (3) This intermediate is converted into a quinonoid intermediate (4), which in turn yields an external aldimine. (5) The aldimine is cleaved to release the newly formed amino acid to complete the cycle.

from 5 to 16 steps (Figure 24.6). The sole exception to this pattern is arginine, inasmuch as the synthesis of this nonessential amino acid *de novo* requires 10 steps. Typically, however, it is made in only 3 steps from ornithine as part of the urea cycle. Tyrosine, classified as a nonessential amino acid because it can be synthesized in 1 step from phenylalanine, requires 10 steps to be synthesized from scratch and is essential if phenylalanine is not abundant. We begin with the biosynthesis of nonessential amino acids.

### Aspartate, alanine, and glutamate are formed by the addition of an amino group to an $\alpha$ -ketoacid

Three  $\alpha$ -ketoacids— $\alpha$ -ketoglutarate, oxaloacetate, and pyruvate—can be converted into amino acids in one step through the addition of an amino group. We have seen that  $\alpha$ -ketoglutarate can be converted into glutamate by reductive amination (Section 23.3). The amino group from glutamate can be transferred to other  $\alpha$ -ketoacids by transamination reactions. Thus, aspartate and alanine can be made from the addition of an amino group to oxaloacetate and pyruvate, respectively.

These reactions are carried out by *pyridoxal phosphate-dependent aminotransferases*. Transamination reactions are required for the synthesis of most amino acids.

In Section 23.3, we considered the mechanism of aminotransferases as applied to the metabolism of amino acids. Let us review the aminotransferase mechanism as it operates in the *biosynthesis* of amino acids (Figure 23.11). The reaction pathway begins with *pyridoxal phosphate* in a Schiff-base linkage with lysine at the aminotransferase active site, forming an internal aldimine (Figure 24.7). An amino group is transferred from glutamate to form pyridoxamine phosphate (PMP), the actual amino donor, in a multistep process. PMP then reacts with an incoming  $\alpha$ -ketoacid to form a ketimine. Proton loss

forms a quinonoid intermediate that then accepts a proton at a different site to form an external aldimine. The newly formed amino acid is released with the concomitant formation of the internal aldimine.

### A common step determines the chirality of all amino acids

 Aspartate aminotransferase is the prototype of a large family of PLP-dependent enzymes. Comparisons of amino acid sequences as well as several three-dimensional structures reveal that almost all amino-transferases having roles in amino acid biosynthesis are related to aspartate aminotransferase by divergent evolution. An examination of the aligned amino acid sequences reveals that two residues are completely conserved. These residues are the lysine residue that forms the Schiff base with the PLP cofactor (lysine 258 in aspartate aminotransferase) and an arginine residue that interacts with the  $\alpha$ -carboxylate group of the ketoacid (Figure 23.12).

An essential step in the transamination reaction is the protonation of the quinonoid intermediate to form the external aldimine. *The chirality of the amino acid formed is determined by the direction from which this proton is added to the quinonoid form* (Figure 24.8). The interaction between the conserved arginine residue and the  $\alpha$ -carboxylate group helps orient the substrate so that the lysine residue transfers a proton to the bottom face of the quinonoid intermediate, generating an aldimine with an L configuration at the  $C_{\alpha}$  center.

**FIGURE 24.8 Stereochemistry of proton addition.** In an aminotransferase active site, the addition of a proton from the lysine residue to the bottom face of the quinonoid intermediate determines the L configuration of the amino acid product. The conserved arginine residue interacts with the  $\alpha$ -carboxylate group and helps establish the appropriate geometry of the quinonoid intermediate.

### The formation of asparagine from aspartate requires an adenylated intermediate

The formation of asparagine from aspartate is chemically analogous to the formation of glutamine from glutamate. Both transformations are amidation reactions and both are driven by the hydrolysis of ATP. The actual reactions are different, however. In bacteria, the reaction for the asparagine synthesis is

Thus, the products of ATP hydrolysis are AMP and  $\text{PP}_i$  rather than ADP and  $\text{P}_i$ . Aspartate is activated by adenylation rather than by phosphorylation.

We have encountered this mode of activation in fatty acid degradation and will see it again in lipid and protein synthesis.

In mammals, the nitrogen donor for asparagine is glutamine rather than ammonia as in bacteria. Ammonia is generated by hydrolysis of the side chain of glutamine and directly transferred to activated aspartate, bound in the active site. An advantage is that the cell is not directly exposed to  $\text{NH}_4^+$ , which is toxic at high levels to human beings and other mammals. *The use of glutamine hydrolysis as a mechanism for generating ammonia for use within the same enzyme is a motif common throughout biosynthetic pathways.*

### Glutamate is the precursor of glutamine, proline, and arginine

The synthesis of glutamate by the reductive amination of  $\alpha$ -ketoglutarate has already been discussed, as has the conversion of glutamate into glutamine (p. 717). Glutamate is the precursor of two other nonessential amino acids: *proline* and *arginine*. First, the  $\gamma$ -carboxyl group of glutamate reacts with ATP to form an acyl phosphate. This mixed anhydride is then reduced by NADPH to an aldehyde.

Glutamic  $\gamma$ -semialdehyde cyclizes with a loss of  $H_2O$  in a nonenzymatic process to give  $\Delta^1$ -pyrroline 5-carboxylate, which is reduced by NADPH to proline. Alternatively, the semialdehyde can be transaminated to ornithine, which is converted in several steps into arginine in the urea cycle (Figure 23.17).

### 3-Phosphoglycerate is the precursor of serine, cysteine, and glycine

Serine is synthesized from 3-phosphoglycerate, an intermediate in glycolysis. The first step is an oxidation to 3-phosphohydroxypyruvate. This  $\alpha$ -ketoacid is transaminated to 3-phosphoserine, which is then hydrolyzed to serine.

Serine is the precursor of *cysteine* and *glycine*. As we shall see, the conversion of serine into cysteine requires the substitution of a sulfur atom derived from methionine for the side-chain oxygen atom. In the formation of glycine,

**FIGURE 24.9 Tetrahydrofolate.** This cofactor includes three components: a pteridine ring, *p*-aminobenzoate, and one or more glutamate residues.

the side-chain methylene group of serine is transferred to *tetrahydrofolate*, a carrier of one-carbon units that will be discussed shortly (Figure 24.9).

This interconversion is catalyzed by *serine hydroxymethyltransferase*, a PLP enzyme that is homologous to aspartate aminotransferase. The formation of the Schiff base of serine renders the bond between its  $\alpha$ - and  $\beta$ -carbon atoms susceptible to cleavage, enabling the transfer of the  $\beta$ -carbon to tetrahydrofolate and producing the Schiff base of glycine.

### Tetrahydrofolate carries activated one-carbon units at several oxidation levels

*Tetrahydrofolate* (also called *tetrahydropteroylglutamate*) is a highly versatile carrier of activated one-carbon units. This cofactor consists of three groups: a substituted pteridine, *p*-aminobenzoate, and a chain of one or more glutamate residues (Figure 24.9). Mammals can synthesize the pteridine ring, but they are unable to conjugate it to the other two units. They obtain tetrahydrofolate from their diets or from microorganisms in their intestinal tracts.

The one-carbon group carried by tetrahydrofolate is bonded to its N-5 or N-10 nitrogen atom (denoted as  $N^5$  and  $N^{10}$ ) or to both. This unit can exist in three oxidation states (Table 24.2). The most-reduced form carries a *methyl* group, whereas the intermediate form carries a *methylene* group. More-oxidized forms carry a *formyl*, *formimino*, or *methenyl* group. The fully oxidized one-carbon unit,  $\text{CO}_2$ , is carried by biotin rather than by tetrahydrofolate.

The one-carbon units carried by tetrahydrofolate are interconvertible (Figure 24.10).  $N^5,N^{10}$ -Methylenetetrahydrofolate can be reduced to  $N^5$ -methyltetrahydrofolate or oxidized to  $N^5,N^{10}$ -methenyltetrahydrofolate.  $N^5,N^{10}$ -Methenyltetrahydrofolate can be converted into  $N^5$ -formiminetetrahydrofolate or  $N^{10}$ -formyltetrahydrofolate, both of which are at the same oxidation level.  $N^{10}$ -Formyltetrahydrofolate can also be synthesized from tetrahydrofolate, formate, and ATP.  $N^5$ -Formyltetrahydrofolate can be reversibly isomerized to  $N^{10}$ -formyltetrahydrofolate or it can be converted into  $N^5,N^{10}$ -methenyltetrahydrofolate.

**TABLE 24.2** One-carbon groups carried by tetrahydrofolate

Oxidation state	Group	
	Formula	Name
Most reduced (= methanol)	$-\text{CH}_3$	Methyl
Intermediate (= formaldehyde)	$-\text{CH}_2-$	Methylene
Most oxidized (= formic acid)	$-\text{CHO}$	Formyl
	$-\text{CHNH}$	Formimino
	$-\text{CH}=\text{}$	Methenyl

FIGURE 24.10 Conversions of one-carbon units attached to tetrahydrofolate.

These tetrahydrofolate derivatives serve as donors of one-carbon units in a variety of biosyntheses. Methionine is regenerated from homocysteine by transfer of the methyl group of *N*<sup>5</sup>-methyltetrahydrofolate, as will be discussed shortly. We shall see in Chapter 25 that some of the carbon atoms of *purines* are acquired from derivatives of *N*<sup>10</sup>-formyltetrahydrofolate. The methyl group of *thymine*, a pyrimidine, comes from *N*<sup>5</sup>, *N*<sup>10</sup>-methylenetetrahydrofolate. This tetrahydrofolate derivative can also donate a one-carbon unit in an alternative synthesis of *glycine* that starts with CO<sub>2</sub> and NH<sub>4</sub><sup>+</sup>, a reaction catalyzed by *glycine synthase* (called the *glycine cleavage enzyme* when it operates in the reverse direction).

Thus, one-carbon units at each of the three oxidation levels are utilized in biosyntheses. Furthermore, *tetrahydrofolate* serves as an acceptor of one-carbon units in degradative reactions. The major source of one-carbon units is the facile conversion of serine into glycine by serine hydroxymethyltransferase (p. 723), which yields *N*<sup>5</sup>,*N*<sup>10</sup>-methylenetetrahydrofolate. Serine can be derived from 3-phosphoglycerate, and so *this pathway enables one-carbon units to be formed de novo from carbohydrates*.

### S-Adenosylmethionine is the major donor of methyl groups

Tetrahydrofolate can carry a methyl group on its N-5 atom, but its transfer potential is not sufficiently high for most biosynthetic methylations.

Rather, the activated methyl donor is usually *S*-adenosylmethionine (SAM), which is synthesized by the transfer of an adenosyl group from ATP to the sulfur atom of methionine.

The methyl group of the methionine unit is activated by the positive charge on the adjacent sulfur atom, which makes the molecule much more reactive than  $N^5$ -methyltetrahydrofolate. The synthesis of *S*-adenosylmethionine is unusual in that the triphosphate group of ATP is split into pyrophosphate and orthophosphate; the pyrophosphate is subsequently hydrolyzed to two molecules of  $\text{P}_i$ . *S*-Adenosylhomocysteine is formed when the methyl group of *S*-adenosylmethionine is transferred to an acceptor. *S*-Adenosylhomocysteine is then hydrolyzed to *homocysteine* and adenosine.

Methionine can be regenerated by the transfer of a methyl group to homocysteine from  $N^5$ -methyltetrahydrofolate, a reaction catalyzed by *methionine synthase* (also known as *homocysteine methyltransferase*).

The coenzyme that mediates this transfer of a methyl group is *methylcobalamin*, derived from vitamin  $\text{B}_{12}$ . In fact, this reaction and the rearrangement of *L*-methylmalonyl CoA to succinyl CoA (p. 654), catalyzed by a homologous enzyme, are the only two  $\text{B}_{12}$ -dependent reactions known to take place in mammals. Another enzyme that converts homocysteine into methionine without vitamin  $\text{B}_{12}$  also is present in many organisms.

These reactions constitute the *activated methyl cycle* (Figure 24.11). Methyl groups enter the cycle in the conversion of homocysteine into

**FIGURE 24.11 Activated methyl cycle.** The methyl group of methionine is activated by the formation of *S*-adenosylmethionine.

methionine and are then made highly reactive by the addition of an adenosyl group, which makes the sulfur atoms positively charged and the methyl groups much more electrophilic. The high transfer potential of the *S*-methyl group enables it to be transferred to a wide variety of acceptors. Among the acceptors modified by *S*-adenosylmethionine are specific bases in bacterial DNA. For instance, the methylation of DNA protects bacterial DNA from cleavage by restriction enzymes (Section 9.3). Methylation is also important for the synthesis of phospholipids (Section 26.1).

*S*-Adenosylmethionine is also the precursor of *ethylene*, a gaseous plant hormone that induces the ripening of fruit. *S*-Adenosylmethionine is cyclized to a cyclopropane derivative that is then oxidized to form ethylene. The Greek philosopher Theophrastus recognized more than 2000 years ago that sycamore figs do not ripen unless they are scraped with an iron claw. The reason is now known: *Wounding triggers ethylene production, which in turn induces ripening.*

### Cysteine is synthesized from serine and homocysteine

In addition to being a precursor of methionine in the activated methyl cycle, homocysteine is an intermediate in the synthesis of cysteine. Serine and homocysteine condense to form *cystathionine*. This reaction is catalyzed by *cystathionine β-synthase*. *Cystathionine* is then deaminated and cleaved to cysteine and α-ketobutyrate by *cystathionine γ-lyase* or *cystathionase*. Both of these enzymes utilize PLP and are homologous to aspartate aminotransferase. The net reaction is

*Note that the sulfur atom of cysteine is derived from homocysteine, whereas the carbon skeleton comes from serine.*

### High homocysteine levels correlate with vascular disease

 People with elevated serum levels of homocysteine (homocysteinemia) or the disulfide-linked dimer homocystine (homocystinuria) have an unusually high risk for coronary heart disease and arteriosclerosis. The most common genetic cause of high homocysteine levels is a mutation within the gene encoding *cystathionine β-synthase*. High levels of homocysteine appear to damage cells lining blood vessels and to increase the growth of vascular smooth muscle. The amino acid raises oxidative stress as well and has also been implicated in the development of type 2 diabetes (Section 27.3). The molecular basis of homocysteine's action has not been clearly identified, but may result from stimulation of the inflammatory response. Vitamin treatments are sometimes effective in reducing homocysteine levels in some people. Treatment with vitamins maximizes the activity of the two major metabolic pathways processing homocysteine. Pyridoxal phosphate, a vitamin B<sub>6</sub> derivative, is necessary for the activity of *cystathionine β-synthase*, which converts homocysteine into *cystathionine*; tetrahydrofolate, as well as vitamin B<sub>12</sub>, supports the methylation of homocysteine to methionine.

## Shikimate and chorismate are intermediates in the biosynthesis of aromatic amino acids

We turn now to the biosynthesis of essential amino acids. These amino acids are synthesized by plants and microorganisms, and those in the human diet are ultimately derived primarily from plants. The essential amino acids are formed by much more complex routes than are the nonessential amino acids. The pathways for the synthesis of aromatic amino acids in bacteria have been selected for discussion here because they are well understood and exemplify recurring mechanistic motifs.

Phenylalanine, tyrosine, and tryptophan are synthesized by a common pathway in *E. coli* (Figure 24.12). The initial step is the condensation of phosphoenolpyruvate (a glycolytic intermediate) with erythrose 4-phosphate (a pentose phosphate pathway intermediate). The resulting seven-carbon open-chain sugar is oxidized, loses its phosphoryl group, and cyclizes to 3-dehydroquinate. Dehydration then yields 3-dehydroshikimate,

**FIGURE 24.12** Pathway to chorismate.

Chorismate is an intermediate in the biosynthesis of phenylalanine, tyrosine, and tryptophan.

**FIGURE 24.13** Synthesis of phenylalanine and tyrosine. Chorismate can be converted into prephenate, which is subsequently converted into phenylalanine and tyrosine.

which is reduced by NADPH to shikimate. The phosphorylation of shikimate by ATP gives shikimate 3-phosphate, which condenses with a second molecule of phosphoenolpyruvate. The resulting 5-enolpyruvyl intermediate loses its phosphoryl group, yielding chorismate, the common precursor of all three aromatic amino acids. The importance of this pathway is revealed by the effectiveness of glyphosate (commercially known as Roundup), a broad-spectrum herbicide. This compound is an uncompetitive inhibitor of the enzyme that produces 5-enolpyruvylshikimate 3-phosphate. It blocks aromatic amino acid biosynthesis in plants but is fairly nontoxic in animals because they lack the enzyme.

The pathway bifurcates at chorismate. Let us first follow the *prephenate branch* (Figure 24.13). A mutase converts chorismate into prephenate, the immediate precursor of the aromatic ring of phenylalanine and tyrosine. This fascinating conversion is a rare example of an electrocyclic reaction in biochemistry, mechanistically similar to the well-known Diels–Alder reaction in organic chemistry. Dehydration and decarboxylation yield *phenylpyruvate*. Alternatively, prephenate can be oxidatively decarboxylated to *p-hydroxyphenylpyruvate*. These  $\alpha$ -ketoacids are then transaminated to form *phenylalanine* and *tyrosine*.

The branch starting with *anthranilate* leads to the synthesis of tryptophan (Figure 24.14). Chorismate acquires an amino group derived from the hydrolysis of the side chain of glutamine and releases pyruvate to form anthranilate. Anthranilate then condenses with *5-phosphoribosyl-1-pyrophosphate (PRPP)*, an activated form of ribose phosphate. PRPP is also an important intermediate in the synthesis of histidine, pyrimidine nucleotides, and purine nucleotides (Sections 25.1 and 25.2). The C-1 atom of ribose 5-phosphate becomes bonded to the nitrogen atom of anthranilate in a reaction that is driven by the release and hydrolysis of

**FIGURE 24.14** Synthesis of tryptophan.

Chorismate can be converted into anthranilate, which is subsequently converted into tryptophan.

pyrophosphate. The ribose moiety of phosphoribosylanthranilate undergoes rearrangement to yield 1-(*o*-carboxyphenylamino)-1-deoxyribulose 5-phosphate. This intermediate is dehydrated and then decarboxylated to indole-3-glycerol phosphate. Tryptophan synthase completes the synthesis of tryptophan with the removal of the side chain of indole-3-glycerol phosphate, yielding glyceraldehyde 3-phosphate, and its replacement with the carbon skeleton of serine.

### Tryptophan synthase illustrates substrate channeling in enzymatic catalysis

The *E. coli* enzyme *tryptophan synthase*, an  $\alpha_2\beta_2$  tetramer, can be dissociated into two  $\alpha$  subunits and a  $\beta_2$  dimer (Figure 24.15). The  $\alpha$  subunit catalyzes the formation of indole from indole-3-glycerol phosphate, whereas each  $\beta$  subunit has a PLP-containing active site that catalyzes the condensation of indole and serine to form tryptophan. Serine forms a Schiff base with this PLP, which is then dehydrated to give the *Schiff base of aminoacrylate*. This reactive intermediate is attacked by indole to give tryptophan.

The synthesis of tryptophan poses a challenge. Indole, a hydrophobic molecule, readily traverses membranes and would be lost from the cell if it were allowed to diffuse away from the enzyme. This problem is solved in an ingenious way. A 25-Å-long channel connects the active site of the  $\alpha$  subunit with that of the adjacent  $\beta$  subunit in the  $\alpha_2\beta_2$  tetramer

**FIGURE 24.16 Substrate channeling.** A 25-Å tunnel runs from the active site of the  $\alpha$  subunit of tryptophan synthase (yellow) to the PLP cofactor (red) in the active site of the  $\beta$  subunit (blue).

**FIGURE 24.15 Structure of tryptophan synthase.** The structure of the complex formed by one  $\alpha$  subunit (yellow) and one  $\beta$  subunit (blue). Notice that pyridoxal phosphate (PLP) is bound deeply inside the  $\beta$  subunit, a considerable distance from the  $\alpha$  subunit. [Drawn from 1BKS.pdb.]

(Figure 24.16). Thus, indole can diffuse from one active site to the other without being released into bulk solvent. Isotopic-labeling experiments showed that indole formed by the  $\alpha$  subunit does not leave the enzyme when serine is present. Furthermore, the two partial reactions are coordinated. Indole is not formed by the  $\alpha$  subunit until the highly reactive aminoacrylate is ready and waiting in the  $\beta$  subunit. We see here a clear-cut example of *substrate channeling* in catalysis by a multienzyme complex. Channeling substantially increases the catalytic rate. Furthermore, a deleterious side reaction—in this case, the potential loss of an intermediate—is prevented. We shall encounter other examples of substrate channeling in Chapter 25.

**FIGURE 24.17 Structure of 3-phosphoglycerate dehydrogenase.** This enzyme, which catalyzes the committed step in the serine biosynthetic pathway, is inhibited by serine. Notice the two serine-binding dimeric regulatory domains—one at the top and the other at the bottom of the structure. [Drawn from 1PSD.pdb.]

### 24.3 Feedback Inhibition Regulates Amino Acid Biosynthesis

The rate of synthesis of amino acids depends mainly on the *amounts* of the biosynthetic enzymes and on their *activities*. We now consider the control of enzymatic activity. The regulation of enzyme synthesis will be discussed in Chapter 31.

In a biosynthetic pathway, the first irreversible reaction, called the *committed step*, is usually an important regulatory site. The final product of the pathway ( $Z$ ) often inhibits the enzyme that catalyzes the committed step ( $A \rightarrow B$ ).

This kind of control is essential for the conservation of building blocks and metabolic energy. Consider the biosynthesis of serine (p. 722). The committed step in this pathway is the oxidation of 3-phosphoglycerate, catalyzed by the enzyme *3-phosphoglycerate dehydrogenase*. The *E. coli* enzyme is a tetramer of four identical subunits, each comprising a catalytic domain and a serine-binding regulatory domain (Figure 24.17). The binding of serine

to a regulatory site reduces the value of  $V_{\max}$  for the enzyme; an enzyme bound to four molecules of serine is essentially inactive. Thus, if serine is abundant in the cell, the enzyme activity is inhibited, and so 3-phosphoglycerate, a key building block that can be used for other processes, is not wasted.

### Branched pathways require sophisticated regulation

The regulation of branched pathways is more complicated because the concentration of two products must be accounted for. In fact, several intricate feedback mechanisms have been found in branched biosynthetic pathways.

**Feedback inhibition and activation.** Two pathways with a common initial step may each be inhibited by its own product and activated by the product of the other pathway. Consider, for example, the biosynthesis of the branched chain amino acids valine, leucine, and isoleucine. A common intermediate, hydroxyethyl thiamine pyrophosphate (hydroxyethyl-TPP; Section 17.1), initiates the pathways leading to all three of these amino acids. Hydroxyethyl-TPP reacts with  $\alpha$ -ketobutyrate in the initial step for the synthesis of isoleucine. Alternatively, hydroxyethyl-TPP reacts with pyruvate in the committed step for the pathways leading to valine and leucine. Thus, the relative concentrations of  $\alpha$ -ketobutyrate and pyruvate determine how much isoleucine is produced compared with valine and leucine. *Threonine deaminase*, the PLP enzyme that catalyzes the formation of  $\alpha$ -ketobutyrate, is allosterically inhibited by isoleucine (Figure 24.18). This enzyme is also allosterically activated by valine. Thus, this enzyme is inhibited by the end product of the pathway that it initiates and is activated by the end product of a competitive pathway. This mechanism balances the amounts of different amino acids that are synthesized.

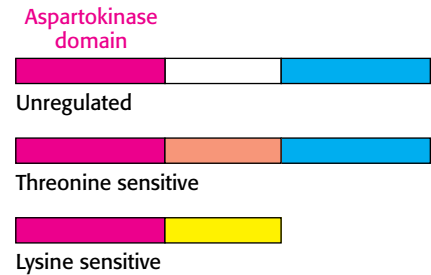

**FIGURE 24.18 Regulation of threonine deaminase.** Threonine is converted into  $\alpha$ -ketobutyrate in the committed step, leading to the synthesis of isoleucine. The enzyme that catalyzes this step, threonine deaminase, is inhibited by isoleucine and activated by valine, the product of a parallel pathway.

 The regulatory domain in threonine deaminase is very similar in structure to the regulatory domain in 3-phosphoglycerate dehydrogenase (Figure 24.19). In the latter enzyme, regulatory domains of two subunits interact to form a dimeric serine-binding regulatory unit, and so the tetrameric enzyme contains two such regulatory units. Each unit is capable of binding two serine molecules. In threonine deaminase, the two regulatory

**FIGURE 24.19 A recurring regulatory domain.** The regulatory domain formed by two subunits of 3-phosphoglycerate dehydrogenase is structurally related to the single-chain regulatory domain of threonine deaminase. Notice that both structures have four  $\alpha$  helices and eight  $\beta$  strands in similar locations. Sequence analyses have revealed this amino acid-binding regulatory domain to be present in other enzymes as well. [Drawn from 1PSD and 1TDJ.pdb.]

**FIGURE 24.20 Domain structures of three aspartokinases.** Each catalyzes the committed step in the biosynthesis of a different amino acid: (top) methionine, (middle) threonine, and (bottom) lysine. They have a catalytic domain in common (red) but differ in their regulatory domains (yellow and orange). The blue domain represents another enzyme (homoserine dehydrogenase) involved in aspartate metabolism. Thus, the top two aspartokinases are bifunctional enzymes.

domains are fused into a single unit with two differentiated amino acid-binding sites, one for isoleucine and the other for valine. Sequence analysis shows that similar regulatory domains are present in other amino acid biosynthetic enzymes. *The similarities suggest that feedback-inhibition processes may have evolved by the linkage of specific regulatory domains to the catalytic domains of biosynthetic enzymes.*

**Enzyme multiplicity.** The committed step can be catalyzed by two or more isozymes, enzymes with essentially identical catalytic mechanisms, but different regulatory properties (Section 10.2). For example, the phosphorylation of aspartate is the committed step in the biosynthesis of threonine, methionine, and lysine. Three distinct aspartokinases, which evolved by gene duplication, catalyze this reaction in *E. coli* (Figure 24.20). The catalytic domains of these enzymes show approximately 30% sequence identity. Although the mechanisms of catalysis are the same, their activities are regulated differently: one enzyme is not subject to feedback inhibition, another is inhibited by threonine, and the third is inhibited by lysine.

**Cumulative feedback inhibition.** A common step is partly inhibited by each of the final products, acting independently. The regulation of glutamine synthetase in *E. coli* is a striking example of cumulative feedback inhibition. Recall that glutamine is synthesized from glutamate,  $\text{NH}_4^+$ , and ATP. *Glutamine synthetase* consists of 12 identical 50-kDa subunits arranged in two hexagonal rings that face each other. This enzyme regulates the flow of nitrogen and hence plays a key role in controlling bacterial metabolism. The amide group of glutamine is a source of nitrogen in the biosyntheses of a variety of compounds, such as tryptophan, histidine, carbamoyl phosphate, glucosamine 6-phosphate, cytidine triphosphate, and adenosine monophosphate. Glutamine synthetase is cumulatively inhibited by each of these final products of glutamine metabolism, as well as by alanine and glycine. *In cumulative inhibition, each inhibitor can reduce the activity of the enzyme, even when other inhibitors are bound at saturating levels.* The enzymatic activity of glutamine synthetase is switched off almost completely when all final products are bound to the enzyme.

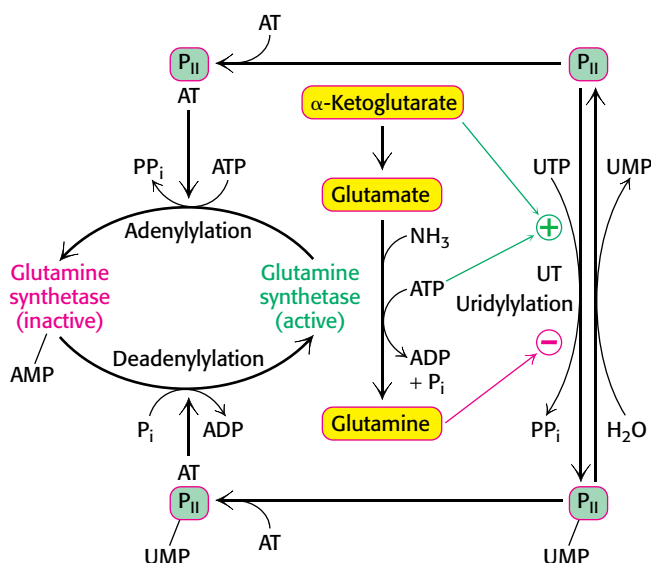

### The sensitivity of glutamine synthetase to allosteric regulation is altered by covalent modification

The activity of glutamine synthetase is also controlled by *reversible covalent modification*—the attachment of an AMP unit by a phosphodiester linkage to the hydroxyl group of a specific tyrosine residue in each subunit. *This adenylylated enzyme is less active and more susceptible to cumulative feedback inhibition than is the deadenylylated form.* The covalently attached AMP unit is removed from the adenylylated enzyme by phosphorolysis.

The adenylation and phosphorolysis reactions are catalyzed by the same enzyme, *adenylyl transferase*. The adenylyl transferase is composed of two homologous halves, one half catalyzing the adenylation reaction and the other half the phosphorolytic deadenylylation reaction. What determines whether an AMP unit is added or removed? The specificity of adenylyl transferase is controlled by a *regulatory protein*  $P_{II}$ , a trimeric protein that can exist in two forms, unmodified ( $P_{II}$ ) or covalently bound to UMP ( $P_{II}$ -UMP). The complex of  $P_{II}$  and adenylyl transferase catalyzes the attachment of an AMP unit to glutamine synthetase, which reduces its activity. Conversely, the complex of  $P_{II}$ -UMP and adenylyl transferase removes AMP from the adenylylated enzyme (Figure 24.21).

This scheme of regulation immediately raises the question, how is the modification of  $P_{II}$  controlled?  $P_{II}$  is converted into  $P_{II}$ -UMP by the attachment of uridine monophosphate to a specific tyrosine residue (Figure 24.21). This reaction, which is catalyzed by *uridylyl transferase*, is stimulated by ATP and  $\alpha$ -ketoglutarate, whereas it is inhibited by glutamine. In turn, the UMP units on  $P_{II}$  are removed by hydrolysis, a reaction promoted by glutamine and inhibited by  $\alpha$ -ketoglutarate. These opposing catalytic activities are present on a single polypeptide chain and are controlled so that the enzyme does not simultaneously catalyze uridylylation and hydrolysis. In essence, if glutamine is present, the covalent modification system favors adenylation and inactivation of glutamine synthetase. If glutamine is absent, as indicated by the presence of its precursors  $\alpha$ -ketoglutarate and ATP, the control system results in the deadenylylation and activation of the synthetase.

The integration of nitrogen metabolism in a cell requires that a large number of input signals be detected and processed. In addition, the regulatory protein  $P_{II}$  also participates in regulating the transcription of genes for glutamine synthetase and other enzymes taking part in nitrogen metabolism. The evolution of covalent regulation superimposed on feedback inhibition provided many more regulatory sites and made possible a finer tuning of the flow of nitrogen in the cell. We have previously seen such a dual regulatory format in the regulation of glycogen metabolism (Section 21.5).

**FIGURE 24.21 Covalent regulation of glutamine synthetase.** Adenylyl transferase (AT), in association with the regulatory protein  $P_{II}$ , adenylylates and inactivates the synthetase. When associated with  $P_{II}$  bound to UMP, AT deadenylylates the synthetase, thereby activating the enzyme. Uridylyl transferase (UT), the enzyme that modifies  $P_{II}$ , is allosterically regulated by  $\alpha$ -ketoglutarate, ATP, and glutamine. [Information from D. L. Nelson and M. M. Cox, *Lehninger Principles of Biochemistry* 6th ed. (W. H. Freeman and Company, 2013), Fig. 22.9.]

## 24.4 Amino Acids Are Precursors of Many Biomolecules

In addition to being the building blocks of proteins and peptides, amino acids serve as precursors of many kinds of small molecules that have important and diverse biological roles. Let us briefly survey some of the biomolecules that are derived from amino acids (Figure 24.22).

**FIGURE 24.22** Selected biomolecules derived from amino acids. The atoms contributed by amino acids are shown in blue.

*Purines* and *pyrimidines* are derived largely from amino acids. The biosynthesis of these precursors of DNA, RNA, and numerous coenzymes will be discussed in detail in Chapter 25. The reactive terminus of *sphingosine*, an intermediate in the synthesis of sphingolipids, comes from serine. *Histamine*, a potent vasodilator, is derived from histidine by decarboxylation. Tyrosine is a precursor of *thyroxine* (tetraiodothyronine, a hormone that modulates metabolism), *epinephrine* (adrenaline), and *melanin* (a complex polymeric molecule responsible for skin pigmentation). The neurotransmitter *serotonin* (5-hydroxytryptamine) and the *nicotinamide ring* of NAD<sup>+</sup> are synthesized from tryptophan. Let us now consider in more detail three particularly important biochemicals derived from amino acids.

### Glutathione, a gamma-glutamyl peptide, serves as a sulfhydryl buffer and an antioxidant

*Glutathione*, a tripeptide containing a sulfhydryl group, is a highly distinctive amino acid derivative with several important roles (Figure 24.23). For example, glutathione, present at high levels (~5 mM) in animal cells, protects red blood cells from oxidative damage by serving as a sulfhydryl buffer (Section 20.5). It cycles between a reduced thiol form (GSH) and an oxidized form (GSSG) in which two tripeptides are linked by a disulfide bond.

**FIGURE 24.23** Glutathione. This tripeptide consists of a cysteine residue flanked by a glycine residue and a glutamate residue that is linked to cysteine by an isopeptide bond between glutamate's side-chain carboxylate group and cysteine's amino group.

GSSG is reduced to GSH by *glutathione reductase*, a flavoprotein that uses NADPH as the electron source. The ratio of GSH to GSSG in most cells is greater than 500. *Glutathione plays a key role in detoxification by reacting with hydrogen peroxide and organic peroxides, the harmful by-products of aerobic life.*

**FIGURE 24.24 Structure of glutathione peroxidase.** This enzyme, which has a role in peroxide detoxification, contains a selenocysteine residue in its active site. [Drawn from 1GP1.pdb.]

**FIGURE 24.25 Catalytic cycle of glutathione peroxidase.** [Information from O. Epp, R. Ladenstein, and A. Wendel. *Eur. J. Biochem.* 133(1983):51–69.]

*Glutathione peroxidase*, the enzyme catalyzing this reaction, is remarkable in having a modified amino acid containing a *selenium* (Se) atom (Figure 24.24). Specifically, its active site contains the selenium analog of cysteine, in which selenium has replaced sulfur. The selenolate ( $E\text{-Se}^-$ ) form of this residue reduces the peroxide substrate to an alcohol and is in turn oxidized to selenenic acid ( $E\text{-SeOH}$ ). Glutathione then comes into action by forming a selenosulfide adduct ( $E\text{-Se-S-G}$ ). A second molecule of glutathione then regenerates the active form of the enzyme by attacking the selenosulfide to form oxidized glutathione (Figure 24.25).

### Nitric oxide, a short-lived signal molecule, is formed from arginine

*Nitric oxide* (NO) is an important messenger in many vertebrate signal-transduction processes, identified first as a relaxing factor in the cardiovascular system. It is now known to have a variety of roles not only in the cardiovascular system, but also in the immune and nervous systems. NO has also been shown to stimulate mitochondrial biogenesis. This free-radical gas is produced endogenously from *arginine* in a complex reaction that is catalyzed by *nitric oxide synthase*. NADPH and  $O_2$  are required for the synthesis of nitric oxide (Figure 24.26). Nitric oxide acts by binding to and activating soluble guanylate cyclase, an important enzyme in signal transduction (Section 32.3). This enzyme is homologous to adenylate cyclase but includes a heme-containing domain that binds NO.

### <sup>15</sup>N labeling: A pioneer's account

"Myself as a Guinea Pig

. . . in 1944, I undertook, together with David Rittenberg, an investigation on the turnover of blood proteins of man. To this end I synthesized 66 g of glycine labeled with 35 percent <sup>15</sup>N at a cost of \$1000 for the <sup>15</sup>N. On 12 February 1945, I started the ingestion of the labeled glycine. Since we did not know the effect of relatively large doses of the stable isotope of nitrogen and since we believed that the maximum incorporation into the proteins could be achieved by the administration of glycine in some continual manner, I ingested 1 g samples of glycine at hourly intervals for the next 66 hours . . . . At stated intervals, blood was withdrawn and after proper preparation the <sup>15</sup>N concentrations of different blood proteins were determined."

—David Shemin

*Bioessays* 10(1989):30

**FIGURE 24.26 Formation of nitric oxide.** NO is generated by the oxidation of arginine.

**FIGURE 24.27 Heme labeling.** The origins of atoms in heme revealed by the results of isotopic labeling studies.

## Porphyrins are synthesized from glycine and succinyl coenzyme A

The participation of an amino acid in the biosynthesis of the porphyrin rings of hemes and chlorophylls was first revealed by isotope-labeling experiments carried out by David Shemin and his colleagues. In 1945, they showed that the nitrogen atoms of heme were labeled after the feeding of [ $^{15}\text{N}$ ]glycine to human subjects, whereas the ingestion of [ $^{15}\text{N}$ ]glutamate resulted in very little labeling.

Experiments using  $^{14}\text{C}$ , which had just become available, revealed that 8 of the carbon atoms of heme in nucleated duck erythrocytes are derived from the  $\alpha$ -carbon atom of glycine and none from the carboxyl carbon atom. Subsequent studies demonstrated that the other 26 carbon atoms of heme can arise from acetate. Moreover, the  $^{14}\text{C}$  in methyl-labeled acetate emerged in 24 of these carbon atoms, whereas the  $^{14}\text{C}$  in carboxyl-labeled acetate appeared only in the other 2 (Figure 24.27).

This highly distinctive labeling pattern suggested that acetate is converted to succinyl-CoA through enzymes from the citric acid cycle (Section 17.2) and that a heme precursor is formed by the condensation of glycine with succinyl-CoA. Indeed, *the first step in the biosynthesis of porphyrins in mammals is the condensation of glycine and succinyl CoA to form  $\delta$ -aminolevulinic acid.*

This reaction is catalyzed by  *$\delta$ -aminolevulinic acid synthase*, a PLP enzyme present in mitochondria. Consistent with the labeling studies described earlier, the carbon atom from the carboxyl group of glycine is lost as carbon dioxide, while the  $\alpha$ -carbon remains in  $\delta$ -aminolevulinic acid.

Two molecules of  $\delta$ -aminolevulinic acid condense to form *porphobilinogen*, the next intermediate. Four molecules of porphobilinogen then condense head to tail to form a linear *tetrapyrrole* in a reaction catalyzed by *porphobilinogen deaminase*. The enzyme-bound linear tetrapyrrole then cyclizes to form *uroporphyrinogen III*, which has an asymmetric arrangement of side chains. This reaction requires a *cosynthase*. In the presence of synthase alone, uroporphyrinogen I, the nonphysiological symmetric isomer, is produced. Uroporphyrinogen III is also a key intermediate in the synthesis of vitamin  $\text{B}_{12}$  by bacteria and that of chlorophyll by bacteria and plants (Figure 24.28).

The porphyrin skeleton is now formed. Subsequent reactions alter the side chains and the degree of saturation of the porphyrin ring (Figure 24.28). *Coproporphyrinogen III* is formed by the decarboxylation of the acetate side chains. The desaturation of the porphyrin ring and the conversion of two of the propionate side chains into vinyl groups yield *protoporphyrin IX*. The chelation of iron finally gives *heme*, the prosthetic group of proteins such as myoglobin, hemoglobin, catalase, peroxidase, and cytochrome *c*. The insertion of the *ferrous* form of iron is catalyzed by *ferrochelatase*. Iron is transported in the plasma by *transferrin*, a protein that binds two ferric ions, and is stored in tissues inside molecules of *ferritin* (Section 32.4).

Studies with  $^{15}\text{N}$ -labeled glycine revealed that the normal human erythrocyte has a life span of about 120 days. The first step in the degradation of the heme group is the cleavage of its  $\alpha$ -methine bridge to form the green pigment *biliverdin*, a linear tetrapyrrole. The central methine bridge

**FIGURE 24.28 Heme biosynthetic pathway.** The pathway for the formation of heme starts with eight molecules of  $\delta$ -aminolevulinic acid.

of biliverdin is then reduced by *biliverdin reductase* to form *bilirubin*, a red pigment (Figure 24.29). The changing color of a bruise is a highly graphic indicator of these degradative reactions.

### Porphyrias accumulate in some inherited disorders of porphyrin metabolism

 *Porphyrias* are inherited or acquired disorders caused by a deficiency of enzymes in the heme biosynthetic pathway. Porphyrin is synthesized in both the erythroblasts and the liver, and either one may be the site of a disorder. *Congenital erythropoietic porphyria*, for example, prematurely destroys erythrocytes. This disease results from insufficient cosynthase. In this porphyria, the synthesis of the required amount of uroporphyrinogen III is accompanied by the formation of very large quantities of uroporphyrinogen I, the useless symmetric isomer. Uroporphyrin

**FIGURE 24.29 Heme degradation.** The formation of the heme-degradation products biliverdin and bilirubin is responsible for the color of bruises. Abbreviations: M, methyl; V, vinyl.

I, coproporphyrin I, and other symmetric derivatives also accumulate. The urine of patients having this disease is red because of the excretion of large amounts of uroporphyrin I. Their teeth exhibit a strong red fluorescence under ultraviolet light because of the deposition of porphyrins. Furthermore, their skin is usually very sensitive to light because photoexcited porphyrins are quite reactive. *Acute intermittent porphyria* is the most prevalent of the porphyrias affecting the liver. This porphyria is characterized by the overproduction of porphobilinogen and  $\delta$ -aminolevulinic acid, which results in severe abdominal pain and neurological dysfunction. The “madness” of George III, king of England during the American Revolution, may have been due to this porphyria.

## SUMMARY

### 24.1 Nitrogen Fixation: Microorganisms Use ATP and a Powerful Reductant to Reduce Atmospheric Nitrogen to Ammonia

Microorganisms use ATP and reduced ferredoxin, a powerful reductant, to reduce  $\text{N}_2$  to  $\text{NH}_3$ . An iron–molybdenum cluster in nitrogenase deftly catalyzes the fixation of  $\text{N}_2$ , a very inert molecule. Higher organisms consume the fixed nitrogen to synthesize amino acids, nucleotides, and other nitrogen-containing biomolecules. The major points of entry of  $\text{NH}_4^+$  into metabolism are glutamine or glutamate.

### 24.2 Amino Acids Are Made from Intermediates of the Citric Acid Cycle and Other Major Pathways

Human beings can synthesize 11 of the basic set of 20 amino acids. These amino acids are called nonessential, in contrast with the

essential amino acids, which must be supplied in the diet. The pathways for the synthesis of nonessential amino acids are quite simple. Glutamate dehydrogenase catalyzes the reductive amination of  $\alpha$ -ketoglutarate to glutamate. A transamination reaction takes place in the synthesis of most amino acids. At this step, the chirality of the amino acid is established. Alanine and aspartate are synthesized by the transamination of pyruvate and oxaloacetate, respectively. Glutamine is synthesized from  $\text{NH}_4^+$  and glutamate, and asparagine is synthesized similarly. Proline and arginine are derived from glutamate. Serine, formed from 3-phosphoglycerate, is the precursor of glycine and cysteine. Tyrosine is synthesized by the hydroxylation of phenylalanine, an essential amino acid. The pathways for the biosynthesis of essential amino acids are much more complex than those for the nonessential ones.

Tetrahydrofolate, a carrier of activated one-carbon units, plays an important role in the metabolism of amino acids and nucleotides. This coenzyme carries one-carbon units at three oxidation states, which are interconvertible: most reduced—methyl; intermediate—methylene; and most oxidized—formyl, formimino, and methenyl. The major donor of activated methyl groups is *S*-adenosylmethionine, which is synthesized by the transfer of an adenosyl group from ATP to the sulfur atom of methionine. *S*-Adenosylhomocysteine is formed when the activated methyl group is transferred to an acceptor. It is hydrolyzed to adenosine and homocysteine, and the latter is then methylated to methionine to complete the activated methyl cycle.

### 24.3 Feedback Inhibition Regulates Amino Acid Biosynthesis

Most of the pathways of amino acid biosynthesis are regulated by feedback inhibition in which the committed step is allosterically inhibited by the final product. The regulation of branched pathways requires extensive interaction among the branches that includes both negative and positive regulation. The regulation of glutamine synthetase in *E. coli* is a striking demonstration of cumulative feedback inhibition and of control by a cascade of reversible covalent modifications.

### 24.4 Amino Acids Are Precursors of Many Biomolecules

Amino acids are precursors of a variety of biomolecules. Glutathione ( $\gamma$ -Glu-Cys-Gly) serves as a sulfhydryl buffer and detoxifying agent. Glutathione peroxidase, a selenoenzyme, catalyzes the reduction of hydrogen peroxide and organic peroxides by glutathione. Nitric oxide, a short-lived messenger, is formed from arginine. Porphyrins are synthesized from glycine and succinyl CoA, which condense to give  $\delta$ -aminolevulinate. Two molecules of this intermediate become linked to form porphobilinogen. Four molecules of porphobilinogen combine to form a linear tetrapyrrole, which cyclizes to uroporphyrinogen III. Oxidation and side-chain modifications lead to the synthesis of protoporphyrin IX, which acquires an iron atom to form heme.

## KEY TERMS

nitrogen fixation (p. 714)

nitrogenase complex (p. 715)

essential amino acids (p. 719)

nonessential amino acids (p. 719)

pyridoxal phosphate (p. 720)

tetrahydrofolate (p. 723)

*S*-adenosylmethionine (SAM) (p. 724)

activated methyl cycle (p. 725)

substrate channeling (p. 729)

committed step (p. 730)

enzyme multiplicity (p. 732)

cumulative feedback inhibition (p. 732)

glutathione (p. 734)

nitric oxide (NO) (p. 735)

porphyria (p. 737)

## PROBLEMS

1. *Out of thin air.* Define nitrogen fixation. What organisms are capable of nitrogen fixation?

2. *Like Trinidad and Tobago.* Match each term with its description.

- |                                    |  |

3. *Teamwork.* Identify the two components of the nitrogenase complex and describe their specific tasks.

4. *The fix is in.* “The mechanistic complexity of nitrogenase is necessary because nitrogen fixation is a thermodynamically unfavorable process.” True or false? Explain.

5. *Siphoning resources.* Nitrogen-fixing bacteria on the roots of some plants can consume as much as 20% of the ATP produced by their host—consumption that does not seem very beneficial to the plant. Explain why this loss of valuable resources is tolerated and what the bacteria are doing with the ATP.

6. *From few, many.* What are the seven precursors of the 20 amino acids?

7. *Vital, in the truest sense.* Why are certain amino acids defined as essential for human beings?

8. *From sugar to amino acid.* Write a balanced equation for the synthesis of alanine from glucose.

9. *From air to blood.* What are the intermediates in the flow of nitrogen from  $N_2$  to heme?

10. *Common component.* What cofactor is required by all aminotransferases?

11. *Here, hold this.* In this chapter, we considered three different cofactors/cosubstrates that act as carriers of one-carbon units. Name them.

12. *One-carbon transfers.* Which derivative of folate is a reactant in the conversion of (a) glycine into serine? (b) homocysteine into methionine?

13. *Telltale tag.* In the reaction catalyzed by glutamine synthetase, an oxygen atom is transferred from the side chain of glutamate to orthophosphate, as shown by the results of  $^{18}O$ -labeling studies. Account for this finding.

14. *Telltale tag, redux.* In contrast to the production of glutamine by glutamine synthetase (problem 13), the generation of asparagine from  $^{18}O$ -labeled aspartate does not result in the transfer of an  $^{18}O$  atom to orthophosphate. In what molecule do you expect to find one of the  $^{18}O$  atoms?

15. *Therapeutic glycine.* Isovaleric acidemia is an inherited disorder of leucine metabolism caused by a deficiency of isovaleryl CoA dehydrogenase. Many infants having this disease die in the first month of life. The administration of large amounts of glycine sometimes leads to marked clinical improvement. Propose a mechanism for the therapeutic action of glycine.

16. *Lending a hand.* The atoms from tryptophan shaded below are derived from two other amino acids. Name them.

17. *Deprived bacteria.* Blue-green algae (cyanobacteria) form heterocysts when deprived of ammonia and nitrate. In this form, the cyanobacteria lack nuclei and are attached to adjacent vegetative cells. Heterocysts have photosystem I activity but are entirely devoid of photosystem II activity. What is their role?

18. *Cysteine and cystine.* Most cytoplasmic proteins lack disulfide bonds, whereas extracellular proteins usually contain them. Why?

19. *Through the looking-glass.* Suppose that aspartate aminotransferase were chemically synthesized with the use of D-amino acids only. What products would you expect if this mirror-image enzyme were treated with (a) L-aspartate and  $\alpha$ -ketoglutarate; (b) D-aspartate and  $\alpha$ -ketoglutarate?

20. *To and fro.* The synthesis of  $\delta$ -aminolevulinic acid takes place in the mitochondrial matrix, whereas the formation of porphobilinogen takes place in the cytoplasm. Propose a reason for the mitochondrial location of the first step in heme synthesis.

21. *Direct synthesis.* Which of the 20 amino acids can be synthesized directly from a common metabolic intermediate by a transamination reaction?

22. *Alternative route to proline.* Certain species of bacteria possess an enzyme, ornithine cyclodeaminase, that can catalyze the conversion of L-ornithine into L-proline in a single catalytic cycle.

The enzyme *lysine cyclodeaminase* has also been identified. Predict the product of the reaction catalyzed by lysine cyclodeaminase.

23. *Lines of communication.* For the following example of a branched pathway, propose a feedback inhibition scheme that would result in the production of equal amounts of Y and Z.

24. *Cumulative feedback inhibition.* Consider the branched pathway in Problem 23. The first common step ( $A \rightarrow B$ ) is partly inhibited by both of the final products, each acting independently of the other. Suppose that a high level of Y alone decreased the rate of the  $A \rightarrow B$  step from 100 to  $60 \text{ s}^{-1}$  and that a high level of Z alone decreased the rate from 100 to  $40 \text{ s}^{-1}$ . What would the rate be in the presence of high levels of both Y and Z?

25. *Recovered activity.* Free sulfhydryl groups can be alkylated with 2-bromoethylamine to the corresponding thioether.

Researchers prepared a mutant form of aspartate aminotransferase in which lysine 258 was replaced by cysteine (Lys258Cys). This mutant protein has no observable catalytic activity. However, treatment of Lys258Cys with 2-bromoethylamine yielded a protein with ~7% activity

relative to the wild-type enzyme. Explain why alkylation recovered some enzyme activity.

### Mechanism Problems

26. *Ethylene formation.* Propose a mechanism for the conversion of S-adenosylmethionine into 1-aminocyclopropane-1-carboxylate (ACC) by ACC synthase, a PLP enzyme. What is the other product?

27. *Mirror-image serine.* Brain tissue contains substantial amounts of D-serine, which acts as a neurotransmitter. D-serine is generated from L-serine by serine racemase, a PLP enzyme. Propose a mechanism for the interconversion of L- and D-serine. What is the equilibrium constant for the reaction  $L\text{-serine} \rightleftharpoons D\text{-serine}$ ?

28. *An unusual amino acid.* Elongation factor-2 (eEF-2), a protein taking part in translation, contains a histidine residue that is modified posttranslationally in several steps to a complex side chain known as diphthamide. An intermediate along this pathway is referred to as diphthine.

(a) Labeling experiments indicate that the diphthine intermediate is formed by the modification of histidine with four molecules of S-adenosylmethionine (indicated by the four colors). Propose a mechanism for the formation of diphthine.

(b) The final conversion of diphthine into diphthamide is known to be ATP dependent. Propose two possible mechanisms for the final amidation step.

## Chapter Integration Problems

29. *Here, hold this again.* In this chapter, we considered three different cofactors/cosubstrates that act as carriers of one-carbon units (problem 11). Now, name another carrier of one carbon units that we have encountered previously.

30. *Connections.* How might increased synthesis of aspartate and glutamate affect energy production in a cell? How would the cell respond to such an effect?

31. *Protection required.* Suppose that a mutation in bacteria resulted in the diminished activity of methionine adenosyl-transferase, the enzyme responsible for the synthesis of SAM from methionine and ATP. Predict how this diminished activity might affect the stability of the mutated bacteria's DNA.

32. *Heme biosynthesis.* Shemin and coworkers used acetate-labeling experiments to conclude that succinyl-CoA is a key intermediate in the biosynthesis of heme. Identify the intermediates in the conversion of acetate into succinyl-CoA.

33. *Comparing  $K_M$ .* Glutamate dehydrogenase (p. 717) and glutamine synthetase (p. 717) are present in all organisms. Most prokaryotes also contain another enzyme, *glutamate synthase*, which catalyzes the reductive amination of  $\alpha$ -ketoglutarate with the use of glutamine as the nitrogen donor.

The side-chain amide of glutamine is hydrolyzed to generate ammonia within the enzyme. When  $\text{NH}_4^+$  is limiting, most of the glutamate is made by the sequential action of glutamine synthetase and glutamate synthase. The sum of these reactions is

Note that this stoichiometry differs from that of the glutamate dehydrogenase reaction in that ATP is hydrolyzed. Why do prokaryotes sometimes use this more-expensive pathway? (Hint: The  $K_M$  value for  $\text{NH}_4^+$  of glutamate dehydrogenase is higher than that of glutamine synthase.)

## Chapter Integration and Data Interpretation Problem

34. *Light effects.* The adjoining graph shows the concentration of several free amino acids in light- and dark-adapted plants.

[Data from B.B. Buchanan, W. Gruissem, and R.L. Jones, *Biochemistry and Molecular Biology of Plants* (American Society of Plant Physiology, 2000), Fig. 8.3, p. 363.]

- Of the amino acids shown, which are most affected by light–dark adaptation?
- Suggest a plausible biochemical explanation for the difference observed.
- White asparagus, a culinary delicacy, is the result of growing asparagus plants in the dark. What chemical might you think enhances the taste of white asparagus?

## Nucleotide Biosynthesis

Nucleotides are required for DNA replication and cell division. A key enzyme for the synthesis of one nucleotide is dihydrofolate reductase (right). Cells grown in the presence of methotrexate, a reductase inhibitor, respond by increasing the number of copies of the reductase gene. The bright yellow regions visible on three of the chromosomes in the fluorescence micrograph (left), which were grown in the presence of methotrexate, contain hundreds of copies of the reductase gene. [(Left) Courtesy of Dr. Barbara Trask and Dr. Joyce Hamlin.]

Nucleotides are key biomolecules required for a variety of life processes. First, nucleotides are the *activated precursors of nucleic acids*, necessary for the replication of the genome and the transcription of the genetic information into RNA. Second, an adenine nucleotide, ATP, is the *universal currency of energy*. A guanine nucleotide, GTP, also serves as an energy source for a more select group of biological processes. Third, nucleotide derivatives such as UDP-glucose *participate in biosynthetic processes*, for example, the formation of glycogen. Fourth, nucleotides are *essential components of signal-transduction pathways*. Cyclic nucleotides such as cyclic AMP and cyclic GMP are second messengers that transmit signals both within and between cells. Furthermore, ATP acts as the donor of phosphoryl groups transferred by protein kinases in a variety of signaling pathways and, in some cases, ATP is secreted as a signal molecule.

In this chapter, we continue along the path begun in Chapter 24, which described the incorporation of nitrogen into amino acids from inorganic sources such as nitrogen gas. The amino acids glycine and aspartate are the scaffolds on which the ring systems present in nucleotides are assembled. Furthermore, aspartate and the side chain of glutamine serve as sources of  $\text{NH}_2$  groups in the formation of nucleotides.

## OUTLINE

- 25.1 The Pyrimidine Ring Is Assembled de Novo or Recovered by Salvage Pathways
- 25.2 Purine Bases Can Be Synthesized de Novo or Recycled by Salvage Pathways
- 25.3 Deoxyribonucleotides Are Synthesized by the Reduction of Ribonucleotides Through a Radical Mechanism
- 25.4 Key Steps in Nucleotide Biosynthesis Are Regulated by Feedback Inhibition
- 25.5 Disruptions in Nucleotide Metabolism Can Cause Pathological Conditions

**FIGURE 25.1 De novo and salvage pathways.** In de novo synthesis, the base itself is synthesized from simpler starting materials, including amino acids. ATP hydrolysis is required for de novo synthesis. In a salvage pathway, a base is reattached to a ribose, activated in the form of 5-phosphoribosyl-1-pyrophosphate (PRPP).

**FIGURE 25.2 De novo pathway for pyrimidine nucleotide synthesis.** The C-2 and N-3 atoms in the pyrimidine ring come from carbamoyl phosphate, whereas the other atoms of the ring come from aspartate.

**TABLE 25.1** Nomenclature of bases, nucleosides, and nucleotides

RNA		
Base	Ribonucleoside	Ribonucleotide (5'-monophosphate)
Adenine (A)	Adenosine	Adenylate (AMP)
Guanine (G)	Guanosine	Guanylate (GMP)
Uracil (U)	Uridine	Uridylate (UMP)
Cytosine (C)	Cytidine	Cytidylate (CMP)
DNA		
Base	Deoxyribonucleoside	Deoxyribonucleotide (5'-monophosphate)
Adenine (A)	Deoxyadenosine	Deoxyadenylate (dAMP)
Guanine (G)	Deoxyguanosine	Deoxyguanylate (dGMP)
Thymine (T)	Thymidine	Thymidylate (TMP)
Cytosine (C)	Deoxycytidine	Deoxycytidylate (dCMP)

Nucleotide biosynthetic pathways are tremendously important as intervention points for therapeutic agents. Many of the most widely used drugs in the treatment of cancer block steps in nucleotide biosynthesis, particularly steps in the synthesis of DNA precursors.

### Nucleotides can be synthesized by de novo or salvage pathways

The pathways for the biosynthesis of nucleotides fall into two classes: *de novo* pathways and *salvage* pathways (Figure 25.1). In de novo (from scratch) pathways, the nucleotide bases are assembled from simpler compounds. The framework for a *pyrimidine* base is assembled first and then attached to ribose. In contrast, the framework for a *purine* base is synthesized piece by piece directly onto a ribose-based structure. These pathways each comprise a small number of elementary reactions that are repeated with variations to generate different nucleotides, as might be expected for pathways that appeared very early in evolution. In salvage pathways, preformed bases are recovered and reconnected to a ribose unit.

De novo pathways lead to the synthesis of *ribonucleotides*. However, DNA is built from *deoxyribonucleotides*. Consistent with the notion that RNA preceded DNA in the course of evolution, all deoxyribonucleotides are synthesized from the corresponding ribonucleotides. The deoxyribose sugar is generated by the reduction of ribose within a fully formed nucleotide. Furthermore, the methyl group that distinguishes the thymine of DNA from the uracil of RNA is added at the last step in the pathway.

The nomenclature of nucleotides and their constituent units was presented in Chapter 4. Recall that a *nucleoside* is a purine or pyrimidine base linked to a sugar and that a *nucleotide* is a phosphate ester of a nucleoside. The names of the major bases of RNA and DNA, and of their nucleoside and nucleotide derivatives, are given in Table 25.1.

## 25.1 The Pyrimidine Ring Is Assembled de Novo or Recovered by Salvage Pathways

In de novo synthesis of pyrimidines, the ring is synthesized first and then it is attached to a ribose phosphate to form a *pyrimidine nucleotide* (Figure 25.2). Pyrimidine rings are assembled from bicarbonate, aspartate, and ammonia. Although an ammonia molecule already present in solution can be used, the ammonia is usually produced from the hydrolysis of the side chain of glutamine.

## Bicarbonate and other oxygenated carbon compounds are activated by phosphorylation

The first step in *de novo* pyrimidine biosynthesis is the synthesis of *carbamoyl phosphate* from bicarbonate and ammonia in a multistep process, requiring the cleavage of two molecules of ATP. This reaction is catalyzed by *carbamoyl phosphate synthetase II* (CPS II). Recall that carbamoyl phosphate synthetase I facilitates ammonia incorporation into urea (Section 23.4). Carbamoyl phosphate synthetase II is a dimer composed of a small subunit that hydrolyzes glutamine to form  $\text{NH}_3$  and a large subunit that completes the synthesis of carbamoyl phosphate. Analysis of the structure of the large subunit reveals two homologous domains, each of which catalyzes an ATP-dependent step (Figure 25.3).

In the first step, bicarbonate is phosphorylated by ATP to form carboxyphosphate and ADP. Ammonia then reacts with carboxyphosphate to form carbamic acid and inorganic phosphate.

The active site for this reaction lies in a domain formed by the amino-terminal third of CPS. This domain forms a structure called an *ATP-grasp fold*, which surrounds ATP and holds it in an orientation suitable for nucleophilic attack at the  $\gamma$  phosphoryl group. Proteins containing ATP-grasp folds catalyze the formation of carbon–nitrogen bonds through acylphosphate intermediates. Such ATP-grasp folds are widely used in nucleotide biosynthesis.

In the second step catalyzed by carbamoyl phosphate synthetase II, carbamic acid is phosphorylated by another molecule of ATP to form carbamoyl phosphate.

This reaction takes place in a second ATP-grasp domain within the enzyme. The active sites leading to carbamic acid formation and carbamoyl phosphate formation are very similar, revealing that this enzyme evolved by a gene duplication event. Indeed, duplication of a gene encoding an ATP-grasp domain followed by specialization was central to the evolution of nucleotide biosynthetic processes (p. 749).

### The side chain of glutamine can be hydrolyzed to generate ammonia

Glutamine is the primary source of ammonia for carbamoyl phosphate synthetase II. In this case, the small subunit of the enzyme hydrolyzes glutamine to form ammonia and glutamate. The active site of the glutamine-hydrolyzing component contains a catalytic dyad comprising a cysteine and a histidine residue. Such a catalytic dyad, reminiscent of the active site of cysteine proteases (Figure 9.16), is conserved in a family of amidotransferases, including CTP synthetase and GMP synthetase.

### Intermediates can move between active sites by channeling

Carbamoyl phosphate synthetase II contains three different active sites (Figure 25.3), separated from one another by a total of 80 Å. Intermediates

**FIGURE 25.3 Structure of carbamoyl phosphate synthetase II.** Notice that the enzyme contains sites for three reactions. This enzyme consists of two chains. The smaller chain (yellow) contains a site for glutamine hydrolysis to generate ammonia. The larger chain includes two ATP-grasp domains (blue and red). In one ATP-grasp domain (blue), bicarbonate is phosphorylated to carboxyphosphate, which then reacts with ammonia to generate carbamic acid. In the other ATP-grasp domain, the carbamic acid is phosphorylated to produce carbamoyl phosphate. [Drawn from 1JDB.pdb.]

**FIGURE 25.4 Substrate channeling.** The three active sites of carbamoyl phosphate synthetase II are linked by a channel (yellow) through which intermediates pass. Glutamine enters one active site, and carbamoyl phosphate, which includes the nitrogen atom from the glutamine side chain, leaves another 80 Å away. [Drawn from 1JDB.pdb.]

generated at one site move to the next without leaving the enzyme. These intermediates move within the enzyme by means of substrate channeling, similar to the process described for tryptophan synthetase (Figure 25.4; also Figure 24.16). The ammonia generated in the glutamine-hydrolysis active site travels 45 Å through a channel within the enzyme to reach the site at which carboxyphosphate has been generated. The carbamic acid generated at this site diffuses an additional 35 Å through an extension of the channel to reach the site at which carbamoyl phosphate is generated. This channeling serves two roles: (1) intermediates generated at one active site are captured with no loss caused by diffusion and (2) labile intermediates, such as carboxyphosphate and carbamic acid (which decompose in less than 1 s at pH 7), are protected from hydrolysis. We will see additional examples of substrate channeling later in this chapter.

### Orotate acquires a ribose ring from PRPP to form a pyrimidine nucleotide and is converted into uridylate

Carbamoyl phosphate reacts with aspartate to form carbamoylaspartate in a reaction catalyzed by *aspartate transcarbamoylase* (Section 10.1). Carbamoylaspartate then cyclizes to form dihydroorotate, which is then oxidized by  $\text{NAD}^+$  to form orotate.

In mammals, the enzymes that form orotate are part of single large polypeptide chain called CAD, for carbamoyl phosphate synthetase, aspartate transcarbamoylase and dihydroorotase.

At this stage, orotate couples to ribose, in the form of 5-phosphoribosyl-1-pyrophosphate (PRPP), a form of ribose activated to accept nucleotide bases. 5-Phosphoribosyl-1-pyrophosphate synthetase synthesizes PRPP by adding a pyrophosphate from ATP to ribose-5-phosphate, which is formed by the pentose phosphate pathway.

Orotate reacts with PRPP to form *orotidylate*, a pyrimidine nucleotide. This reaction is driven by the hydrolysis of pyrophosphate. The enzyme that catalyzes this addition, *orotate phosphoribosyltransferase*, is homologous to a number of other phosphoribosyltransferases that add different groups to PRPP to form the other nucleotides. Orotidylate is then decarboxylated to form *uridylate* (UMP), a major pyrimidine nucleotide that is a precursor to RNA. This reaction is catalyzed by *orotidylate decarboxylase*, also called orotidine-5' phosphate decarboxylase.

Orotidylate decarboxylase is one of the most proficient enzymes known. In its absence, decarboxylation is extremely slow and is estimated to take place once every 78 million years; with the enzyme present, it takes place approximately once per second, a rate enhancement of  $10^{17}$ -fold. The phosphoribosyltransferase and decarboxylase activities are located on the same polypeptide chain, providing another example of a bifunctional enzyme. The bifunctional enzyme is called *uridine monophosphate synthetase*.

### Nucleotide mono-, di-, and triphosphates are interconvertible

How is the other major pyrimidine ribonucleotide, cytidine, formed? It is synthesized from the uracil base of UMP, but the synthesis can take place only after UMP has been converted into UTP. Recall that the diphosphates and triphosphates are the active forms of nucleotides in biosynthesis and energy conversions. Nucleoside monophosphates are converted into nucleoside triphosphates in stages. First, nucleoside monophosphates are converted into diphosphates by specific *nucleoside monophosphate kinases* that utilize ATP as the phosphoryl-group donor. For example, UMP is phosphorylated to UDP by *UMP kinase*.

Nucleoside diphosphates and triphosphates are interconverted by *nucleoside diphosphate kinase*, an enzyme that has broad specificity, in contrast with the monophosphate kinases. X and Y represent any of several ribonucleosides or even deoxyribonucleosides:

### CTP is formed by amination of UTP

After uridine triphosphate has been formed, it can be transformed into *cytidine triphosphate* by the replacement of a carbonyl group by an amino group, a reaction catalyzed by *cytidine triphosphate synthetase*.

Like the synthesis of carbamoyl phosphate, this reaction requires ATP and uses glutamine as the source of the amino group. The reaction proceeds through an analogous mechanism in which the O-4 atom is phosphorylated to form a reactive intermediate, and then the phosphate is displaced by ammonia, freed from glutamine by hydrolysis. CTP can then be used in many biochemical processes, including lipid and RNA synthesis.

### Salvage pathways recycle pyrimidine bases

Pyrimidine bases can be recovered from the breakdown products of DNA and RNA by the use of *salvage pathways*. In these pathways, a preformed base is reincorporated into a nucleotide. We will consider the salvage for the pyrimidine base thymine. Thymine is found in DNA and base-pairs with adenine in the DNA double helix. Thymine released from degraded DNA is salvaged in two steps. First, thymine is converted into the nucleoside thymidine by *thymidine phosphorylase*.

Thymidine is then converted into a nucleotide by *thymidine kinase*.

 Viral thymidine kinase differs from the mammalian enzyme and thus provides a therapeutic target. For instance, herpes simplex infections are treated with acyclovir (acycloguanosine), which viral thymidine kinase converts into acyclovir monophosphate by adding a phosphate to the hydroxyl group of acyclovir. Viral thymidine kinase binds acyclovir more than 200 times as tightly as cellular thymidine kinase, accounting for its effect on infected cells only. Acyclovir monophosphate is phosphorylated by cellular enzymes to yield acyclovir triphosphate. Acyclovir triphosphate competes with dGTP for DNA polymerase. Once incorporated into viral DNA, it acts as a chain terminator since it lacks a 3'-hydroxyl required for chain extension. As we will see shortly, thymidine kinase also plays a role in the de novo synthesis of thymidylate.

**FIGURE 25.5 De novo pathway for purine nucleotide synthesis.** The origins of the atoms in the purine ring are indicated.

## 25.2 Purine Bases Can Be Synthesized de Novo or Recycled by Salvage Pathways

Like pyrimidine nucleotides, *purine nucleotides* can be synthesized de novo or by a salvage pathway. When synthesized de novo, purine synthesis begins with simple starting materials such as amino acids and bicarbonate (Figure 25.5). Unlike the bases of pyrimidines, the purine bases are assembled already attached to the ribose ring. Alternatively, purine bases, released by the hydrolytic degradation of nucleic acids and nucleotides, can be salvaged and recycled. Purine salvage pathways are especially noted for the energy that they save and the remarkable effects of their absence (p. 761).

## The purine ring system is assembled on ribose phosphate

De novo purine biosynthesis, like pyrimidine biosynthesis, requires PRPP but, for purines, PRPP provides the foundation on which the bases are constructed step by step. The initial step is the displacement of pyrophosphate by ammonia, rather than by a preassembled base, to produce 5-phosphoribosyl-1-amine, with the amine in the  $\beta$  configuration.

Glutamine phosphoribosyl amidotransferase catalyzes this reaction, which is the committed step in purine regulation. This enzyme comprises two domains: the first is homologous to the phosphoribosyltransferases in purine salvage pathways (p. 752), whereas the second produces ammonia from glutamine by hydrolysis. However, this glutamine-hydrolysis domain is distinct from the domain that performs the same function in carbamoyl phosphate synthetase II. In glutamine phosphoribosyl amidotransferase, a cysteine residue located at the amino terminus facilitates glutamine hydrolysis. To prevent wasteful hydrolysis of either substrate, the amidotransferase assumes the active configuration only on binding of both PRPP and glutamine. As is the case with carbamoyl phosphate synthetase II, the ammonia generated at the glutamine-hydrolysis active site passes through a channel to reach PRPP without being released into solution.

## The purine ring is assembled by successive steps of activation by phosphorylation followed by displacement

 Nine additional steps are required to assemble the purine ring. Remarkably, the first six steps are analogous reactions. Most of these steps are catalyzed by enzymes with ATP-grasp domains that are homologous to those in carbamoyl phosphate synthetase. Each step consists of the activation of a carbon-bound oxygen atom (typically a carbonyl oxygen atom) by phosphorylation, followed by the displacement of the phosphoryl group by ammonia or an amine group acting as a nucleophile (Nu).

De novo purine biosynthesis proceeds as shown in Figure 25.6. Table 25.2 lists the enzymes that catalyze each step of the reaction.

1. The carboxylate group of a glycine residue is activated by phosphorylation and then coupled to the amino group of phosphoribosylamine. A new amide bond is formed, and the amino group of glycine is free to act as a nucleophile in the next step.
2.  $N^{10}$ -formyltetrahydrofolate donates a formyl moiety to this amino group to form formylglycinamide ribonucleotide.

**TABLE 25.2** The enzymes of de novo purine synthesis

Step	Enzyme
1	Glycinamide ribonucleotide (GAR) synthetase
2	GAR transformylase
3	Formylglycinamide synthase
4	Aminoimidazole ribonucleotide synthetase
5	Carboxyaminoimidazole ribonucleotide synthetase
6	Succinylaminoimidazole carboxamide ribonucleotide synthetase
7	Adenylosuccinate lyase
8	Aminoimidazole carboxamide ribonucleotide transformylase
9	Inosine monophosphate cyclohydrolyase

**FIGURE 25.6 De novo purine biosynthesis.** (1) Glycine is coupled to the amino group of phosphoribosylamine. (2) *N*<sup>10</sup>-Formyltetrahydrofolate (THF) transfers a formyl group to the amino group of the glycine residue. (3) The inner amide group is phosphorylated and converted into an amidine by the addition of ammonia derived from glutamine. (4) An intramolecular coupling reaction forms the five-membered imidazole ring. (5) Bicarbonate adds first to the exocyclic amino group and then to a carbon atom of the imidazole ring. (6) The imidazole carboxylate is phosphorylated, and the phosphate is displaced by the amino group of aspartate. (7) Fumarate is released. (8) A second formyl group is donated from *N*<sup>10</sup>-formyltetrahydrofolate (THF). (9) Cyclization completes the synthesis of inosinate, a purine nucleotide.

3. The inner carbonyl group is activated by phosphorylation and then converted into an amidine by the addition of ammonia derived from glutamine.

4. The product of this reaction, formylglycinamide ribonucleotide, cyclizes to form the five-membered imidazole ring found in purines. Although this cyclization is likely to be favorable thermodynamically, a molecule of ATP is consumed to ensure irreversibility. The familiar pattern is repeated: a phosphoryl group from the ATP molecule activates the carbonyl group and is displaced by the nitrogen atom attached to the ribose molecule. Cyclization is thus an intramolecular reaction in which the nucleophile and phosphate-activated carbon atom are present within the same molecule. In higher eukaryotes, the enzymes catalyzing steps 1, 2, and 4 (Table 25.2) are components of a single polypeptide chain.

5. Bicarbonate is activated by phosphorylation and then attacked by the exocyclic amino group. The product of the reaction in step 5 rearranges to transfer the carboxylate group to the imidazole ring. Interestingly, mammals do not require ATP for this step; bicarbonate apparently attaches directly to the exocyclic amino group and is then transferred to the imidazole ring.

6. The imidazole carboxylate group is phosphorylated again and the phosphate group is displaced by the amino group of aspartate. Once again, in higher eukaryotes, the enzymes catalyzing steps 5 and 6 (Table 25.2) share a single polypeptide chain.

7. Fumarate, an intermediate in the citric acid cycle, is eliminated, leaving the nitrogen atom from aspartate joined to the imidazole ring. The use of aspartate as an amino-group donor and the concomitant release of fumarate are reminiscent of the conversion of citrulline into arginine in the urea cycle, and these steps are catalyzed by homologous enzymes in the two pathways (Section 23.4).

8. A formyl group from  $N^{10}$ -formyltetrahydrofolate is added to this nitrogen atom to form a final 5-formaminoimidazole-4-carboxamide ribonucleotide.

9. 5-Formaminoimidazole-4-carboxamide ribonucleotide cyclizes with the loss of water to form inosinate.

Many of the intermediates in the de novo purine biosynthesis pathway degrade rapidly in water. Their instability in water suggests that the product of one enzyme must be channeled directly to the next enzyme along the pathway. Recent evidence shows that the enzymes do indeed form complexes when purine synthesis is required (p. 752).

### AMP and GMP are formed from IMP

A few steps convert inosinate into either AMP or GMP (Figure 25.7). *Adenylylate* is synthesized from inosinate by the substitution of an amino group for the carbonyl oxygen atom at C-6. Again, the addition of aspartate followed by the elimination of fumarate contributes the amino group. GTP, rather than ATP, is the phosphoryl-group donor in the synthesis of the adenylosuccinate intermediate from inosinate and aspartate. In accord with the use of GTP, the enzyme that promotes this conversion, *adenylosuccinate synthetase*, is structurally related to the G-protein family and does not contain an ATP-grasp domain.

**FIGURE 25.7** Generating AMP and GMP.

Inosinate is the precursor of AMP and GMP. AMP is formed by the addition of aspartate followed by the release of fumarate. GMP is generated by the addition of water, dehydrogenation by  $NAD^+$ , and the replacement of the carbonyl oxygen atom by  $-NH_2$  derived by the hydrolysis of glutamine.

**FIGURE 25.8 Formation of purinosomes.**

A gene construct encoding a fusion protein consisting of formylglycinamide synthase and GFP was transfected into and expressed in HeLa cells, a human cell line.

(A) In the presence of purines (the absence of purine synthesis), the GFP was seen as a diffuse stain throughout the cytoplasm.

(B) When the cells were shifted to a purine-free medium, purinosomes formed, seen as cytoplasmic granules, and purine synthesis occurred. White scale bars, 10  $\mu\text{m}$

[S. An, R. Kumar, E. D. Sheets, and S. J. Benkovic. *Science* 320:103–106. Figure 2, C and D, 2008.]

*Guanylate* is synthesized by the oxidation of inosinate to xanthylate (XMP), followed by the incorporation of an amino group at C-2.  $\text{NAD}^+$  is the hydrogen acceptor in the oxidation of inosinate. Xanthylate is activated by the transfer of an AMP group (rather than a phosphoryl group) from ATP to the oxygen atom in the newly formed carbonyl group. Ammonia, generated by the hydrolysis of glutamine, then displaces the AMP group to form guanylate, in a reaction catalyzed by *GMP synthetase*. Note that the synthesis of adenylate requires GTP, whereas the synthesis of guanylate requires ATP. This reciprocal use of nucleotides by the pathways creates an important regulatory opportunity (Section 25.4).

### Enzymes of the purine synthesis pathway associate with one another in vivo

Biochemists believe that the enzymes of many metabolic pathways, such as glycolysis and the citric acid cycle, are physically associated with one another. Such associations would increase the efficiency of pathways by facilitating the movement of the product of one enzyme to the active site of the next enzyme in the pathway. The evidence for such associations comes primarily from experiments in which one component of a pathway, carefully isolated from the cell, is found to be bound to other components of the pathway. However, these observations raise the question, do enzymes associate with one another in vivo or do they spuriously associate during the isolation procedure? Recent in vivo evidence shows that the enzymes of the purine synthesis pathway associate with one another when purine synthesis is required. Various enzymes of the pathway were fused with the green fluorescent protein (Figure 2.65) and transfected into cells. When cells were grown in the presence of purine, the GFP was spread diffusely throughout the cytoplasm (Figure 25.8A). When the cells were switched to growth media without purines, purine synthesis began and the enzymes became associated with one another, forming complexes dubbed *purinosomes* (Figure 25.8B). The experiments were repeated with other enzymes of the purine synthesis pathway bearing the GFP, and the results were the same: purine synthesis occurs when the enzymes form the purinosomes. What actually causes complex formation? While the results are not yet established, it appears that several G-protein coupled receptors, including those responding to epinephrine as well as ATP and ADP (purinergic receptors), instigate complex formation, while human creatine kinase II (hCK2), responding to the presence of purines, causes disassembly of the purinosome.

### Salvage pathways economize intracellular energy expenditure

As we have seen, the de novo synthesis of purines requires a substantial investment of ATP. Purine salvage pathways provide a more economical means of generating purines. Free purine bases, derived from the turnover of nucleotides or from the diet, can be attached to PRPP to form purine nucleoside monophosphates, in a reaction analogous to the formation of orotidylate. Two salvage enzymes with different specificities recover purine bases. *Adenine phosphoribosyltransferase* catalyzes the formation of adenylate (AMP):

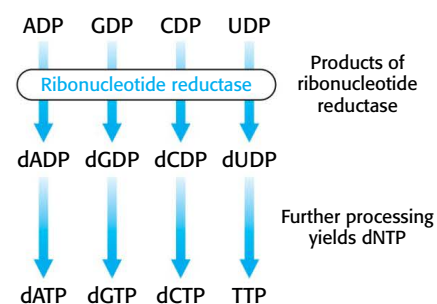

whereas *hypoxanthine-guanine phosphoribosyltransferase* (HGPRT) catalyzes the formation of guanylate (GMP) as well as inosinate (inosine monophosphate, IMP), a precursor of guanylate and adenylate.

## 25.3 Deoxyribonucleotides Are Synthesized by the Reduction of Ribonucleotides Through a Radical Mechanism

We turn now to the synthesis of deoxyribonucleotides. These precursors of DNA are formed by the reduction of ribonucleotides; specifically, the 2'-hydroxyl group on the ribose moiety is replaced by a hydrogen atom. The substrates are ribonucleoside diphosphates, and the ultimate reductant is NADPH. The enzyme *ribonucleotide reductase* is responsible for the reduction reaction for all four ribonucleotides. The ribonucleotide reductases of different organisms are a remarkably diverse set of enzymes. Yet detailed studies have revealed that they have a common reaction mechanism, and their three-dimensional structural features indicate that these enzymes are homologous. We will focus on the best understood of these enzymes, that of *E. coli* living aerobically.

### Mechanism: A tyrosyl radical is critical to the action of ribonucleotide reductase

The ribonucleotide reductase of *E. coli* consists of two subunits: R1 (an 87-kDa dimer) and R2 (a 43-kDa dimer). The R1 subunit contains the active site as well as two allosteric control sites (Section 25.4). This subunit includes three conserved cysteine residues and a glutamate residue, all four of which participate in the reduction of ribose to deoxyribose (Figure 25.9). The R2 subunit's role in catalysis is to generate a free radical in each of its two chains. Each R2 chain contains a *tyrosyl radical* with an unpaired electron delocalized onto its aromatic ring, generated by a nearby *iron center* consisting of two ferric ( $\text{Fe}^{3+}$ ) ions bridged by an oxide ( $\text{O}^{2-}$ ) ion (Figure 25.10). This very unusual free radical is remarkably stable, with a half-life of 4 days at 4°C. By contrast, free tyrosine radicals in solution have microsecond lifetimes.

In the synthesis of a deoxyribonucleotide, the OH bonded to C-2' of the ribose ring is replaced by H, with retention of the configuration at the C-2' carbon atom (Figure 25.11).

**FIGURE 25.9 Ribonucleotide reductase.** Ribonucleotide reductase reduces ribonucleotides to deoxyribonucleotides in its active site, which contains three key cysteine residues and one glutamate residue. Each R2 subunit contains a tyrosyl radical that accepts an electron from one of the cysteine residues in the active site to initiate the reduction reaction. Two R1 subunits come together to form a dimer as do two R2 subunits.

**FIGURE 25.10 Ribonucleotide reductase R2 subunit.** The R2 subunit contains a stable free radical on a tyrosine residue. This radical is generated by the reaction of oxygen (not shown) at a nearby site containing two iron atoms. Two R2 subunits come together to form a dimer. [Drawn from 1RIB.pdb.]

**FIGURE 25.11 Ribonucleotide reductase mechanism.** (1) An electron is transferred from a cysteine residue on R1 to a tyrosine radical on R2, generating a highly reactive cysteine thiyl radical. (2) This radical abstracts a hydrogen atom from C-3' of the ribose unit. (3) The radical at C-3' releases  $\text{OH}^-$  from the C-2' carbon atom. Combined with a proton from a second cysteine residue, the  $\text{OH}^-$  is eliminated as water. (4) A hydride ion is transferred from a third cysteine residue with the concomitant formation of a disulfide bond. (5) The C-3' radical recaptures the originally abstracted hydrogen atom. (6) An electron is transferred from R2 to reduce the thiyl radical, which also accepts a proton. The deoxyribonucleotide is free to leave R1. The disulfide formed in the active site must be reduced to begin another cycle.

1. The reaction begins with the transfer of an electron from a cysteine residue on R1 to the tyrosyl radical on R2. The loss of an electron generates a highly reactive *cysteine thiyl radical* within the active site of R1.
2. This radical then abstracts a hydrogen atom from C-3' of the ribose unit, generating a radical at that carbon atom.
3. The radical at C-3' promotes the release of the  $\text{OH}^-$  from the C-2' carbon atom. Protonated by a second cysteine residue, the departing  $\text{OH}^-$  leaves as a water molecule.
4. A hydride ion (a proton with two electrons) is then transferred from a third cysteine residue to complete the reduction of the position, form a disulfide bond, and re-form a radical.
5. This C-3' radical recaptures the same hydrogen atom originally abstracted by the first cysteine residue, and the deoxyribonucleotide is free to leave the enzyme.
6. R2 provides an electron to reduce the thiyl radical. The disulfide bond generated in the enzyme's active site must then be reduced to regenerate the active enzyme.

The electrons for this reduction come from NADPH, but not directly. One carrier of reducing power linking NADPH with the reductase is *thioredoxin*, a 12-kDa protein with two exposed cysteine residues near each other. These sulfhydryls are oxidized to a disulfide in the reaction catalyzed by ribonucleotide reductase itself. In turn, reduced thioredoxin is regenerated by electron flow from NADPH. This reaction is catalyzed by *thioredoxin reductase*, a flavoprotein. Electrons flow from NADPH to bound FAD of the reductase, to the disulfide of oxidized thioredoxin, and then to ribonucleotide reductase and finally to the ribose unit.

### Stable radicals other than tyrosyl radical are employed by other ribonucleotide reductases

 Ribonucleotide reductases that do not contain tyrosyl radicals have been characterized in other organisms. Instead, these enzymes contain other stable radicals that are generated by other processes. For example, in one class of reductases, the coenzyme adenosylcobalamin (vitamin B<sub>12</sub>) is the radical source (Section 22.3). Despite differences in the stable radical employed, the active sites of these enzymes are similar to that of the *E. coli* ribonucleotide reductase, and they appear to act by the same mechanism, based on the exceptional reactivity of cysteine radicals. Thus, these enzymes have a common ancestor but evolved a range of mechanisms for generating stable radical species that function well under different growth conditions. The primordial enzymes appear to have been inactivated by oxygen, whereas enzymes such as the *E. coli* enzyme make use of oxygen to generate the initial tyrosyl radical. Note that the reduction of ribonucleotides to deoxyribonucleotides is a difficult reaction chemically, likely to require a sophisticated catalyst. The existence of a common protein enzyme framework for this process strongly suggests that proteins joined the RNA world before the evolution of DNA as a stable storage form for genetic information.

### Thymidylate is formed by the methylation of deoxyuridylate

Uracil, produced by the pyrimidine synthesis pathway, is not a component of DNA. Rather, DNA contains *thymine*, a methylated analog of uracil. Another step is required to generate thymidylate from uracil. *Thymidylate synthase* catalyzes this finishing touch: deoxyuridylate (dUMP) is methylated to thymidylate (TMP). Recall that thymidylate synthase also functions in the thymine salvage pathway (p. 748). As will be described in Chapter 28, the methylation of this nucleotide marks sites of DNA damage for repair and, hence, helps preserve the integrity of the genetic information stored in DNA. The methyl donor in this reaction is N<sup>5</sup>, N<sup>10</sup>-methylene tetrahydrofolate rather than S-adenosylmethionine (Section 24.2).

The methyl group becomes attached to the C-5 atom within the aromatic ring of dUMP, but this carbon atom is not a good nucleophile and

**FIGURE 25.12 Thymidylate synthesis.**

Thymidylate synthase catalyzes the addition of a methyl group (derived from *N*<sup>5</sup>, *N*<sup>10</sup>-methylene tetrahydrofolate) to dUMP to form TMP. The addition of a thiolate from the enzyme activates dUMP. Opening the five-membered ring of the THF derivative prepares the methylene group for nucleophilic attack by the activated dUMP. The reaction is completed by the transfer of a hydride ion to form dihydrofolate.

cannot itself attack the appropriate group on the methyl donor. Thymidylate synthase promotes methylation by adding a thiolate from a cysteine side chain to this ring to generate a nucleophilic species that can attack the methylene group of *N*<sup>5</sup>, *N*<sup>10</sup>-methylene tetrahydrofolate (Figure 25.12). This methylene group, in turn, is activated by distortions imposed by the enzyme that favor opening the five-membered ring. The activated dUMP's attack on the methylene group forms the new carbon–carbon bond. The intermediate formed is then converted into product: a hydride ion is transferred from the tetrahydrofolate ring to transform the methylene group into a methyl group, and a proton is abstracted from the carbon atom bearing the methyl group to eliminate the cysteine and regenerate the aromatic ring. The tetrahydrofolate derivative loses both its methylene group and a hydride ion and, hence, is oxidized to dihydrofolate. For the synthesis of more thymidylate, tetrahydrofolate must be regenerated.

### Dihydrofolate reductase catalyzes the regeneration of tetrahydrofolate, a one-carbon carrier

Tetrahydrofolate is regenerated from the dihydrofolate that is produced in the synthesis of thymidylate. This regeneration is accomplished by *dihydrofolate reductase* with the use of NADPH as the reductant.

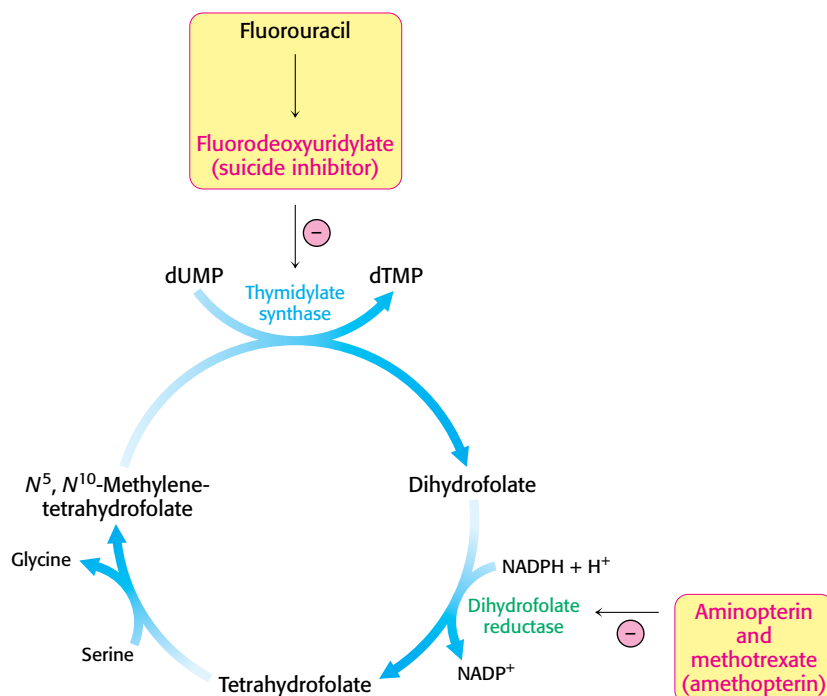

A hydride ion is directly transferred from the nicotinamide ring of NADPH to the pteridine ring of dihydrofolate. The bound dihydrofolate and NADPH are held in close proximity to facilitate the hydride transfer.

## Several valuable anticancer drugs block the synthesis of thymidylate

 Rapidly dividing cells require an abundant supply of thymidylate for the synthesis of DNA. The vulnerability of these cells to the inhibition of TMP synthesis has been exploited in the treatment of cancer. Thymidylate synthase and dihydrofolate reductase are choice targets of chemotherapy (Figure 25.13).

*Fluorouracil*, an anticancer drug, is converted in vivo into *fluorodeoxyuridylate* (F-dUMP). This analog of dUMP irreversibly inhibits thymidylate synthase after acting as a normal substrate through part of the catalytic cycle. Recall that the formation of TMP requires the removal of a proton ( $H^+$ ) from C-5 of the bound nucleotide (Figure 25.12). However, the enzyme cannot abstract  $F^+$  from F-dUMP, and so catalysis is blocked at the stage of the covalent complex formed by F-dUMP, methylenetetrahydrofolate, and the sulfhydryl group of the enzyme (Figure 25.14). We see here an example of *suicide inhibition*, in which an enzyme converts a substrate into a reactive inhibitor that halts the enzyme's catalytic activity (Section 8.5).

The synthesis of TMP can also be blocked by inhibiting the regeneration of tetrahydrofolate. Analogs of dihydrofolate, such as *aminopterin* and *methotrexate* (amethopterin), are potent competitive inhibitors ( $K_i < 1 \text{ nM}$ ) of dihydrofolate reductase.

**FIGURE 25.13 Anticancer drug targets.** Thymidylate synthase and dihydrofolate reductase are choice targets in cancer chemotherapy because the generation of large quantities of precursors for DNA synthesis is required for rapidly dividing cancer cells.

Methotrexate is a valuable drug in the treatment of many rapidly growing tumors, such as those in acute leukemia and choriocarcinoma, a cancer derived from placental cells. However, methotrexate kills rapidly replicating

**FIGURE 25.14 Suicide inhibition.** Fluorodeoxyuridylate (generated from fluorouracil) traps thymidylate synthase in a form that cannot proceed down the reaction pathway.

cells whether they are malignant or not. Stem cells in bone marrow, epithelial cells of the intestinal tract, and hair follicles are vulnerable to the action of this folate antagonist, accounting for its toxic side effects, which include weakening of the immune system, nausea, and hair loss.

Folate analogs such as *trimethoprim* have potent antibacterial and antiprotozoal activity. Trimethoprim binds  $10^5$ -fold less tightly to mammalian dihydrofolate reductase than it does to reductases of susceptible microorganisms. Small differences in the active-site clefts of these enzymes account for the highly selective antimicrobial action. The combination of trimethoprim and sulfamethoxazole (an inhibitor of folate synthesis) is widely used to treat infections such as bronchitis, traveler's diarrhea, and urinary tract infections.

## 25.4 Key Steps in Nucleotide Biosynthesis Are Regulated by Feedback Inhibition

Nucleotide biosynthesis is regulated by feedback inhibition in a manner similar to the regulation of amino acid biosynthesis (Section 24.3). These regulatory pathways ensure that the various nucleotides are produced in the required quantities.

### Pyrimidine biosynthesis is regulated by aspartate transcarbamoylase

Aspartate transcarbamoylase, one of the key enzymes for the regulation of pyrimidine biosynthesis in bacteria, was described in detail in Chapter 10. Recall that *ATCase* is inhibited by *CTP*, the final product of pyrimidine biosynthesis, and stimulated by *ATP*.

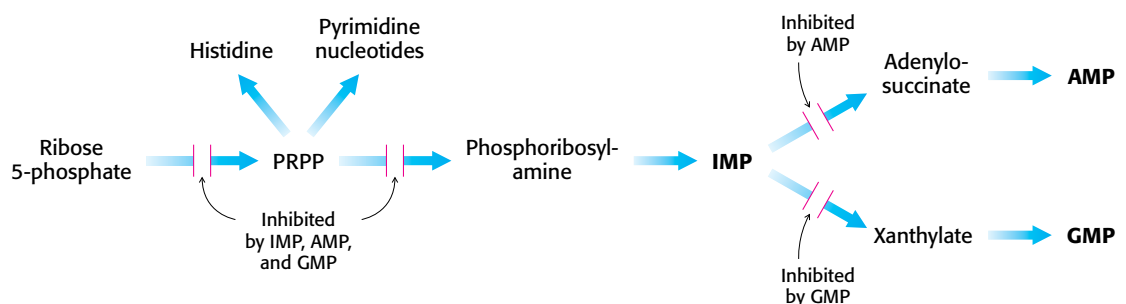

Carbamoyl phosphate synthetase II is also a site of feedback inhibition in both prokaryotes and eukaryotes.

### The synthesis of purine nucleotides is controlled by feedback inhibition at several sites

The regulatory scheme for purine nucleotides is more complex than that for pyrimidine nucleotides (Figure 25.15).

1. The committed step in purine nucleotide biosynthesis is the conversion of PRPP into phosphoribosylamine by *glutamine phosphoribosyl amidotransferase*. This important enzyme is feedback-inhibited by many purine ribonucleotides. It is noteworthy that AMP and GMP, the final products of the pathway, synergistically inhibit the amidotransferase.

**FIGURE 25.15 Control of purine biosynthesis.** Feedback inhibition controls both the overall rate of purine biosynthesis and the balance between AMP and GMP production.

**FIGURE 25.16 Regulation of ribonucleotide reductase.** (A) Each subunit in the R1 dimer contains two allosteric sites in addition to the active site. One site regulates the overall activity and the other site regulates substrate specificity. (B) The patterns of regulation with regard to different nucleoside diphosphates demonstrated by ribonucleotide reductase.

2. Inosinate is the branch point in the synthesis of AMP and GMP. The reactions leading away from inosinate are sites of feedback inhibition. AMP inhibits the conversion of inosinate into adenylosuccinate, its immediate precursor. Similarly, GMP inhibits the conversion of inosinate into xanthylate, its immediate precursor.

3. As already noted, GTP is a substrate in the synthesis of AMP, whereas ATP is a substrate in the synthesis of GMP (Figure 25.7). This reciprocal substrate relation tends to balance the synthesis of adenine and guanine ribonucleotides.

Note that the synthesis of PRPP by PRPP synthetase is highly regulated even though it is not the committed step in purine synthesis. Mutations have been identified in PRPP synthetase that result in a loss of allosteric response to nucleotides without any effect on catalytic activity of the enzyme. A consequence of this mutation is an overabundance of purine nucleotides that can result in gout, a pathological condition discussed later in the chapter.

### The synthesis of deoxyribonucleotides is controlled by the regulation of ribonucleotide reductase

The reduction of ribonucleotides to deoxyribonucleotides is precisely controlled by allosteric interactions. Each polypeptide of the R1 subunit of the aerobic *E. coli* ribonucleotide reductase contains two allosteric sites: one of them controls the overall activity of the enzyme, and the other regulates substrate specificity (Figure 25.16A). The overall catalytic activity of ribonucleotide reductase is diminished by the binding of dATP, which signals an abundance of deoxyribonucleotides (Figure 25.16B). The binding of ATP reverses this feedback inhibition. The binding of dATP or ATP to the substrate-specificity control site enhances the reduction of UDP and CDP, the pyrimidine nucleotides. The binding of thymidine triphosphate (TTP) promotes the reduction of GDP and inhibits the further reduction of pyrimidine ribonucleotides. The subsequent increase in the level of dGTP stimulates the reduction of ATP to dATP. This complex pattern of regulation supplies the appropriate balance of the four deoxyribonucleotides needed for the synthesis of DNA.

 Ribonucleotide reductase is an attractive target for cancer therapy and a number of clinically approved anticancer drugs mimic substrates and regulators of the enzyme. The pyrimidine analog gemcitabine, once converted to the diphosphate form in vivo, becomes a suicide inhibitor

of the reductase used to treat advanced pancreatic cancer. The purine analogs clofarabine and cladribine, upon conversion to their triphosphate forms *in vivo*, are dATP analogs and act as allosteric inhibitors of the enzyme. Clofarabine is used to treat pediatric acute myeloid leukemia while cladribine is effective against some forms of chronic lymphoid leukemia.

## 25.5 Disruptions in Nucleotide Metabolism Can Cause Pathological Conditions

Nucleotides are vital to a host of biochemical processes. It is not surprising, then, that disruption of nucleotide metabolism would have a variety of physiological effects. The nucleotides of a cell undergo continual turnover. Nucleotides are hydrolytically degraded to nucleosides by *nucleotidases*. The phosphorylytic cleavage of nucleosides to free bases and ribose 1-phosphate (or deoxyribose 1-phosphate) is catalyzed by *nucleoside phosphorylases*. Ribose 1-phosphate is isomerized by *phosphoribomutase* to ribose 5-phosphate, a substrate in the synthesis of PRPP. Some of the bases are reused to form nucleotides by salvage pathways. Others are degraded to products that are excreted (Figure 25.17). A deficiency of an enzyme can disrupt these pathways, leading to a pathological condition.

### The loss of adenosine deaminase activity results in severe combined immunodeficiency

 The pathway for the degradation of AMP includes an extra step because adenosine is not a substrate for nucleoside phosphorylase. First, the phosphate is removed by a nucleotidase to yield the nucleoside adenosine (Figure 25.17). In the extra step, adenosine is deaminated by *adenosine deaminase* to form inosine.

A deficiency in adenosine deaminase activity is associated with some forms of *severe combined immunodeficiency* (SCID), an immunological disorder.

**FIGURE 25.17 Purine catabolism.** Purine bases are converted first into xanthine and then into urate for excretion. Xanthine oxidase catalyzes two steps in this process.

Persons with the disorder have acute recurring infections, often leading to death at an early age. SCID is characterized by a loss of T cells, which are crucial to the immune response (Section 34.5). Although the biochemical basis of the disorder is not clearly established, a lack of adenosine deaminase results in an increase of 50 to 100 times the normal level of dATP, which inhibits ribonucleotide reductase and, consequently, DNA synthesis. Moreover, adenosine itself is a powerful signal molecule with a role in a number of regulatory pathways. Disruption in the levels of adenosine may also be deleterious. SCID is often called the “bubble boy disease” because its treatment may include complete isolation of the patient from the environment. Adenosine deaminase deficiency has been successfully treated by gene therapy.

### Gout is induced by high serum levels of urate

 Inosine generated by adenosine deaminase is subsequently metabolized by *nucleoside phosphorylase* to hypoxanthine. *Xanthine oxidase*, a molybdenum- and iron-containing flavoprotein, oxidizes hypoxanthine to *xanthine* and then to *uric acid*. Molecular oxygen, the oxidant in both reactions, is reduced to  $\text{H}_2\text{O}_2$ , which is decomposed to  $\text{H}_2\text{O}$  and  $\text{O}_2$  by catalase. Uric acid loses a proton at physiological pH to form *urate*. *In human beings, urate is the final product of purine degradation and is excreted in the urine.*

High serum levels of urate (hyperuricemia) induce the painful joint disease *gout*. In this disease, the sodium salt of urate crystallizes in the fluid and lining of the joints. The small joint at the base of the big toe is a common site for sodium urate buildup, although the salt accumulates at other joints also. Painful inflammation results when cells of the immune system engulf the sodium urate crystals. The kidneys, too, may be damaged by the deposition of urate crystals. Gout is a common medical problem, affecting 1% of the population of Western countries. It is nine times as common in men as in women.

Administration of *allopurinol*, an analog of hypoxanthine, is one treatment for gout. The mechanism of action of allopurinol is interesting: it acts *first as a substrate and then as an inhibitor* of xanthine oxidase. The oxidase hydroxylates allopurinol to *alloxanthine (oxipurinol)*, which then remains tightly bound to the active site. The binding of alloxanthine keeps the molybdenum atom of xanthine oxidase in the +4 oxidation state instead of it returning to the +6 oxidation state as in a normal catalytic cycle. We see here another example of *suicide inhibition*.

The synthesis of urate from hypoxanthine and xanthine decreases soon after the administration of allopurinol. The serum concentrations of hypoxanthine and xanthine rise, and that of urate drops.

 The average serum level of urate in human beings is close to the solubility limit and is higher than levels found in other primates. What is the selective advantage of a urate level so high that it teeters on the brink of gout in many people? It turns out that urate has a markedly beneficial action. Urate is a highly effective scavenger of reactive oxygen species. Indeed, urate is about as effective as ascorbate (vitamin C) as an antioxidant. The increased level of urate in human beings may protect against reactive oxygen species that are implicated in a host of pathological conditions (Table 18.3).

### Lesch–Nyhan syndrome is a dramatic consequence of mutations in a salvage-pathway enzyme

 Mutations in genes that encode nucleotide biosynthetic enzymes can reduce levels of needed nucleotides and can lead to an accumulation of intermediates. A nearly total absence of hypoxanthine-guanine phosphoribosyltransferase (HGPRT) has unexpected and devastating consequences. The most striking expression of this inborn error of metabolism, called the

*Lesch–Nyhan syndrome*, is *compulsive self-destructive behavior*. At age 2 or 3, children with this disease begin to bite their fingers and lips and will chew them off if unrestrained. These children also behave aggressively toward others. *Mental deficiency* and *spasticity* are other characteristics of the Lesch–Nyhan syndrome. Elevated levels of urate in the serum lead to the formation of kidney stones early in life, followed by the symptoms of gout years later. The disease is inherited as a sex-linked recessive disorder.

What is the connection between the absence of HGPRT activity and the behavioral characteristics of Lesch–Nyhan syndrome? The answer is not clear, but it is possible to speculate. The brain has limited capacity for de novo purine synthesis. Consequently, lack of HGPRT results in a deficiency of purine nucleotides. ATP and ADP, formed from inosinate, are especially important in the brain as signal molecules. These nucleotides bind to and activate G-protein coupled receptors that regulate the dopamine secreting neurons. Thus, the lack of HGPRT results in an imbalance of key neurotransmitters. Moreover, the guanosine nucleotides required for G-protein function may also be in short supply. The Lesch–Nyhan syndrome demonstrates that the salvage pathway for the synthesis of IMP and GMP is not of minor importance. Moreover, the Lesch–Nyhan syndrome reveals that *abnormal behavior such as self-mutilation and extreme hostility can be caused by the absence of a single enzyme*. Psychiatry will no doubt benefit from the unraveling of the molecular basis of such mental disorders.

#### Folic acid deficiency promotes birth defects such as spina bifida

*Spina bifida* is one of a class of birth defects characterized by the incomplete or incorrect formation of the neural tube early in development. In the United States, the prevalence of *neural-tube defects* is approximately 1 case per 1000 births. A variety of studies have demonstrated that the prevalence of neural-tube defects is reduced by as much as 70% when women take folic acid as a dietary supplement before and during the first trimester of pregnancy. One hypothesis is that more folate derivatives are needed for the synthesis of DNA precursors when cell division is frequent and substantial amounts of DNA must be synthesized.

## SUMMARY

### 25.1 The Pyrimidine Ring Is Assembled de Novo or Recovered by Salvage Pathways

The pyrimidine ring is assembled first and then linked to ribose phosphate to form a pyrimidine nucleotide. 5-Phosphoribosyl-1-pyrophosphate is the donor of the ribose phosphate moiety. The synthesis of the pyrimidine ring starts with the formation of carbamoylaspartate from carbamoyl phosphate and aspartate, a reaction catalyzed by aspartate transcarbamoylase. Dehydration, cyclization, and oxidation yield orotate, which reacts with PRPP to give orotidylate. Decarboxylation of this pyrimidine nucleotide yields UMP. CTP is then formed by the amination of UTP.

### 25.2 Purine Bases Can Be Synthesized de Novo or Recycled by Salvage Pathways

The purine ring is assembled from a variety of precursors: glutamine, glycine, aspartate,  $N^{10}$ -formyltetrahydrofolate, and  $\text{CO}_2$ . The committed step in the de novo synthesis of purine nucleotides is the formation of 5-phosphoribosylamine from PRPP and glutamine. The purine ring is assembled on ribose phosphate, in contrast with the de novo synthesis of pyrimidine nucleotides. The addition of glycine, followed

by formylation, amination, and ring closure, yields 5-aminoimidazole ribonucleotide. This intermediate contains the completed five-membered ring of the purine skeleton. The addition of  $\text{CO}_2$ , the nitrogen atom of aspartate, and a formyl group, followed by ring closure, yields inosinate, a purine ribonucleotide. AMP and GMP are formed from IMP. Purine ribonucleotides can also be synthesized by a salvage pathway in which a preformed base reacts directly with PRPP.

### 25.3 Deoxyribonucleotides Are Synthesized by the Reduction of Ribonucleotides Through a Radical Mechanism

Deoxyribonucleotides, the precursors of DNA, are formed in *E. coli* by the reduction of ribonucleoside diphosphates. These conversions are catalyzed by ribonucleotide reductase. Electrons are transferred from NADPH to sulfhydryl groups at the active sites of this enzyme by thioredoxin. A tyrosyl free radical generated by an iron center in the reductase initiates a radical reaction on the sugar, leading to the exchange of H for OH at C-2'. TMP is formed by the methylation of dUMP. The donor of a methylene group and a hydride in this reaction is  $N^5, N^{10}$ -methylenetetrahydrofolate, which is converted into dihydrofolate. Tetrahydrofolate is regenerated by the reduction of dihydrofolate by NADPH. Dihydrofolate reductase, which catalyzes this reaction, is inhibited by folate analogs such as aminopterin and methotrexate. These compounds and fluorouracil, an inhibitor of thymidylate synthase, are used as anticancer drugs.

### 25.4 Key Steps in Nucleotide Biosynthesis Are Regulated by Feedback Inhibition

Pyrimidine biosynthesis in *E. coli* is regulated by the feedback inhibition of aspartate transcarbamoylase, the enzyme that catalyzes the committed step. CTP inhibits and ATP stimulates this enzyme. The feedback inhibition of glutamine-PRPP amidotransferase by purine nucleotides is important in regulating their biosynthesis. Disruption of the regulation and activity of ribonucleotide reductase by drugs is an effective chemotherapy for some types of cancer.

### 25.5 Disruptions in Nucleotide Metabolism Can Cause Pathological Conditions

Severe combined immunodeficiency results from the absence of adenosine deaminase, an enzyme in the purine degradation pathway. Purines are degraded to urate in human beings. Gout, a disease that affects joints and leads to arthritis, is associated with an excessive accumulation of urate. The Lesch–Nyhan syndrome, a genetic disease characterized by self-mutilation, mental deficiency, and gout, is caused by the absence of hypoxanthine-guanine phosphoribosyltransferase. This enzyme is essential for the synthesis of purine nucleotides by the salvage pathway. Neural-tube defects are more frequent when a pregnant woman is deficient in folate derivatives early in pregnancy, possibly because of the important role of these derivatives in the synthesis of DNA precursors.

## KEY TERMS

pyrimidine nucleotide (p. 744)	salvage pathway (p. 748)	severe combined immunodeficiency (SCID) (p. 760)
carbamoyl phosphate synthetase II (CPS II) (p. 745)	purine nucleotide (p. 748)	gout (p. 761)
ATP-grasp fold (p. 745)	glutamine phosphoribosyl amidotransferase (p. 749)	Lesch–Nyhan syndrome (p. 761)
5-phosphoribosyl-1-pyrophosphate (PRPP) (p. 746)	ribonucleotide reductase (p. 753)	spina bifida (p. 762)
orotidylate (p. 747)	thymidylate synthase (p. 755)	neural-tube defect (p. 762)
	dihydrofolate reductase (p. 756)	

## PROBLEMS

1. *From the beginning or extract and save and reuse.* Differentiate between the de novo synthesis of nucleotides and salvage-pathway synthesis.

2. *Finding their roots 1.* Identify the source of the atoms in the pyrimidine ring

3. *Finding their roots 2.* Identify the source of the atoms in the purine ring.

4. *Multifaceted.* List some of the biochemical roles played by nucleotides.

5. *An s instead of a t?* Differentiate between a nucleoside and a nucleotide.

6. *Associate 'em.*

7. *Safe passage.* What is substrate channeling? How does it affect enzyme efficiency?

8. *Activated ribose phosphate.* Write a balanced equation for the synthesis of PRPP from glucose through the oxidative branch of the pentose phosphate pathway.

9. *Making a pyrimidine.* Write a balanced equation for the synthesis of orotate from glutamine, CO<sub>2</sub>, and aspartate.

10. *Identifying the donor.* What is the activated reactant in the biosynthesis of each of the following compounds?

- (a) Phosphoribosylamine (c) Orotidylate (from orotate)  
 (b) Carbamoylaspartate (d) Phosphoribosylanthranilate

11. *Inhibiting purine biosynthesis.* Amidotransferases are inhibited by the antibiotic azaserine (*O*-diazooacetyl-L-serine), which is an analog of glutamine.

Which intermediates in purine biosynthesis would accumulate in cells treated with azaserine?

12. *The price of methylation.* Write a balanced equation for the synthesis of TMP from dUMP that is coupled to the conversion of serine into glycine.

13. *Sulfa action.* Bacterial growth is inhibited by sulfanilamide and related sulfa drugs, and there is a concomitant accumulation of 5-aminoimidazole-4-carboxamide ribonucleotide. This inhibition is reversed by the addition of *p*-aminobenzoate.

Propose a mechanism for the inhibitory effect of sulfanilamide.

14. *HAT medium.* Mutant cells unable to synthesize nucleotides by salvage pathways are very useful tools in molecular and cell biology. Suppose that cell A lacks thymidine kinase, the enzyme catalyzing the phosphorylation of thymidine to thymidylate, and that cell B lacks hypoxanthine-guanine phosphoribosyl transferase.

(a) Cell A and cell B do not proliferate in a HAT medium containing hypoxanthine, aminopterin or amethopterin (methotrexate), and thymine. However, cell C, formed by the fusion of cells A and B, grows in this medium. Why?

(b) Suppose that you want to introduce foreign genes into cell A. Devise a simple means of distinguishing between cells that have taken up foreign DNA and those that have not.

15. *Vitamin requirement.* What is the role of folate in pyrimidine synthesis and what is the consequence of a folate deficiency during development?

16. *Bringing equilibrium.* What is the reciprocal substrate relation in the synthesis of ATP and GTP?

17. *Find the label.* Suppose that cells are grown on amino acids that have all been labeled at the  $\alpha$  carbons with <sup>13</sup>C. Identify the atoms in cytosine and guanine that will be labeled with <sup>13</sup>C.

18. *Need a map?* Describe the path for the synthesis of TTP from UTP.

19. *Adjunct therapy.* Allopurinol is sometimes given to patients with acute leukemia who are being treated with anticancer drugs. Why is allopurinol used?

20. *A hobbled enzyme.* Both side-chain oxygen atoms of aspartate 27 at the active site of dihydrofolate reductase form hydrogen bonds with the pteridine ring of folates. The

importance of this interaction was assessed by studying two mutants at this position, Asn 27 and Ser 27. The dissociation constant of methotrexate was 0.07 nM for the wild type, 1.9 nM for the Asn 27 mutant, and 210 nM for the Ser 27 mutant, at 25°C. Calculate the standard free energy of the binding of methotrexate by these three proteins. What is the decrease in binding energy resulting from each mutation?

21. *Needed supplies.* Why are cancer cells especially sensitive to inhibitors of TMP synthesis?

22. *Alternative routes.* Orotic aciduria results when one of the enzyme activities of UMP synthetase is absent. This syndrome is characterized by large amounts of orotic acid in the blood and urine, megaloblastic anemia (characterized by large, immature, and dysfunctional red blood cells) and retarded growth. Suggest a possible treatment for this condition.

23. *Correcting deficiencies.* Suppose that a person is found who is deficient in an enzyme required for IMP synthesis. How might this person be treated?

24. *Labeled nitrogen.* Purine biosynthesis is allowed to take place in the presence of [<sup>15</sup>N]aspartate, and the newly synthesized GTP and ATP are isolated. What positions are labeled in the two nucleotides?

25. *On the trail of carbons.* Tissue culture cells were incubated with glutamine labeled with <sup>15</sup>N in the amide group. Subsequently, IMP was isolated and found to contain some <sup>15</sup>N. Which atoms in IMP were labeled?

26. *Mechanism of action.* What is the biochemical basis of allopurinol treatment for gout?

27. *Changed inhibitor.* Xanthine oxidase treated with allopurinol results in the formation of a new compound that is an extremely potent inhibitor of the enzyme. Propose a structure for this compound.

28. *Calculate the ATP footprint.* How many molecules of ATP are required to synthesize one molecule of CTP from scratch?

29. *Blockages.* What intermediate in purine synthesis will accumulate if a strain of bacteria is lacking each of the following biochemicals?

- |                      |               |
|----------------------|---------------|
| (a) Aspartate        | (c) Glycine   |
| (b) Tetrahydrofolate | (d) Glutamine |

### Mechanism Problems

30. *The same and not the same.* Write out mechanisms for the conversion of phosphoribosylamine into glycinamide ribonucleotide and of xanthylate into guanylate.

31. *Closing the ring.* Propose a mechanism for the conversion of 5-formamidoimidazole-4-carboxamide ribonucleotide into inosinate.

### Chapter Integration Problems

32. *Different strokes.* Human beings contain two different carbamoyl phosphate synthetase enzymes. One uses glutamine as a substrate, whereas the other uses ammonia. What are the functions of these two enzymes?

33. *A generous donor.* What major biosynthetic reactions utilize PRPP?

34. *They're everywhere!* Nucleotides play a variety of roles in the cell. Give an example of a nucleotide that acts in each of the following roles or processes.

- |                                 |                           |
|---------------------------------|---------------------------|
| (a) Second messenger            | (e) Transfer of electrons |
| (b) Phosphoryl-group transfer   | (f) DNA sequencing        |
| (c) Activation of carbohydrates | (g) Chemotherapy          |
| (d) Activation of acetyl groups | (h) Allosteric effector   |

35. *Pernicious anemia.* Purine biosynthesis is impaired by vitamin B<sub>12</sub> deficiency. Why? How might fatty acid and amino acid metabolism also be affected by a vitamin B<sub>12</sub> deficiency?

36. *Folate deficiency.* Suppose someone was suffering from a folate deficiency. What cells would you think might be most affected? Symptoms may include diarrhea and anemia.

37. *Hyperuricemia.* Many patients with glucose 6-phosphatase deficiency have high serum levels of urate. Hyperuricemia can be induced in normal people by the ingestion of alcohol or by strenuous exercise. Propose a common mechanism that accounts for these findings.

38. *Labeled carbon.* Succinate uniformly labeled with <sup>14</sup>C is added to cells actively engaged in pyrimidine biosynthesis. Propose a mechanism by which carbon atoms from succinate could be incorporated into a pyrimidine. At what positions is the pyrimidine labeled?

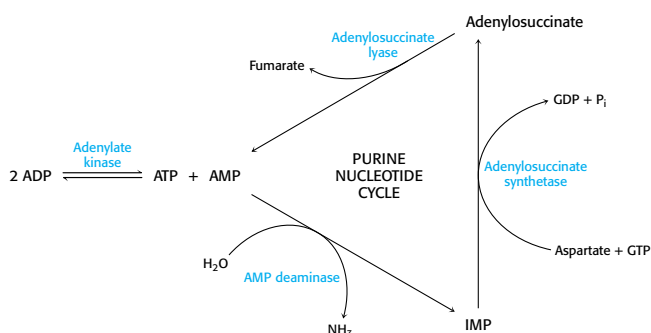

39. *Something funny going on here.* Cells were incubated with glucose labeled with <sup>14</sup>C in carbon 2, shown in red in the structure below. Later, uracil was isolated and found to contain <sup>14</sup>C in carbons 4 and 6. Account for this labeling pattern.

40. *Side effects.* Azathioprine is an immunosuppressant drug used in kidney transplants. In vivo, azathioprine is

metabolized to the hypoxanthine analog 6-mercaptopurine, which is then converted into 6-mercaptopurine ribose monophosphate, the active form of the drug. 6-Mercaptopurine ribose monophosphate also inhibits de novo purine synthesis, reducing uric acid levels in the blood and urine. However, when administered to Lesch–Nyhan patients, there was no effect on uric acid levels. Explain why this is the case.

41. *Exercising muscle.* Some interesting reactions take place in muscle tissue to facilitate the generation of ATP for contraction. In muscle contraction, ATP is converted into ADP. Adenylate kinase converts two molecules of ADP into a molecule of ATP and AMP.

- (a) Why is this reaction beneficial to contracting muscle?  
 (b) Why is the equilibrium for the adenylate kinase approximately equal to 1?  
 Muscle can metabolize AMP by using the purine nucleotide cycle. The initial step in this cycle, catalyzed by AMP deaminase, is the conversion of AMP into IMP.  
 (c) Why might the deamination of AMP facilitate ATP formation in muscle?  
 (d) How does the purine nucleotide cycle assist the aerobic generation of ATP?

42. *A common step.* What three reactions transfer an amino group from aspartate to yield the aminated product and fumarate?

43. *Your pet duck.* You suspect that your pet duck has gout. Why should you think twice before administering a dose of allopurinol-laced bread?

### Data Interpretation Problem

44. *Not all absences are equal.* In order to better understand the nature of the defects in HGPRT in patients suffering from Lesch–Nyhan disease, cell lines from two Lesch–Nyhan patients (LND 1 and LND 2) as well as a normal individual were established. HGPRT was then purified from each of the cell lines using the techniques examined in Chapter 3. Using the purified enzyme, the basic kinetics of the three enzymes were compared, as shown in Figure A. In each case, the same amount of purified enzyme was used in the analysis.

(a) Describe the results shown in the figure.

- (b) Suggest some possible explanations for the appearance of Lesch–Nyhan disease even in the presence of apparently normal enzyme.  
 (c) The stability of the HGPRT was tested to determine if the LND 1 enzyme was more labile. The same amounts of the normal and LND 1 enzyme were incubated at 37 °C in the absence of any substrates or products. At various times, a portion of the enzyme was removed and assayed for enzyme activity. The results are shown in Figure B. Explain these results.

# The Biosynthesis of Membrane Lipids and Steroids

Fats such as the triacylglycerol molecule (below) are widely used to store excess energy for later use and to fulfill other purposes, illustrated by the insulating blubber of whales. The natural tendency of fats to exist in nearly water free forms makes these molecules well suited to these roles. [(Left) François Gohier/Science Source.]

This chapter examines the biosynthesis of three important components of biological membranes—phospholipids, sphingolipids, and cholesterol—which were introduced in Chapter 12. Triacylglycerols also are considered here because the pathway for their synthesis overlaps that of phospholipids. Cholesterol is of interest both as a membrane component and as a precursor of potent signal molecules, such as the steroid hormones progesterone, testosterone, estrogen, and cortisol.

The transport and uptake of cholesterol vividly illustrate a recurring mechanism for the entry of metabolites and signal molecules into cells. Cholesterol is transported in blood by the low-density lipoprotein (LDL) and taken up into cells by the LDL receptor on the cell surface. The LDL receptor is absent in people with *familial hypercholesterolemia*, a genetic disease. People lacking the receptor have markedly elevated cholesterol levels in the blood and cholesterol deposits on blood vessels, and they are prone to childhood heart attacks. Indeed, cholesterol is implicated in the development of atherosclerosis in people who do not have genetic defects. Thus, the regulation of cholesterol synthesis and transport can be a source of especially clear insight into the role that our understanding of biochemistry plays in medicine.

## OUTLINE

- 26.1 Phosphatidate Is a Common Intermediate in the Synthesis of Phospholipids and Triacylglycerols
- 26.2 Cholesterol Is Synthesized from Acetyl Coenzyme A in Three Stages
- 26.3 The Complex Regulation of Cholesterol Biosynthesis Takes Place at Several Levels
- 26.4 Important Derivatives of Cholesterol Include Bile Salts and Steroid Hormones

## 26.1 Phosphatidate Is a Common Intermediate in the Synthesis of Phospholipids and Triacylglycerols

Lipid synthesis requires the coordinated action of gluconeogenesis and fatty acid metabolism, as illustrated in Figure 26.1. The common step in the synthesis of both phospholipids for membranes and triacylglycerols for energy storage is the formation of *phosphatidate* (diacylglycerol 3-phosphate). In mammalian cells, phosphatidate is synthesized in the endoplasmic reticulum and the outer mitochondrial membrane. The pathway begins with *glycerol 3-phosphate*, which is formed primarily by the reduction of dihydroxyacetone phosphate (DHAP) synthesized by the gluconeogenic pathway, and to a lesser extent by the phosphorylation of glycerol. The addition of two fatty acids to glycerol-3-phosphate yields phosphatidate. First, acyl coenzyme A contributes a fatty acid chain to form *lysophosphatidate* and, then, a second acyl CoA contributes a fatty acid chain to yield phosphatidate.

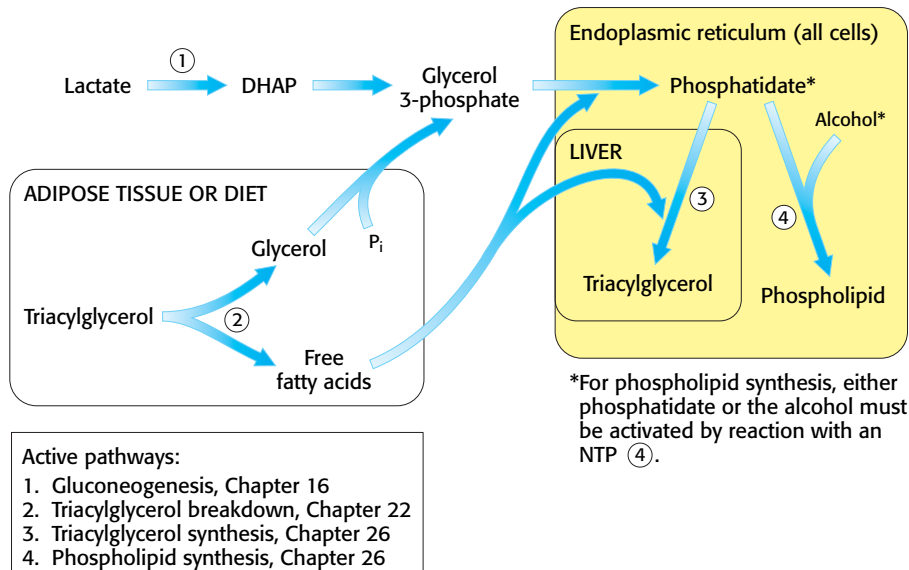

These acylations are catalyzed by *glycerol phosphate acyltransferase*. In most phosphatidates, the fatty acid chain attached to the C-1 atom is saturated, whereas the one attached to the C-2 atom is unsaturated. Phosphatidate can also be synthesized from *diacylglycerol* (DAG), in what is essentially a salvage pathway, by the action of *diacylglycerol kinase*:

The phospholipid and triacylglycerol pathways diverge at phosphatidate. In the synthesis of triacylglycerols, a key enzyme in the regulation of lipid synthesis, *phosphatidic acid phosphatase*, hydrolyzes phosphatidate to give a diacylglycerol. This intermediate is acylated to a *triacylglycerol* through the addition of a third fatty acid chain in a reaction that is catalyzed by *diglyceride acyltransferase*. Both enzymes are associated in a *triacylglycerol synthetase complex* that is bound to the endoplasmic reticulum membrane.

**FIGURE 26.1 PATHWAY INTEGRATION:** Sources of intermediates in the synthesis of triacylglycerols and phospholipids.

Phosphatidate, synthesized from dihydroxyacetone phosphate (DHAP) produced in gluconeogenesis and fatty acids, can be further processed to produce triacylglycerol or phospholipids. Phospholipids and other membrane lipids are continuously produced in all cells.

\*For phospholipid synthesis, either phosphatidate or the alcohol must be activated by reaction with an NTP (4).

The liver is the primary site of triacylglycerol synthesis. From the liver, the triacylglycerols are transported to the muscles for energy conversion or to the adipose cells for storage.

### The synthesis of phospholipids requires an activated intermediate

Membrane-lipid synthesis continues in the endoplasmic reticulum and in the Golgi apparatus. *Phospholipid* synthesis requires the combination of a diacylglycerol with an alcohol. As in most anabolic reactions, one of the components must be activated. In this case, either the diacylglycerol or the alcohol may be activated, depending on the source of the reactants.

The synthesis of some phospholipids begins with the reaction of phosphatidate with cytidine triphosphate (CTP) to form the activated diacylglycerol, *cytidine diphosphodiacylglycerol* (CDP-diacylglycerol). This reaction, like those of many biosyntheses, is driven forward by the hydrolysis of pyrophosphate.

The activated phosphatidyl unit then reacts with the hydroxyl group of an alcohol to form a phosphodiester linkage. If the alcohol is inositol, the products are *phosphatidylinositol* and cytidine monophosphate (CMP).

Subsequent phosphorylations catalyzed by specific kinases lead to the synthesis of *phosphatidylinositol 4,5-bisphosphate*, the precursor of two intracellular messengers—diacylglycerol and inositol 1,4,5-trisphosphate (Section 14.2). If the alcohol is phosphatidylglycerol, the products are *diphosphatidylglycerol* (*cardiolipin*) and CMP. In eukaryotes, cardiolipin is synthesized in the mitochondria and is located exclusively in inner mitochondrial membranes. Cardiolipin plays an important role in the organization of the protein components of oxidative phosphorylation. For example, it is required for the full activity of cytochrome *c* oxidase (Section 18.3).

The fatty acid components of phospholipids may vary, and thus cardiolipin, as well as most other phospholipids, represents a class of molecules rather than a single species. As a result, a single mammalian cell may contain thousands of distinct phospholipids. Phosphatidylinositol is unusual in that it has a nearly fixed fatty acid composition. Stearic acid usually occupies the C-1 position and arachidonic acid the C-2 position.

### Some phospholipids are synthesized from an activated alcohol

Phosphatidylethanolamine, the major phospholipid of the inner leaflet of cell membranes, is synthesized from the alcohol ethanolamine. To activate the alcohol, ethanolamine is phosphorylated by ATP to form the precursor, *phosphorylethanolamine*. This precursor then reacts with CTP to form the activated alcohol, *CDP-ethanolamine*. The phosphorylethanolamine unit of CDP-ethanolamine is transferred to a diacylglycerol to form *phosphatidylethanolamine*.

### Phosphatidylcholine is an abundant phospholipid

The most common phospholipid in mammals is phosphatidylcholine, comprising approximately 50% of the membrane mass. Dietary choline is activated in a series of reactions analogous to those in the activation of ethanolamine. CTP-phosphocholine cytidyltransferase (CCT) catalyzes the formation of CDP-choline, the rate-limiting step in phosphatidylcholine synthesis. CCT is an amphitropic enzyme, a class of enzymes whose regulator ligand is the membrane itself. A portion of the enzyme, normally associated with the membrane, detects a fall in phosphatidylcholine as an alteration in the physical properties of the membrane. When this occurs, another portion of the enzyme is inserted into the membrane, leading to enzyme activation. Indeed, the  $k_{\text{cat}}/K_M$  value (Section 8.4) increases three orders of magnitude upon activation, resulting in the restoration of phosphatidylcholine levels.

Earlier (Section 22.4) we examined how cancer cells increase lipogenesis to meet the fatty acid needs for membrane synthesis. Evidence is accumulating that CCT is specifically activated in some cancers to generate the required phosphocholine.

The importance of phosphatidylcholine is attested to by the fact that the liver possesses an enzyme, *phosphatidylethanolamine methyltransferase*, which synthesizes phosphatidylcholine from phosphatidylethanolamine when dietary choline is insufficient. The amino group of this phosphatidylethanolamine is methylated three times to form *phosphatidylcholine*. *S-Adosylmethionine* is the methyl donor (Section 24.2).

Thus, phosphatidylcholine can be produced by two distinct pathways in mammals, ensuring that this phospholipid can be synthesized even if the components for one pathway are in limited supply.

### Excess choline is implicated in the development of heart disease

 Choline is a popular dietary supplement that is believed by some to enhance liver and neuronal function. Although the effectiveness of choline supplements is not established, the dangers of excess choline consumption are becoming clear. Gut bacteria convert excess choline into trimethylamine (TMA), a gas that smells like rotten fish, and the liver converts the absorbed TMA into trimethylamine-*N*-oxide (TMAO). TMAO stimulates cholesterol uptake by macrophages, a process that can result in atherosclerosis (p. 787). Foods rich in phosphatidylcholine, such as red meats and dairy products, may also result in TMAO production.

**Trimethylamine**

**Trimethylamine-*N*-oxide**

### Base-exchange reactions can generate phospholipids

Phosphatidylserine makes up 10% of the phospholipids in mammals. This phospholipid is synthesized in a *base-exchange reaction* of serine with phosphatidylcholine or phosphatidylethanolamine. In the reaction, serine replaces choline or ethanolamine.

Phosphatidylserine is normally located in the inner leaflet of the plasma membrane bilayer but is moved to the outer leaflet in apoptosis (Section 18.6). There, it serves to attract phagocytes to consume the cell remnants after apoptosis is complete. Phosphatidylserine is translocated from one side of the membrane to the other by an ATP-binding cassette translocase (Section 13.2).

Note that a cytidine nucleotide plays the same role in the synthesis of these phosphoglycerides as a uridine nucleotide does in the formation of glycogen (Section 21.4). In all of these biosyntheses, an activated intermediate (UDP-glucose, CDP-diacylglycerol, or CDP-alcohol) is formed from a phosphorylated substrate (glucose 1-phosphate, phosphatidate, or a phosphoryl alcohol) and a nucleoside triphosphate (UTP or CTP). The activated intermediate then reacts with a hydroxyl group (the terminus of glycogen, an alcohol, or a diacylglycerol).

### Sphingolipids are synthesized from ceramide

We now turn from glycerol-based phospholipids to another class of membrane lipid—the *sphingolipids*. These lipids are found in the plasma membranes of all eukaryotic cells, although the concentration is highest in the cells of the central nervous system. The backbone of a sphingolipid is *sphingosine*, rather than glycerol. Palmitoyl CoA and serine condense to form 3-ketosphinganine. The serine–palmitoyl transferase catalyzing this reaction is the rate-limiting step in the pathway and requires pyridoxal phosphate, revealing again the dominant role of this cofactor in transformations that include amino acids. Ketosphinganine is then reduced to dihydrosphingosine before conversion into *ceramide*, a lipid consisting of a fatty acid chain attached to the amino group of a sphingosine backbone (Figure 26.2).

In all sphingolipids, the amino group of ceramide is acylated. The terminal hydroxyl group also is substituted (Figure 26.3). In *sphingomyelin*, a component of the myelin sheath covering many nerve fibers, the substituent is phosphorylcholine, which comes from phosphatidylcholine. In a *cerebroside*, the substituent is glucose or galactose. UDP-glucose or UDP-galactose is the sugar donor.

### Gangliosides are carbohydrate-rich sphingolipids that contain acidic sugars

Gangliosides are the most complex sphingolipids. In a *ganglioside*, an *oligosaccharide chain* is linked to the terminal hydroxyl group of ceramide by a glucose residue (Figure 26.4). This oligosaccharide chain contains at least one acidic sugar, either *N-acetylneuraminate* or *N-glycolylneuraminate*. These acidic sugars are called *sialic acids*. Their nine-carbon backbones are synthesized from phosphoenolpyruvate (a three-carbon unit) and *N*-acetylmannosamine 6-phosphate (a six-carbon unit).

Gangliosides are synthesized by the ordered, step-by-step addition of sugar residues to ceramide. The synthesis of these complex lipids requires

**FIGURE 26.2** Synthesis of ceramide.

Palmitoyl CoA and serine combine to initiate the synthesis of ceramide.

**FIGURE 26.3** Synthesis of sphingolipids.

Ceramide is the starting point for the formation of sphingomyelin and gangliosides.

the activated sugars UDP-glucose, UDP-galactose, and UDP-*N*-acetylgalactosamine, as well as the CMP derivative of *N*-acetylneuramate. CMP-*N*-acetylneuramate is synthesized from CTP and *N*-acetylneuramate. The sugar composition of the resulting ganglioside is determined by the specificity of the glycosyltransferases in the cell. Almost 200 different gangliosides have been characterized (see Figure 26.4 for the composition of ganglioside  $G_{M1}$ ).

Ganglioside-binding by the cholera toxin is the first step in the development of cholera, a pathological condition characterized by severe diarrhea (Section 14.5). Enterotoxigenic *E. coli*, the most common cause of diarrhea, including traveler's diarrhea, produces a toxin that also gains access to the cell by first binding to gangliosides. Gangliosides are also crucial for binding immune-system cells to sites of injury in the inflammatory response.

### Sphingolipids confer diversity on lipid structure and function

The structures of sphingolipids and the more abundant glycerophospholipids are very similar (Figure 12.8). Given the structural similarity of these two types of lipids, why are sphingolipids required at all? Indeed, the prefix “sphingo” was applied to capture the “sphinxlike” properties of this enigmatic class of lipids. Although the precise role of sphingolipids is not firmly established, progress toward solving the riddle of their function is being made. As discussed in Chapter 12, sphingolipids are important components of lipid rafts, highly organized regions of the plasma membrane that are important in signal transduction. Sphingosine, sphingosine 1-phosphate, and ceramide serve as second messengers in the regulation of cell growth, differentiation, and death. For instance, ceramide

**FIGURE 26.4** Ganglioside  $G_{M1}$ .

This ganglioside consists of five monosaccharides linked to ceramide: one glucose (Glc) molecule, two galactose (Gal) molecules, one *N*-acetylgalactosamine (GalNAc) molecule, and one *N*-acetylneuramate (NAN) molecule.

$R_2 = \text{H}$ , *N*-acetylneuramate  
 $R_2 = \text{OH}$ , *N*-glycolylneuramate

membrane formation (p. 771 and Section 22.4). How do cancer cells prevent ceramide-induced cell death? It appears that these cells destroy the apoptotic signal by converting it into a pro-mitotic signal. *Ceramidase* removes the fatty acid from the amino group of ceramide, generating sphingosine. Sphingosine is then converted into sphingosine 1-phosphate by sphingosine kinase, which stimulates cell division.

Thus, cancer cells convert a potentially lethal signal molecule into one that promotes tumor growth. Efforts are underway to develop inhibitors of ceramidase for use as chemotherapeutic agents.

### Phosphatidic acid phosphatase is a key regulatory enzyme in lipid metabolism

Although the details of the regulation of lipid synthesis remain to be elucidated, evidence suggests that *phosphatidic acid phosphatase* (PAP), working in concert with diacylglycerol kinase, plays a key role in the regulation of lipid synthesis. PAP, also called lipin 1 in mammals, controls the extent to which triacylglycerols are synthesized relative to phospholipids and regulates the type of phospholipid synthesized (Figure 26.6). For instance, when PAP activity is high, phosphatidate is dephosphorylated and diacylglycerol is produced, which can react with the appropriate activated alcohols to yield phosphatidylethanolamine, phosphatidylserine, or phosphatidylcholine. Diacylglycerol can also be converted into triacylglycerols, and evidence suggests that the formation of triacylglycerols may act as a fatty acid buffer. This buffering helps to regulate the levels of diacylglycerol and sphingolipids, which serve signaling functions.

When PAP activity is lower, phosphatidate is used as a precursor for different phospholipids, such as phosphatidylinositol and cardiolipin. Moreover, phosphatidate is a signal molecule itself. Phosphatidate

**FIGURE 26.6 Regulation of lipid synthesis.** Phosphatidic acid phosphatase is the key regulatory enzyme in lipid synthesis. When active, PAP generates diacylglycerol (DAG), which can react with activated alcohols to form phospholipids or with fatty acyl CoA to form triacylglycerols. When PAP is inactive, phosphatidate is converted into CMP-DAG for the synthesis of different phospholipids. PAP also controls the amount of DAG and phosphatidate, both of which function as second messengers.

regulates the growth of endoplasmic reticulum and nuclear membranes and acts as a cofactor that stimulates the expression of genes in phospholipid synthesis.

What are the signal molecules that regulate the activity of PAP? CDP-diacylglycerol, phosphatidylinositol, and cardiolipin enhance PAP activity, and sphingosine and dihydrosphingosine inhibit it. The enzyme also undergoes extensive phosphorylation and dephosphorylation. When phosphorylated, the enzyme resides in the cytoplasm. Upon dephosphorylation, the enzyme associates with the endoplasmic reticulum, the location of its substrate phosphatidate. Details of the covalent modification are under investigation.

Studies in mice clearly show the importance of PAP for the regulation of fatty acid synthesis. The loss of PAP function prevents normal adipose-tissue development, leading to lipodystrophy (severe loss of body fat) and insulin resistance. Excess PAP activity results in obesity. The regulation of phospholipid synthesis is an exciting area of research that will be active for some time to come.

## 26.2 Cholesterol Is Synthesized from Acetyl Coenzyme A in Three Stages

**FIGURE 26.7 Labeling of cholesterol.** Isotope-labeling experiments reveal the source of carbon atoms in cholesterol synthesized from acetate labeled in its methyl group (blue) or carboxylate atom (red).

We now turn our attention to the synthesis of the fundamental lipid *cholesterol*. This steroid modulates the fluidity of animal cell membranes (Section 12.5) and is the precursor of steroid hormones such as progesterone, testosterone, estradiol, and cortisol. All 27 carbon atoms of cholesterol are derived from acetyl CoA in a three-stage synthetic process (Figure 26.7).

1. Stage one is the synthesis of isopentenyl pyrophosphate, an activated isoprene unit that is the key building block of cholesterol.
2. Stage two is the condensation of six molecules of isopentenyl pyrophosphate to form squalene.
3. In stage three, squalene cyclizes and the tetracyclic product is subsequently converted into cholesterol.

The first stage takes place in the cytoplasm, and the next two in the endoplasmic reticulum.

### The synthesis of mevalonate, which is activated as isopentenyl pyrophosphate, initiates the synthesis of cholesterol

The first stage in the synthesis of cholesterol is the formation of isopentenyl pyrophosphate from acetyl CoA. This set of reactions starts with the formation of 3-hydroxy-3-methylglutaryl CoA (HMG CoA) from acetyl CoA and acetoacetyl CoA. This intermediate is reduced to *mevalonate* for the synthesis of cholesterol (Figure 26.8). Recall that, alternatively, 3-hydroxy-3-methylglutaryl CoA may be generated in the mitochondria and processed to form ketone bodies, which are subsequently secreted to provide fuel for other tissues, notably the brain under starvation conditions (Section 22.3).

*The synthesis of mevalonate is the committed step in cholesterol formation.* The enzyme catalyzing this irreversible step, 3-hydroxy-3-methylglutaryl

### Cholesterol

“Cholesterol is the most highly decorated small molecule in biology. Thirteen Nobel Prizes have been awarded to scientists who devoted major parts of their careers to cholesterol. Ever since it was isolated from gallstones in 1784, cholesterol has exerted an almost hypnotic fascination for scientists from the most diverse areas of science and medicine. . . . Cholesterol is a Janus-faced molecule. The very property that makes it useful in cell membranes, namely its absolute insolubility in water, also makes it lethal.”

—Michael Brown and Joseph Goldstein, on the occasion of their receipt of a Nobel Prize for elucidating the control of blood levels of cholesterol. Nobel Lectures (1985) © The Nobel Foundation, 1985

**FIGURE 26.8 Fates of 3-hydroxy-3-methylglutaryl CoA.** In the cytoplasm, HMG-CoA is converted into mevalonate. In mitochondria, it is converted into acetyl CoA and acetoacetate.

*CoA reductase* (HMG-CoA reductase), is an important control site in cholesterol biosynthesis, as will be discussed shortly.

HMG-CoA reductase is an integral membrane protein in the endoplasmic reticulum.

Mevalonate is converted into *3-isopentenyl pyrophosphate* in three consecutive reactions requiring ATP (Figure 26.9). In the last step, the release of CO<sub>2</sub> yields isopentenyl pyrophosphate, an activated isoprene unit that is a key building block for many important biomolecules throughout the kingdoms of life.

### Squalene (C<sub>30</sub>) is synthesized from six molecules of isopentenyl pyrophosphate (C<sub>5</sub>)

Squalene is synthesized from isopentenyl pyrophosphate by the reaction sequence

This stage in the synthesis of cholesterol starts with the isomerization of *isopentenyl pyrophosphate* to *dimethylallyl pyrophosphate*.

These two isomeric C<sub>5</sub> units (one of each type) condense to form a C<sub>10</sub> compound: isopentenyl pyrophosphate attacks an allylic carbocation

**FIGURE 26.9 Synthesis of isopentenyl pyrophosphate.** This activated intermediate is formed from mevalonate in three steps requiring ATP, followed by a decarboxylation.

**FIGURE 26.10 Condensation mechanism in cholesterol synthesis.** The isomeric  $C_5$  units dimethylallyl pyrophosphate and isopentenyl pyrophosphate join to form geranyl pyrophosphate. The same mechanism is used to add an additional isopentenyl pyrophosphate to form farnesyl pyrophosphate.

formed from dimethylallyl pyrophosphate to yield *geranyl pyrophosphate* (Figure 26.10). The same kind of reaction takes place again: geranyl pyrophosphate is converted into an allylic carbonium ion, which is attacked by isopentenyl pyrophosphate. The resulting  $C_{15}$  compound is called *farnesyl pyrophosphate*. The same enzyme, *geranyl transferase*, catalyzes each of these condensations.

The last step in the synthesis of *squalene* is a reductive tail-to-tail condensation of two molecules of farnesyl pyrophosphate catalyzed by the endoplasmic reticulum enzyme *squalene synthase*.

The reactions leading from  $C_5$  units to squalene, a  $C_{30}$  isoprenoid, are summarized in Figure 26.11.

### Squalene cyclizes to form cholesterol

The final stage of cholesterol biosynthesis starts with the cyclization of squalene (Figure 26.12). Squalene is first activated by conversion into squalene epoxide (2,3-oxidosqualene) in a reaction that uses  $O_2$  and NADPH. Squalene epoxide is then cyclized to *lanosterol* by *oxidosqualene cyclase*. The enzyme holds squalene epoxide in an appropriate conformation and initiates

**FIGURE 26.11 Squalene synthesis.** One molecule of dimethylallyl pyrophosphate and two molecules of isopentenyl pyrophosphate condense to form farnesyl pyrophosphate. The tail-to-tail coupling of two molecules of farnesyl pyrophosphate yields squalene.

**FIGURE 26.12 Squalene cyclization.** The formation of the steroid nucleus from squalene begins with the formation of squalene epoxide. This intermediate is protonated to form a carbocation that cyclizes to form a tetracyclic structure, which rearranges to form lanosterol.

the reaction by protonating the epoxide oxygen. The carbocation formed spontaneously rearranges to produce lanosterol. Lanosterol is converted into cholesterol in a multistep process by the removal of three methyl groups, the reduction of one double bond by NADPH, and the migration of the other double bond (Figure 26.13).

### 26.3 The Complex Regulation of Cholesterol Biosynthesis Takes Place at Several Levels

Cholesterol can be obtained from the diet or it can be synthesized de novo. Cholesterol biosynthesis is one of the most highly regulated metabolic pathways known. Biosynthetic rates may vary several hundredfold, depending on how much cholesterol is consumed in the diet. An adult on a low-cholesterol diet typically synthesizes about 800 mg of cholesterol per day. The liver is the major site of cholesterol synthesis in mammals, although the intestine also forms significant amounts. The rate of cholesterol formation by these organs is highly responsive to the cellular level of cholesterol. *This feedback regulation is mediated primarily by changes in the amount and activity of 3-hydroxy-3-methylglutaryl CoA reductase.* As described earlier (p. 776), this enzyme catalyzes the formation of mevalonate, the committed step in cholesterol biosynthesis. HMG CoA reductase is controlled in multiple ways:

1. The rate of *synthesis of reductase mRNA* is controlled by the *sterol regulatory element binding protein* (SREBP), a member of a family of transcription factors that regulate the proteins required for lipid synthesis. This transcription factor binds to a short DNA sequence called the *sterol regulatory element* (SRE) on the 5' side of the reductase gene when cholesterol levels are low, enhancing transcription of the gene. In its inactive state, the SREBP resides in the endoplasmic reticulum membrane, where it is associated with

**FIGURE 26.13 Cholesterol formation.** Lanosterol is converted into cholesterol in a complex process.

**FIGURE 26.14 The SREBP pathway.** SREBP resides in the endoplasmic reticulum (ER), where it is bound to SCAP by its regulatory (Reg) domain. When cholesterol levels fall, SCAP and SREBP move to the Golgi complex, where SREBP undergoes successive proteolytic cleavages by a serine protease and a metalloprotease. The released DNA-binding domain moves to the nucleus to alter gene expression. [Information from an illustration provided by Dr. Michael Brown and Dr. Joseph Goldstein.]

the SREBP cleaving activating protein (SCAP), an integral membrane protein. SCAP is the cholesterol sensor. When cholesterol levels fall, SCAP escorts SREBP in small membrane vesicles to the Golgi complex, where it is released from the membrane by two specific proteolytic cleavages (Figure 26.14). The first cleavage frees a fragment of SREBP from SCAP, whereas the second cleavage releases the regulatory domain from the membrane. The released protein migrates to the nucleus and binds the SRE of the HMG-CoA reductase gene, as well as several other genes in the cholesterol biosynthetic pathway, to enhance transcription. When cholesterol levels rise, the proteolytic release of the SREBP is blocked, and the SREBP in the nucleus is rapidly degraded by proteasomes located in the nucleus. These two events halt the transcription of genes of the cholesterol biosynthetic pathways.

What is the molecular mechanism that retains SCAP–SREBP in the ER when cholesterol is present but allows movement to the Golgi complex when cholesterol concentration is low? When cholesterol is low, SCAP binds to vesicular proteins that facilitate the transport of SCAP–SREBP to the Golgi apparatus, as heretofore described. When cholesterol is present, SCAP binds cholesterol, which causes a structural change in SCAP so that it binds to another endoplasmic reticulum protein called Insig (*insulin-induced gene*) (Figure 26.15). Insig is the anchor that retains SCAP and thus SREBP in the endoplasmic reticulum in the presence of cholesterol. The interactions between SCAP and Insig can also be forged when Insig binds 25-hydroxycholesterol, a metabolite of cholesterol. Thus, two distinct steroid–protein interactions prevent the inappropriate movement of SCAP–SREBP to the Golgi complex.

**FIGURE 26.15 Insig regulates SCAP–SREBP movement.** In the presence of cholesterol, Insig interacts with SCAP–SREBP and prevents the activation of SREBP. Cholesterol binding to SCAP or 25-hydroxycholesterol binding to Insig facilitates the interaction of Insig and SCAP, retaining SCAP–SREBP in the endoplasmic reticulum. [Information from M. S. Brown and J. L. Goldstein. Cholesterol feedback: From Schoenheimer’s bottle to Scap’s MELADL, *J. Lipid Res.* 50:S15–S27, 2009.]

2. The rate of *translation of reductase mRNA* is inhibited by nonsterol metabolites derived from mevalonate.

3. The *degradation of the reductase* is stringently controlled. The enzyme is bipartite: its cytoplasmic domain carries out catalysis and its *membrane domain senses signals that lead to its degradation*. The membrane domain may undergo structural changes in response to increasing concentrations of sterols such as lanosterol and 25-hydroxycholesterol. Under these conditions, the reductase appears to bind to a subset of Insigs that are also associated with the ubiquitinating enzymes (Figure 26.16). The reductase is polyubiquitinated and subsequently extracted from the membrane in a process that requires geranylgeraniol. The extracted reductase is then degraded by the proteasome (Section 23.2). The combined regulation at the levels of transcription, translation, and degradation can alter the amount of enzyme in the cell more than 200-fold.

4. *Phosphorylation decreases the activity of the reductase*. This enzyme, like acetyl CoA carboxylase (which catalyzes the committed step in fatty acid synthesis, Section 22.5), is switched off by an AMP-activated protein kinase. Thus, cholesterol synthesis ceases when the ATP level is low.

**FIGURE 26.16 Insig facilitates the degradation of HMG–CoA reductase.** In the presence of sterols, a subclass of Insig associated with ubiquitinating enzymes binds HMG–CoA reductase. This interaction results in the ubiquitination of the enzyme. This modification and the presence of geranylgeraniol results in extraction of the enzyme from the membrane and degradation by the proteasome. [Information from R. A. DeBose-Boyd. Feedback regulation of cholesterol synthesis: Sterol-accelerated ubiquitination and degradation of HMG CoA reductase, *Cell Res.* 18:609–621, 2008.]

**TABLE 26.1** Properties of plasma lipoproteins

Plasma lipoproteins	Density (g ml <sup>-1</sup> )	Diameter (nm)	Apolipoprotein	Physiological role	Composition (%)				
					TAG	CE	C	PL	P
Chylomicron	<0.95	75–1200	B-48, C, E	Dietary fat transport	86	3	1	8	2
Very low density lipoprotein	0.95–1.006	30–80	B-100, C, E	Endogenous fat transport	52	14	7	18	8
Intermediate-density lipoprotein	1.006–1.019	15–35	B-100, E	LDL precursor	38	30	8	23	11
Low-density lipoprotein	1.019–1.063	18–25	B-100	Cholesterol transport	10	38	8	22	21
High-density lipoprotein	1.063–1.21	7.5–20	A	Reverse cholesterol transport	5–10	14–21	3–7	19–29	33–57

Abbreviations: TAG, triacylglycerol; CE, cholesteryl ester; C, free cholesterol; PL, phospholipid; P, protein.

### Lipoproteins transport cholesterol and triacylglycerols throughout the organism

Cholesterol and triacylglycerols are transported in body fluids in the form of *lipoprotein particles*, which are important for a number of reasons. First, lipoprotein particles are the means by which triacylglycerols are delivered to tissues, from the intestine or liver, for use as fuel or for storage. Second, the fatty acid constituents of the triacylglycerol components of the lipoprotein particles are incorporated into phospholipids for membrane synthesis. Likewise, cholesterol is a vital component of membranes and is a precursor to the powerful signal molecules, the steroid hormones. Finally, cells are not able to degrade the steroid nucleus. Consequently, the cholesterol must be used biochemically or excreted by the liver. Excess cholesterol plays a role in the development of atherosclerosis. Lipoprotein particles function in cholesterol homeostasis, transporting the molecule from sites of synthesis to sites of use, and finally to the liver for excretion.

Each lipoprotein particle consists of a core of hydrophobic lipids surrounded by a shell of more-polar lipids and proteins. The protein components of these macromolecular aggregates, called apoproteins, have two roles: *they solubilize hydrophobic lipids and contain cell-targeting signals*. Apolipoproteins are synthesized and secreted by the liver and the intestine. Lipoprotein particles are classified according to increasing density (Table 26.1): *chylomicrons*, *chylomicron remnants*, *very low density lipoproteins* (VLDLs), *intermediate-density lipoproteins* (IDLs), *low-density lipoproteins* (LDLs), and *high-density lipoproteins* (HDLs). These classes have numerous subtypes. Moreover, lipoprotein particles can shift between classes as they release or pick up cargo, thereby changing their density.

Triacylglycerols, cholesterol, and other lipids obtained from the diet are carried away from the intestine in the form of large *chylomicrons* (Section 22.1). These particles have a very low density because triacylglycerols constitute about 90% of their content. Apolipoprotein B-48 (apo B-48), a large protein (240 kDa), forms an amphipathic spherical shell around the fat globule; the external face of this shell is hydrophilic. The triacylglycerols in chylomicrons are released through hydrolysis by *lipoprotein lipases*. These enzymes are located on the lining of blood vessels in muscle and other tissues that use fatty acids as fuels or in the synthesis of lipids. The liver then takes up the cholesterol-rich residues, known as *chylomicron remnants*.

Lipoprotein particles are also crucial for the transport of lipids from the liver, which is a major site of triacylglycerol and cholesterol synthesis, to other tissues in the body (Figure 26.17). Triacylglycerols and cholesterol in excess of the liver's own needs are exported into the blood in the form of very low density lipoproteins. These particles are stabilized by two apolipoproteins—apo B-100 (513 kDa) and apo E (34 kDa). Triacylglycerols in very low density

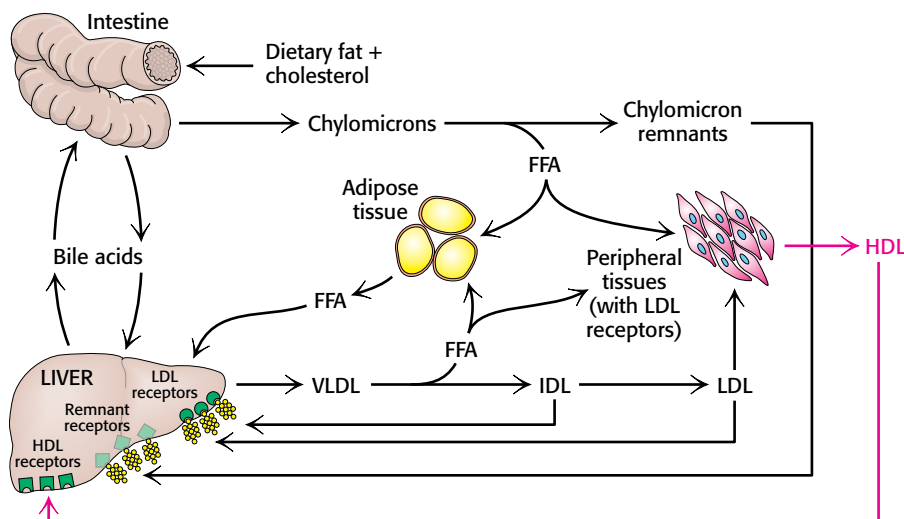

**FIGURE 26.17 Site of cholesterol synthesis.** Electron micrograph of a part of a liver cell actively engaged in the synthesis and secretion of very low density lipoprotein (VLDL). **FIGURE 26.18 Schematic model of low-density lipoprotein.** The LDL particle is approximately 22 nm (220 Å) in diameter.

lipoproteins, as in chylomicrons, are hydrolyzed by lipases on capillary surfaces, with the released fatty acids being taken up by the muscle and other tissues. The resulting remnants, which are rich in cholesteryl esters, are called *intermediate-density lipoproteins*. These particles have two fates. Half of them are taken up by the liver for processing, and half are converted into low-density lipoprotein by the removal of more triacylglycerol by tissue lipases that absorb the released fatty acids. Interestingly, apo B-100, one of the largest proteins known, is a longer version of apo B-48, the protein component of chylomicrons. Both apo B proteins are encoded by the same gene and produced from the same initial RNA transcript. In the intestine, RNA editing (Section 29.3) modifies the transcript to generate the mRNA for apo B-48, the truncated form.

*Low-density lipoprotein is the major carrier of cholesterol in blood* (Figure 26.18). It contains a core of some 1500 cholesterol molecules esterified to fatty acids; the most common fatty acid chain in these esters is linoleate, a polyunsaturated fatty acid. A shell of phospholipids and unesterified cholesterol molecules surrounds this highly hydrophobic core. The shell also contains a single copy of apo B-100, which is recognized by target cells. *The role of LDL is to transport cholesterol to peripheral tissues and regulate de novo cholesterol synthesis at these sites*, as described on page 784. A different purpose is served by *high-density lipoprotein*, which picks up cholesterol released into the plasma from dying cells and from membranes undergoing turnover and delivers the cholesterol to the liver for excretion. An acyltransferase in HDL esterifies these cholesterols, which are then returned by HDL to the liver (Figure 26.19).

**FIGURE 26.19 An overview of lipoprotein particle metabolism.** Fatty acids are abbreviated FFA. [Information from J. G. Hardman (Ed.), L. L. Limbird (Ed.), and A. G. Gilman (Consult. Ed.), *Goodman and Gilman's The Pharmacological Basis of Therapeutics*, 10th ed. (McGraw-Hill, 2001), p. 975, Fig. 36.1.]

**FIGURE 26.20 Receptor-mediated endocytosis.** The process of receptor-mediated endocytosis is illustrated for the cholesterol-carrying complex, low-density lipoprotein (LDL): (1) LDL binds to a specific receptor, the LDL receptor; (2) this complex invaginates to form an endosome; (3) after separation from its receptor, the LDL-containing vesicle fuses with a lysosome, leading to the degradation of the LDL and the release of the cholesterol.

## Low-density lipoproteins play a central role in cholesterol metabolism

Cholesterol metabolism must be precisely regulated to prevent atherosclerosis. The mode of control in the liver, the primary site of cholesterol synthesis, has already been considered: dietary cholesterol reduces the activity and amount of 3-hydroxy-3-methylglutaryl CoA reductase, the enzyme catalyzing the committed step. In general, cells outside the liver and intestine obtain cholesterol from the plasma rather than synthesizing it *de novo*. Specifically, *their primary source of cholesterol is the low-density lipoprotein*. The process of LDL uptake, called *receptor-mediated endocytosis*, serves as a paradigm for the uptake of many molecules (Figure 26.20).

Endocytosis begins when apolipoprotein B-100 on the surface of an LDL particle binds to a specific receptor protein on the plasma membrane of nonhepatic cells. The receptors for LDL are localized in specific regions called *coated pits*, which contain a protein called *clathrin*. The receptor-LDL complex is then internalized by *endocytosis*; that is, the plasma membrane in the vicinity of the complex invaginates and then fuses to form an endocytic vesicle called an *endosome*. The endosome is acidified by an ATP-dependent proton pump homologous to the  $\text{Na}^+/\text{K}^+$  ATPase (Section 13.2), which causes the receptor to release its cargo. Some of the receptor is returned to the cell membrane in a recycling vesicle, while a portion is degraded along with its cargo (p. 787). The round-trip time for a receptor is about 10 minutes; in its lifetime of about a day, each receptor may bring hundreds of LDL particles into the cell. The vesicles containing LDL and in some cases the receptor subsequently fuse with *lysosomes*, acidic vesicles that carry a wide array of degradative enzymes. The protein component of LDL is hydrolyzed to free amino acids. The cholesteryl esters in LDL are hydrolyzed by a lysosomal acid lipase. *The released unesterified cholesterol can then be used for membrane biosynthesis*. Alternatively, it can be *reesterified for storage inside the cell*. In fact, free cholesterol activates *acyl CoA:cholesterol acyltransferase (ACAT)*, the enzyme catalyzing this reaction. Reesterified cholesterol contains mainly oleate and palmitoleate, which are monounsaturated fatty acids, in contrast with the cholesteryl esters in LDL, which are rich in linoleate, a polyunsaturated fatty acid (Table 12.1). It is imperative that the cholesterol be reesterified. High concentrations of unesterified cholesterol disrupt the integrity of cell membranes.

The synthesis of the LDL receptor is itself subject to feedback regulation. Studies of cultured fibroblasts show that, *when cholesterol is abundant inside the cell, new LDL receptors are not synthesized, and so the uptake of additional cholesterol from plasma LDL is blocked*. The gene for the LDL receptor, like that for the reductase, is regulated by SREBP, which binds to a sterol regulatory element that controls the rate of mRNA synthesis.

## The absence of the LDL receptor leads to hypercholesterolemia and atherosclerosis

 The pioneering studies of *familial hypercholesterolemia* by Michael Brown and Joseph Goldstein revealed the physiological importance of the LDL receptor. The total concentration of cholesterol and LDL in the blood plasma is markedly elevated in this genetic disorder, which results from a mutation at a single autosomal locus. The cholesterol level in the plasma of homozygotes is typically  $680 \text{ mg dl}^{-1}$ , compared with

**FIGURE 26.21 The effects of excess cholesterol.** Cross section of (A) a normal artery and (B) an artery blocked by a cholesterol-rich plaque. [SPL/Photo Researchers.]

300 mg dl<sup>-1</sup> in heterozygotes (clinical assay results are often expressed in milligrams per deciliter, which is equal to milligrams per 100 milliliters). A value of < 200 mg dl<sup>-1</sup> is regarded as desirable, but many people have higher levels. In *familial hypercholesterolemia*, cholesterol is deposited in various tissues because of the high concentration of LDL cholesterol in the plasma. Nodules of cholesterol called *xanthomas* are prominent in skin and tendons. LDL accumulates under the endothelial cells lining the blood vessels. Of particular concern is the oxidation of the excess LDL to form oxidized LDL (oxLDL), which can instigate the inflammatory response by the immune system, a response that has been implicated in the development of cardiovascular disease. The oxLDL is taken up by immune system cells called macrophages, which become engorged to form foam cells. These foam cells become trapped in the walls of the blood vessels and contribute to the formation of atherosclerotic plaques that cause arterial narrowing and lead to heart attacks (Figure 26.21). In fact, *most homozygotes die of coronary artery disease in childhood*. The disease in heterozygotes (1 in 500 people) has a milder and more variable clinical course.

The molecular defect in most cases of *familial hypercholesterolemia* is an absence or deficiency of functional receptors for LDL. Receptor mutations that disrupt each of the stages in the endocytotic pathway have been identified. Homozygotes have almost no functional receptors for LDL, whereas heterozygotes have about half the normal number. Consequently, the entry of LDL into liver and other cells is impaired, leading to an increased level of LDL in the blood plasma. Furthermore, less IDL enters liver cells because IDL entry, too, is mediated by the LDL receptor. Consequently, IDL stays in the blood longer in familial hypercholesterolemia, and more of it is converted into LDL than in normal people. All deleterious consequences of an absence or deficiency of the LDL receptor can be attributed to the ensuing elevated level of LDL cholesterol in the blood.

### Mutations in the LDL receptor prevent LDL release and result in receptor destruction

One class of mutations that results in familial hypercholesterolemia generates receptors that are reluctant to give up the LDL cargo. Let us begin by examining the makeup of the receptor. The human LDL receptor is a 160-kDa glycoprotein, which is composed of six different types of domains (Figure 26.22A). The amino-terminal region of the receptor, which is the site of LDL binding, consists of seven homologous LDL receptor type-A (LA) domains, with domains 4 and 5 most important for LDL binding.

**FIGURE 26.22 LDL receptor releases LDL in the endosome.** (A) A schematic representation of the domain structure of the LDL receptor. (B) In the endosome, the receptor converts from the open structure into the closed structure, resulting in the release of the LDL into the endosome. [Information from I. D. Campbell, *Biochem. Soc. Trans.* 31 (pt. 6p):1107–1114, 2003, Fig. 1A.]

A second type of domain is homologous to one found in the epidermal growth factor (EGF). This domain is repeated three times, and in between the second and third repeat is a propeller structure consisting of six bladelike domains. This part of the receptor is crucial in releasing LDL in the endosome. The fourth domain, which is very rich in serine and threonine residues, contains *O*-linked sugars. These oligosaccharides function as struts to keep the receptor extended from the membrane so that the LDL-binding domain is accessible to LDL. The fifth type of domain consists of 22 hydrophobic residues that span the plasma membrane. The sixth and final domain consists of 50 residues and emerges on the cytoplasmic side of the membrane, where it controls the interaction of the receptor with coated pits and participates in endocytosis.

How does the LDL receptor relinquish its cargo on entering the endosome? The receptor exists in two interconvertible states: an extended or open state, capable of binding LDL, and a closed state that results in release of the LDL in the endosome. The receptor maintains the open state while in the plasma membrane, on binding LDL, and throughout its journey to the endosome. The conversion from the open state into the closed state takes place on exposure to the acidic environment of the endosome (Figure 26.22B). Three contiguous modules LA7, EGFA, and EGFB rigidly position the propeller module to facilitate displacement of the LDL as the closed state is formed. Under neutral pH, aspartate residues of the propeller blades form hydrogen bonds that hold each blade to the rest of the propeller structure. Exposure to the low-pH environment of the endosome causes the propeller-like structures to interact with the LDL-binding domain. This interaction displaces the LDL, which is then digested by the lysosome. The receptor is often returned to the plasma membrane to again bind LDL. The importance of this process is highlighted by the fact that more than half of the point mutations that result in familial hypercholesterolemia are due to disruptions in the interconversion between the open state and the closed state. These mutations result in a failure to release the LDL cargo and loss of the receptor by degradation.

### Cycling of the LDL receptor is regulated

PCSK9 (proprotein convertase subtilisin/kexin type) is a protease, secreted by the liver, which plays a crucial role in the regulation of cycling of the LDL receptor. Despite the fact that PCSK9 is a protease, enzymatic activity of the protein is not required for cycling regulation. PCSK9 in the blood binds to the EGFA domain of the receptor (Figure 26.22). PCSK9 locks the receptor in the open conformation even in the acidic conditions of the endosome. Failure to adopt the closed conformation prevents the receptor from returning to the plasma membrane, and it is degraded in the lysosome along with its cargo.

Individuals having a mutation that reduces the amount of PCSK9 in the blood have greatly reduced levels of LDL in the blood and display an almost 90% reduction in the rate of cardiovascular disease. Presumably, reduced levels of PCSK9 allow more receptor cycling and more efficient removal of LDL from the blood. Much research is now being directed at inhibiting PCSK9-mediated receptor degradation in individuals with high cholesterol levels. Phase 3 trials (Section 36.4) are underway, testing the efficacy of a monoclonal antibody to PCSK9. Monoclonal antibody treatments are expensive, so the search continues for a chemical inhibitor of the protein.

### HDL appears to protect against atherosclerosis

Although the events that result in atherosclerosis take place rapidly in familial hypercholesterolemia, a similar sequence of events takes place in people who develop atherosclerosis over decades. In particular, the formation of foam cells and plaques are especially hazardous occurrences. HDL and its role in returning cholesterol to the liver appear to be important in mitigating these life-threatening circumstances.

HDL has a number of antiatherogenic properties, including the inhibition of LDL oxidation, but the best-characterized property is the removal of cholesterol from cells, especially macrophages. Earlier, we learned that HDL retrieves cholesterol from other tissues in the body to return the cholesterol to the liver for excretion as bile or in the feces. This transport, called *reverse cholesterol transport*, is especially important in regard to macrophages. Indeed, when the transport fails, macrophages become foam cells and facilitate the formation of plaques. Macrophages that collect cholesterol from LDL normally transport the cholesterol to HDL particles. The more HDL, the more readily this transport takes place and the less likely that the macrophages will develop into foam cells. Presumably, this robust reverse cholesterol transport accounts for the observation that higher HDL levels confer protection against atherosclerosis.

The importance of reverse cholesterol transport is illustrated by the occurrence of mutations that inactivate a cholesterol-transport protein in endothelial cells and macrophages, ABCA1 (ATP-binding cassette transporter, subfamily A1) (Figure 13.7). Loss of activity of cholesterol-transport protein ABCA1 results in a very rare condition called *Tangier disease*, which is characterized by HDL deficiency, accumulation of cholesterol in macrophages, and premature atherosclerosis. Under normal conditions, the apoprotein component of HDL, apoA-I, binds to ABCA1 to facilitate LDL transport. Moreover, the interaction between apoA-I and ABCA1 initiates a signal transduction pathway in the endothelial cells that inhibits the inflammatory response.

Until recently, high levels of HDL-bound cholesterol (“good cholesterol”) relative to LDL-bound cholesterol (“bad cholesterol”) were believed to protect against cardiovascular disease. This belief was based on epidemiological studies. However, a number of recent clinical trials revealed that increased levels of HDL-bound cholesterol had no protective effects at all.

These studies do not discount the protective effects of HDL alone, but they illustrate the danger of equating free HDL and cholesterol-bound HDL.

### The clinical management of cholesterol levels can be understood at a biochemical level

 Homozygous familial hypercholesterolemia can be treated only by a liver transplant. A more generally applicable therapy is available for heterozygotes and others with high levels of cholesterol. *The goal is to reduce the amount of cholesterol in the blood by stimulating the synthesis of more than the customary number of LDL receptors.* We have already observed that the production of LDL receptors is controlled by the cell's need for cholesterol. The therapeutic strategy is to deprive the cell of ready sources of cholesterol. When cholesterol is required, the amount of mRNA for the LDL receptor rises and more receptors are found on the cell surface. This state can be induced by a two-pronged approach. First, the reabsorption of bile salts from the intestine is inhibited. Bile salts are cholesterol derivatives that promote the absorption of dietary cholesterol and dietary fats. Second, de novo synthesis of cholesterol is blocked.

The reabsorption of bile is impeded by oral administration of positively charged polymers, such as cholestyramine, that bind negatively charged bile salts and are not themselves absorbed. Cholesterol synthesis can be effectively blocked by a class of compounds called *statins*. A well-known example of such a compound is lovastatin, which is also called mevacor (Figure 26.23). These compounds are potent competitive inhibitors ( $K_i = 1 \text{ nM}$ ) of HMG-CoA reductase, the essential control point in the biosynthetic pathway. Plasma cholesterol levels decrease by 50% in many patients given both lovastatin and inhibitors of bile-salt reabsorption. Lovastatin and other inhibitors of HMG-CoA reductase are widely used to lower the plasma-cholesterol level in people who have atherosclerosis, which is the leading cause of death in industrialized societies. Preliminary studies suggest that reducing levels of PCSK9 (p. 787) and HMG-CoA reductase activity may be an especially effective means of reducing cholesterol levels. The development of statins as effective drugs is further described in Chapter 36.

**FIGURE 26.23** Lovastatin, a competitive inhibitor of HMG-CoA reductase. The part of the structure that resembles the 3-hydroxy-3-methylglutaryl moiety is shown in red.

## 26.4 Important Derivatives of Cholesterol Include Bile Salts and Steroid Hormones

Although cholesterol is well known in its own right as a contributor to the development of heart disease, metabolites of cholesterol—the steroid hormones—also appear in the news frequently. Indeed, steroid-hormone abuse seems to be as prominent in the sports pages as any athlete is. In addition to steroid hormones, cholesterol is a precursor for two other important molecules: bile salts and vitamin D. We begin with a look at the bile salts, molecules crucial for the uptake of lipids in the diet.

**Bile salts.** *Bile salts* are polar derivatives of cholesterol. These compounds are highly effective *detergents* because they contain both polar and nonpolar regions. Bile salts are synthesized in the liver, stored and concentrated in the gallbladder, and then released into the small intestine. Bile salts, the major constituent of bile, *solubilize dietary lipids*. Solubilization increases the effective surface area of lipids with two consequences: (1) more surface area is exposed to the digestive action of lipases and (2) lipids are more readily absorbed by the intestine. Bile salts are also the major breakdown products of cholesterol. The bile salts glycocholate, the primary bile salt, and taurocholate are shown in Figure 26.24.

**FIGURE 26.24 Synthesis of bile salts.**

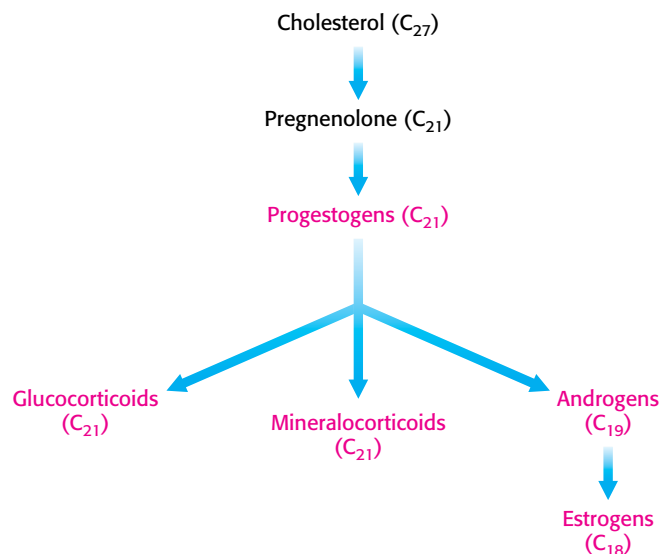

The OH groups in red are added to cholesterol, as are the groups shown in blue.

In addition to bile salts, bile is composed of cholesterol, phospholipids, and the breakdown products of heme, bilirubin, and biliverdin (Section 24.4). If too much cholesterol is present in the bile, it will precipitate to form gallbladder stones (cholelithiasis). These stones may block bile secretion and inflame the gallbladder, a condition called cholecystitis. Symptoms include pain in the upper right abdomen, especially after a fatty meal, and nausea. If need be, the gall bladder is removed, and bile flows from the liver through the bile duct directly into the intestine.

**Steroid hormones.** Cholesterol is the precursor of the five major classes of *steroid hormones*: progestagens, glucocorticoids, mineralocorticoids, androgens, and estrogens (Figure 26.25). These hormones are powerful signal molecules that regulate a host of organismal functions. *Progesterone*, a *progestogen*, prepares the lining of the uterus for the implantation of an ovum. Progesterone is also essential for the maintenance of pregnancy by preventing premature uterine contractions. *Androgens* (such as *testosterone*) are responsible for the development of male secondary sex characteristics, whereas *estrogens* (such as *estradiol*) are required for the development of female secondary sex characteristics. Estrogens, along with progesterone, also participate in the ovarian cycle. *Glucocorticoids* (such as *cortisol*) promote gluconeogenesis and glycogen synthesis, enhance the degradation of fat and protein, and inhibit the inflammatory response. They enable animals to respond to stress; indeed, the absence of glucocorticoids can be fatal. *Mineralocorticoids* (primarily *aldosterone*) act on the distal tubules of the kidney to increase the reabsorption of  $\text{Na}^+$  and the excretion of  $\text{K}^+$  and  $\text{H}^+$ , which leads to an increase in blood volume and blood pressure. The major sites of synthesis of these classes of hormones are the corpus luteum, for progestogens; the testes, for androgens; the ovaries, for estrogens; and the adrenal cortex, for glucocorticoids and mineralocorticoids.

Steroid hormones bind to and activate receptor molecules that serve as transcription factors to regulate gene expression (Section 32.2). These small similar molecules

**FIGURE 26.25 Biosynthetic relations of classes of steroid hormones and cholesterol.**

**FIGURE 26.26 Cholesterol carbon numbering.** The numbering scheme for the carbon atoms in cholesterol and other steroids.

are able to have greatly differing effects because the slight structural differences among them allow interactions with specific receptor molecules.

### Letters identify the steroid rings and numbers identify the carbon atoms

Carbon atoms in steroids are numbered, as shown for cholesterol in Figure 26.26. The rings in steroids are denoted by the letters A, B, C, and D. Cholesterol contains two angular methyl groups: the C-19 methyl group is attached to C-10, and the C-18 methyl group is attached to C-13. The C-18 and C-19 methyl groups of cholesterol lie *above* the plane containing the four rings. A substituent that is above the plane is termed  $\beta$  oriented, whereas a substituent that is below the plane is  $\alpha$  oriented.

If a hydrogen atom is attached to C-5, it can be either  $\alpha$  or  $\beta$  oriented. The A and B steroid rings are fused in a *trans* conformation if the C-5 hydrogen is  $\alpha$  oriented, and *cis* if it is  $\beta$  oriented. The absence of a Greek letter for the C-5 hydrogen atom on the steroid nucleus implies a *trans* fusion. The C-5 hydrogen atom is  $\alpha$  oriented in all steroid hormones that contain a hydrogen atom in that position. In contrast, bile salts have a  $\beta$ -oriented hydrogen atom at C-5. Thus, a *cis* fusion is characteristic of the bile salts, whereas a *trans* fusion is characteristic of all steroid hormones that possess a hydrogen atom at C-5. A *trans* fusion yields a nearly planar structure, whereas a *cis* fusion gives a buckled structure.

### Steroids are hydroxylated by cytochrome P450 monooxygenases that use NADPH and O<sub>2</sub>

The addition of OH groups plays an important role in the synthesis of cholesterol from squalene and in the conversion of cholesterol into steroid hormones and bile salts. All these hydroxylations require NADPH and O<sub>2</sub>. The oxygen atom of the incorporated hydroxyl group comes from O<sub>2</sub> rather than from H<sub>2</sub>O. Whereas one oxygen atom of the O<sub>2</sub> molecule goes into the substrate, the other is reduced to water. The enzymes catalyzing these reactions are called *monooxygenases* (or *mixed-function oxygenases*). Recall that a monooxygenase also participates in the hydroxylation of aromatic amino acids (Section 23.5).

*Hydroxylation requires the activation of oxygen.* In the synthesis of steroid hormones and bile salts, activation is accomplished by members of the *cytochrome P450* family, a family of cytochromes that absorb light maximally at

**FIGURE 26.27 Cytochrome P450 mechanism.** 1. Substrate binds to the enzyme. 2. Adrenodoxin donates an electron, reducing the heme iron. 3. Oxygen binds to  $\text{Fe}^{2+}$ . 4. Adrenodoxin donates a second electron. 5. The bond between the oxygen atoms is cleaved, a molecule of water is released, and an  $\text{Fe}^{4+}=\text{O}$  intermediate is formed. 6. The  $\text{Fe}^{4+}=\text{O}$  intermediate forms the hydroxylated product and returns the iron to the  $\text{Fe}^{3+}$  state, ready for another reaction cycle.

450 nm when complexed *in vitro* with exogenous carbon monoxide. These membrane-anchored proteins (~50 kDa) contain a heme prosthetic group. Oxygen is activated through its binding to the iron atom in the heme group.

Because the hydroxylation reactions promoted by P450 enzymes are oxidation reactions, it is at first glance surprising that they also consume the reductant NADPH. NADPH transfers its high-potential electrons to a flavoprotein, which transfers them, one at a time, to *adrenodoxin*, a non-heme iron protein. Adrenodoxin transfers one electron to reduce the ferric ( $\text{Fe}^{3+}$ ) form of P450 to the ferrous ( $\text{Fe}^{2+}$ ) form (Figure 26.27).

Without the addition of this electron, P450 will not bind oxygen. Recall that only the ferrous form ( $\text{Fe}^{2+}$ ) of myoglobin and hemoglobin binds oxygen (Section 7.1). The binding of  $\text{O}_2$  to the heme is followed by the acceptance of a second electron from adrenodoxin. The acceptance of this second electron leads to cleavage of the  $\text{O}-\text{O}$  bond. One of the oxygen atoms is then protonated and released as water. The remaining oxygen atom forms a highly reactive ferryl ( $\text{Fe}^{4+}$ )  $\text{Fe}=\text{O}$  intermediate. This intermediate abstracts a hydrogen atom from the substrate  $\text{RH}$  to form  $\text{R}\cdot$ . This transient free radical captures the  $\text{OH}$  group from the iron atom to form  $\text{ROH}$ , the hydroxylated product, returning the iron atom to the ferric state.

### The cytochrome P450 system is widespread and performs a protective function

 The cytochrome P450 system, which in mammals is located primarily in the smooth endoplasmic reticulum of the liver and small intestine, is also important in the *detoxification of foreign substances* (xenobiotic compounds). For example, the hydroxylation of phenobarbital, a barbiturate, *increases its solubility* and *facilitates its excretion*. Likewise, polycyclic aromatic hydrocarbons that are ingested by drinking contaminated water are hydroxylated by P450, providing sites for conjugation with highly polar units (e.g., glucuronate or sulfate) that markedly increase the solubility of the modified aromatic molecule. One of the most relevant functions of the cytochrome P450 system to human beings is its role in metabolizing drugs such as caffeine and ibuprofen (Chapter 36). Some members of the cytochrome P450 system also metabolize ethanol (Section 27.6). The duration of

action of many medications depends on their rate of inactivation by the P450 system. Despite its general protective role in the removal of foreign chemicals, the action of the P450 system is not always beneficial. *Some of the most powerful carcinogens are generated from harmless compounds by the P450 system in vivo* in the process of *metabolic activation* (Figure 28.34). In plants, the cytochrome P450 system plays a role in the synthesis of toxic compounds as well as the pigments of flowers.

Earlier (Section 9.1), we examined the use of protease inhibitors to treat HIV infection. These inhibitors, in conjunction with inhibitors of other HIV enzymes, have drastically reduced deaths due to AIDS. The effectiveness of these drugs is sometimes compromised because P450 enzymes, such as cytochrome P450-3A4, inactivate them. The drug ritonavir was developed in the search for more effective inhibitors. Interestingly, ritonavir, although a protease inhibitor, is also a potent inhibitor of cytochrome P450-3A4. This serendipitous “side-effect” allows the clinician to administer low doses of ritonavir in combination with other protease inhibitors, effectively increasing the concentrations of these drugs while allowing a reduction in dosage and dosing frequency.

### Pregnenolone, a precursor of many other steroids, is formed from cholesterol by cleavage of its side chain

Steroid hormones contain 21 or fewer carbon atoms, whereas cholesterol contains 27. Thus, the first stage in the synthesis of steroid hormones is the removal of a six-carbon unit from the side chain of cholesterol to form *pregnenolone*. The side chain of cholesterol is hydroxylated at C-20 and then at C-22, and the bond between these carbon atoms is subsequently cleaved by *desmolase*. Three molecules of NADPH and three molecules of O<sub>2</sub> are consumed in this six-electron oxidation.

### Progesterone and corticosteroids are synthesized from pregnenolone

*Progesterone* is synthesized from pregnenolone in two steps. The 3-hydroxyl group of pregnenolone is oxidized to a 3-keto group, and the  $\Delta^5$  double bond is isomerized to a  $\Delta^4$  double bond (Figure 26.28). *Cortisol*, the major glucocorticoid, is synthesized from progesterone by hydroxylations at C-11, C-17, and C-21; C-17 must be hydroxylated before C-21 is hydroxylated, whereas C-11 can be hydroxylated at any stage. The enzymes catalyzing these hydroxylations are highly specific. The initial step in the synthesis of *aldosterone*, the major mineralocorticoid, is the hydroxylation of progesterone at C-21. The resulting deoxycorticosterone is hydroxylated at C-11. The oxidation of the C-18 angular methyl group to an aldehyde then yields aldosterone.

### Androgens and estrogens are synthesized from pregnenolone

Androgens and estrogens also are synthesized from pregnenolone through the intermediate progesterone. Androgens contain 19 carbon atoms. The synthesis of androgens starts with the hydroxylation of progesterone at

FIGURE 26.28 Pathways for the formation of progesterone, cortisol, and aldosterone.

C-17 (Figure 26.29). The side chain consisting of C-20 and C-21 is then cleaved to yield *androstenedione*, an androgen. *Testosterone*, another androgen, is formed by the reduction of the 17-keto group of androstenedione. Testosterone, through its actions in the brain, is paramount in the development of male sexual behavior. It is also important for the maintenance of the testes and the development of muscle mass. Owing to the latter activity, testosterone is referred to as an *anabolic steroid*. Testosterone is reduced by *5 $\alpha$ -reductase* to yield *dihydrotestosterone* (DHT), a powerful embryonic androgen that instigates the development and differentiation of the male phenotype (Problems 21 and 24).

Estrogens are synthesized from androgens by the loss of the C-19 angular methyl group and the formation of an aromatic A ring. *Estrone*, an estrogen, is derived from androstenedione, whereas *estradiol*, the biologically most potent estrogen, is formed from testosterone. Estradiol can also be formed from estrone. The formation of the aromatic A ring is catalyzed by the P450 enzyme *aromatase*.

Because breast and ovarian cancers frequently depend on estrogens for growth, aromatase inhibitors are often used as a treatment for these cancers. Anastrozole is a competitive inhibitor of the enzyme, whereas exemestane is a suicide inhibitor that covalently modifies and inactivates the enzyme.

FIGURE 26.29 Pathways for the formation of androgens and estrogens.

### Vitamin D is derived from cholesterol by the ring-splitting activity of light

Cholesterol is also the precursor of vitamin D, which plays an essential role in the control of calcium and phosphorus metabolism. 7-Dehydrocholesterol (*provitamin D<sub>3</sub>*) is photolyzed by the ultraviolet light of sunlight to *previtamin D<sub>3</sub>*, which spontaneously isomerizes to *vitamin D<sub>3</sub>* (Figure 26.30). Vitamin D<sub>3</sub>

FIGURE 26.30 Vitamin D synthesis. The pathway for the conversion of 7-dehydrocholesterol into vitamin D<sub>3</sub> and then into calcitriol, the active hormone.

(cholecalciferol) is converted into *calcitriol* (1,25-dihydroxycholecalciferol), the active hormone, by hydroxylation reactions in the liver and kidneys. Although not a steroid, vitamin D acts in an analogous fashion. It binds to a receptor, structurally similar to the steroid receptors, to form a complex that functions as a transcription factor, regulating gene expression.

Vitamin D deficiency in childhood produces *rickets*, a disease characterized by inadequate calcification of cartilage and bone. Rickets was so common in seventeenth-century England that it was called the “children’s disease of the English.” The 7-dehydrocholesterol in the skin of these children was not photolyzed to previtamin D<sub>3</sub>, because there was little sunlight for many months of the year. Furthermore, their diets provided little vitamin D, because most naturally occurring foods have a low content of this vitamin. Fish-liver oils are a notable exception. Cod-liver oil, abhorred by generations of children because of its unpleasant taste, was used in the past as a rich source of vitamin D. Today, the most reliable dietary sources of vitamin D are fortified foods. Milk, for example, is fortified to a level of 400 international units per quart (10 μg per quart). The recommended daily intake of vitamin D is 200 international units until age 50, after which it increases with age. In adults, vitamin D deficiency leads to softening and weakening of bones, a condition called *osteomalacia*. The occurrence of osteomalacia in Muslim women who are clothed so that only their eyes are exposed to sunlight is a striking reminder that vitamin D is needed by adults as well as by children.

Research over the past few years indicates that vitamin D may play a much larger biochemical role than simply the regulation of bone metabolism. Muscle seems to be a target of vitamin D action. In muscle, vitamin D appears to affect a number of biochemical processes with the net effect being enhanced muscle performance. Studies also suggest that vitamin D prevents cardiovascular disease, reduces the incidence of a variety of cancers, and protects against autoimmune diseases including diabetes. Moreover, vitamin D deficiency appears to be more common than previously thought. In the United States, 75% of Blacks and many Hispanics and Asians have insufficient blood levels of vitamin D. This recent research on vitamin D shows again the dynamic nature of biochemical investigations. Vitamin D, a chemical whose biochemical role was believed to be well established, now offers new frontiers of biomedical research.

## SUMMARY

### 26.1 Phosphatidate Is a Common Intermediate in the Synthesis of Phospholipids and Triacylglycerols

Phosphatidate is formed by successive acylations of glycerol 3-phosphate by acyl CoA. Hydrolysis of its phosphoryl group followed by acylation yields a triacylglycerol. CDP-diacylglycerol, the activated intermediate in the *de novo* synthesis of several phospholipids, is formed from phosphatidate and CTP. The activated phosphatidyl unit is then transferred to the hydroxyl group of a polar alcohol, such as inositol, to form a phospholipid such as phosphatidylinositol. In mammals, phosphatidylethanolamine is formed by CDP-ethanolamine and diacylglycerol. Phosphatidylethanolamine is methylated by *S*-adenosylmethionine to form phosphatidylcholine. In mammals, this phosphoglyceride can also be synthesized by a pathway that utilizes dietary choline. CDP-choline is the activated intermediate in this route.

Sphingolipids are synthesized from ceramide, which is formed by the acylation of sphingosine. Gangliosides are sphingolipids that contain an oligosaccharide unit having at least one residue of *N*-acetylneuraminic acid or a related sialic acid. They are synthesized by the step-by-step addition of activated sugars, such as UDP-glucose, to ceramide.

### 26.2 Cholesterol Is Synthesized from Acetyl Coenzyme A in Three Stages

Cholesterol is a steroid component of animal membranes and a precursor of steroid hormones. The committed step in its synthesis is the formation of mevalonate from 3-hydroxy-3-methylglutaryl CoA (derived from acetyl CoA and acetoacetyl CoA). Mevalonate is converted into isopentenyl pyrophosphate ( $C_5$ ), which condenses with its isomer, dimethylallyl pyrophosphate ( $C_5$ ), to form geranyl pyrophosphate ( $C_{10}$ ). The addition of a second molecule of isopentenyl pyrophosphate yields farnesyl pyrophosphate ( $C_{15}$ ), which condenses with itself to form squalene ( $C_{30}$ ). This intermediate cyclizes to lanosterol ( $C_{30}$ ), which is modified to yield cholesterol ( $C_{27}$ ).

### 26.3 The Complex Regulation of Cholesterol Biosynthesis Takes Place at Several Levels

In the liver, cholesterol synthesis is regulated by changes in the amount and activity of 3-hydroxy-3-methylglutaryl CoA reductase. Transcription of the gene, translation of the mRNA, and degradation of the enzyme are stringently controlled. In addition, the activity of the reductase is regulated by phosphorylation.

Triacylglycerols exported by the intestine are carried by chylomicrons and then hydrolyzed by lipases lining the capillaries of target tissues. Cholesterol and other lipids in excess of those needed by the liver are exported in the form of very low density lipoprotein. After delivering its content of triacylglycerols to adipose tissue and other peripheral tissue, VLDL is converted into intermediate-density lipoprotein and then into low-density lipoprotein. IDL and LDL carry cholesteryl esters, primarily cholesteryl linoleate. Liver and peripheral tissue cells take up LDL by receptor-mediated endocytosis. The LDL receptor, a protein spanning the plasma membrane of the target cell, binds LDL and mediates its entry into the cell. Absence of the LDL receptor in the homozygous form of familial hypercholesterolemia leads to a markedly elevated plasma level of LDL cholesterol and the deposition of cholesterol on blood-vessel walls, which in turn may result in childhood heart attacks. High-density lipoproteins transport cholesterol from the peripheral tissues to the liver.

### 26.4 Important Derivatives of Cholesterol Include Bile Salts and Steroid Hormones

In addition to bile salts, which facilitate the digestion of lipids, five major classes of steroid hormones are derived from cholesterol: progestogens, glucocorticoids, mineralocorticoids, androgens, and estrogens. Hydroxylations by P450 monooxygenases that use NADPH and  $O_2$  play an important role in the synthesis of steroid hormones and bile salts from cholesterol. P450 enzymes, a large superfamily, also participate in the detoxification of drugs and other foreign substances.

Pregnenolone ( $C_{21}$ ) is an essential intermediate in the synthesis of steroids. This steroid is formed by scission of the side chain of cholesterol. Progesterone ( $C_{21}$ ), synthesized from pregnenolone, is the precursor of cortisol and aldosterone. Hydroxylation of progesterone and cleavage of its side chain yields androstenedione, an androgen ( $C_{19}$ ).

Estrogens ( $C_{18}$ ) are synthesized from androgens by the loss of an angular methyl group and the formation of an aromatic A ring. Vitamin D, which is important in the control of calcium and phosphorus metabolism, is formed from a derivative of cholesterol by the action of light.

## KEY TERMS

phosphatidate (p. 768)	cholesterol (p. 776)	low-density lipoprotein (LDL) (p. 782)
triacylglycerol (p. 769)	mevalonate (p. 776)	high-density lipoprotein (HDL) (p. 782)
phospholipid (p. 769)	3-hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase) (p. 776)	receptor-mediated endocytosis (p. 784)
cytidine diphosphodiacylglycerol (CDP-diacylglycerol) (p. 769)	3-isopentenyl pyrophosphate (p. 777)	reverse cholesterol transport (p. 787)
sphingolipid (p. 772)	sterol regulatory element binding protein (SREBP) (p. 779)	bile salt (p. 788)
ceramide (p. 772)	lipoprotein particles (p. 782)	steroid hormone (p. 789)
cerebroside (p. 772)		cytochrome P450 monooxygenase (p. 790)
ganglioside (p. 772)		

## PROBLEMS

- Different roles.* Describe the roles of glycerol 3-phosphate, phosphatidate, and diacylglycerol in triacylglycerol and phospholipid synthesis.
- Needed supplies.* How is the glycerol 3-phosphate required for phosphatidate synthesis generated?
- Making fat.* Write a balanced equation for the synthesis of a triacylglycerol, starting from glycerol and fatty acids.
- Making a phospholipid.* Write a balanced equation for the synthesis of phosphatidylethanolamine by the de novo pathway, starting from ethanolamine, glycerol, and fatty acids.
- ATP needs.* How many high-phosphoryl-transfer-potential molecules are required to synthesize phosphatidylethanolamine from ethanolamine and diacylglycerol? Assume that the ethanolamine is the activated component.
- Identifying differences.* Differentiate among sphingomyelin, a cerebroside, and a ganglioside.
- Let's count the ways.* There may be 50 ways to leave your lover, but, in principle, there are only three ways to make a glycerol-based phospholipid. Describe the three pathways.
- Activated donors.* What is the activated reactant in each of the following biosyntheses?
  - Phosphatidylinositol from inositol
  - Phosphatidylethanolamine from ethanolamine
  - Ceramide from sphingosine
  - Sphingomyelin from ceramide
  - Cerebroside from ceramide
  - Ganglioside  $G_{M1}$  from ganglioside  $G_{M2}$
  - Farnesyl pyrophosphate from geranyl pyrophosphate
- No DAG, no TAG.* What would be the effect of a mutation that decreased the activity of phosphatidic acid phosphatase?
- Like Wilbur and Orville.* Match each term with its description.
 

(a) Phosphatidate ____	1. Glycerol-based membrane lipid
(b) Triacylglycerol ____	2. Product of the committed step in cholesterol synthesis
(c) Phospholipid ____	3. Ceramide with either glucose or galactose attached
(d) Sphingolipid ____	4. Storage form of fatty acids
(e) Cerebroside ____	5. Squalene is a precursor to this molecule
(f) Ganglioside ____	6. Transports cholesterol and lipids
(g) Cholesterol ____	7. Derived from cholesterol
(h) Mevalonate ____	8. Precursor to both phospholipids and triacylglycerols
(i) Lipoprotein particle ____	9. Formed from ceramide by the attachment of phosphocholine
(j) Steroid hormone ____	10. Ceramide with multiple carbohydrates attached
- The Law of Three Stages.* What are the three stages required for the synthesis of cholesterol?
- Many regulations to follow.* Outline the mechanisms of the regulation of cholesterol biosynthesis.
- Telltale labels.* What is the distribution of isotopic labeling in cholesterol synthesized from each of the following precursors?
  - Mevalonate labeled with  $^{14}C$  in its carboxyl carbon atom
  - Malonyl CoA labeled with  $^{14}C$  in its carboxyl carbon atom

14. *Too much, too soon.* What is familial hypercholesterolemia and what are its causes?

15. *Familial hypercholesterolemia.* Several classes of LDL-receptor mutations have been identified as causes of this disease. Suppose that you have been given cells from patients with different mutations, an antibody specific for the LDL receptor that can be seen with an electron microscope, and access to an electron microscope. What differences in antibody distribution might you expect to find in the cells from different patients?

16. *Breakfast conversation.* You and a friend are eating breakfast together. While eating, your friend is reading the back of her cereal box and comes across the following statement: "Cholesterol plays beneficial roles in your body, making cells, hormones, and tissues." Knowing that you are taking biochemistry, she asks if the statement makes sense. What do you reply?

17. *A good thing.* What are statins? What is their pharmacological function?

18. *Too much of a good thing.* Would the development of a "super statin" that inhibited all HMG CoA reductase activity be a useful drug? Explain.

19. *RNA editing.* A shortened version (apo B-48) of apolipoprotein B is formed by the intestine, whereas the full-length protein (apo B-100) is synthesized by the liver. A glutamine codon (CAA) is changed into a stop codon. Propose a simple mechanism for this change.

20. *A means of entry.* Describe the process of receptor-mediated endocytosis by using LDL as an example.

21. *Inspiration for drug design.* Some actions of androgens are mediated by dihydrotestosterone, which is formed by the reduction of testosterone. This finishing touch is catalyzed by an NADPH-dependent  $5\alpha$ -reductase (p. 793). Chromosomal XY males with a genetic deficiency of this reductase are born with a male internal urogenital tract but predominantly female external genitalia. These people are usually reared as girls. At puberty, they masculinize because the testosterone level rises. The testes of these reductase-deficient men are normal, whereas their prostate glands remain small. How might this information be used to design a drug to treat *benign prostatic hypertrophy*, a common consequence of the normal aging process in men? A majority of men older than age 55 have some degree of prostatic enlargement, which often leads to urinary obstruction.

22. *Drug idiosyncrasies.* Debrisoquine, a  $\beta$ -adrenergic blocking agent, has been used to treat hypertension. The optimal dose varies greatly (20–400 mg daily) in a population of patients. The urine of most patients taking the drug contains a high level of 4-hydroxydebrisoquine. However, those most sensitive to the drug (about 8% of the group studied) excrete

debrisoquine and very little of the 4-hydroxy derivative. Propose a molecular basis for this drug idiosyncrasy. Why should caution be exercised in giving other drugs to patients who are very sensitive to debrisoquine?

Debrisoquine

23. *Removal of odorants.* Many odorant molecules are highly hydrophobic and concentrate within the olfactory epithelium. They would give a persistent signal independent of their concentration in the environment if they were not rapidly modified. Propose a mechanism for converting hydrophobic odorants into water-soluble derivatives that can be rapidly eliminated.

24. *Development difficulties.* Propecia (finasteride) is a synthetic steroid that functions as a competitive and specific inhibitor of  $5\alpha$ -reductase (p. 793), the enzyme responsible for the synthesis of dihydrotestosterone from testosterone.

Finasteride

In addition to its use as a treatment for benign prostatic hypertrophy (Problem 21), finasteride is also widely used to retard the development of male pattern hair loss. Pregnant women are advised to avoid handling this drug. Why is it vitally important that pregnant women avoid contact with Propecia?

25. *Life-style consequences.* Human beings and the plant *Arabidopsis* evolved from the same distant ancestor possessing a small number of cytochrome P450 genes. Human beings have approximately 50 such genes, whereas *Arabidopsis* has more than 250 of them. Propose a role for the large number of P450 isozymes in plants.

26. *Personalized medicine.* The cytochrome P450 system metabolizes many medicinally useful drugs. Although all human beings have the same number of P450 genes, individual polymorphisms exist that alter the specificity and efficiency of the proteins encoded by the genes. How could knowledge of individual polymorphisms be useful clinically?

27. *Honeybee crisis.* In 2006, there was a sudden, unexplained die-off of honeybee colonies throughout the United States. The die-off was economically significant because one-third of the human diet comes from insect-pollinated plants, and honeybees are responsible for 80% of the pollination. In October of 2006, the sequence of the honeybee

genome was reported. Interestingly, the genome was found to contain far fewer cytochrome P450 genes than do the genomes of other insects. Suggest how the die-off and the paucity of P450 genes may be related.

28. *Missing enzyme.* Congenital adrenal hyperplasia is a life-threatening condition that results from a deficiency in the P450 enzyme steroid 21-hydroxylase. This enzyme catalyzes the first step in the conversion of progesterone into cortisol and aldosterone (Figures 26.28 and 26.29). A characteristic of congenital adrenal hyperplasia is an increase in sex hormone production. Explain why this is the case.

29. *Let the sun shine in.* At a biochemical level, vitamin D functions like a steroid hormone (Chapter 31). Therefore, it is sometimes referred to as an honorary steroid. Why is vitamin D not an actual steroid?

### Mechanism Problems

30. *An interfering phosphate.* In the course of the overall reaction catalyzed by HMG-CoA reductase, a histidine residue protonates a coenzyme A thiolate,  $\text{CoA-S}^-$ , generated in an earlier step.

A nearby serine residue can be phosphorylated by AMP-dependent kinase, which results in a loss of activity. Propose an explanation for why phosphorylation of the serine residue inhibits enzyme activity.

31. *Demethylation.* Methyl amines are often demethylated by cytochrome P450 enzymes. Propose a mechanism for the formation of methylamine from dimethylamine catalyzed by cytochrome P450. What is the other product?

### Chapter Integration Problems

32. *Similarities.* Compare the role of CTP in phosphoglyceride synthesis with the role of UTP in glycogen synthesis.

33. *Hold on tight or you might be thrown to the cytoplasm.* Many proteins are modified by the covalent attachment of a farnesyl ( $\text{C}_{15}$ ) or a geranylgeranyl ( $\text{C}_{20}$ ) unit to the carboxyl-terminal cysteine residue of the protein. Suggest why this modification might occur.

34. *Fork in the road.* 3-Hydroxy-3-methylglutaryl CoA is on the pathway for cholesterol biosynthesis. It is also a component of another pathway. Name the pathway. What determines which pathway 3-hydroxy-3-methylglutaryl CoA follows?

35. *Requires a club membership.* How is methionine metabolism related to the synthesis of phosphatidylcholine?

36. *Drug resistance.* Dichlorodiphenyltrichloroethane (DDT) is a potent insecticide rarely used today because of its effects on other forms of life. In insects, DDT disrupts sodium channel function, leading to eventual death. Mosquitos have developed resistance to DDT and other insecticides that function in a similar fashion. Suggest two means by which DDT resistance might develop.

37. *ATP requirements.* Explain how cholesterol synthesis depends on the activity of ATP-citrate lyase.

### Data Interpretation and Chapter Integration Problem

38. *Cholesterol feeding.* Mice were divided into four groups, two of which were fed a normal diet and two of which were fed a cholesterol-rich diet. HMG-CoA reductase mRNA and protein from liver were then isolated and quantified. Graph A shows the results of the mRNA isolation.

(a) What is the effect of cholesterol feeding on the amount of HMG-CoA reductase mRNA?

(b) What is the purpose of also isolating the mRNA for the protein actin, which is not under the control of the sterol regulatory element?

HMG-CoA reductase protein was isolated by precipitation with a monoclonal antibody to HMG-CoA reductase. The

amount of HMG-CoA protein in each group is shown in graph B.

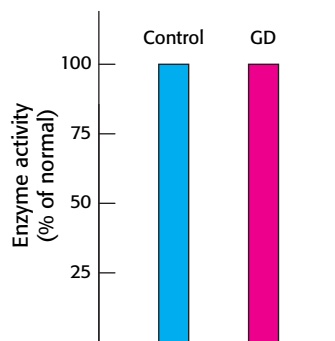

(c) What is the effect of the cholesterol diet on the amount of HMG-CoA reductase protein?

(d) Why is this result surprising in light of the results in graph A?

(e) Suggest possible explanations for the results in graph B.

39. *Gaucher disease*. Gaucher disease, the most common lysosomal storage disease in humans, is caused by mutations in the gene encoding glucocerebrosidase (GCase), the lysosomal enzyme that degrades glucocerebrosides. The disease has a variety of symptoms depending on the severity of the disease and the person affected. Identical twins can display very different levels of severity. Symptoms include bone pain, enlarged liver, excessive fatigue, and mental retardation.

In order to better understand the disease, researchers undertook a series of experiments to characterize the nature of the defect in the enzyme. Cells were obtained from a person without the disease (control) as well as from a patient with the disease (GD). The cells were grown in culture, the enzyme was isolated, and enzyme activity of 10  $\mu\text{g}$  of each sample was measured (Figure A).

(A)

[Data from J. Lu, Proc. Natl. Acad. Sci. U. S. A. 107:21665–21670, 2012.]

(a) What do the results tell about the catalytic activity of the enzyme from the GD cells? Why were these results surprising to the researchers?

Again, cells were grown in culture and cell extracts were made from the control and GD samples. Care was taken to insure that the same number of cells were used in both extractions. A western blot with antibodies to GCase was

performed on the cell extracts, with the results shown in Figure B.

(B)

[Data from J. Lu, Proc. Natl. Acad. Sci. U. S. A. 107:21665–21670, 2012.]

(b) Provide two possible explanations for the result shown in Figure B. Why was it crucial to insure that the extract was made from the same number of cells? What was the purpose of including the western blot of actin?

(c) The researchers then measured the amount of mRNA for the enzyme in both the control and GD cells. The amount of mRNA was identical in the two samples. With this information, reinterpret the results shown in Figure B.

Next, cells from the control and GD individuals were grown in the presence and absence of a potent proteasome inhibitor. The amount of GCase was determined using western blots. The results are shown in Figure C.

(C)

(d) Suggest the nature of the defect in the GD enzyme. What is the significance of the increase in activity of the enzyme from the normal cell observed in the presence of the inhibitor?

## The Integration of Metabolism

The image above shows a detail of runners on a Greek amphora painted in the sixth century B.C. Athletic feats, as well as others as seemingly simple as the maintenance of blood-glucose levels, require elaborate metabolic integration. The representation at the right shows the organs that have essential roles in the metabolic integration that regulates blood-glucose levels during exercise and at rest. Insulin and leptin (secreted by adipocytes) are two of the hormones that modulate the metabolic pathways of organs throughout the body such that adequate energy is available to meet the demands of living. [(Left) Copyright © The Metropolitan Museum of Art/Art Resource, NY.]

We have been examining the biochemistry of metabolism one pathway at a time. We have seen how useful energy is extracted from fuels and used to power biosynthetic reactions and signal-transduction pathways. In Chapters 28 through 30, we will extend our study of biosynthetic reactions to the synthesis of nucleic acids and proteins. Before we do that, however, in this chapter we will take a step back to examine large-scale biochemical interactions that constitute the physiology of the organism. In keeping with a central theme of life—energy manipulations—we will look at the regulation of energy at the organismal level, which boils down to an apparently simple but actually quite complex question: At the biochemical level, how does an organism know when to eat and when to refrain from eating? The ability to maintain adequate but not excessive energy stores is called *caloric homeostasis* or *energy homeostasis*.

Next, we will examine a significant perturbation of caloric homeostasis—obesity—and how this physiological condition affects insulin action, frequently resulting in diabetes. We then turn our attention to a biochemical consideration of one of the most beneficial activities that humans can

engage in—exercise—and see how exercise mitigates the effects of diabetes as well as how different forms of exercise use different sources of fuel.

At the opposite end of the physiological spectrum from obesity and overnutrition are fasting and starvation, and we will examine the biochemical responses to these challenges. The chapter ends with a consideration of another biochemical energy perturbation—excess alcohol consumption.

We have already encountered instances of organismal energy regulation when we considered the actions of insulin and glucagon. Recall that insulin, secreted by the  $\beta$  cells of the pancreas, causes glucose to be removed from the blood and stimulates the synthesis of glycogen and lipids. Glucagon, secreted by the  $\alpha$  cells of the pancreas, has effects opposite those of insulin. Glucagon increases the level of blood glucose by stimulating glycogen breakdown and gluconeogenesis. This chapter introduces two other hormones that play key roles in caloric homeostasis. Leptin and adiponectin, secreted by the adipose tissue, work in concert with insulin to regulate caloric homeostasis.

## 27.1 Caloric Homeostasis Is a Means of Regulating Body Weight

By now in our study of biochemistry, we are well aware of the fact that carbohydrates and lipids are sources of energy. We consume these energy sources as foods, convert the energy into ATP, and use the ATP to power our lives. Like all energy transformations, our energy consumption and expenditure are governed by the laws of thermodynamics. Recall that the First Law of Thermodynamics states that energy can neither be created nor destroyed. Translated into the practical terms of our diets,

$$\text{Energy consumed} = \text{energy expended} + \text{energy stored}$$

This simple equation has severe physiological and health implications: according to the First Law of Thermodynamics, if we consume more energy than we expend, we will become overweight or obese. Obesity is generally defined as a body mass index (BMI) of more than  $30 \text{ kg m}^{-2}$ , whereas overweight is defined as a BMI of more than  $25 \text{ kg m}^{-2}$  (Figure 27.1). Recall that excess fat is stored in adipocytes as triacylglycerols. The number of adipocytes becomes fixed in adults, and so obesity results in engorged adipocytes. Indeed, the cells may increase as much as 1000-fold in size.

We are all aware that many of us, especially in the developed world, are becoming obese or have already attained that state. In the United States, obesity has become an epidemic, with nearly 30% of adults classified as such. Obesity is identified as a risk factor in a host of pathological conditions including diabetes mellitus, hypertension, and cardiovascular disease (Table 27.1). The cause of obesity is quite simple in most cases: more food is consumed than is needed, and the excess calories are stored as fat. We will consider the biochemical basis of pathologies caused by obesity later in the chapter.

Before we undertake a biochemical analysis of the results of overconsumption, let us consider why the obesity epidemic is occurring in the first place. There are several possible, overlapping explanations. The first is a commonly held view that our bodies are programmed to rapidly store excess calories in times of plenty, an evolutionary adaptation from times past when humans were not assured of having ample food, as many of us are today. Consequently, we store calories as if a fast might begin tomorrow, but no such fast arrives. A second possible explanation is that we no longer face the risks of predation. Evidence indicates that predation was a common cause of death for our ancestors. An obese individual would more likely have been culled from a group of our ancestors than would a more nimble, lean individual. As the risk of predation declined, leanness became less beneficial.

A third possibility, one currently receiving much attention, is that calorie-dense highly palatable foods—foods rich in sugar and fats—that are readily accessible to most people in the developed world, act as drugs, triggering the same reward pathways in the brain that are triggered by drugs such as cocaine. These reward pathways can be strong enough to override appetite-suppressing signals. Fourth, a growing body of research suggests that our intestinal microbiome—the bacteria that inhabit our guts—plays a significant role in how we process our food. For instance, germ-free mice do not become obese, even when given unfettered access to a high-fat diet. However, when such mice are exposed to the intestinal flora of obese mice, the mice now become obese even on a normal chow diet. Moreover, the intestinal microbiome of obese mice triggers an inflammatory response that may blunt the effect of signal molecules that normally regulate the desire to eat as well as how the mice process the calories they consume. Many of these results have been extended to humans. Finally, it is evident that individuals respond differently to obesity-inducing environmental conditions and that

**TABLE 27.1 Health consequences of obesity or being overweight**

Coronary heart disease
Type 2 diabetes
Cancers (endometrial, breast, colon and others)
Hypertension (high blood pressure)
Dyslipidemia (disruption of lipid metabolism, e.g., high cholesterol and triacylglycerols)
Stroke
Liver and gallbladder disease
Sleep apnea and respiratory problems
Osteoarthritis (degeneration of cartilage and underlying bone at a joint)
Gynecological problems (abnormal menses, infertility)

Information from: Centers for Disease Control and Prevention Web site (www.cdc.gov).

this difference has a large genetic component. Various studies have indicated the heritability of fat mass to be between 30% and 70%, indicating that the tendency toward obesity may be highly heritable.

Regardless of why we may have a propensity to gain weight, this propensity can be counteracted behaviorally—by eating less and exercising more. It also appears that it is easier to prevent weight gain than it is to lose weight. Clearly, caloric homeostasis is a complicated biological phenomenon. Understanding this phenomenon will engage biomedical research scientists for some time to come.

As disturbing as the obesity epidemic is, an equally intriguing, almost amazing observation is that many people are able to maintain an approximately constant weight throughout adult life, despite consuming tons of food over a lifetime (Problems 1 and 2). Although will power, exercise, and a bathroom scale often play a role in this homeostasis, some biochemical signaling must be taking place to achieve this remarkable physiological feat.

## 27.2 The Brain Plays a Key Role in Caloric Homeostasis

What makes this remarkable balance of energy input and output possible? As one might imagine, the answer is complicated, entailing many biochemical signals as well as a host of behavioral factors. We will focus on a few key biochemical signals, and divide our discussion into two parts: short-term signals that are active during a meal and long-term signals that report on the overall energy status of the body. These signals originate in the gastrointestinal tract, the  $\beta$  cells of the pancreas, and fat cells. The primary target of these signals is the brain, in particular a groups of neurons in a region of the hypothalamus called the arcuate nucleus.

### Signals from the gastrointestinal tract induce feelings of satiety

Short-term signals relay feelings of satiety from the gut to various regions of the brain and thus reduce the urge to eat (Figure 27.2). The best-studied short-term signal is cholecystokinin (CCK). *Cholecystokinin* is actually a family of peptide hormones of various lengths (from 8 to 58 amino acids in length, depending on posttranslational processing) secreted into the blood by cells in the duodenum and jejunum regions of the small intestine as a

**FIGURE 27.2 Satiety signals.**

Cholecystokinin (CCK) and glucagon-like peptide 1 (GLP-1) are signal molecules that induce feelings of satiety in the brain. CCK is secreted by specialized cells of the small intestine in response to a meal and activates satiety pathways in the brain. GLP-1, secreted by L cells in the intestine, also activates satiety pathways in the brain and potentiates insulin action in the pancreas. [Information from S. C. Wood, *Cell Metab.* 9:489–498, 2009, Fig. 1.]

postprandial satiation signal. The CCK binds to the CCK receptor, a G-protein-coupled receptor (Section 14.1) located in various peripheral neurons, that relay signals to the brain. This binding initiates a signal-transduction pathway in the brain that generates a feeling of satiety. CCK also plays an important role in digestion, stimulating the secretion of pancreatic enzymes and bile salts from the gallbladder.

Another important gut signal is *glucagon-like peptide 1* (GLP-1), a hormone of approximately 30 amino acids in length. GLP-1 is secreted by intestinal L cells, hormone-secreting cells located throughout the lining of the gastrointestinal tract. GLP-1 has a variety of effects, all apparently facilitated by binding to its receptor, another G-protein-coupled receptor. Like CCK, GLP-1 induces feelings of satiety that inhibit further eating. GLP-1 also potentiates glucose-induced insulin secretion by the  $\beta$  cells of the pancreas while inhibiting glucagon secretion.

Although we have examined only two short-term signals, many others are believed to exist (Table 27.2). Most of the short-term signals thus far identified are appetite suppressants. Ghrelin, a peptide that is 28 amino acids in length and secreted by the stomach, acts on regions of the hypothalamus to stimulate appetite through its receptor, a G-protein-coupled receptor. Ghrelin secretion increases before a meal and decreases afterward.

### Leptin and insulin regulate long-term control over caloric homeostasis

Two key signal molecules regulate energy homeostasis over the time scale of hours or days: *leptin*, which is secreted by the adipocytes, and *insulin*, which is secreted by the  $\beta$  cells of the pancreas. Leptin reports on the status of the triacylglycerol stores, whereas insulin reports on the status of glucose in the blood—in other words, of carbohydrate availability. We will consider leptin first.

Adipose tissue was formerly considered an inert depot of triacylglycerols. However, recent work has shown that adipose tissue is an active endocrine tissue, secreting signal molecules called *adipokines*, such as leptin, that regulate a host of physiological processes. Leptin is secreted by the adipocytes in direct proportion to the amount of fat present. The more fat in a body, the more leptin is secreted. Leptin binding to its receptor throughout the body increases the sensitivity of muscle and the liver to insulin, stimulates  $\beta$  oxidation of fatty acids, and decreases triacylglycerol synthesis.

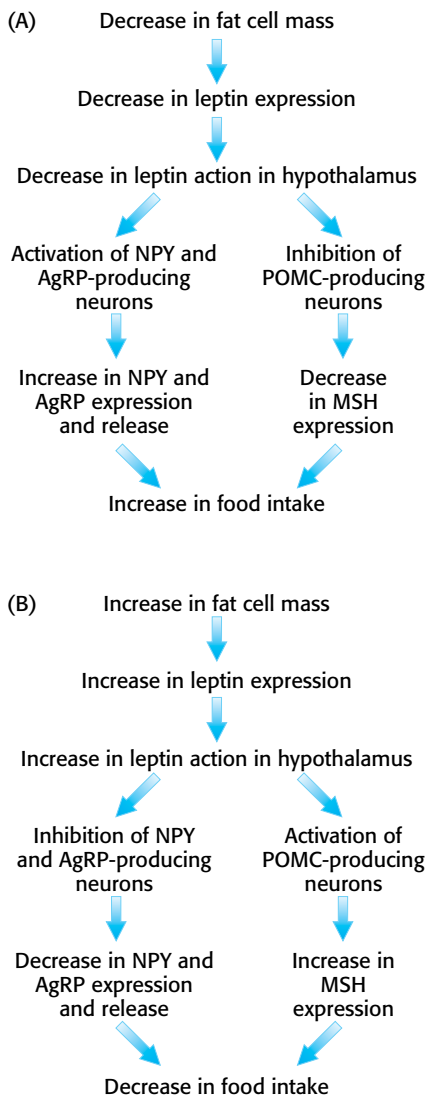

Let us consider the effects of leptin in the brain. Leptin binds to its receptor, thereby activating a signal transduction pathway. The leptin receptor is found in various regions of the brain, but particularly in the arcuate nucleus of the hypothalamus. There, one population of neurons expresses appetite-stimulating (orexigenic) peptides, called neuropeptide Y (NPY) and agouti-related peptide (AgRP). Fasting stimulates the production of NPY and AgRP owing to the decrease in leptin levels that results from diminishing adipose tissue (Figure 27.3A). Leptin, on the other hand, inhibits the NPY/AgRP neurons, preventing the release of NPY and AgRP and thus repressing the desire to eat (Figure 27.3B).

The second population of neurons containing leptin receptors expresses a large precursor polypeptide, proopiomelanocortin (POMC). In response to leptin binding to its receptor on POMC neurons, POMC is proteolytically processed to yield a variety of signal molecules, one of which, *melanocyte-stimulating hormone* (MSH), is especially important in this context. MSH, originally discovered as a stimulator of melanocytes (cells that synthesize the pigment melanin), activates appetite-suppressing (anorexigenic) neurons and thus inhibits food consumption. Fasting inhibits MSH activity and thus stimulates eating. AgRP inhibits MSH activity by acting as an antagonist, binding to the MSH receptor but

**FIGURE 27.3 The effects of leptin in the brain.** Leptin is an adipokine secreted by adipose tissue in direct relation to fat mass. (A) When leptin levels fall, as in fasting, appetite-enhancing neuropeptides NPY and AgRP are secreted, whereas the secretion of appetite-suppressing signals such as MSH is inhibited. (B) When fat mass increases, leptin inhibits NPY and AgRP secretion while stimulating the release of appetite-suppressing hormone MSH. [Information from M. H. Stipanuk, *Biochemical, Physiological, & Molecular Aspects of Human Nutrition*, 2d ed. (Saunders/Elsevier, 2006), Fig. 22-2.]

failing to activate the receptor (Figure 27.3). Thus, the net effect of leptin binding to its receptor is the initiation of a complex signal-transduction pathway that ultimately curtails food intake.

Insulin receptors are also present in the hypothalamus, although the mechanism of insulin action in the brain is less clear than that of leptin. Insulin appears to inhibit NPY/AgRP-producing neurons, thus inhibiting food consumption.

### Leptin is one of several hormones secreted by adipose tissue

Leptin was the first adipokine discovered because of the dramatic effects of its absence. Researchers discovered a strain of mice called *ob/ob* mice, which lack leptin and, as a result, are extremely obese (refer to Chapter 22 opening figure on p. 643). These mice display hyperphagia (overeating), hyperlipidemia (accumulation of triacylglycerols in muscle and liver), and an insensitivity to insulin. Since the discovery of leptin, other adipokines have been detected. For instance, *adiponectin* is another signal molecule produced by the adipocytes. Secretion of adiponectin falls in direct proportion to increases in fat mass. A key function of adiponectin appears to be increasing the sensitivity of the organism to insulin. Both leptin and adiponectin exert their effects through the key regulatory enzyme, AMP-activated protein kinase (AMPK). Recall that this enzyme is active when AMP levels are elevated and ATP levels are diminished, and this activation leads to a decrease in anabolism and an increase in catabolism, most notably an increase in fatty acid oxidation (Section 22.6). In insulin-resistant obese animals such as the *ob/ob* mice, leptin levels increase while those of adiponectin decrease.

Adipocytes also produce two hormones, *RBP4* (originally discovered as a retinol binding protein) and *resistin*, that promote insulin resistance. Although it is unclear why adipocytes secrete hormones that facilitate insulin resistance, a pathological condition, we can speculate on the reason. These signal molecules may help to fine-tune the actions of leptin and adiponectin or perhaps to act as “brakes” on the action of leptin and adiponectin to prevent hypoglycemia in the fasted state. Some evidence indicates that enlarged adipocytes that result from obesity may secrete higher levels of insulin-antagonizing hormones and thus contribute to insulin resistance. Resistin has recently been implicated as a causal factor in the increased incidence of cardiovascular disease in obese individuals.

### Leptin resistance may be a contributing factor to obesity

If leptin is produced in proportion to body-fat mass and leptin inhibits eating, why do people become obese? Obese people, in most cases, have both functioning leptin receptors and a high blood concentration of leptin. The failure to respond to the anorexigenic effects of leptin is called *leptin resistance*. What is the basis of leptin resistance?

As for most questions in the exciting area of energy homeostasis, the answer is not well worked out, but recent evidence suggests that a group of proteins called *suppressors of cytokine signaling* (SOCS) may take part. These proteins fine-tune some hormonal systems by inhibiting receptor action. SOCS proteins inhibit receptor signaling by a number of means. Consider, for example, the effect of SOCS proteins on the insulin receptor. Recall that insulin stimulates the autophosphorylation of tyrosine residues on the insulin receptor, which in turn phosphorylates IRS-1, initiating the insulin-signaling pathway (Figure 27.4A). SOCS proteins bind to phosphorylated tyrosine residues on receptors or other members of the signal-transduction pathway, thereby disrupting signal flow and thus altering the cell’s biochemical activity (Figure 27.4B). In other cases, the binding of SOCS proteins to components

**FIGURE 27.4 Suppressors of cytokine signaling (SOCS) regulate receptor function.**

(A) Insulin binding results in phosphorylation of the receptor and subsequent phosphorylation of IRS-1. These processes initiate the insulin-signaling pathway. (B) SOCS proteins disrupt interactions of components of the insulin-signaling pathway by binding phosphorylated proteins and thereby inhibiting the pathway. The binding of a signal component by SOCS results in proteasomal degradation in some cases. (IRS-1, insulin-receptor substrate 1; SOCS, suppressor of cytokine signaling.)

of the signal-transduction pathway may also enhance proteolytic degradation of these components by the proteasome (Section 23.2). Evidence in support of a role for SOCS in leptin resistance comes from mice that have had SOCS selectively deleted from POMC-expressing neurons. These mice display an enhanced sensitivity to leptin and are resistant to weight gain even when fed a high-fat diet. The reason why the activity of SOCS proteins increases, leading to leptin resistance, remains to be determined.

### Dieting is used to combat obesity

Given the obesity epidemic that we currently face and its associated disorders, much attention has been focused on determining the most effective weight-loss diet. In general, two categories of diet try to help us control our caloric intake—low-carbohydrate diets and low-fat diets. Low-carbohydrate diets usually emphasize protein consumption. Although studies of the effects of diets on humans are immensely complex, data are beginning to accumulate suggesting that low-carbohydrate-high-protein diets *may* be the most effective for losing weight. The exact reasons are not clear, but there are two common hypotheses. First, proteins seem to induce a feeling of satiation more effectively than do fats or carbohydrates. Second, proteins require more energy to digest than do fats or carbohydrates, and the increased energy expenditure contributes to weight loss. For instance, some studies show that a diet that is 30% protein requires almost 30% more energy to digest than that required by a diet that is 10% protein. The mechanisms by which protein-rich diets enhance energy expenditure and feelings of satiation remain to be determined. Regardless of the type of diet, the adage “Eat less, exercise more” always applies.

## 27.3 Diabetes Is a Common Metabolic Disease Often Resulting from Obesity

Having taken an overview of the regulation of body weight, we now examine the biochemical results when regulation fails because of behavior, genetics, or a combination of the two. The most common result of such a failure is

**Diabetes**

Named for the excessive urination in the disease. Aretaeus, a Cappadocian physician of the second century A.D., wrote: "The epithet diabetes has been assigned to the disorder, being something like passing of water by a siphon." He perceptively characterized diabetes as "being a melting-down of the flesh and limbs into urine."

**Mellitus**

From Latin, meaning "sweetened with honey." Refers to the presence of sugar in the urine of patients having the disease. *Mellitus* distinguishes this disease from diabetes *insipidus*, which is caused by impaired renal reabsorption of water.

obesity, a condition in which excess energy is stored as triacylglycerols. Recall that all excess food consumption is ultimately converted into triacylglycerols. Humans maintain about a day's worth of glycogen and, after these stores have been replenished, excess carbohydrates are converted into fats and then into triacylglycerols. Amino acids are not stored at all, and so excess amino acids are ultimately converted into fats also. Thus, regardless of the type of food consumed, excess consumption results in increased fat stores.

We begin our consideration of the effects of disruptions in caloric homeostasis with *diabetes mellitus*, a complex disease characterized by grossly abnormal fuel usage: *glucose is overproduced by the liver and underutilized by other organs*. The incidence of diabetes mellitus (usually referred to simply as *diabetes*) is about 5% of the world population. *Type 1 diabetes* is caused by the autoimmune destruction of the insulin-secreting  $\beta$  cells in the pancreas and usually begins before age 20. Type 1 diabetes is also referred to as insulin-dependent diabetes, meaning that the affected person requires the administration of insulin to live. Most diabetics, in contrast, have a normal or even higher level of insulin in their blood, but they are unresponsive to the hormone, a characteristic called *insulin resistance*. This form of the disease, known as *type 2 diabetes*, typically arises later in life than does the insulin-dependent form. Type 2 diabetes accounts for approximately 90% of the diabetes cases throughout the world and is the most common metabolic disease in the world. In the United States, it is the leading cause of blindness, kidney failure, and amputation. *Obesity is a significant predisposing factor for the development of type 2 diabetes*.

**Insulin initiates a complex signal-transduction pathway in muscle**

What is the biochemical basis of insulin resistance? How does insulin resistance lead to failure of the  $\beta$  cells of the pancreas that results in type 2 diabetes? How does obesity contribute to this progression? To answer these questions and begin to unravel the mysteries of metabolic disorders, let us examine the mechanism of action of insulin in muscle, the largest tissue target of insulin. Indeed, muscle uses about 85% of the glucose ingested during a meal.

In a normal cell, insulin binds to its receptor, which then autophosphorylates on tyrosine residues, with each subunit of the receptor phosphorylating its partner. Phosphorylation of the receptor generates binding sites for insulin-receptor substrates (IRSs), such as IRS-1 (Figure 27.5). Subsequent phosphorylation of IRS-1 by the tyrosine kinase activity of the insulin receptor engages the insulin-signaling pathway (1). Phosphorylated IRS-1 binds to phosphoinositide 3-kinase (PI3K) and activates it. PI3K catalyzes the conversion of phosphatidylinositol into phosphatidylinositol 3,4,5-trisphosphate

**FIGURE 27.5 Insulin signaling.** The binding of insulin results in the cross-phosphorylation and activation of the insulin receptor. Phosphorylated sites on the receptor act as binding sites for insulin-receptor substrates such as IRS-1. The lipid kinase phosphoinositide 3-kinase binds to phosphorylated sites on IRS-1 through its regulatory domain and then converts PIP<sub>2</sub> into PIP<sub>3</sub>. Binding to PIP<sub>3</sub> activates PIP<sub>3</sub>-dependent protein kinase, which phosphorylates and activates kinases such as Akt. Activated Akt can then diffuse throughout the cell and continue the signal-transduction pathway.

(PIP<sub>3</sub>), a second messenger (2). PIP<sub>3</sub> activates the phosphatidylinositol-dependent protein kinase (PDK) (3), which in turn activates several other kinases, most notably Akt (4), also known as protein kinase B (PKB). Akt facilitates the translocation of the glucose transporter (GLUT4)-containing vesicles to the cell membrane, which leads to a more robust absorption of glucose from the blood. Moreover, Akt phosphorylates and inhibits glycogen synthase kinase (GSK3). Recall that GSK3 inhibits glycogen synthase (Section 21.5). Thus, insulin leads to the absorption of glucose from the blood, activation of glycogen synthase, and enhanced glycogen synthesis.

Like all signal pathways, the insulin-signaling cascade must be capable of being turned off. Three different processes contribute to the down-regulation of insulin signaling. First, phosphatases deactivate the insulin receptor and destroy a key second messenger. *Tyrosine phosphatase IB* removes phosphoryl groups from the receptor, thus inactivating it. The second messenger PIP<sub>3</sub> is inactivated by the phosphatase *PTEN* (phosphatase and *tensin* homolog), which dephosphorylates it, forming PIP<sub>2</sub>, which itself has no second-messenger properties.

Second, the IRS protein can be inactivated by phosphorylation on serine residues by specific Ser/Thr kinases. These kinases are activated by overnutrition and other stress signals and may play a role in the development of insulin resistance. Finally, SOCS proteins, the regulatory proteins discussed earlier, interact with the insulin receptor and IRS-1 and apparently facilitate their proteolytic degradation by the proteasome complex.

### Metabolic syndrome often precedes type 2 diabetes

With our knowledge of the key components of energy homeostasis, let us begin our investigation of the biochemical basis of insulin resistance and type 2 diabetes. Obesity is a contributing factor to the development of insulin resistance, which is an early development on the path to type 2 diabetes. Indeed, a cluster of pathologies—including insulin resistance, hyperglycemia, dyslipidemia (high blood levels of triacylglycerols, cholesterol, and low-density lipoproteins)—often develop together. This clustering, called *metabolic syndrome*, is thought to be a predecessor of type 2 diabetes.

**FIGURE 27.6 The storage capacity of fat tissue can be exceeded in obesity.** In caloric excess, the storage capacity of adipocytes can be exceeded with deleterious results. The excess fat accumulates in other tissues, resulting in biochemical malfunction of the tissues. When the pancreas, muscle, liver, and cells lining the blood vessels are affected, metabolic syndrome, a condition that often precedes type 2 diabetes, may result. [Information from S. Fröjdö, H. Vidal, and L. Pirola, *Biochim. Biophys. Acta* 1792:83–92, 2009, Fig. 1.]

A consequence of obesity is that the amount of triacylglycerols consumed exceeds the adipose tissue's storage capacity. As a result, other tissues begin to accumulate fat, most notably liver and muscle (Figure 27.6). For reasons to be presented later in the chapter, this accumulation results in insulin resistance and ultimately in pancreatic failure. We will focus on muscle and the  $\beta$  cells of the pancreas.

### Excess fatty acids in muscle modify metabolism

We have seen many times the importance of fats as fuels. In regard to obesity, more fats are present than can be processed by muscle. Although the rate of  $\beta$  oxidation increases in response to the high concentration of fats, mitochondria are not capable of processing all of the fatty acids by  $\beta$  oxidation; fatty acids accumulate in the mitochondria and eventually spill over into the cytoplasm. Indeed, the inability to process all of the fatty acids results in their reincorporation into triacylglycerols and the accumulation of fat in the cytoplasm. In the cytoplasm, levels of diacylglycerol and ceramide (a component of sphingolipids) also increase. Diacylglycerol is a second messenger that activates protein kinase C (PKC) (Section 14.1). When active, PKC and other Ser/Thr protein kinases are capable of phosphorylating IRS and reducing the ability of IRS to propagate the insulin signal. Saturated and trans unsaturated fatty acids may also activate kinases that block the insulin signal. Ceramide or its metabolites

inhibit glucose uptake and glycogen synthesis, apparently by inhibiting PDK and Akt (p. 808). The result is a diet-induced insulin resistance (Figure 27.7).

### Insulin resistance in muscle facilitates pancreatic failure

What is the effect of overnutrition on the pancreas? This question is important because a primary function of the pancreas is to respond to the presence of glucose in the blood by secreting insulin, a process referred to as *glucose-stimulated insulin secretion* (GSIS). Indeed, the  $\beta$  cell is a virtual insulin factory. Proinsulin mRNA, which encodes proinsulin, the precursor to insulin, constitutes 20% of the total mRNA in the pancreas. Proinsulin constitutes 50% of the total protein synthesized in the pancreas.

Glucose enters the  $\beta$  cells of the pancreas through the glucose transporter GLUT2. Recall that GLUT2 will allow glucose transport only when blood glucose is plentiful, ensuring that insulin is secreted only when glucose is abundant, such as after a meal (Section 16.2). The  $\beta$  cell metabolizes glucose to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  in the process of cellular respiration, generating ATP (Chapters 16, 17, and 18). The resulting increase in the ATP/ADP ratio closes an ATP-sensitive  $\text{K}^+$  channel that, when open, allows potassium to flow out of the cell (Figure 27.8). The resulting alteration in the cellular ionic environment opens a  $\text{Ca}^{2+}$  channel. The influx of  $\text{Ca}^{2+}$  causes insulin-containing secretory vesicles to fuse with the cell membrane and release insulin into the blood. Thus, the increase in energy charge resulting from the metabolism of glucose has been translated by the membrane proteins into a physiological response—the secretion of insulin and the subsequent removal of glucose from the blood.

What aspect of  $\beta$  cell function ultimately fails as a result of overnutrition, causing the transition from insulin resistance to full-fledged type 2 diabetes? Recall that, under normal circumstances, the  $\beta$  cells of the

**FIGURE 27.7** Excess fat in peripheral tissues can result in insulin insensitivity.

Excess fat accumulation in peripheral tissues, most notably muscle, can disrupt some signal-transduction pathways and inappropriately activate others. In particular, diacylglycerols and ceramide activate stress-induced pathways that interfere with insulin signaling, resulting in insulin resistance. (Abbreviations: DAG, diacylglycerol; TGs, triacylglycerols; ROS, reactive oxygen species; CA1, carnitine acyltransferase 1; GLUT4, glucose transporter 4; IR, insulin receptor; ETC, electron-transport chain; TCA, tricarboxylic acid cycle.)

pancreas synthesize large amounts of proinsulin. The proinsulin folds into its three-dimensional structure in the endoplasmic reticulum, is processed to insulin, and is subsequently packaged into vesicles for secretion. As insulin resistance develops in the muscle, the  $\beta$  cells respond by synthesizing yet more insulin in a futile attempt to drive insulin action. The ability of the endoplasmic reticulum to process all of the proinsulin and insulin becomes compromised, a condition known as *endoplasmic reticulum (ER) stress*, and unfolded or misfolded proteins accumulate. ER stress initiates a signal pathway called the *unfolded protein response (UPR)*, a pathway intended to save the cell. UPR consists of several steps. First, general protein synthesis is inhibited so as to prevent more proteins from entering the ER. Second, chaperone synthesis is stimulated. Recall that chaperones are proteins that assist the folding of other proteins (Section 2.6). Third, misfolded proteins are removed from the ER and are subsequently delivered to the proteasome for destruction. Finally, if the described response fails to alleviate the ER stress, programmed cell death is triggered, which ultimately leads to  $\beta$  cell death and full-fledged type 2 diabetes.

What are the treatments for type 2 diabetes? Most are behavioral in nature. Diabetics are advised to count calories, making sure that energy intake does not exceed energy output; to consume a diet rich in vegetables, fruits, and grains; and to get plenty of aerobic exercise. Note that these guidelines are the same as those for healthy living, even for

**FIGURE 27.8** Insulin release is regulated by ATP.

The metabolism of glucose by glycolysis and cellular respiration increases the concentration of ATP, which causes an ATP-sensitive potassium channel to close. The closure of this channel alters the charge across the membrane ( $\psi$ ) and causes a calcium channel to open. The influx of calcium causes insulin-containing granules to fuse with the plasma membrane, releasing insulin into the blood.

those not suffering from type 2 diabetes. Treatments specific for type 2 diabetes include the monitoring of blood-glucose concentration so that it is within the target range (normal is 3.6 to 6.1 mM). For those who are not able to maintain proper glucose levels with the behaviors described herein, drug treatments are required. The administration of insulin may be necessary upon pancreatic failure, and treatment with metformin (Glucophage), which activates AMPK, may be effective. AMPK promotes the oxidation of fats while inhibiting fat synthesis and storage. It also stimulates glucose uptake and storage by muscle while inhibiting gluconeogenesis in the liver.

### Metabolic derangements in type 1 diabetes result from insulin insufficiency and glucagon excess

We now turn to the more-straightforward type 1 diabetes. In type 1 diabetes, insulin production is insufficient because of autoimmune destruction of the  $\beta$  cells of the pancreas. Consequently, the glucagon/insulin ratio is at higher-than-normal levels. In essence, the diabetic person is in biochemical fasting mode despite a high concentration of blood glucose. Because insulin is deficient, *the entry of glucose into adipose and muscle cells is impaired*. The liver becomes stuck in a gluconeogenic and ketogenic state. The gluconeogenic state is characterized by excessive production of glucose. The excessive level of glucagon relative to that of insulin leads to a decrease in the amount of fructose

**FIGURE 27.9 Regulation of glycolysis and gluconeogenesis.** Phosphofruktokinase is the key enzyme in the regulation of glycolysis, whereas fructose 1,6-bisphosphatase is the principal enzyme controlling the rate of gluconeogenesis. Note the reciprocal relation between the pathways and the signal molecules.

2,6-bisphosphate (F-2, 6-BP), which stimulates glycolysis and inhibits gluconeogenesis in the liver. Hence, glycolysis is inhibited and gluconeogenesis is stimulated because of the opposite effects of F-2, 6-BP on phosphofruktokinase and fructose-1, 6-bisphosphatase (Section 16.4; Figure 27.9). Essentially, the cells' response to a lack of insulin amplifies the amount of glucose in the blood. The high glucagon/insulin ratio in diabetes also promotes glycogen breakdown. Hence, *an excessive amount of glucose is produced by the liver and released into the blood*. Glucose is excreted in the urine (hence the name *mellitus*) when its concentration in the blood exceeds the reabsorptive capacity of the renal tubules. Water

accompanies the excreted glucose, and so an untreated diabetic in the acute phase of the disease is hungry and thirsty.

Because carbohydrate utilization is impaired, a lack of insulin leads to the uncontrolled breakdown of lipids and proteins, resulting in the ketogenic state. Large amounts of acetyl CoA are then produced by  $\beta$  oxidation. However, much of the acetyl CoA cannot enter the citric acid cycle, because there is insufficient oxaloacetate for the condensation step. Recall that mammals can synthesize oxaloacetate from pyruvate, a product of glycolysis, but not from acetyl CoA; instead, they generate ketone bodies (Section 22.3). *A striking feature of diabetes is the shift in fuel usage from carbohydrates to fats; glucose, more abundant than ever, is spurned*. In high concentrations, ketone bodies overwhelm the kidney's capacity to maintain acid–base balance. The untreated diabetic can go into a coma because of a lowered blood-pH level and dehydration. Interestingly, diabetic ketosis is rarely a problem in type 2 diabetes because insulin is active enough to prevent excessive lipolysis in liver and adipose tissue.

What is the treatment for type 1 diabetes? Many of the behaviors recommended for type 2 diabetes apply to type 1: watching calories, exercising, and eating a healthy diet. Likewise, blood-glucose levels must be monitored. Insulin treatments are required for survival.

## 27.4 Exercise Beneficially Alters the Biochemistry of Cells

Skeletal muscle accounts for  $\approx 40\%$  of total body mass and  $\approx 35\%$  of resting metabolic activity. Moreover, skeletal muscle is the largest target tissue for insulin. Given its biochemical prominence, increased muscle activity—exercise—coupled with a healthy diet, is one of the most effective treatments for diabetes as well as a host of other pathological conditions. These include coronary disease, hypertension, depression, and a variety of cancers. With regard to diabetes, exercise increases the insulin sensitivity of people who are insulin resistant or type 2 diabetics. What is the basis of this beneficial effect?

### Mitochondrial biogenesis is stimulated by muscular activity

When muscle is stimulated to contract during exercise by receiving nerve impulses from motor neurons, calcium is released from the sarcoplasmic reticulum. Calcium induces muscle contraction, as will be discussed in Chapter 35. Recall that calcium is also a potent second messenger and frequently works in association with the calcium-binding protein calmodulin (Section 14.1). In its capacity as a second messenger, calcium stimulates various calcium-dependent enzymes, such as calmodulin-dependent protein kinase. The calcium-dependent enzymes, as well as AMPK, subsequently activate particular transcription-factor complexes. As we will see in Chapters 29 and 31, transcription factors are proteins that control gene expression. Two patterns of gene expression, in particular, change in response to regular exercise (Figure 27.10). Regular exercise enhances the production of proteins required for fatty acid metabolism, such as the enzymes of  $\beta$  oxidation. Interestingly, fatty acids themselves function as signal molecules to activate the transcription of enzymes of fatty acid metabolism. Additionally, another set of transcription factors activated by the calcium signal cascade initiates a signal pathway that increases mitochondrial biogenesis. In concert, *the increase in fatty acid oxidizing capability and additional mitochondria allow for the efficient metabolism of fatty acids*. Because an excess of fatty acids results in insulin resistance, as already discussed, efficient metabolism of fatty acids results in *an increase in insulin sensitivity*. Indeed, muscles of well-trained athletes may contain high concentrations of triacylglycerols and still maintain exquisite sensitivity to insulin. These alterations of muscle biochemistry are some of the molecular manifestations of the training effect of exercise.

### Fuel choice during exercise is determined by the intensity and duration of activity

In keeping with our theme of energy use under different physiological conditions, we now examine how fuels are used in different types of exercise. The fuels used in anaerobic exercises—sprinting, for example—differ from those used in aerobic exercises—such as distance running. The selection of fuels during these different forms of exercise illustrates many important facets of energy transduction and metabolic integration. ATP directly powers myosin, the protein immediately responsible for converting chemical energy into movement (Chapter 35). However, the amount of ATP in muscle is small. Hence, the power output and, in turn, the velocity of running depend on the rate of ATP production from other fuels. As shown in Table 27.3, *creatine phosphate* (phosphocreatine) can swiftly

**FIGURE 27.10 Exercise results in mitochondrial biogenesis and enhanced fat metabolism.** An action potential causes  $\text{Ca}^{2+}$  release from the sarcoplasmic reticulum (SR), the muscle-cell equivalent of the endoplasmic reticulum. The  $\text{Ca}^{2+}$ , in addition to instigating muscle contraction, activates nuclear transcription factors that stimulate the expression of specific genes. The products of these genes, in conjunction with the products of mitochondrial genes, are responsible for mitochondrial biogenesis. Fatty acids activate a different set of genes that increase the fatty acid oxidation capability of mitochondria. [Information from D. A. Hood, *J Appl. Physiol.* 90:1137–1157, 2001, Fig. 2.]

TABLE 27.3 Fuel sources for muscle contraction

Fuel source	Maximal rate of ATP production (mmol s <sup>-1</sup> )	Total ~P available (mmol)
Muscle ATP		223
Creatine phosphate	73.3	446
Conversion of muscle glycogen into lactate	39.1	6,700
Conversion of muscle glycogen into CO <sub>2</sub>	16.7	84,000
Conversion of liver glycogen into CO <sub>2</sub>	6.2	19,000
Conversion of adipose-tissue fatty acids into CO <sub>2</sub>	6.7	4,000,000

Note: Fuels stored are estimated for a 70-kg person having a muscle mass of 28 kg.

Data from E. Hultman and R. C. Harris. In *Principles of Exercise Biochemistry*, edited by J. R. Poortmans (Karger, 2004), pp. 78–119.

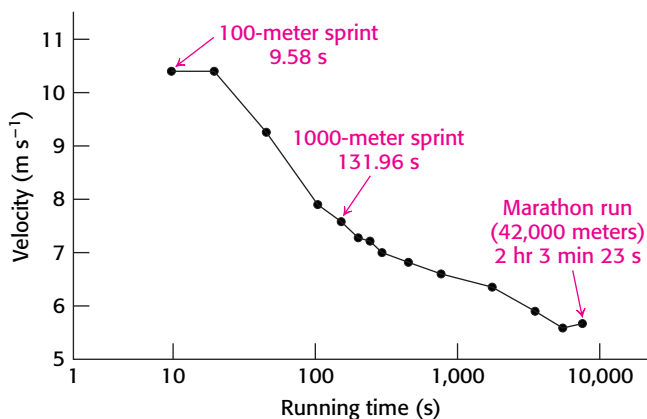

transfer its high-potential phosphoryl group to ADP to generate ATP. However, the amount of creatine phosphate, like that of ATP itself, is limited. Creatine phosphate and ATP can power intense muscle contraction for 5 to 6 s. Maximum speed in a sprint can thus be maintained for only 5 to 6 s (Figure 15.7). Thus, the winner in a 100-meter sprint is the runner who both achieves the highest initial velocity and then slows down the least.

During a ~10 second sprint, the ATP level in muscle drops from 5.2 to 3.7 mM, and that of creatine phosphate decreases from 9.1 to 2.6 mM. Anaerobic glycolysis provides fuel to make up for the loss of ATP and creatine phosphate. *A 100-meter sprint is powered by stored ATP, creatine phosphate, and the anaerobic glycolysis of muscle glycogen.* The conversion of muscle glycogen into lactate can generate a good deal more ATP, but the rate is slower than that of phosphoryl-group transfer from creatine phosphate. Because of anaerobic glycolysis, the blood-lactate level is elevated from 1.6 to 8.3 mM. The release of H<sup>+</sup> from the intensely active muscle concomitantly lowers the blood pH from 7.42 to 7.24. Sprinting is powered by fast twitch muscle fiber (type IIb) specialized for anaerobic glycolysis. Recall that one of the effects of high-intensity training is to increase the amount of lactate transporters in the membranes of slow twitch fibers (type 1), which remove lactate from the blood and slow the fall in blood pH (Section 16.4). Nonetheless, the pace of a 100-meter sprint cannot be sustained in a 1000-meter run (~132 s) for two reasons. First, creatine phosphate is consumed within a few seconds. Second, the lactate produced would cause acidosis. Thus, alternative fuel sources are needed.

Let us examine the fuel use of a middle-distance runner. The complete oxidation of muscle glycogen to CO<sub>2</sub> by aerobic respiration substantially increases the energy available to power the 1000-meter run, but this aerobic process is a good deal slower than anaerobic glycolysis. Because ATP is produced more slowly by oxidative phosphorylation than by glycolysis (Table 27.3), the runner's pace is necessarily slower than in a 100-meter sprint. The championship velocity for the 1000-meter run is about 7.6 m s<sup>-1</sup>, compared with approximately 10.4 m s<sup>-1</sup> for the 100-meter event (Figure 27.11).

The running of a marathon (26 miles 385 yards, or 42,200 meters) requires a different selection of fuels and is characterized by cooperation (depending on the capabilities of the runner) between muscle, liver, and adipose tissue. Liver glycogen complements muscle glycogen as an energy store that can be tapped. Elite marathoners can use the aerobic combustion of glucose to power the entire race, provided they consume fuels during the race. However, for most of us, the total body glycogen stores

FIGURE 27.11 Dependency of the velocity of running on the duration of the race. The values shown are world track records. [Data from trackandfieldnews.com.]

(103 mol of ATP at best) are insufficient to provide the 150 mol of ATP needed for this grueling event. Much larger quantities of ATP can be obtained by the oxidation of fatty acids derived from the breakdown of *fat in adipose tissue*, but the maximal rate of ATP generation is slower yet than that of glycogen oxidation and is more than 10-fold slower than that with creatine phosphate. Thus, *ATP is generated much more slowly from high-capacity stores than from limited ones*, accounting for the different velocities of anaerobic and aerobic events. Fats are rapidly consumed in activities such as distance running, explaining why extended aerobic exercise is beneficial for people who are insulin resistant.

Is it possible to determine the contribution of each fuel as a function of exercise intensity? The percentage contribution of each fuel can be measured with the use of a respirometer, which measures the respiratory quotient (RQ), the ratio of CO<sub>2</sub> produced to O<sub>2</sub> consumed. Consider the complete combustion of glucose:

The RQ for glucose is 1. Now consider the oxidation of a typical fatty acid, palmitate:

The RQ for palmitate oxidation is 0.7. Thus, as aerobic exercise intensity increases, the RQ will rise from 0.7 (only fats are used as fuel) to 1.0 (only glucose is used as fuel). Between these values, a mixture of fuels is used (Figure 27.12).

What is the optimal mix of fuels for use during a marathon? As suggested above, this is a complex question that varies with the athlete and level of training. Studies have shown that, when muscle glycogen has been depleted, the power output of the muscle falls to approximately 50% of maximum. Power output decreases despite the fact that ample supplies of fat are available, suggesting that fats can supply only about 50% of maximal aerobic effort. Indeed, depletion of glycogen stores during a race is referred to as “bonking” or “hitting the wall,” with the result that the athlete must greatly reduce the pace.

How is an optimal mix of these fuels achieved? *A low blood-sugar level leads to a high glucagon/insulin ratio, which in turn mobilizes fatty acids from adipose tissue.* Fatty acids readily enter muscle, where they are degraded by  $\beta$  oxidation to acetyl CoA and then to CO<sub>2</sub>. The elevated acetyl CoA level decreases the activity of the pyruvate dehydrogenase complex to block the conversion of pyruvate into acetyl CoA. Hence, fatty acid oxidation decreases the funneling of glucose into the citric acid cycle and oxidative phosphorylation. Glucose is spared so that just enough remains available at the end of the marathon to increase the pace as the finish line draws near. The simultaneous use of both fuels gives a higher mean velocity than would be attained if glycogen were totally consumed before the start of fatty acid oxidation. It is important to bear in mind that fuel utilization is only one of many factors that determine running ability.

If carbohydrate-rich meals are consumed after glycogen depletion, glycogen stores are rapidly restored. In addition, glycogen synthesis continues during the consumption of carbohydrate-rich meals, increasing glycogen stores far above normal. This phenomenon is called “super compensation” or, more commonly, carbo-loading.

**FIGURE 27.12** An idealized representation of fuels use as a function of aerobic exercise intensity. (A) With increased exercise intensity, the use of fats as fuels falls as the utilization of glucose increases. (B) The respiratory quotient (RQ) measures the alteration in fuel use.

## 27.5 Food Intake and Starvation Induce Metabolic Changes

Thus far, we have been considering metabolism in the context of excess consumption of calories, as in obesity, or extreme caloric needs, as in exercise. We now look at the opposite physiological condition—lack of calories.

### The starved–fed cycle is the physiological response to a fast

We begin with a physiological condition called the *starved–fed cycle*, which we all experience in the hours after an evening meal and through the night's fast. This nightly starved–fed cycle has three stages: the well-fed state after a meal, the early fasting during the night, and the refed state after breakfast. A major goal of the many biochemical alterations in this period is to maintain *glucose homeostasis*—that is, a constant blood-glucose concentration. Maintaining glucose homeostasis is crucial because glucose is normally the only fuel source for the brain. As discussed earlier, the major defect in diabetes is the inability to perform this vital task. The two primary signals regulating the starved–fed cycle are insulin and glucagon.

1. *The well-fed, or postprandial, state.* After we consume and digest an evening meal, glucose and amino acids are transported from the intestine to the blood. The dietary lipids are packaged into chylomicrons and transported to the blood by the lymphatic system. This fed condition leads to the secretion of insulin, which signals the fed state. Insulin stimulates glycogen synthesis in both muscle and the liver, suppresses gluconeogenesis by the liver, and stimulates protein synthesis. Insulin also accelerates glycolysis in the liver, which in turn increases the synthesis of fatty acids.

The liver helps to limit the amount of glucose in the blood during times of plenty by storing it as glycogen so as to be able to release glucose in times of scarcity. How is the excess blood glucose present after a meal removed? The liver is able to trap large quantities of glucose because it possesses an isozyme of hexokinase called *glucokinase*, which converts glucose into glucose 6-phosphate, which cannot be transported out of the cell. Recall that glucokinase has a high  $K_M$  value and is thus active only when blood-glucose concentration is high (Section 16.2). Furthermore, glucokinase is not inhibited by glucose 6-phosphate as hexokinase is. Consequently, *the liver forms glucose 6-phosphate more rapidly as the blood-glucose concentration rises. The increase in glucose 6-phosphate, which activates glycogen synthase, coupled with insulin action leads to a buildup of glycogen stores.* The hormonal effects on glycogen synthesis and storage are reinforced by a direct action of glucose itself. *Phosphorylase a is a glucose sensor in addition to being the enzyme that cleaves glycogen.* When the glucose level is high, the binding of glucose to phosphorylase *a* renders the enzyme susceptible to the action of a phosphatase that converts it into phosphorylase *b*, which does not readily degrade glycogen (Figure 21.24). Thus, *glucose allosterically shifts the glycogen system from a degradative to a synthetic mode.*

The high insulin level in the fed state also promotes *the entry of glucose into muscle and adipose tissue.* Insulin stimulates the synthesis of glycogen by muscle as well as by the liver. The entry of glucose into adipose tissue provides glycerol 3-phosphate for the synthesis of triacylglycerols. The action of insulin also extends to amino acid and protein metabolism. Insulin promotes the uptake of branched-chain amino acids (valine, leucine, and isoleucine) by muscle. Indeed, insulin has a general stimulating effect on protein synthesis, which favors a building up of muscle protein. In addition, it inhibits the intracellular degradation of proteins.

2. *The early fasting, or postabsorptive, state.* The blood-glucose concentration begins to drop several hours after a meal, leading to a decrease in insulin secretion and a rise in glucagon secretion by the  $\alpha$  cells of the pancreas. The regulation of glucagon secretion is poorly understood, but when glucose is abundant,  $\beta$  cells inhibit glucagon secretion. When glucose concentration falls, the inhibition is relieved and glucagon is secreted by the  $\alpha$  cells of the pancreas. Just as insulin signals the fed state, glucagon signals the starved state, serving to mobilize glycogen stores when there is no dietary intake of glucose. *The main target organ of glucagon is the liver.* Glucagon stimulates glycogen breakdown and inhibits glycogen synthesis by triggering the cyclic AMP cascade leading to the phosphorylation and activation of phosphorylase and the inhibition of glycogen synthase (Section 21.5). Glucagon also inhibits fatty acid synthesis by diminishing the production of pyruvate and by maintaining the inactive phosphorylated state of acetyl CoA carboxylase. In addition, glucagon stimulates gluconeogenesis in the liver and blocks glycolysis by lowering the level of F-2, 6-BP (Figure 27.9).

All known actions of glucagon are mediated by protein kinases that are activated by cyclic AMP. The activation of the cyclic AMP cascade results in a higher level of phosphorylase *a* activity and a lower level of glycogen synthase *a* activity. Glucagon's effect on this cascade is reinforced by the low concentration of glucose in the blood. The diminished binding of glucose to phosphorylase *a* makes the enzyme less susceptible to the hydrolytic action of the phosphatase. Instead, the phosphatase remains bound to phosphorylase *a*, and so the synthase stays in the inactive phosphorylated form. Consequently, there is a rapid mobilization of glycogen.

The large amount of glucose formed by the hydrolysis of glucose 6-phosphate derived from glycogen is then released from the liver into the blood. The entry of glucose into muscle and adipose tissue decreases in response to a low insulin level. The diminished utilization of glucose by muscle and adipose tissue also contributes to the maintenance of the blood-glucose concentration. The net result of these actions of glucagon is to *markedly increase the release of glucose by the liver*. Both muscle and the liver use fatty acids as fuel when the blood-glucose concentration drops, saving the glucose for use by the brain and red blood cells. Thus, *the blood-glucose concentration is kept at or above 4.4 mM by three major factors: (1) the mobilization of glycogen and the release of glucose by the liver, (2) the release of fatty acids by adipose tissue, and (3) the shift in the fuel used from glucose to fatty acids by muscle and the liver.*

What is the result of the depletion of the liver's glycogen stores? Gluconeogenesis from lactate and alanine continues, but this process merely replaces glucose that had already been converted into lactate and alanine by tissues such as muscle and red blood cells. Moreover, the brain oxidizes glucose completely to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Thus, for the net synthesis of glucose to take place, another source of carbon is required. Glycerol released from adipose tissue on lipolysis provides some of the carbon atoms, with the remaining carbon atoms coming from the hydrolysis of muscle proteins.

3. *The refed state.* What are the biochemical responses to a hearty breakfast? Fat is processed exactly as it is processed in the normal fed state. However, that is not the case for glucose. The liver does not initially absorb glucose from the blood, but, instead, leaves it for the other tissues. Moreover, the liver remains in a gluconeogenic mode. Now, however, the newly synthesized glucose is used to replenish the liver's glycogen stores. As the blood-glucose concentration continues to rise, the liver completes the replenishment of its glycogen stores and begins to process the remaining excess glucose for fatty acid synthesis.

**TABLE 27.4** Fuel reserves in a typical 70-kg man

Organ	Available energy in kilojoules (kJ)					
	Glucose or glycogen		Triacylglycerols		Mobilizable proteins	
Blood	250	(60)	20	(45)	0	(0)
Liver	1700	(400)	2000	(450)	1700	(400)
Brain	30	(8)	0	(0)	0	(0)
Muscle	5000	(1200)	2000	(450)	100,000	(24,000)
Adipose tissue	330	(80)	560,000	(135,000)	170	(40)

Data from G. F. Cahill, Jr., *Clin. Endocrinol. Metab.* 5:398, 1976.

### Metabolic adaptations in prolonged starvation minimize protein degradation

Earlier, we considered the metabolic results of overnutrition, a condition becoming all too common in prosperous nations. Let us now examine the opposite extreme. What are the adaptations if fasting is prolonged to the point of starvation, a circumstance affecting nearly a billion people worldwide? A typical well-nourished 70-kg man has fuel reserves totaling about 670,000 kJ (161,000 kcal; Table 27.4). The energy need for a 24-hour period ranges from about 6700 kJ (1600 kcal) to 25,000 kJ (6000 kcal), depending on the extent of activity. Thus, stored fuels suffice to meet caloric needs in starvation for 1 to 3 months. However, the carbohydrate reserves are exhausted in only a day.

Even under starvation conditions, the blood-glucose concentration must be maintained above 2.2 mM. *The first priority of metabolism in starvation is to provide sufficient glucose to the brain and other tissues (such as red blood cells) that are absolutely dependent on this fuel.* However, precursors of glucose are not abundant. Most energy is stored in the fatty acyl moieties of triacylglycerols. Moreover, recall that fatty acids cannot be converted into glucose, because acetyl CoA resulting from fatty acid breakdown cannot be transformed into pyruvate (Section 22.3). The glycerol moiety of triacylglycerol can be converted into glucose, but only a limited amount is available. The only other potential source of glucose is the carbon skeletons of amino acids derived from the breakdown of proteins. However, proteins are not stored, and so any breakdown will necessitate a loss of function. Thus, *the second priority of metabolism in starvation is to preserve protein, which is accomplished by shifting the fuel being used from glucose to fatty acids and ketone bodies* (Figure 27.13).

**FIGURE 27.13** Fuel choice during starvation. The plasma levels of fatty acids and ketone bodies increase in starvation, whereas that of glucose decreases.

The metabolic changes on the first day of starvation are like those after an overnight fast. The low blood-sugar level leads to decreased secretion of insulin and increased secretion of glucagon. *The dominant metabolic processes are the mobilization of triacylglycerols in adipose tissue and gluconeogenesis by the liver.* The liver obtains energy for its own needs by oxidizing fatty acids released from adipose tissue. The concentrations of acetyl CoA and citrate consequently increase, which switches off glycolysis. The uptake of glucose by muscle is markedly diminished because of the low insulin level, whereas fatty acids enter freely. Consequently, *muscle uses no glucose and relies exclusively on fatty acids for fuel.* The  $\beta$  oxidation of fatty acids by muscle halts the conversion of pyruvate into acetyl CoA, because acetyl CoA stimulates the phosphorylation of the pyruvate dehydrogenase complex, which renders it inactive (Section 17.3). Hence, any available pyruvate, lactate, and alanine are exported to the liver for conversion into glucose. Glycerol derived from the cleavage of triacylglycerols is another raw material for the synthesis of glucose by the liver.

Proteolysis also provides carbon skeletons for gluconeogenesis. During starvation, degraded proteins are not replenished and serve as carbon

**TABLE 27.5** Fuel metabolism in starvation

Fuel exchanges and consumption	Amount formed or consumed in 24 hours (grams)	
	3d day	40th day
<b>Fuel use by the brain</b>		
Glucose	100	40
Ketone bodies	50	100
All other use of glucose	50	40
<b>Fuel mobilization</b>		
Adipose-tissue lipolysis	180	180
Muscle-protein degradation	75	20
<b>Fuel output of the liver</b>		
Glucose	150	80
Ketone bodies	150	150

sources for glucose synthesis. Initial sources of protein are those that turn over rapidly, such as proteins of the intestinal epithelium and the secretions of the pancreas. Proteolysis of muscle protein provides some of the three-carbon precursors of glucose. However, survival for most animals depends on being able to move rapidly, which requires a large muscle mass, and so muscle loss must be minimized.

How is the loss of muscle curtailed? After about 3 days of starvation, the liver forms large amounts of the ketone bodies, acetoacetate and D-3-hydroxybutyrate (Figure 27.14). Their synthesis from acetyl CoA increases markedly because the citric acid cycle is unable to oxidize all the acetyl units generated by the degradation of fatty acids. Gluconeogenesis depletes the supply of oxaloacetate, which is essential for the entry of acetyl CoA into the citric acid cycle. Consequently, the liver produces large quantities of ketone bodies, which are released into the blood. At this time, *the brain begins to consume significant amounts of acetoacetate in place of glucose*. After 3 days of starvation, about a quarter of the energy needs of the brain are met by ketone bodies (Table 27.5). The heart also uses ketone bodies as fuel.

After several weeks of starvation, ketone bodies become the major fuel of the brain. Acetoacetate is activated by the transfer of CoA from succinyl CoA to give acetoacetyl CoA (Figure 27.15). Cleavage by thiolase then yields two molecules of acetyl CoA, which enter the citric acid cycle. In essence, *ketone bodies are equivalents of fatty acids that are an accessible fuel source for the brain*. Only 40 g of glucose is then needed per day for the brain, compared with about 120 g in the first day of starvation. *The effective conversion of fatty acids into ketone bodies by the liver and their use by the brain markedly diminishes the need for glucose. Hence, less muscle is degraded than in the first days of starvation*. The breakdown of 20 g of muscle daily compared with 75 g early in starvation is most important for survival. A person's survival time is mainly determined by the size of the triacylglycerol depot.

What happens after depletion of the triacylglycerol stores? The only source of fuel that remains is protein. Protein degradation accelerates, and death inevitably results from a loss of heart, liver, or kidney function.

## 27.6 Ethanol Alters Energy Metabolism in the Liver

Ethanol has been a part of the human diet for centuries, partly because of its intoxicating effects and partly because alcoholic beverages provided a safe means of hydration when pure water was scarce. However, its consumption

**FIGURE 27.14** Synthesis of ketone bodies by the liver.

**FIGURE 27.15** Entry of ketone bodies into the citric acid cycle.

in excess can result in a number of health problems, most notably liver damage. What is the biochemical basis of these health problems?

### Ethanol metabolism leads to an excess of NADH

Ethanol cannot be excreted and must be metabolized, primarily by the liver. This metabolism is accomplished by two pathways. The first pathway comprises two steps. The first step, catalyzed by the enzyme *alcohol dehydrogenase*, takes place in the cytoplasm:

The second step, catalyzed by *aldehyde dehydrogenase*, takes place in mitochondria:

Note that *ethanol consumption leads to an accumulation of NADH*. This high concentration of NADH inhibits gluconeogenesis by preventing the oxidation of lactate to pyruvate. In fact, the high concentration of NADH will cause the reverse reaction to predominate, and lactate will accumulate. The consequences may be hypoglycemia and lactic acidosis.

The overabundance of NADH also inhibits fatty acid oxidation. An important metabolic purpose of fatty acid oxidation is to generate NADH for ATP generation by oxidative phosphorylation, but an alcohol consumer's NADH needs are met by ethanol metabolism. In fact, the excess NADH signals that conditions are right for fatty acid synthesis. Hence, triacylglycerols accumulate in the liver, leading to a condition known as "fatty liver" that is exacerbated in obese persons. The biochemical effects of ethanol consumption can be quite rapid. For instance, fat accumulates in the liver within a few days of moderate alcohol consumption. This accumulation is reversible with a decrease in alcohol intake.

The second pathway for ethanol metabolism uses cytochrome P450 enzymes. This means of ethanol metabolism is also called the *microsomal ethanol-oxidizing system* (MEOS). This cytochrome P450-dependent pathway (Section 26.4) generates acetaldehyde and subsequently acetate while oxidizing biosynthetic reducing power, NADPH, to NADP<sup>+</sup>. Because it uses oxygen, this pathway generates free radicals that damage tissues. Moreover, because the system consumes NADPH, the antioxidant glutathione cannot be regenerated (Section 20.5), exacerbating the oxidative stress.

What are the effects of the other metabolites of ethanol? Liver mitochondria can convert acetate into acetyl CoA in a reaction requiring ATP. The enzyme is the thiokinase that normally activates short-chain fatty acids.

However, further processing of the acetyl CoA by the citric acid cycle is blocked, because NADH inhibits two important citric acid cycle regulatory enzymes—*isocitrate dehydrogenase* and *α-ketoglutarate dehydrogenase*. The accumulation of acetyl CoA has several consequences. First, ketone bodies will form and be released into the blood, aggravating the acidic condition already resulting from the high lactate concentration. The processing of the acetate in the liver becomes inefficient, leading to a buildup of acetaldehyde. This very reactive compound forms covalent bonds with many

important functional groups in proteins, impairing protein function. If ethanol is consistently consumed at high levels, the acetaldehyde can significantly damage the liver, eventually leading to cell death.

Liver damage from excessive ethanol consumption occurs in three stages. The first stage is the aforementioned development of fatty liver. In the second stage—alcoholic hepatitis—groups of cells die and inflammation results. This stage can itself be fatal. In stage three—cirrhosis—fibrous structure and scar tissue are produced around the dead cells. Cirrhosis impairs many of the liver's biochemical functions. The cirrhotic liver is unable to convert ammonia into urea, and blood levels of ammonia rise. Ammonia is toxic to the nervous system and can cause coma and death. Cirrhosis of the liver arises in about 25% of alcoholics, and about 75% of all cases of liver cirrhosis are the result of alcoholism. Viral hepatitis is a non-alcoholic cause of liver cirrhosis.

### Excess ethanol consumption disrupts vitamin metabolism

The adverse effects of ethanol are not limited to the metabolism of ethanol itself. Vitamin A (retinol) is converted into retinoic acid, an important signal molecule for growth and development in vertebrates, by the same dehydrogenases that metabolize ethanol. Consequently, this activation does not take place in the presence of ethanol, which acts as a competitive inhibitor. Moreover, the P450 enzymes induced by ethanol inactivate retinoic acid. These disruptions in the retinoic acid signaling pathway are believed to be responsible, at least in part, for fetal alcohol syndrome as well as the development of a variety of cancers.

The disruption of vitamin A metabolism is a direct result of the biochemical changes induced by excess ethanol consumption. Other disruptions in metabolism result from another common characteristic of alcoholics—malnutrition. Alcoholics will frequently drink instead of eating. A dramatic neurological disorder, referred to as *Wernicke–Korsakoff syndrome*, results from insufficient intake of the vitamin thiamine. Symptoms include mental confusion, unsteady gait, and lack of fine motor skills. The symptoms of Wernicke–Korsakoff syndrome are similar to those of beriberi (Section 17.4) because both conditions result from a lack of thiamine. Thiamine is converted into the coenzyme thiamine pyrophosphate, a key constituent of the pyruvate dehydrogenase complex. Recall that this complex links glycolysis with the citric acid cycle. Disruptions in the pyruvate dehydrogenase complex are most evident as neuromuscular disorders because the nervous system is normally dependent on glucose for energy generation.

Alcoholic scurvy is occasionally observed because of an insufficient ingestion of vitamin C. Vitamin C is required for the formation of stable collagen fibers. The symptoms of scurvy include skin lesions and blood-vessel fragility. Most notable are bleeding gums, the loss of teeth, and periodontal infections. Gums are especially sensitive to a lack of vitamin C because the collagen in gums turns over rapidly. What is the biochemical basis for scurvy? Vitamin C is required for the synthesis of 4-hydroxyproline, an amino acid necessary for collagen stability. To form this unusual amino acid, proline residues on the amino side of glycine residues in nascent collagen chains become hydroxylated. One oxygen atom from  $O_2$  becomes attached to C-4 of proline while the other oxygen atom is taken up by  $\alpha$ -ketoglutarate, which is converted into succinate (Figure 27.16). This reaction is catalyzed by *prolyl hydroxylase*, a *dioxygenase*, which requires an  $Fe^{2+}$  ion to activate  $O_2$ . The enzyme also converts  $\alpha$ -ketoglutarate into succinate without hydroxylating proline. In this partial reaction, an oxidized iron complex is formed, which inactivates the enzyme. How is the active enzyme regenerated? *Ascorbate (vitamin C)* comes to the rescue by reducing the ferric ion of

**FIGURE 27.16 Formation of 4-hydroxyproline.** Proline is hydroxylated at C-4 by the action of prolyl hydroxylase, an enzyme that activates molecular oxygen.

the inactivated enzyme. In the recovery process, ascorbate is oxidized to dehydroascorbic acid (Figure 27.17). Thus, ascorbate serves here as a specific *antioxidant*. Why does impaired hydroxylation have such devastating consequences? *Collagen synthesized in the absence of ascorbate is less stable than the normal protein.* Hydroxyproline stabilizes the collagen triple helix by forming interstrand hydrogen bonds. The abnormal fibers formed by insufficiently hydroxylated collagen account for the symptoms of scurvy.

**FIGURE 27.17 Forms of ascorbic acid (vitamin C).** Ascorbate is the ionized form of vitamin C, and dehydroascorbic acid is the oxidized form of ascorbate.

## SUMMARY

### 27.1 Caloric Homeostasis Is a Means of Regulating Body Weight

Many people are able to maintain a near-constant body weight throughout adult life. This ability is a demonstration of caloric homeostasis, a physiological condition in which energy needs match energy intake. When energy intake is greater than energy needs, weight gain results. In the developed world, obesity is at epidemic proportions and is implicated as a contributing factor in a host of pathological conditions.

### 27.2 The Brain Plays a Key Role in Caloric Homeostasis

Various signal molecules act on the brain to control appetite. Short-term signals such as CCK and GLP-1 relay satiety signals to the brain while eating is in progress. Long-term signals include leptin and insulin. Leptin, secreted by adipose tissue in direct proportion to adipose-tissue mass, is an indication of fat stores. Leptin inhibits eating. Insulin also works in the brain, signaling carbohydrate availability.

Leptin acts by binding to a receptor in brain neurons, which initiates signal-transduction pathways that reduce appetite. Obesity can develop in individuals with normal amounts of leptin and the leptin receptor, suggesting that such individuals are leptin resistant. Suppressors of cytokine signaling may inhibit leptin signaling, leading to leptin resistance and obesity.

### 27.3 Diabetes Is a Common Metabolic Disease Often Resulting from Obesity

Diabetes is the most common metabolic disease in the world. Type 1 diabetes results when insulin is absent due to autoimmune destruction of the  $\beta$  cells of the pancreas. Type 2 diabetes is characterized by normal or higher levels of insulin, but the target tissues of insulin, notably muscle, do not respond to the hormone, a condition called insulin resistance. Obesity is a significant predisposing factor for type 2 diabetes.

In muscle, excess fats accumulate in an obese individual. These fats are processed to second messengers that activate signal-transduction pathways that inhibit insulin signaling, leading to insulin resistance. Insulin resistance in target tissues ultimately leads to pancreatic  $\beta$ -cell failure. The pancreas tries to compensate for a lack of insulin action by synthesizing more insulin, resulting in ER stress and subsequent activation of apoptotic pathways that lead to  $\beta$ -cell death.

Type 1 diabetes is due to metabolic derangements resulting in an insufficiency of insulin and an excess of glucagon relative to a person's needs. The result is an elevated blood-glucose level, the mobilization of triacylglycerols, and excessive ketone-body formation. Accelerated ketone-body formation can lead to acidosis, coma, and death in untreated insulin-dependent diabetics.

### 27.4 Exercise Beneficially Alters the Biochemistry of Cells

Exercise is a useful prescription for insulin resistance and type 2 diabetes. Muscle activity stimulates mitochondrial biogenesis in a calcium-dependent manner. The increase in the number of mitochondria facilitates fatty acid oxidation in the muscle, resulting in increased insulin sensitivity.

Fuel choice in exercise is determined by the intensity and duration of the bout of exercise. Sprinting and marathon running are powered by different fuels to maximize power output. The 100-meter sprint is powered by stored ATP, creatine phosphate, and anaerobic glycolysis. In contrast, the oxidation of both muscle glycogen and fatty acids derived from adipose tissue is essential in the running of a marathon, a highly aerobic process.

### 27.5 Food Intake and Starvation Induce Metabolic Changes

Insulin signals the fed state; it stimulates the formation of glycogen and triacylglycerols and the synthesis of proteins. In contrast, glucagon signals a low blood-glucose level; it stimulates glycogen breakdown and gluconeogenesis by the liver and triacylglycerol hydrolysis by adipose tissue. After a meal, the rise in the blood-glucose level leads to an increased secretion of insulin and a decreased secretion of glucagon. Consequently, glycogen is synthesized in muscle and the liver. When the blood-glucose level drops several hours later, glucose is then formed by the degradation of glycogen and by the gluconeogenic pathway, and fatty acids are released by the hydrolysis of triacylglycerols. The liver and muscle then increasingly use fatty acids instead of glucose to meet their own energy needs so that glucose is conserved for use by the brain and the red blood cells.

The metabolic adaptations in starvation serve to minimize protein degradation. Large amounts of ketone bodies are formed by the liver from fatty acids and released into the blood within a few days after the onset of starvation. After several weeks of starvation, ketone bodies become the major fuel of the brain. The diminished need for glucose decreases the rate of muscle breakdown, and so the likelihood of survival is enhanced.

## 27.6 Ethanol Alters Energy Metabolism in the Liver

The oxidation of ethanol results in an unregulated overproduction of NADH, which has several consequences. A rise in the blood levels of lactic acid and ketone bodies causes a fall in blood pH, or acidosis. The liver is damaged because the excess NADH causes excessive fat formation as well as the generation of acetaldehyde, a reactive molecule. Severe liver damage can result.

## KEY TERMS

caloric homeostasis (energy homeostasis) (p. 801)	adiponectin (p. 806)	endoplasmic reticulum (ER) stress (p. 811)
cholecystokinin (CCK) (p. 804)	leptin resistance (p. 806)	unfolded protein response (UPR) (p. 811)
glucagon-like peptide 1 (GLP-1) (p. 805)	type 1 diabetes (p. 808)	starved–fed cycle (p. 816)
leptin (p. 805)	insulin resistance (p. 808)	glucose homeostasis (p. 816)
insulin (p. 805)	type 2 diabetes (p. 808)	
	metabolic syndrome (p. 809)	

## PROBLEMS

- Weight control.* As disturbing as the obesity epidemic is, an equally intriguing, almost amazing observation is that many people are able to maintain an approximately constant weight throughout adult life. A few simple calculations of a simplified situation illustrates how remarkable this feat is. Consider a 120-pound woman whose weight does not change significantly between the ages of 25 and 65. Let us say that the woman requires 8,400 kJ (2000 kcal) day<sup>-1</sup>. For simplicity's sake, let us assume that the woman's diet consists predominantly of fatty acids derived from lipids. The energy density of fatty acids is 38 kJ (9 kcal) g<sup>-1</sup>. How much food has she consumed over the 40 years in question?
- Spare tire.* Suppose that our test subject from problem 1 gained 55 pounds between the ages of 25 and 65 (a sadly common occurrence), and that her weight at 65 years of age is 175 pounds. Calculate how many excess calories she consumed per day to gain the 55 pounds over 40 years. Assume that our test subject is 5 feet 6 inches tall. What is her BMI? Would she be considered obese at 175 lbs?
- Depot fat.* Adipose tissue was once only considered a storage site for fat. Why is this view no longer considered correct?
- Balancing act.* What is meant by caloric homeostasis?
- Dynamic duo.* What are the key hormones responsible for maintaining caloric homeostasis?
- Dual roles.* What two biochemical roles does CCK play? GLP-1?
- Failure to communicate.* Leptin inhibits eating and is secreted in amounts in direct proportion to body fat. Moreover, obese people have normal amounts of leptin and leptin receptor. Why, then, do people become obese?
- Many signals.* Match the characteristic (a–i) with the appropriate hormone (1–6).
 

(a) Secreted by adipose tissue _____	1. leptin
(b) Stimulates liver gluconeogenesis _____	2. adiponectin
(c) GPCR pathway _____	3. GLP-1
(d) Satiety signal _____	4. CCK
(e) Enhances insulin secretion _____	5. insulin
(f) Secreted by the pancreas during a fast _____	6. glucagon
(g) Secreted after a meal _____	
(h) Stimulates glycogen synthesis _____	
(i) Missing in type 1 diabetes _____	
- A key chemical.* What are the sources of glucose 6-phosphate in liver cells?
- Neither option is good.* Differentiate between type 1 and type 2 diabetes.
- Fighting diabetes.* Leptin is considered an “anti-diabetogenic” hormone. Explain.
- Metabolic energy and power.* The rate of energy expenditure of a typical 70-kg person at rest is about 70 watts (W), like that of a light bulb.
 

(a) Express this rate in kilojoules per second and in kilocalories per second.
(b) How many electrons flow through the mitochondrial electron-transport chain per second under these conditions?
(c) Estimate the corresponding rate of ATP production.

(d) The total ATP content of the body is about 50 g. Estimate how often an ATP molecule turns over in a person at rest.

13. *Respiratory quotient (RQ)*. This classic metabolic index is defined as the volume of CO<sub>2</sub> released divided by the volume of O<sub>2</sub> consumed.

(a) Calculate the RQ values for the complete oxidation of glucose and of tripalmitoylglycerol.

(b) What do RQ measurements reveal about the contributions of different energy sources during intense exercise? (Assume that protein degradation is negligible.)

14. *Camel's hump*. Compare the H<sub>2</sub>O yield from the complete oxidation of 1 g of glucose with that of 1 g of tripalmitoylglycerol. Relate these values to the evolutionary selection of the contents of a camel's hump.

15. *Hungry–nourished*. What is meant by the starved–fed cycle?

16. *Of course, too much is bad for you*. What are the primary means of processing ethanol?

17. *Started out with burgundy, but soon hit the harder stuff*. Describe the three stages of ethanol consumption that lead to liver damage and possibly death.

18. *The wages of sin*. How long does a person have to jog to offset the calories obtained from eating 10 macadamia nuts (75 kJ, or 18 kcal, per nut)? (Assume an incremental power consumption of 400 W.)

19. *Sweet hazard*. Ingesting large amounts of glucose before a marathon might seem to be a good way of increasing the fuel stores. However, experienced runners do not ingest glucose before a race. What is the biochemical reason for their avoidance of this potential fuel? (Hint: Consider the effect of glucose ingestion on the level of insulin.)

20. *Lipodystrophy*. Lipodystrophy is a condition in which an individual lacks adipose tissue. The muscles and liver from such individuals are insulin resistant, and both tissues accumulate large amounts of triacylglycerols (hyperlipidemia). The administration of leptin partly ameliorates this condition. What does it indicate about the relation of adipose tissue to insulin action?

21. *Therapeutic target*. What would be the effect of a mutation in the gene for PTP1B (protein tyrosine phosphatase 1B) that inactivated the enzyme in a person who has type 2 diabetes?

22. *An effect of diabetes*. Insulin-dependent diabetes is often accompanied by hypertriglyceridemia, which is an excess blood level of triacylglycerols in the form of very low density lipoproteins. Suggest a biochemical explanation.

23. *Sharing the wealth*. The hormone glucagon signifies the starved state, yet it inhibits glycolysis in the liver. How

does this inhibition of an energy-production pathway benefit the organism?

24. *Compartmentation*. Glycolysis takes place in the cytoplasm, whereas fatty acid degradation takes place in mitochondria. What metabolic pathways depend on the interplay of reactions that take place in both compartments?

25. *Kwashiorkor*. The most common form of malnutrition in children in the world, kwashiorkor, is caused by a diet having ample calories but little protein. The high levels of carbohydrate result in high levels of insulin. What is the effect of high levels of insulin on

(a) lipid utilization?

(b) protein metabolism?

(c) Children suffering from kwashiorkor often have large distended bellies caused by water from the blood leaking into extracellular spaces. Suggest a biochemical basis for this condition.

26. *One for all, all for one*. How is the metabolism of the liver coordinated with that of skeletal muscle during strenuous exercise?

27. *A little help, please?* What is the advantage of converting pyruvate into lactate in skeletal muscle?

28. *Fuel choice*. What is the major fuel for resting muscle? What is the major fuel for muscle under strenuous work conditions?

29. *Hefty reimbursement*. Endurance athletes sometimes follow the exercise-and-diet plan described here: 7 days before an event, do exhaustive exercises so as to all but deplete glycogen stores. For the next 2 to 3 days, consume few carbohydrates and do moderate- to low-intensity exercises. Finally, 3 to 4 days before the event, consume a diet rich in carbohydrates. Explain the benefits of this regime.

30. *Oxygen deficit*. After light exercise, the oxygen consumed in recovery is approximately equal to the oxygen deficit, which is the amount of additional oxygen that would have been consumed had oxygen consumption reached steady state immediately. How is the oxygen consumed in recovery used?

31. *Excess post-exercise oxygen consumption*. The oxygen consumed after strenuous exercise stops is significantly greater than the oxygen deficit and is termed *excess post-exercise oxygen consumption* (EPOC). Why is so much more oxygen required after intense exercise?

32. *Psychotropic effects*. Ethanol is unusual in that it is freely soluble in both water and lipids. Thus, it has access to all regions of the highly vascularized brain. Although the molecular basis of ethanol action in the brain is not clear, ethanol evidently influences a number of neurotransmitter

receptors and ion channels. Suggest a biochemical explanation for the diverse effects of ethanol.

33. *Fiber type.* Skeletal muscle has several distinct fiber types. Type I is used primarily for aerobic activity, whereas type IIb is specialized for short, intense bursts of activity. How could you distinguish between these types of muscle fiber if you viewed them with an electron microscope?

34. *Tour de France.* Cyclists in the Tour de France (more than 2000 miles in 3 weeks) require about 836,000 kJ (200,000 kcal) of energy, or 41,840 kJ (10,000 kcal) day<sup>-1</sup> (a resting male requires, 8368 kJ, or 2000 kcal, day<sup>-1</sup>).

(a) With the assumptions that the energy yield of ATP is about 50.2 kJ (12 kcal) mol<sup>-1</sup> and that ATP has a molecular weight of 503 g mol<sup>-1</sup>, how much ATP would be expended by a Tour de France cyclist?

(b) Pure ATP can be purchased at a cost of approximately \$150 per gram. How much would it cost to power a cyclist through the Tour de France if the ATP had to be purchased?

35. *Responding to stress.* Why does it make good physiological sense that regular bouts of prolonged exercise will result in mitochondrial biogenesis?

36. *Burning fats.* How does the activation of AMP-activated protein kinase (AMPK) during aerobic exercise foster the switch to fatty acid oxidation for distance running?

37. *Saving protein.* What metabolic and hormonal changes account for decreased gluconeogenesis during the first several weeks of starvation in humans?

38. *Did I do that!?* Alcohol consumption on an empty stomach results in some interesting biochemical as well as embarrassing behavioral alterations. We will ignore the latter. Gluconeogenesis falls; there are increases in intracellular ratios of lactate to pyruvate, of glycerol 3-phosphate to dihydroxyacetone phosphate, of glutamate to  $\alpha$ -ketoglutarate, and of D-3-hydroxybutyrate to acetoacetate. Hypoglycemia develops rapidly. Blood pH also falls. Alcohol consumption by a well-fed individual does not lead to hypoglycemia or alteration in blood pH.

(a) Why does ethanol consumption result in the altered ratios?

(b) Why does hypoglycemia and blood acidosis result in the hungry individual?

(c) Why does the well-fed person not experience hypoglycemia?

39. *Skip the candy bar.* Humans can survive longer by total fasting than on a diet consisting entirely of small amounts of carbohydrates. What is going on?

40. *Too much of a good thing.* What is the relation between fatty acid oxidation and insulin resistance in the muscle?

41. *Aneurin? Really?* Why are the symptoms of beriberi similar to those of Wernicke–Korsakoff syndrome?

### Data Interpretation Problem

42. *Lactate threshold.* The graph shows the relation between blood-lactate levels, oxygen consumption, and heart rate during exercise of increasing intensity. The values for oxygen consumption and heart rate are indicators of the degree of exertion.

(a) Why is some lactate produced even when exercise is moderate?

(b) Biochemically, what is taking place when the lactate concentration begins to rise rapidly, a point called the lactate threshold?

(c) Endurance athletes will sometimes measure blood-lactate levels during training so that they know their lactate threshold. Then, during events, they will race just at or below their lactate threshold until the late stages of the race. Biochemically, why is this practice wise?

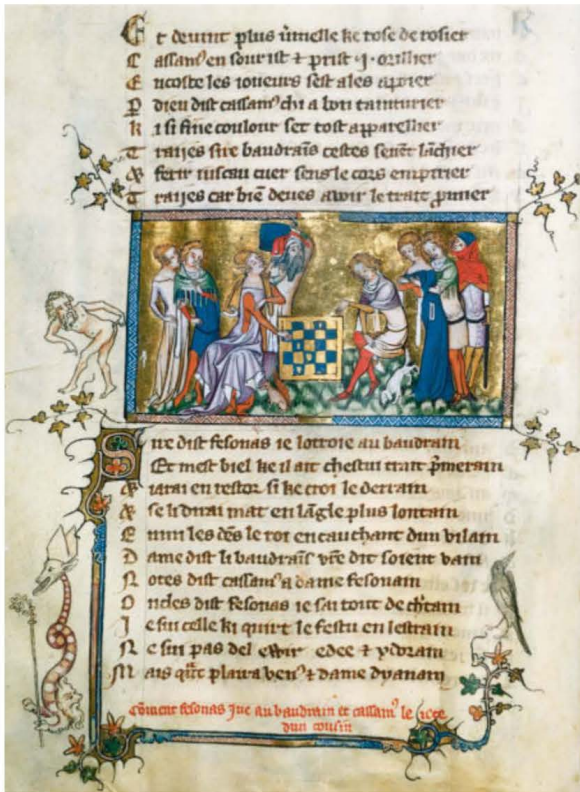

(d) Training can increase the lactate threshold. Explain.

### Chapter Integration Problems

43. *Feeling the burn.* Under certain circumstances, the respiratory quotient (RQ value) for an athlete exercising intensely can rise above one. How is this possible?

44. *So many channels.* Like cable TV. Describe the role of ion channels in insulin secretion by the  $\beta$  cells of the pancreas.

# DNA Replication, Repair, and Recombination

Faithful copying is essential to the storage of genetic information. With the precision of a diligent monk copying an illuminated manuscript, a DNA polymerase (above) copies DNA strands, preserving the precise sequence of bases with very few errors. [(Left) The Pierpont Morgan Library/Art Resource.]

Perhaps the most exciting aspect of the structure of DNA deduced by Watson and Crick was, as expressed in their words, that the “specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material.” A double helix separated into two single strands can be replicated because each strand serves as a template on which its complementary strand can be assembled (Figure 28.1). To preserve the information encoded in DNA through many cell divisions, copying of the genetic information must be extremely faithful. To replicate the human genome without mistakes, an error rate of less than 1 bp per  $6 \times 10^9$  bp must be achieved. Such remarkable accuracy is achieved through a multi-layered system of accurate DNA synthesis (which has an error rate of 1 per  $10^3$ – $10^4$  bases inserted), proofreading during DNA synthesis (which reduces that error rate to approximately 1 per  $10^6$ – $10^7$  bp), and postreplication mismatch repair (which reduces the error rate to approximately 1 per  $10^9$ – $10^{10}$  bp).

Even after DNA has been initially replicated, the genome is still not safe. Although DNA is remarkably robust, ultraviolet light as well as a range of

- 28.4 Many Types of DNA Damage Can Be Repaired
- 28.5 DNA Recombination Plays Important Roles in Replication, Repair, and Other Processes

**FIGURE 28.1 DNA replication.** Each strand of one double helix (shown in blue) acts as a template for the synthesis of a new complementary strand (shown in red).

chemical species can damage DNA, introducing changes in the DNA sequence (mutations) or lesions that can block further DNA replication (Figure 28.2). All organisms contain DNA-repair systems that detect DNA damage and act to preserve the original sequence. Mutations in genes that encode components of DNA-repair systems are key factors in the development of cancer. Among the most potentially devastating types of DNA damage are double-stranded breaks in DNA. With both strands of the double helix broken in a local region, neither strand is intact to act as a template for future DNA synthesis. A mechanism used to repair such lesions relies on DNA recombination—that is, the reassortment of DNA sequences present on two different double helices. In addition to its role in DNA repair, recombination is crucial for the generation of genetic diversity in meiosis. Recombination is also the key to generating a highly diverse repertoire of genes for key molecules in the immune system (Chapter 34).

**FIGURE 28.2 DNA Replication, damage, and repair.** Some errors (shown as a black dot) may arise in the replication processes. Additional defects (shown in yellow), including modified bases, cross-links, and single- and double-strand breaks, are introduced into DNA by subsequent DNA-damaging reactions. Many of the errors are detected and subsequently repaired.

**FIGURE 28.3 DNA repair in action.** The bacterium *Deinococcus radiodurans* can reassemble its genome over the course of 3 hours after irradiation with gamma rays to fragment the genome into many pieces. To aid analysis, the genomic DNA samples were digested with a restriction enzyme that cuts at only a few sites within the genome. [Adapted from K. Zahradka et al., *Nature* 445:569–573, 2006.]

The bacterium *Deinococcus radiodurans* illustrates the extraordinary power of DNA repair systems. This bacterium was discovered in 1956 when scientists were studying the use of high doses of gamma radiation to sterilize canned meat. In some cases, the meat still spoiled due to the growth of a bacterial species that withstood doses of gamma radiation more than 1000 times larger than those that would kill a human being. Each *D. radiodurans* cell contains between 4 and 10 copies of its genome. Even when these bacterial chromosomes are broken into many fragments by the ionizing radiation, they can reassemble and recombine to regenerate the intact genome with essentially no loss of information (Figure 28.3). These cells can also survive extreme desiccation, that is, drying out, much better than other organisms. This ability is believed to be the selective advantage that favored the evolution of this and related species.

## 28.1 DNA Replication Proceeds by the Polymerization of Deoxyribonucleoside Triphosphates Along a Template

The base sequences of newly synthesized DNA must faithfully match the sequences of parent DNA. To achieve faithful replication, each strand within the parent double helix acts as a *template* for the synthesis of a new DNA strand with a complementary sequence. The building blocks for the synthesis of the new strands are deoxyribonucleoside triphosphates. They are added, one at a time, to the 3' end of an existing strand of DNA.

Although this reaction is in principle quite simple, it is significantly complicated by specific features of the DNA double helix. First, the two strands of the double helix run in opposite directions. Because DNA

strand synthesis always proceeds in the 5'-to-3' direction, the DNA replication process must have special mechanisms to accommodate the oppositely directed strands. Second, the two strands of the double helix interact with one another in such a way that the bases, key templates for replication, are on the inside of the helix. Thus, the two strands must be separated from each other so as to generate appropriate templates. Finally, the two strands of the double helix wrap around each other. Thus, strand separation also entails the unwinding of the double helix. This unwinding creates supercoils that must themselves be resolved as replication continues. We begin with a consideration of the chemistry that underlies the formation of the phosphodiester backbone of newly synthesized DNA.

### DNA polymerases require a template and a primer

*DNA polymerases* catalyze the formation of polynucleotide chains. Each incoming nucleoside triphosphate first forms an appropriate base pair with a base in the template. Only then does the DNA polymerase link the incoming base with the predecessor in the chain. Thus, *DNA polymerases are template-directed enzymes*.

DNA polymerases add nucleotides to the 3' end of a polynucleotide chain. The polymerase catalyzes the nucleophilic attack by the 3'-hydroxyl-group terminus of the polynucleotide chain on the  $\alpha$  phosphoryl group of the nucleoside triphosphate to be added (Figure 4.25). To initiate this reaction, DNA polymerases require a *primer* with a free 3'-hydroxyl group already base-paired to the template. They cannot start from scratch by adding nucleotides to a free single-stranded DNA template. RNA polymerase, in contrast, can initiate RNA synthesis without a primer, as we shall see in Chapter 29.

### All DNA polymerases have structural features in common

The three-dimensional structures of a number of DNA polymerase enzymes are known. The first such structure was elucidated by Tom Steitz and coworkers, who determined the structure of the so-called *Klenow fragment* of DNA polymerase I from *E. coli* (Figure 28.4). This fragment comprises two main parts of the full enzyme, including the polymerase unit. This unit approximates the shape of a right hand with domains that are referred to as the fingers, the thumb, and the palm. In addition to the polymerase, the Klenow fragment includes a domain with 3'  $\rightarrow$  5' *exonuclease* activity that participates in proofreading and correcting the polynucleotide product.

 DNA polymerases are remarkably similar in overall shape, although they differ substantially in detail. At least five structural classes have been identified; some of them are clearly homologous, whereas others appear to be the products of convergent evolution. In all cases, the finger and thumb domains wrap around DNA and hold it across the enzyme's active site, which comprises residues primarily from the palm domain. Furthermore, all DNA polymerases use similar strategies to catalyze the polymerase reaction, making use of a mechanism in which two metal ions take part.

### Two bound metal ions participate in the polymerase reaction

Like all enzymes with nucleoside triphosphate substrates, DNA polymerases require metal ions for activity. Examination of the structures of DNA polymerases with bound substrates and substrate analogs reveals the presence of two metal ions in the active site. One metal ion binds both the deoxynucleoside triphosphate (dNTP) and the 3'-hydroxyl group of the

#### Primer

The initial segment of a polymer that is to be extended on which elongation depends.

#### Template

A sequence of DNA or RNA that directs the synthesis of a complementary sequence.

 **FIGURE 28.4 DNA polymerase structure.** The first DNA polymerase structure determined was that of a fragment of *E. coli* DNA polymerase I called the Klenow fragment. Notice that, like other DNA polymerases, the polymerase unit resembles a right hand with fingers (blue), palm (yellow), and thumb (red). The Klenow fragment also includes an exonuclease domain that removes incorrect nucleotide bases. [Drawn from 1DPI.pdb.]

**FIGURE 28.5 DNA polymerase mechanism.** Two metal ions (typically,  $Mg^{2+}$ ) participate in the DNA polymerase reaction. One metal ion coordinates the 3'-hydroxyl group of the primer, whereas the other metal ion interacts only with the dNTP. The phosphoryl group of the nucleoside triphosphate bridges between the two metal ions. The hydroxyl group of the primer attacks the phosphoryl group to form a new O—P bond.

primer, whereas the other interacts only with the dNTP (Figure 28.5). The two metal ions are bridged by the carboxylate groups of two aspartate residues in the palm domain of the polymerase. These side chains hold the metal ions in the proper positions and orientations. The metal ion bound to the primer activates the 3'-hydroxyl group of the primer, facilitating its attack on the  $\alpha$  phosphoryl group of the dNTP substrate in the active site. The two metal ions together help stabilize the negative charge that accumulates on the pentacoordinate transition state. The metal ion initially bound to dNTP stabilizes the negative charge on the pyrophosphate product.

### The specificity of replication is dictated by complementarity of shape between bases

DNA must be replicated with high fidelity. Each base added to the growing chain should, with high probability, be the Watson–Crick complement of the base in the corresponding position in the template strand. The binding of the dNTP containing the proper base is favored by the formation of a base pair with its partner on the template strand. Although hydrogen bonding contributes to the formation of this base pair, overall shape complementarity is crucial. Studies show that a nucleotide with a base that is very similar in shape to adenine but lacks the ability to form base-pairing hydrogen bonds can still direct the incorporation of thymidine, both in vitro and in vivo (Figure 28.6).

**FIGURE 28.6 Shape complementarity.** The base analog on the right has the same shape as adenosine, but groups that form hydrogen bonds between base pairs have been replaced by groups (shown in red) not capable of hydrogen bonding. Nonetheless, studies reveal that, when incorporated into the template strand, this analog directs the insertion of thymidine in DNA replication.

**FIGURE 28.7 Minor-groove interactions.** DNA polymerases donate two hydrogen bonds to base pairs in the minor groove. Hydrogen-bond acceptors are present in these two positions for all Watson–Crick base pairs, including the A—T base pair shown.

An examination of the crystal structures of various DNA polymerases reveals why shape complementarity is so important. First, residues of the enzyme form hydrogen bonds with *the minor-groove side of the base pair in the active site* (Figure 28.7). In the minor groove, hydrogen-bond acceptors are present in the same positions for all Watson–Crick base pairs. These interactions act as a “ruler” that measures whether a properly spaced base pair has formed in the active site.

Second, DNA polymerases close down around the incoming dNTP (Figure 28.8). The binding of a deoxyribonucleoside triphosphate into the active site of a DNA polymerase triggers a conformational change: the finger domain rotates to form a tight pocket into which only a properly shaped base pair will readily fit. Many of the residues lining this pocket are important to ensure the efficiency and fidelity of DNA synthesis. For example, mutation of a conserved tyrosine residue that forms part of the pocket results in a polymerase that is approximately 40 times as error prone as the parent polymerase.

**FIGURE 28.8 Shape selectivity.** The binding of a deoxyribonucleoside triphosphate (dNTP) to DNA polymerase induces a conformational change, generating a tight pocket for the base pair consisting of the dNTP and its partner on the template strand. Such a conformational change is possible only when the dNTP corresponds to the Watson–Crick partner of the template base. [Drawn from 2BDP.pdb and 1T7P.pdb.]

### An RNA primer synthesized by primase enables DNA synthesis to begin

DNA polymerases cannot initiate DNA synthesis without a primer, a section of nucleic acid having a free 3' end that forms a double helix with the template. How is this primer formed? An important clue came from the observation that RNA synthesis is essential for the initiation of DNA synthesis. In fact, *RNA primes the synthesis of DNA*. An RNA polymerase called *primase* synthesizes a short stretch of RNA (about five nucleotides) that is complementary to one of the template DNA strands (Figure 28.9). Primase, like other RNA polymerases, can initiate synthesis without a primer. After DNA synthesis has been initiated, the short stretch of RNA is removed by hydrolysis and replaced by DNA.

### One strand of DNA is made continuously, whereas the other strand is synthesized in fragments

Both strands of parental DNA serve as templates for the synthesis of new DNA. The site of DNA synthesis is called the *replication fork* because the complex formed by the newly synthesized daughter helices arising from the parental duplex resembles a two-pronged fork. Recall that the two strands are antiparallel; that is, they run in opposite directions. During DNA replication, both daughter strands appear on cursory examination to grow in the same direction. However, all known DNA polymerases synthesize DNA in the 5' → 3' direction but not in the 3' → 5' direction. How then does one of the daughter DNA strands appear to grow in the 3' → 5' direction?

This dilemma was resolved by Reiji Okazaki, who found that *a significant proportion of newly synthesized DNA exists as small fragments*. These units of about a thousand nucleotides (called *Okazaki fragments*) are present briefly in the vicinity of the replication fork (Figure 28.10).

**FIGURE 28.9 Priming.** DNA replication is primed by a short stretch of RNA that is synthesized by primase, an RNA polymerase. The RNA primer is removed at a later stage of replication.

**FIGURE 28.10 Okazaki fragments.** At a replication fork, both strands are synthesized in the 5' → 3' direction. The leading strand is synthesized continuously, whereas the lagging strand is synthesized in short pieces termed Okazaki fragments.

**FIGURE 28.11 DNA ligase reaction.** DNA ligase catalyzes the joining of one DNA strand with a free 3'-hydroxyl group to another with a free 5'-phosphoryl group. In eukaryotes and archaea, ATP is cleaved to AMP and  $PP_i$  to drive this reaction. In bacteria,  $NAD^+$  is cleaved to AMP and nicotinamide mononucleotide (NMN).

As replication proceeds, these fragments become covalently joined through the action of the enzyme DNA ligase to form a continuous daughter strand. The other new strand is synthesized continuously. The strand formed from Okazaki fragments is termed the *lagging strand*, whereas the one synthesized without interruption is the *leading strand*. The discontinuous assembly of the lagging strand enables  $5' \rightarrow 3'$  polymerization at the nucleotide level to give rise to overall growth in the  $3' \rightarrow 5'$  direction.

### DNA ligase joins ends of DNA in duplex regions

The joining of Okazaki fragments requires an enzyme that catalyzes the joining of the ends of two DNA chains. The existence of circular DNA molecules also points to the existence of such an enzyme. In 1967, scientists in several laboratories simultaneously discovered *DNA ligase*. This enzyme catalyzes the formation of a phosphodiester linkage between the 3'-hydroxyl group at the end of one DNA chain and the 5'-phosphoryl group at the end of the other (Figure 28.11). An energy source is required to drive this thermodynamically uphill reaction. In eukaryotes and archaea, ATP is the energy source. In bacteria,  $NAD^+$  typically plays this role.

DNA ligase cannot link two molecules of single-stranded DNA or circularize single-stranded DNA. Rather, *ligase seals breaks in double-stranded DNA molecules*. The enzyme from *E. coli* ordinarily forms a phosphodiester bridge only if there are at least a few bases of single-stranded DNA on the end of a double-stranded fragment that can come together with those on another fragment to form base pairs. Ligase encoded by T4 bacteriophage can link two blunt-ended double-helical fragments, a capability that is exploited in recombinant DNA technology.

**FIGURE 28.12 Helicase structure.** The structure of the hexameric helicase from bacteriophage T7. One of the six subunits is shown in yellow with the P-loop NTPase shown in purple. The loops that participate in DNA binding are highlighted by a yellow oval. Notice that each subunit interacts closely with its neighbors and that the DNA-binding loops line the hole in the center of the structure. [Drawn from 1E0K.pdb.]

### The separation of DNA strands requires specific helicases and ATP hydrolysis

For a double-stranded DNA molecule to replicate, the two strands of the double helix must be separated from each other, at least locally. This separation allows each strand to act as a template on which a new polynucleotide chain can be assembled. Specific enzymes, termed *helicases*, utilize the energy of ATP hydrolysis to power strand separation.

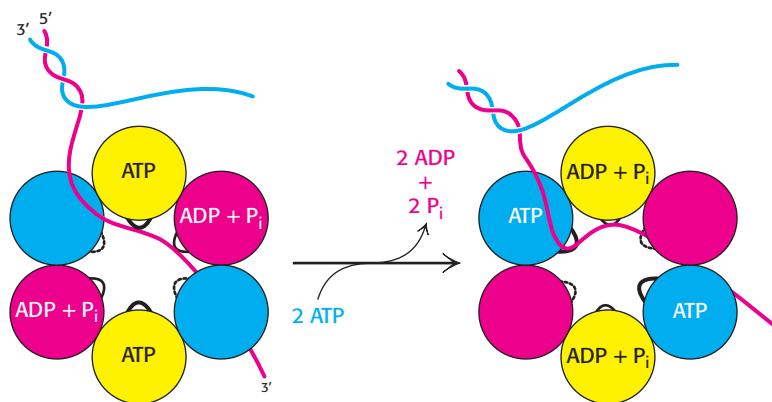

Helicases are a large and diverse family of enzymes taking part in many biological processes. The helicases in DNA replication are typically oligomers containing six subunits that form a ring structure. The structure of one such helicase, that from bacteriophage T7, has been a source of considerable insight into the helicase mechanism (Figure 28.12). Each of the subunits within this hexameric structure has a core structure that includes a P-loop NTPase domain (Figure 9.49). In addition to the P-loop, each subunit has two loops that extend toward the center of the ring structure and interact with DNA. Each subunit interacts closely with its two neighbors within the ring structure. Closer examination of this structure reveals that the ring deviates significantly from six-fold symmetry. This deviation is even more

apparent when helicase is crystallized in the presence of the nonhydrolyzable ATP analog AMP-PNP.

The AMP-PNP binds to only four of the six subunits within the ring (Figure 28.13). Furthermore, the four nucleotide-binding sites are not identical but fall into two classes. One class appears to be well positioned to bind ATP but not catalyze its hydrolysis, whereas the other class is more well suited to catalyze the hydrolysis but not release the hydrolysis products. The classes are analogous to myosin's two different conformations—one for binding ATP and one for hydrolyzing it (Section 9.4). Finally, the six subunits fall into three classes with regard to their orientation with respect to the overall ring structure, with differences in rotation around an axis in the plane of the ring of approximately  $30^\circ$ . These differences in orientation affect the position of the two DNA-binding loops in each subunit.

These observations are consistent with the following mechanism for the helicase (Figure 28.14). Only a single strand of DNA can fit through the center on the ring. This single strand binds to loops on two adjacent subunits, one of which has bound ATP and the other of which has bound  $\text{ADP} + \text{P}_i$ . The binding of ATP to the domains that initially had no bound nucleotides leads to a conformational change within the entire hexamer, leading to the release of  $\text{ADP} + \text{P}_i$  from two subunits and the binding of the single-stranded DNA by one of the domains that just bound ATP. This conformational change pulls the DNA through the center of the hexamer. The protein acts as a wedge, forcing the two strands of the double helix apart. This cycle then repeats itself, moving two bases along the DNA strand with each cycle.

**FIGURE 28.13 Helicase asymmetry.** The structure of the T7 helicase complexes with the ATP analog AMP-PNP is shown. The three classes of helicase subunits are shown in blue, red, and yellow. The rotation relative to the plane of the hexamer is shown for each subunit. Notice that only four of the subunits, those shown in blue and yellow, bind AMP-PNP. [Drawn from 1E0K.pdb.]

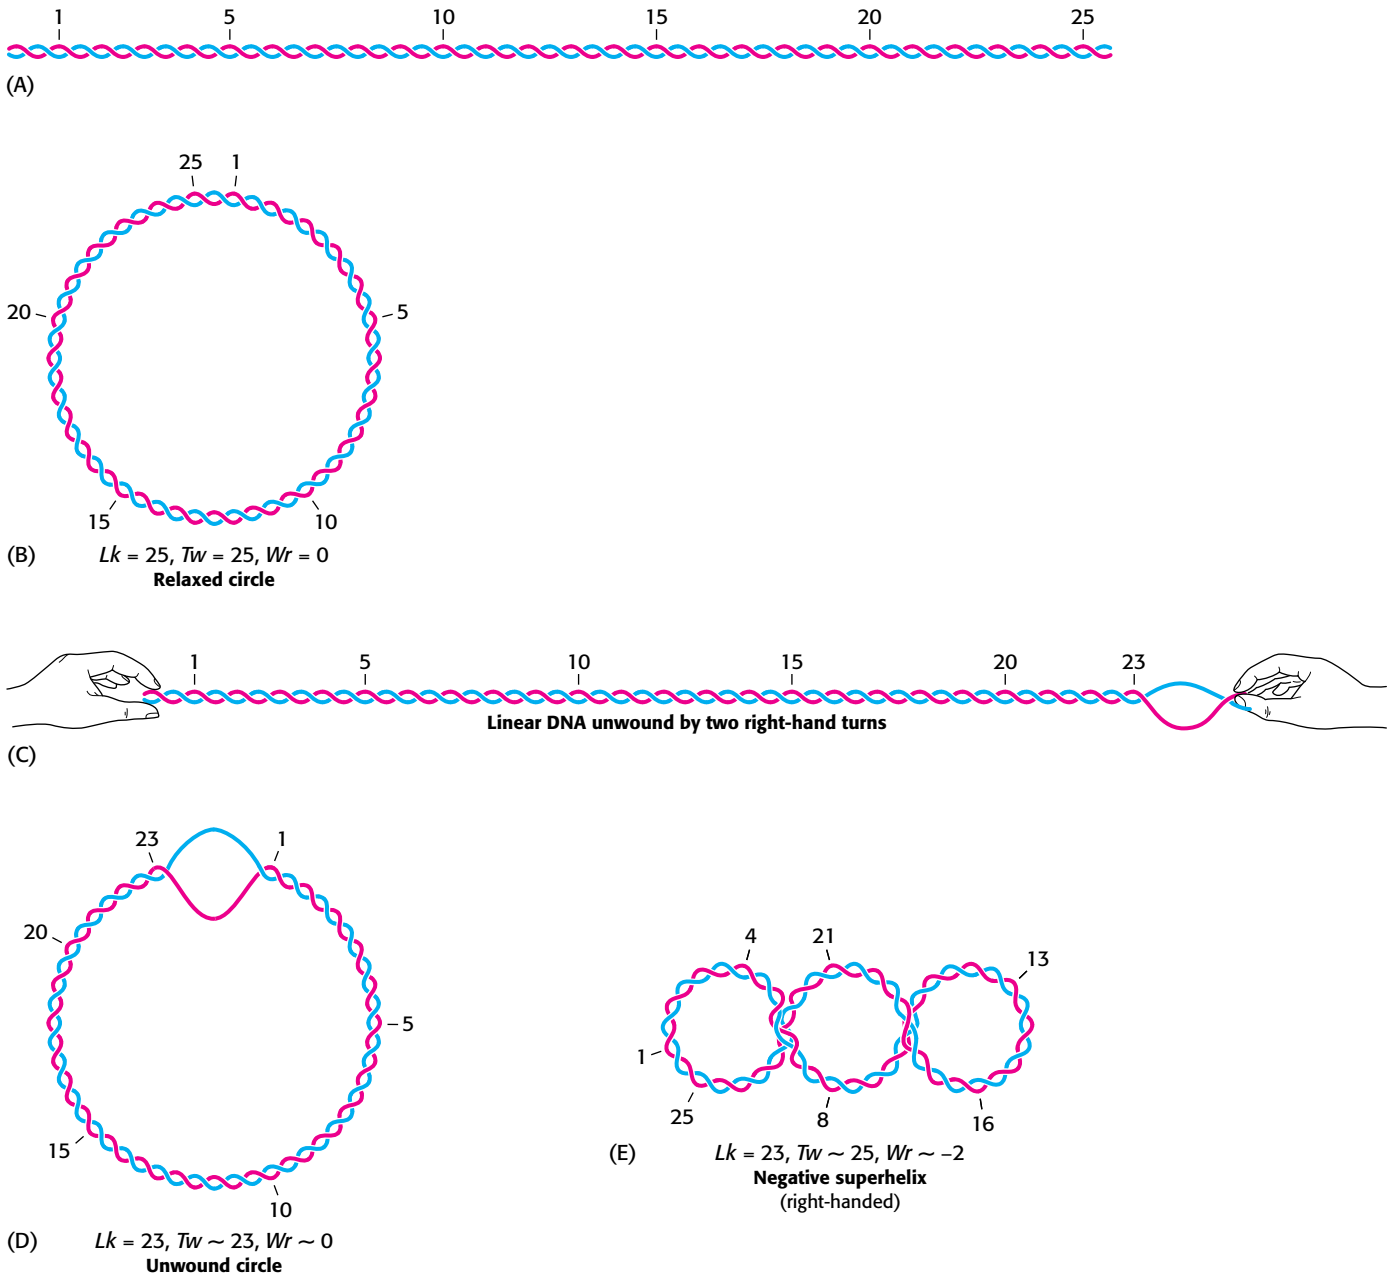

**FIGURE 28.14 Helicase mechanism.** One of the strands of the double helix passes through the hole in the center of the helicase, bound to the loops of two adjacent subunits. Two of the subunits do not contain bound nucleotides. On the binding of ATP to these two subunits and the release of  $\text{ADP} + \text{P}_i$  from two other subunits, the helicase hexamer undergoes a conformational change, pulling the DNA through the helicase. The helicase acts as a wedge to force separation of the two strands of DNA.

## 28.2 DNA Unwinding and Supercoiling Are Controlled by Topoisomerases

As a helicase moves along unwinding DNA, the DNA in front of the helicase will become overwound in the absence of other changes. As discussed in Section 4.2, DNA double helices that are torsionally stressed tend to fold

up on themselves to form tertiary structures created by *supercoiling*. We will first consider the supercoiling of DNA in quantitative terms and then turn to topoisomerases, enzymes that can directly modulate DNA winding and supercoiling. Supercoiling is most readily understood by considering circular DNA molecules, but it also applies to linear DNA molecules constrained to be in loops by other means. Most DNA molecules inside cells are subject to supercoiling.

Consider a linear 260-bp DNA duplex in the B-DNA form (Figure 28.15A). Because the number of base pairs per turn in an unstressed DNA molecule averages 10.4, this linear DNA molecule has 25 (260/10.4) turns. The ends of this helix can be joined to produce a *relaxed* circular DNA (Figure 28.15B). A different circular DNA can be formed by unwinding

**FIGURE 28.15 Linking number.** The relations between the linking number ( $Lk$ ), twisting number ( $Tw$ ), and writhing number ( $Wr$ ) of a circular DNA molecule revealed schematically. [Information from W. Saenger, *Principles of Nucleic Acid Structure* (Springer Verlag, 1984), p. 452.]

the linear duplex by two turns before joining its ends (Figure 28.15C). What is the structural consequence of unwinding before ligation? Two limiting conformations are possible. The DNA can fold into a structure containing 23 turns of B helix and an unwound loop (Figure 28.15D). Alternatively, the double helix can fold up to cross itself. Such crossings are called *supercoils*. In particular, a supercoiled structure with 25 turns of B helix and 2 turns of *right-handed* (termed *negative*) superhelix can be formed (Figure 28.15E).

Supercoiling markedly alters the overall form of DNA. A *supercoiled DNA molecule is more compact than a relaxed DNA molecule of the same length*. Hence, supercoiled DNA moves faster than relaxed DNA when analyzed by centrifugation or electrophoresis. Unwinding will cause supercoiling in circular DNA molecules, whether covalently closed or constrained in closed configurations by other means.

### The linking number of DNA, a topological property, determines the degree of supercoiling

Our understanding of the conformation of DNA is enriched by concepts drawn from topology, a branch of mathematics dealing with structural properties that are unchanged by deformations such as stretching and bending. A key topological property of a circular DNA molecule is its *linking number* ( $Lk$ ), which is equal to the number of times that a strand of DNA winds in the right-handed direction around the helix axis when the axis lies in a plane, as in Figure 28.15A. For the relaxed DNA shown in Figure 28.15B,  $Lk = 25$ . For the partly unwound molecule shown in part D and the supercoiled one shown in part E,  $Lk = 23$  because the linear duplex was unwound two complete turns before closure. Molecules differing only in linking number are *topological isomers*, or *topoisomers*, of one another. *Topoisomers of DNA can be interconverted only by cutting one or both DNA strands and then rejoining them.*

The unwound DNA and supercoiled DNA shown in Figure 28.15D and E are topologically identical but geometrically different. They have the same value of  $Lk$  but differ in *twist* ( $Tw$ ) and *writhe* ( $Wr$ ). Although the rigorous definitions of twist and writhe are complex, twist is a measure of the helical winding of the DNA strands around each other, whereas writhe is a measure of the coiling of the axis of the double helix—that is, supercoiling. A right-handed coil is assigned a negative number (negative supercoiling) and a left-handed coil is assigned a positive number (positive supercoiling).

Is there a relation between  $Tw$  and  $Wr$ ? Indeed, there is. Topology tells us that the sum of  $Tw$  and  $Wr$  is equal to  $Lk$ .

$$Lk = Tw + Wr$$

In Figure 28.15, the partly unwound circular DNA has  $Tw \sim 23$ , meaning the helix has 23 turns and  $Wr \sim 0$ , meaning the helix has not crossed itself to create a supercoil. The supercoiled DNA, however has  $Tw \sim 25$  and  $Wr \sim -2$ . These forms can be interconverted without cleaving the DNA chain because they have the same value of  $Lk$ —namely, 23. The partitioning of  $Lk$  (which must be an integer) between  $Tw$  and  $Wr$  (which need not be integers) is determined by energetics. The free energy is minimized when about 70% of the change in  $Lk$  is expressed in  $Wr$  and 30% is expressed in  $Tw$ . Hence, the most stable form would be one with  $Tw = 24.4$  and  $Wr = -1.4$ . Thus, a lowering of  $Lk$  causes both right-handed (negative) supercoiling of the DNA axis and unwinding of the duplex. Topoisomers differing by just 1 in  $Lk$ , and consequently

**FIGURE 28.16 Topoisomers.** An electron micrograph showing negatively supercoiled and relaxed DNA. [Courtesy of Dr. Jack Griffith.]

by 0.7 in  $Wr$ , can be readily separated by agarose gel electrophoresis because their hydrodynamic volumes are quite different; *supercoiling condenses DNA* (Figure 28.16).

### Topoisomerases prepare the double helix for unwinding

Most naturally occurring DNA molecules are negatively supercoiled. What is the basis for this prevalence? As already stated, negative supercoiling arises from the unwinding or underwinding of the DNA. In essence, negative supercoiling prepares DNA for processes requiring separation of the DNA strands, such as replication. Positive supercoiling condenses DNA as effectively, but it makes strand separation more difficult.

The presence of supercoils in the immediate area of unwinding would, however, make unwinding difficult. Therefore, negative supercoils must be continuously removed, and the DNA relaxed, as the double helix unwinds. Specific enzymes called *topoisomerases* that introduce or eliminate supercoils were discovered by James Wang and Martin Gellert. *Type I topoisomerases* catalyze the relaxation of supercoiled DNA, a thermodynamically favorable process. *Type II topoisomerases* utilize free energy from ATP hydrolysis to add negative supercoils to DNA. Both type I and type II topoisomerases play important roles in DNA replication as well as in transcription and recombination.

These enzymes alter the linking number of DNA by catalyzing a three-step process: (1) the *cleavage* of one or both strands of DNA, (2) the *passage* of a segment of DNA through this break, and (3) the *resealing* of the DNA break. Type I topoisomerases cleave just one strand of DNA, whereas type II enzymes cleave both strands. The two types of enzymes have several common features, including the use of key tyrosine residues to form covalent links to the polynucleotide backbone that is transiently broken.

### Type I topoisomerases relax supercoiled structures

The three-dimensional structures of several type I topoisomerases have been determined (Figure 28.17). These structures reveal many features of the reaction mechanism. Human type I topoisomerase comprises four domains, which are arranged around a central cavity having a diameter of 20 Å, just the correct size to accommodate a double-stranded DNA molecule. This cavity also includes a tyrosine residue (Tyr 723), which acts as a nucleophile to cleave the DNA backbone in the course of catalysis.

**FIGURE 28.17 Structure of topoisomerase I.** The structure of a complex between a fragment of human topoisomerase I and DNA is shown. Notice that DNA lies in a central cavity within the enzyme. [Drawn from 1EJ9.pdb.]

**FIGURE 28.18 Topoisomerase I mechanism.** On binding to DNA, topoisomerase I cleaves one strand of the DNA by means of a tyrosine (Y) residue attacking a phosphoryl group. When the strand has been cleaved, it rotates in a controlled manner around the other strand. The reaction is completed by religation of the cleaved strand. This process results in partial or complete relaxation of a supercoiled plasmid.

From analyses of these structures and the results of other studies, the relaxation of negatively supercoiled DNA molecules is known to proceed in the following manner (Figure 28.18). First, the DNA molecule binds inside the cavity of the topoisomerase. The hydroxyl group of tyrosine 723 attacks a phosphoryl group on one strand of the DNA backbone to form a phosphodiester linkage between the enzyme and the DNA, cleaving the DNA and releasing a free 5'-hydroxyl group.

With the backbone of one strand cleaved, the DNA can now rotate around the remaining strand, its movement driven by the release of energy stored because of the supercoiling. The rotation of the DNA unwinds the supercoils. The enzyme controls the rotation so that the unwinding is not rapid. The free hydroxyl group of the DNA attacks the phosphotyrosine residue to reseal the backbone and release tyrosine. The DNA is then free to dissociate from the enzyme. Thus, reversible cleavage of one strand of supercoiled DNA allows controlled rotation to partly relax the supercoils.

### Type II topoisomerases can introduce negative supercoils through coupling to ATP hydrolysis

Supercoiling requires an input of energy because a supercoiled molecule, in contrast with its relaxed counterpart, is torsionally stressed. The introduction of an additional supercoil into a 3000-bp plasmid typically requires about  $30 \text{ kJ mol}^{-1}$  ( $7 \text{ kcal mol}^{-1}$ ).

**FIGURE 28.19 Structure of topoisomerase II.** The dimeric structure of a typical topoisomerase II, that from the archaeon *Sulfolobus shibatae*. Notice that each half of the enzyme has one domain (shown in yellow) that contains a region for binding a DNA double helix and another domain (shown in green) that contains ATP binding sites. [Drawn from 2ZBK.pdb.]

Supercoiling can be catalyzed by type II topoisomerases. These elegant molecular machines couple the binding and hydrolysis of ATP to the directed passage of one DNA double helix through another, temporarily cleaved DNA double helix. These enzymes have several mechanistic features in common with the type I topoisomerases.

Topoisomerase II molecules are dimeric with a large internal cavity (Figure 28.19). The large cavity has gates at both the top and the bottom that are crucial to topoisomerase action. The reaction begins with the binding of one double helix (hereafter referred to as the G, for gate, segment) to the enzyme (Figure 28.20). Each strand is positioned next to a tyrosine residue, one from each monomer, capable of forming a covalent linkage with the DNA backbone. This complex then loosely binds a second DNA double helix (hereafter referred to as the T, for transported, segment). Each monomer of the enzyme has a domain that binds ATP; this ATP binding leads to a conformational change that strongly favors the coming together of the two domains. As these domains come closer together, they trap the bound T segment. This conformational change also forces the separation and cleavage of the two strands of the G segment. Each strand is linked to the enzyme by a tyrosine–phosphodiester bond. Unlike the type I enzymes,

**FIGURE 28.20 Topoisomerase II mechanism.** Topoisomerase II first binds one DNA duplex termed the G (for gate) segment. The binding of ATP to the two N-terminal domains brings these two domains together. This conformational change leads to the cleavage of both strands of the G segment and the binding of an additional DNA duplex, the T segment. This T segment then moves through the break in the G segment and out the bottom of the enzyme. The hydrolysis of ATP resets the enzyme with the G segment still bound. The orientation of the entering T segment results in the introduction of negative supercoils.

the type II topoisomerases hold the DNA tightly so that it cannot rotate. The T segment then passes through the cleaved G segment and into the large central cavity. The ligation of the G segment leads to the release of the T segment through the gate at the bottom of the enzyme. The hydrolysis of ATP and the release of ADP and orthophosphate allow the ATP-binding domains to separate, preparing the enzyme to bind another T segment. The overall process leads to a decrease in the linking number by two.

 The bacterial topoisomerase II (often called DNA gyrase) is the target of several antibiotics that inhibit the prokaryotic enzyme much more than the eukaryotic one. *Novobiocin* blocks the binding of ATP to gyrase. *Nalidixic acid* and *ciprofloxacin*, in contrast, interfere with the breakage and rejoining of DNA chains. These two gyrase inhibitors are widely used to treat urinary tract and other infections including those due to *Bacillus anthracis* (anthrax). *Camptothecin*, an antitumor agent, inhibits human topoisomerase I by stabilizing the form of the enzyme covalently linked to DNA.

## 28.3 DNA Replication Is Highly Coordinated

DNA replication must be very rapid, given the sizes of the genomes and the rates of cell division. The *E. coli* genome contains 4.6 million base pairs and is copied in less than 40 minutes. Thus, 2000 bases are incorporated per second. Enzyme activities must be highly coordinated to replicate entire genomes precisely and rapidly.

We begin our consideration of the coordination of DNA replication by looking at *E. coli*, which has been extensively studied. For this organism with a relatively small genome, replication begins at a single site and continues around the circular chromosome. The coordination of eukaryotic DNA replication is much more complex because there are many initiation sites throughout the genome and an additional enzyme is needed to replicate the ends of linear chromosomes.

### DNA replication requires highly processive polymerases

Replicative polymerases are characterized by their *very high catalytic potency, fidelity, and processivity*. *Processivity* refers to the ability of an enzyme to catalyze many consecutive reactions without releasing its substrate. These polymerases are assemblies of many subunits that have evolved to grasp their templates and not let go until many nucleotides have been added. The source of the processivity was revealed by the determination of the three-dimensional structure of the  $\beta_2$  subunit of the *E. coli* replicative polymerase called DNA polymerase III (Figure 28.21). This unit keeps the polymerase associated with the DNA double helix. It has the form of a star-shaped ring. A 35-Å-diameter hole in its center can readily accommodate a duplex DNA molecule and leaves enough space between the DNA and the protein to allow rapid sliding during replication. To achieve a

 **FIGURE 28.21 Structure of a sliding DNA clamp.** The dimeric  $\beta$  subunit of DNA polymerase III forms a ring that surrounds the DNA duplex. Notice the central cavity through which the DNA template slides. Clasping the DNA molecule in the ring, the polymerase enzyme is able to move without falling off the DNA substrate. [Drawn from 2POL.pdb.]

**Processive enzyme**

From the Latin *procedere*, “to go forward.”

An enzyme that catalyzes multiple rounds of the elongation or digestion of a polymer while the polymer stays bound. A *distributive enzyme*, in contrast, releases its polymeric substrate between successive catalytic steps.

catalytic rate of 1000 nucleotides polymerized per second requires that 100 turns of duplex DNA (a length of 3400 Å, or 0.34 mm) slide through the central hole of  $\beta_2$  per second. Thus,  $\beta_2$  plays a key role in replication by serving as a *sliding DNA clamp*.

How does DNA become entrapped inside the sliding clamp? Replicative polymerases also include assemblies of subunits that function as *clamp loaders*. These enzymes grasp the sliding clamp and, utilizing the energy of ATP binding, pull apart one of the interfaces between the two subunits of the sliding clamp. DNA can move through the gap, inserting itself through the central hole. ATP hydrolysis then releases the clamp, which closes around the DNA.

### The leading and lagging strands are synthesized in a coordinated fashion

Replicative polymerases such as DNA polymerase III synthesize the leading and lagging strands simultaneously at the replication fork (Figure 28.22). DNA polymerase III begins the synthesis of the leading strand starting from the RNA primer formed by primase. The duplex DNA ahead of the polymerase is unwound by a hexameric helicase called DnaB. Copies of single-stranded-binding protein (SSB) bind to the unwound strands, keeping the strands separated so that both strands can serve as templates. The leading strand is synthesized continuously by polymerase III. Topoisomerase II concurrently introduces right-handed (negative) supercoils to avert a topological crisis.

The mode of synthesis of the lagging strand is necessarily more complex. As mentioned earlier, the lagging strand is synthesized in fragments so that 5' → 3' polymerization leads to overall growth in the 3' → 5' direction. Yet the synthesis of the lagging strand is coordinated with the synthesis of the leading strand. How is this coordination accomplished? Examination of the subunit composition of the DNA polymerase III holoenzyme reveals an elegant solution (Figure 28.23). The holoenzyme includes two copies of the polymerase core enzyme, which consists of the DNA polymerase itself (the  $\alpha$  subunit); the  $\epsilon$  subunit, a 3'-to-5' proofreading exonuclease; another subunit called  $\theta$ ; and two copies of the dimeric  $\beta$ -subunit sliding clamp. The core enzymes are linked to a central structure having the subunit composition  $\gamma\tau_2\delta\delta'\chi\phi$ . The  $\gamma\tau_2\delta\delta'$  complex is the clamp loader, and the  $\chi$  and  $\phi$  subunits

**FIGURE 28.22 Replication fork.** A schematic view of the arrangement of DNA polymerase III and associated enzymes and proteins present in the replication of DNA. The helicase separates the two strands of the parent double helix, allowing DNA polymerases to use each strand as a template for DNA synthesis. Abbreviation: SSB, single-stranded-binding protein.

**FIGURE 28.23 DNA polymerase holoenzyme.** Each holoenzyme consists of two copies of the polymerase core enzyme, which comprises the  $\alpha$ ,  $\epsilon$ , and  $\theta$  subunits and two copies of the  $\beta$  subunit, linked to a central structure. The central structure includes the clamp-loader complex and the hexameric helicase DnaB.

interact with the single-stranded-DNA-binding protein. The entire apparatus interacts with the hexameric helicase DnaB. Eukaryotic replicative polymerases have similar, albeit slightly more complicated, subunit compositions and structures.

The lagging-strand template is looped out so that it passes through the polymerase site in one subunit of a dimeric polymerase III in the same direction as that of the leading-strand template in the other subunit,  $5' \rightarrow 3'$ . DNA polymerase III lets go of the lagging-strand template after adding about 1000 nucleotides by releasing the sliding clamp. A new loop is then formed, a sliding clamp is added, and primase again synthesizes a short stretch of RNA primer to initiate the formation of another Okazaki fragment. This mode of replication has been termed the *trombone model* because the size of the loop lengthens and shortens like the slide on a trombone (Figure 28.24).

**FIGURE 28.24 Trombone model.** The replication of the leading and lagging strands is coordinated by the looping out of the lagging strand to form a structure that acts somewhat as a trombone slide, growing as the replication fork moves forward. When the polymerase on the lagging strand reaches a region that has been replicated, the sliding clamp is released and a new loop is formed.

**FIGURE 28.25 Origin of replication in *E. coli*.** The *oriC* locus has a length of 245 bp. It contains a tandem array of three nearly identical 13-nucleotide sequences (green) and five binding sites (yellow) for the DnaA protein.

**FIGURE 28.26 Assembly of DnaA.**

Monomers of DnaA bind to their binding sites (shown in yellow) in *oriC* and come together to form a complex structure, possibly the cyclic hexamer shown here. This structure marks the origin of replication and favors DNA strand separation in the AT-rich sites (green).

**FIGURE 28.27 Prepriming complex.** The AT-rich regions are unwound and trapped by the single-stranded-binding protein (SSB). The hexameric DNA helicase DnaB is loaded on each strand. At this stage, the complex is ready for the synthesis of the RNA primers and assembly of the DNA polymerase III holoenzyme.

The gaps between fragments of the nascent lagging strand are filled by DNA polymerase I. This essential enzyme also uses its 5' → 3' exonuclease activity to remove the RNA primer lying ahead of the polymerase site. The primer cannot be erased by DNA polymerase III, because the enzyme lacks 5' → 3' editing capability. Finally, DNA ligase connects the fragments.

### DNA replication in *Escherichia coli* begins at a unique site

In *E. coli*, DNA replication starts at a unique site within the entire  $4.6 \times 10^6$  bp genome. This *origin of replication*, called the *oriC* locus, is a 245-bp region that has several unusual features (Figure 28.25). The *oriC* locus contains five copies of a sequence that is the preferred binding site for the origin-recognition protein DnaA. In addition, the locus contains a tandem array of 13-bp sequences that are rich in AT base pairs. Several steps are required to prepare for the start of replication:

1. *The binding of DnaA proteins to DNA is the first step in the preparation for replication.* DnaA is a member of the P-loop NTPase family related to the hexameric helicases. Each DnaA monomer comprises an ATPase domain linked to a DNA-binding domain at its C-terminus. DnaA molecules are able to bind to each other through their ATPase domains; a group of bound DnaA molecules will break apart on the binding and hydrolysis of ATP. The binding of DnaA molecules to one another signals the start of the preparatory phase, and their breaking apart signals the end of that phase. The DnaA proteins bind to the five high-affinity sites in *oriC* and then come together with DnaA molecules bound to lower-affinity sites to form an oligomer, possibly a cyclic hexamer. The DNA is wrapped around the outside of the DnaA hexamer (Figure 28.26).

2. *Single DNA strands are exposed in the prepriming complex.* With DNA wrapped around a DnaA hexamer, additional proteins are brought into play. The hexameric helicase DnaB is loaded around the DNA with the help of the helicase loader protein DnaC. Local regions of *oriC*, including the AT regions, are unwound and trapped by the single-stranded-DNA-binding protein. The result of this process is the generation of a structure called the *prepriming complex*, which makes single-stranded DNA accessible to other proteins (Figure 28.27). Significantly, the primase, DnaG, is now able to insert the RNA primer.

3. *The polymerase holoenzyme assembles.* The DNA polymerase III holoenzyme assembles on the prepriming complex, initiated by interactions between DnaB and the sliding-clamp subunit of DNA polymerase III. These interactions also trigger ATP hydrolysis within the DnaA subunits, signaling the initiation of DNA replication. The breakup of the DnaA

**FIGURE 28.28 Eukaryotic origins of replication.** The image shows a single molecule of DNA containing two origins of replication. The origins were identified by labeling new replicated DNA in human cells first with one thymine analog (iodo-deoxyuridine, I-dU) and then another (chloro-deoxyuridine, Cl-dU). DNA molecules from these cells were then extended on a microscope slide and labeled with antibodies to I-dU (green) and Cl-dU (red) to visualize the DNA. This method allows the detection of replication origins as well as determination of the rate of DNA synthesis. [Courtesy Aaron Bensimon. Data from C. Conti, et al., *Mol. Biol. Cell.* 18:3059-3067, 2007.]

assembly prevents additional rounds of replication from beginning at the replication origin.

### DNA synthesis in eukaryotes is initiated at multiple sites

Replication in eukaryotes is mechanistically similar to replication in prokaryotes but is more challenging for a number of reasons. One of them is sheer size: *E. coli* must replicate 4.6 million base pairs, whereas a human diploid cell must replicate more than 6 billion base pairs. Second, the genetic information for *E. coli* is contained on 1 chromosome, whereas, in human beings, 23 pairs of chromosomes must be replicated. Finally, whereas the *E. coli* chromosome is circular, human chromosomes are linear. Unless countermeasures are taken, linear chromosomes are subject to shortening with each round of replication.

The first two challenges are met by the use of multiple origins of replication. In human beings, replication requires about 30,000 origins of replication, with each chromosome containing several hundred. Each origin of replication is the starting site for a replication unit, or *replicon*. DNA replication can be monitored by single-molecule methods, revealing bidirectional synthesis from different sites (Figure 28.28). In contrast with *E. coli*, the origins of replication in human beings do not contain regions of sharply defined sequence. Instead, more broadly defined AT-rich sequences are the sites around which the *origin of replication complexes* (ORCs) are assembled.

1. *The assembly of the ORC is the first step in the preparation for replication.* In human beings, the ORC is composed of six different proteins, each homologous to DnaA. These proteins come together to form a hexameric structure analogous to the assembly formed by DnaA.
2. *Licensing factors recruit a helicase that exposes single strands of DNA.* After the ORC has been assembled, additional proteins are recruited, including Cdc6, a homolog of the ORC subunits, and Cdt1. These proteins, in turn, recruit a hexameric helicase with six distinct subunits called Mcm2-7. These proteins, including the helicase, are sometimes called *licensing factors* because they permit the formation of the initiation complex. After the initiation complex has formed, Mcm2-7 separates the parental DNA strands, and the single strands are stabilized by the binding of *replication protein A*, a single-stranded-DNA-binding protein.
3. *Two distinct polymerases are needed to copy a eukaryotic replicon.* An initiator polymerase called *polymerase  $\alpha$*  begins replication but is soon replaced by a more processive enzyme. This process is called *polymerase switching* because

TABLE 28.1 Some types of DNA polymerases

Name	Function
<b>Prokaryotic Polymerases</b>	
DNA polymerase I	Erases primer and fills in gaps on lagging strand
DNA polymerase II (error-prone polymerase)	DNA repair
DNA polymerase III	Primary enzyme of DNA synthesis
<b>Eukaryotic Polymerases</b>	
DNA polymerase $\alpha$	Initiator polymerase
Primase subunit	Synthesizes the RNA primer
DNA polymerase unit	Adds stretch of about 20 nucleotides to the primer
DNA polymerase $\beta$ (error-prone polymerase)	DNA repair
DNA polymerase $\delta$	Primary enzyme of DNA synthesis

one polymerase has replaced another. This second enzyme, called *DNA polymerase  $\delta$* , is the principal replicative polymerase in eukaryotes (Table 28.1).

Replication begins with the binding of DNA polymerase  $\alpha$ . This enzyme includes a primase subunit, used to synthesize the RNA primer, as well as an active DNA polymerase. After this polymerase has added a stretch of about 20 deoxynucleotides to the primer, another replication protein, called *replication factor C* (RFC), displaces DNA polymerase  $\alpha$ . Replication factor C attracts a sliding clamp called *proliferating cell nuclear antigen* (PCNA), which is homologous to the  $\beta_2$  subunit of *E. coli* polymerase III. The binding of PCNA to DNA polymerase  $\delta$  renders the enzyme highly processive and suitable for long stretches of replication. Replication continues in both directions from the origin of replication until adjacent replicons meet and fuse. RNA primers are removed and the DNA fragments are ligated by DNA ligase.

The use of multiple origins of replication requires mechanisms for ensuring that each sequence is replicated once and only once. The events of eukaryotic DNA replication are linked to the eukaryotic *cell cycle* (Figure 28.29). The processes of DNA synthesis and cell division are coordinated in the cell cycle so that the replication of all DNA sequences is complete before the cell progresses into the next phase of the cycle. This coordination requires several *checkpoints* that control the progression along the cycle. A family of small proteins termed *cyclins* are synthesized and degraded by proteasomal digestion in the course of the cell cycle. Cyclins act by binding to specific *cyclin-dependent protein kinases* and activating them. One such kinase, cyclin-dependent kinase 2 (cdk2) binds to assemblies at origins of replication and regulates replication through a number of interlocking mechanisms.

FIGURE 28.29 Eukaryotic cell cycle.

DNA replication and cell division must take place in a highly coordinated fashion in eukaryotes. Mitosis (M) takes place only after DNA synthesis (S). Two gaps ( $G_1$  and  $G_2$ ) in time separate the two processes.

### Telomeres are unique structures at the ends of linear chromosomes

Whereas the genomes of essentially all prokaryotes are circular, the chromosomes of human beings and other eukaryotes are linear. The free ends of linear DNA molecules introduce several complications that must be resolved by special enzymes. In particular, complete replication of DNA ends is difficult because polymerases act only in the  $5' \rightarrow 3'$  direction. The lagging strand would have an incomplete  $5'$  end after the removal of the RNA primer. Each round of replication would further shorten the chromosome.

The first clue to how this problem is resolved came from sequence analyses of the ends of chromosomes, which are called *telomeres* (from the Greek *telos*, “an end”). Telomeric DNA contains hundreds of tandem repeats of a six-nucleotide sequence. One of the strands is G rich at the  $3'$  end, and it is

slightly longer than the other strand. In human beings, the repeating G-rich sequence is AGGGTT.

The structure adopted by telomeres has been extensively investigated. Evidence suggests that they may form large duplex loops (Figure 28.30). The single-stranded region at the very end of the structure has been proposed to loop back to form a DNA duplex with another part of the repeated sequence, displacing a part of the original telomeric duplex. This loop-like structure is formed and stabilized by specific telomere-binding proteins. Such structures would nicely mask and protect the end of the chromosome.

### Telomeres are replicated by telomerase, a specialized polymerase that carries its own RNA template

How are the repeated sequences generated? An enzyme, termed *telomerase*, that executes this function has been purified and characterized. When a primer ending in GGTT is added to human telomerase in the presence of deoxynucleoside triphosphates, the sequences GGTTAGGGTT and GGTTAGGGTTAGGGTT, as well as longer products, are generated. Elizabeth Blackburn and Carol Greider discovered that the enzyme adding the repeats contains an RNA molecule that serves as the template for the elongation of the G-rich strand (Figure 28.31). Thus, telomerase carries the information necessary to generate the telomere sequences. The exact number of repeated sequences is not crucial.

Subsequently, a protein component of telomerases also was identified. This component is related to reverse transcriptases, enzymes first discovered in retroviruses that copy RNA into DNA (Section 5.2). Thus, *telomerase is a specialized reverse transcriptase that carries its own template*. Telomerase is generally expressed at high levels only in rapidly growing cells. Thus, telomeres and telomerase can play important roles in cancer-cell biology and in cell aging.

 Because cancer cells express high levels of telomerase, whereas most normal cells do not, telomerase is a potential target for anticancer therapy. A variety of approaches for blocking telomerase expression or blocking its activity are under investigation for cancer treatment and prevention.

## 28.4 Many Types of DNA Damage Can Be Repaired

We have examined how even very large and complex genomes can, in principle, be replicated with considerable fidelity. However, DNA does become damaged, both in the course of replication and through other processes. Damage to DNA can be as simple as the misincorporation of a single base or it can take more-complex forms such as the chemical modification of bases, chemical cross-links between the two strands of the double helix, or breaks in one or both of the phosphodiester backbones. The results may be cell death or cell transformation, changes in the DNA sequence that can be inherited by future generations, or blockage of the DNA replication process itself. A variety of DNA-repair systems have evolved that can recognize these defects and, in many cases, restore the DNA molecule to its undamaged form. We begin with some of the sources of DNA damage.

**FIGURE 28.30 Proposed model for telomeres.** A single-stranded segment of the G-rich strand extends from the end of the telomere. In one model for telomeres, this single-stranded region invades the duplex to form a large duplex loop.

**FIGURE 28.31 Telomere formation.** Mechanism of synthesis of the G-rich strand of telomeric DNA. The RNA template of telomerase is shown in blue and the nucleotides added to the G-rich strand of the primer are shown in red. [Information from E. H. Blackburn, *Nature* 350:569–573, 1991.]

## Errors can arise in DNA replication

Errors introduced in the replication process are the simplest source of damage in the double helix. With the addition of each base, there is the possibility that an incorrect base might be incorporated, forming a non-Watson–Crick base pair. These non-Watson–Crick base pairs can locally distort the DNA double helix. Furthermore, such mismatches can be *mutagenic*; that is, they can result in permanent changes in the DNA sequence. When a double helix containing a non-Watson–Crick base pair is replicated, the two daughter double helices will have different sequences because the mismatched base is very likely to pair with its Watson–Crick partner. Errors other than mismatches include insertions, deletions, and breaks in one or both strands. Furthermore, replicative polymerases can stall or even fall off a damaged template entirely. As a consequence, replication of the genome may halt before it is complete.

A variety of mechanisms have evolved to deal with such interruptions, including specialized DNA polymerases that can replicate DNA across many lesions. A drawback is that such polymerases are substantially more error prone than are normal replicative polymerases. Nonetheless, these *translesion* or *error-prone polymerases* allow the completion of a draft sequence of the genome that can be at least partly repaired by DNA-repair processes. DNA recombination (Section 28.5) provides an additional mechanism for salvaging interruptions in DNA replication.

**FIGURE 28.32 Oxoguanine–adenine base pair.** When guanine is oxidized to 8-oxoguanine, the damaged base can form a base pair with adenine through an edge of the base that does not normally participate in base-pair formation.

## Bases can be damaged by oxidizing agents, alkylating agents, and light

A variety of chemical agents can alter specific bases within DNA after replication is complete. Such *mutagens* include reactive oxygen species such as hydroxyl radical. For example, hydroxyl radical reacts with guanine to form 8-oxoguanine. 8-Oxoguanine is mutagenic because it often pairs with adenine rather than cytosine in DNA replication. Its choice of pairing partner differs from that of guanine because it uses a different edge of the base to form base pairs (Figure 28.32). Deamination is another potentially deleterious process. For example, adenine can be deaminated to form hypoxanthine (Figure 28.33). This process is mutagenic because hypoxanthine pairs with cytosine rather than thymine. Guanine and cytosine also can be deaminated to yield bases that pair differently from the parent base.

**FIGURE 28.33 Adenine deamination.** The base adenine can be deaminated to form hypoxanthine. Hypoxanthine forms base pairs with cytosine in a manner similar to that of guanine, and so the deamination reaction can result in mutation.

In addition to oxidation and deamination, nucleotide bases are subject to alkylation. Electrophilic centers can be attacked by nucleophiles such as N-7 of guanine and adenine to form alkylated adducts. Some compounds are converted into highly active electrophiles through the action of enzymes that normally play a role in detoxification. A striking example is aflatoxin B<sub>1</sub>, a compound produced by molds that grow on peanuts and other foods. A cytochrome P450 enzyme (Section 26.4) converts this compound into a

highly reactive epoxide (Figure 28.34). This agent reacts with the N-7 atom of guanosine to form a mutagenic adduct that frequently leads to a G–C-to-T–A transversion.

The ultraviolet component of sunlight is a ubiquitous DNA-damaging agent. Its major effect is to covalently link adjacent pyrimidine residues along a DNA strand (Figure 28.35). Such a pyrimidine dimer cannot fit into a double helix, and so replication and gene expression are blocked until the lesion is removed.

**FIGURE 28.35 Cross-linked dimer of two thymine bases.** Ultraviolet light induces cross-links between adjacent pyrimidines along one strand of DNA.

A thymine dimer is an example of an *intrastrand* cross-link because both participating bases are in the same strand of the double helix. Cross-links between bases on opposite strands also can be introduced by various agents. Psoralens are compounds, produced by a number of plants including the common fig, that form such *interstrand* cross-links (Figure 28.36). Interstrand cross-links disrupt replication because they prevent strand separation.

High-energy electromagnetic radiation such as x-rays can damage DNA by producing high concentrations of reactive species in solution. X-ray exposure can induce several types of DNA damage including single- and double-stranded breaks in DNA. This ability to induce such DNA damage led Hermann Muller to discover the mutagenic effects of x-rays in *Drosophila* in 1927. This discovery contributed to the development of *Drosophila* as one of the premier organisms for genetic studies.

### DNA damage can be detected and repaired by a variety of systems

To protect the genetic message, a wide range of DNA-repair systems are present in most organisms. Many systems repair DNA by using sequence information from the uncompromised strand. Such single-strand replication systems follow a similar mechanistic outline:

1. Recognize the offending base(s).
2. Remove the offending base(s).
3. Repair the resulting gap with a DNA polymerase and DNA ligase.

We will briefly consider examples of several repair pathways. Although many of these examples are taken from *E. coli*, corresponding repair systems are present in most other organisms, including humans.

The replicative DNA polymerases themselves are able to correct many DNA mismatches produced in the course of replication. For example, the  $\epsilon$  subunit of *E. coli* DNA polymerase III functions as a 3'-to-5' exonuclease. This domain removes mismatched nucleotides from the 3' end of DNA by hydrolysis. How does the enzyme sense whether a newly added base is correct? As a new strand of DNA is synthesized, it is *proofread*. If an incorrect base is inserted, then DNA synthesis slows down owing to the difficulty of threading

**FIGURE 28.34 Aflatoxin activation.** The compound, produced by molds that grow on peanuts, is activated by cytochrome P450 to form a highly reactive species that modifies bases such as guanine in DNA, leading to mutations.

**FIGURE 28.36 A cross-linking agent.** The compound psoralen and its derivatives can form interstrand cross-links through two reactive sites that can form adducts with nucleotide bases.

**FIGURE 28.37 Proofreading.** The growing polynucleotide chain occasionally leaves the polymerase site and migrates to the active site of the exonuclease. There, one or more nucleotides are excised from the newly synthesized chain, removing potentially incorrect bases.

**FIGURE 28.38 Mismatch repair.** DNA mismatch repair in *E. coli* is initiated by the interplay of MutS, MutL, and MutH proteins. A G—T mismatch is recognized by MutS. MutH cleaves the backbone in the vicinity of the mismatch. A segment of the DNA strand containing the erroneous T is removed by exonuclease I and synthesized anew by DNA polymerase III. [Information from R. F. Service, *Science* 263:1559–1560, 1994.]

a non-Watson–Crick base pair into the polymerase. In addition, the mismatched base is weakly bound and therefore able to fluctuate in position. The delay from the slowdown allows time for these fluctuations to take the newly synthesized strand out of the polymerase active site and into the exonuclease active site (Figure 28.37). There, the DNA is degraded, one nucleotide at a time, until it moves back into the polymerase active site and synthesis continues.

A second mechanism is present in essentially all cells to correct errors made in replication that are not corrected by proofreading (Figure 28.38). *Mismatch-repair* systems consist of at least two proteins, one for detecting the mismatch and the other for recruiting an endonuclease that cleaves the newly synthesized DNA strand close to the lesion to facilitate repair. In *E. coli*, these proteins are called MutS and MutL and the endonuclease is called MutH.

Another mechanism of DNA repair is *direct repair*, one example of which is the photochemical cleavage of pyrimidine dimers. Nearly all cells contain a *photoreactivating enzyme* called *DNA photolyase*. The *E. coli* enzyme, a 35-kd protein that contains bound  $N^5, N^{10}$ -methenyltetrahydrofolate and flavin adenine dinucleotide (FAD) cofactors, binds to the distorted region of DNA. The enzyme uses light energy—specifically, the absorption of a photon by the  $N^5, N^{10}$ -methenyltetrahydrofolate coenzyme—to form an excited state that cleaves the dimer into its component bases.

The excision of modified bases such as 3-methyladenine by the *E. coli* enzyme *AlkA* is an example of *base-excision repair*. The binding of this enzyme to damaged DNA flips the affected base out of the DNA double helix and into the active site of the enzyme (Figure 28.39). The enzyme then

**FIGURE 28.39 Structure of DNA-repair enzyme.** A complex between the DNA-repair enzyme AlkA and an analog of a DNA molecule missing a purine base (an apurinic site) is shown. Notice that the backbone sugar in the apurinic site is flipped out of the double helix into the active site of the enzyme. [Drawn from 1BNK.pdb.]

acts as a *glycosylase*, cleaving the glycosidic bond to release the damaged base. At this stage, the DNA backbone is intact, but a base is missing. This hole is called an *AP site* because it is apurinic (devoid of A or G) or apyrimidinic (devoid of C or T). An *AP endonuclease* recognizes this defect and nicks the backbone adjacent to the missing base. *Deoxyribose phosphodiesterase* excises the residual deoxyribose phosphate unit, and DNA polymerase I inserts an undamaged nucleotide, as dictated by the base on the undamaged complementary strand. Finally, the repaired strand is sealed by DNA ligase.

One of the best-understood examples of *nucleotide-excision repair* is utilized for the excision of a pyrimidine dimer. Three enzymatic activities are essential for this repair process in *E. coli* (Figure 28.40). First, an enzyme complex consisting of the proteins encoded by the *uvrABC* genes detects the distortion produced by the DNA damage. The UvrABC enzyme then cuts the damaged DNA strand at two sites, 8 nucleotides away from the damaged site on the 5' side and 4 nucleotides away on the 3' side. The 12-residue oligonucleotide excised by this highly specific *excinuclease* (from the Latin *exci*, "to cut out") then diffuses away. DNA polymerase I enters the gap to carry out repair synthesis. The 3' end of the nicked strand is the primer, and the intact complementary strand is the template. Finally, the 3' end of the newly synthesized stretch of DNA and the original part of the DNA chain are joined by DNA ligase.

DNA ligase is able to seal simple breaks in one strand of the DNA backbone. However, alternative mechanisms are required to repair breaks on both strands that are close enough together to separate the DNA into two double helices. Several distinct mechanisms are able to repair such damage. One mechanism, *nonhomologous end joining* (NHEJ), does not depend on other DNA molecules in the cell. In NHEJ, the free double-stranded ends are bound by a heterodimer of two proteins, Ku70 and Ku80. These proteins stabilize the ends and mark them for subsequent manipulations. Through mechanisms that are not yet well understood, the Ku70/80 heterodimers act as handles used by other proteins to draw the two double-stranded ends close together so that enzymes can seal the break.

Alternative mechanisms of double-stranded-break repair can operate if an intact stretch of double-stranded DNA with an identical or very similar sequence is present in the cell. These repair processes use homologous recombination, presented in Section 28.5.

As noted in Section 5.4, researchers can now take advantage of double-stranded-break repair mechanisms for executing targeted changes in eukaryotic genomes. Specific engineered nucleases are used to introduce double-strand breaks in particular locations within the genome. The DNA repair machinery in the targeted cells will then repair the break, through either NHEJ to disrupt the gene or homologous recombination-based repair with added double-stranded DNA fragments to introduce more elaborate modifications. For example, mutations associated with human diseases can be specifically introduced into the genomes of model organisms such as mice or zebrafish to examine the consequences.

### The presence of thymine instead of uracil in DNA permits the repair of deaminated cytosine

The presence in DNA of thymine rather than uracil, as in RNA, was an enigma for many years. Both bases pair with adenine. The only difference between them is a methyl group in thymine in place of the C-5 hydrogen atom in uracil. Why is a methylated base employed in DNA and

**FIGURE 28.40 Nucleotide-excision repair.** Repair of a region of DNA containing a thymine dimer by the sequential action of a specific excinuclease, a DNA polymerase, and a DNA ligase. The thymine dimer is shown in blue and the new region of DNA is in red. [Information from P. C. Hanawalt, *Endavour* 31:83, 1982.]

**FIGURE 28.41 Uracil repair.** Uracil bases in DNA, formed by the deamination of cytosine, are excised and replaced by cytosine.

not in RNA? The existence of an active repair system to correct the deamination of cytosine provides a convincing solution to this puzzle.

Cytosine in DNA spontaneously deaminates at a perceptible rate to form uracil. The deamination of cytosine is potentially mutagenic because uracil pairs with adenine, and so one of the daughter strands will contain a U–A base pair rather than the original C–G base pair. This mutation is prevented by a repair system that recognizes uracil to be foreign to DNA (Figure 28.41). The repair enzyme, *uracil DNA glycosylase*, is homologous to AlkA. The enzyme hydrolyzes the glycosidic bond between the uracil and deoxyribose moieties but does not attack thymine-containing nucleotides. The AP site generated is repaired to reinsert cytosine. Thus, *the methyl group on thymine is a tag that distinguishes thymine from deaminated cytosine*. If thymine were not used in DNA, uracil correctly in place would be indistinguishable from uracil formed by deamination. The defect would persist unnoticed, and so a C–G base pair would necessarily be mutated to U–A in one of the daughter DNA molecules. This mutation is prevented by a repair system that searches for uracil and leaves thymine alone. *Thymine is used instead of uracil in DNA to enhance the fidelity of the genetic message.*

### Some genetic diseases are caused by the expansion of repeats of three nucleotides

 Some genetic diseases are caused by the presence of DNA sequences that are inherently prone to errors in the course of repair and replication. A particularly important class of such diseases is characterized by the presence of long tandem arrays of repeats of three nucleotides. An example is *Huntington disease*, an autosomal dominant neurological disorder with a variable age of onset. The mutated gene in this disease expresses a protein in the brain called huntingtin, which contains a stretch of consecutive glutamine residues. These glutamine residues are encoded by a tandem array of CAG sequences within the gene. In unaffected persons, this array is between 6 and 31 repeats, whereas, in those with the disease, the array is between 36 and 82 repeats or longer. Moreover, the array tends to become longer from one generation to the next. The consequence is a phenomenon called *anticipation*: the children of an affected parent tend to show symptoms of the disease at an earlier age than did the parent.

The tendency of these *trinucleotide repeats* to expand is explained by the formation of alternative structures in the course of DNA repair. On cleavage of the DNA backbone, part of the array can loop out without disrupting base-pairing outside this region. Then, in replication, DNA polymerase extends this strand through the remainder of the array, leading to an increase in the number of copies of the trinucleotide sequence.

A number of other neurological diseases are characterized by expanding arrays of trinucleotide repeats. How do these long stretches of repeated amino acids cause disease? For huntingtin, it appears that the polyglutamine stretches become increasingly prone to aggregate as their length increases; the additional consequences of such aggregation are still under investigation.

### Many cancers are caused by the defective repair of DNA

 As described in Chapter 14, cancers are caused by mutations in genes associated with growth control. Defects in DNA-repair systems increase the overall frequency of mutations and, hence, the likelihood of cancer-causing mutations. Indeed, the synergy between studies of mutations that predispose people to cancer and studies of DNA repair

TABLE 28.2

Disease	Selected Genes	Repair Pathway
Xeroderma pigmentosum (skin)	XPA, XPB, XPC	Nucleotide excision repair
Lynch syndrome (colon cancer)	MSH2, MLH1	Mismatch repair
Breast and ovarian cancer	BRCA1 and BRCA2	Double-strand break repair
Renal and lung cancer	OGG1	Base excision repair

in model organisms has been tremendous in revealing the biochemistry of DNA-repair pathways. Genes for DNA-repair proteins are often *tumor suppressor genes*; that is, they suppress tumor development when at least one copy of the gene is free of a deleterious mutation. When both copies of a gene are mutated, however, tumors develop at rates greater than those for the population at large. People who inherit defects in a single tumor-suppressor allele do not necessarily develop cancer but are susceptible to developing the disease because only the one remaining normal copy of the gene must develop a new defect to further the development of cancer. Table 28.2 lists selected genes that are associated with diseases including cancer and that encode proteins involved with DNA repair processes.

Consider, for example, *xeroderma pigmentosum*, a rare human skin disease. The skin of an affected person is extremely sensitive to sunlight or ultraviolet light. In infancy, severe changes in the skin become evident and worsen with time. The skin becomes dry, and there is a marked atrophy of the dermis. Keratoses appear, the eyelids become scarred, and the cornea ulcerates. Skin cancer usually develops at several sites. Many patients die before age 30 from metastases of these malignant skin tumors. Studies of xeroderma pigmentosum patients have revealed that mutations occur in genes for a number of different proteins. These proteins are components of the human nucleotide-excision-repair pathway, including homologs of the UvrABC subunits.

Defects in other repair systems can increase the frequency of other tumors. For example, *hereditary nonpolyposis colorectal cancer* (HNPCC, or *Lynch syndrome*) results from defective DNA mismatch repair. HNPCC is not rare—as many as 1 in 200 people will develop this form of cancer. Mutations in two genes, called *hMSH2* and *hMLH1*, account for most cases of this hereditary predisposition to cancer. The striking finding is that these genes encode the human counterparts of MutS and MutL of *E. coli*. Mutations in *hMSH2* and *hMLH1* seem likely to allow mutations to accumulate throughout the genome. In time, genes important in controlling cell proliferation become altered, resulting in the onset of cancer.

Not all tumor-suppressor genes are specific to particular types of cancer. *The gene for a protein called p53 is mutated in more than half of all tumors.* The p53 protein helps control the fate of damaged cells. First, it plays a central role in sensing DNA damage, especially double-stranded breaks. Then, after sensing damage, the protein either promotes a DNA-repair pathway or activates the apoptosis pathway, leading to cell death. Most mutations in the p53 gene are sporadic; that is, they occur in somatic cells rather than being inherited. People who inherit a deleterious mutation in one copy of the p53 gene suffer from *Li-Fraumeni syndrome* and have a high probability of developing several types of cancer.

Cancer cells often have two characteristics that make them especially vulnerable to agents that damage DNA molecules. First, they divide frequently, and so their DNA replication pathways are more active than they

**FIGURE 28.42 Ames test.** (A) A petri plate containing about  $10^9$  *Salmonella* bacteria that cannot synthesize histidine and (B) a petri plate containing a filter-paper disc with a mutagen, which produces a large number of revertants that can synthesize histidine. After 2 days, the revertants appear as rings of colonies around the disc. The small number of visible colonies in plate A are spontaneous revertants. [Reprinted from *Mutation Research/Environmental Mutagenesis and Related Subjects*, 31:6, Ames, B.N., et al. Methods for detecting carcinogens and mutagens with the *Salmonella*/mammalian-microsome mutagenicity test, p. 347–363, Copyright 1975, with permission from Elsevier.]

are in most cells. Second, as already noted, cancer cells often have defects in DNA-repair pathways. Several agents widely used in cancer chemotherapy, including cyclophosphamide and cisplatin, act by damaging DNA. Cancer cells are less able to avoid the effect of the induced damage than are normal cells, providing a therapeutic window for specifically killing cancer cells.

### Many potential carcinogens can be detected by their mutagenic action on bacteria

Many human cancers are caused by exposure to chemicals that cause mutations. It is important to identify such compounds and to ascertain their potency so that human exposure to them can be minimized. Bruce Ames devised a simple and sensitive test for detecting chemical mutagens. In the *Ames test*, a thin layer of agar containing about  $10^9$  bacteria of a specially constructed tester strain of *Salmonella* is placed on a petri plate. These bacteria are unable to grow in the absence of histidine, because a mutation is present in one of the genes for the biosynthesis of this amino acid. The addition of a chemical mutagen to the center of the plate results in many new mutations. A small proportion of them reverse the original mutation, and histidine can be synthesized. These *revertants* multiply in the absence of an external source of histidine and appear as discrete colonies after the plate has been incubated at  $37^\circ\text{C}$  for 2 days (Figure 28.42). For example,  $0.5\ \mu\text{g}$  of 2-aminoanthracene gives 11,000 revertant colonies, compared with only 30 spontaneous revertants in its absence. A series of concentrations of a chemical can be readily tested to generate a dose-response curve.

Some of the tester strains are responsive to *base-pair substitutions*, whereas others detect *deletions or additions of base pairs (frameshifts)*. The sensitivity of these specially designed strains has been enhanced by the genetic deletion of their excision-repair systems. Potential mutagens enter the tester strains easily because the lipopolysaccharide barrier that normally coats the surface of *Salmonella* is incomplete in these strains. A key feature of this detection system is the inclusion of a *mammalian liver homogenate*. Recall that some potential carcinogens such as aflatoxin are converted into their active forms by enzyme systems in the liver or other mammalian tissues. Bacteria lack these enzymes, and so the test plate requires a few milligrams of a liver homogenate to activate this group of mutagens.

The *Salmonella* test is extensively used to help evaluate the mutagenic and carcinogenic risks of a large number of chemicals. This rapid and inexpensive bacterial assay for mutagenicity complements epidemiological surveys and animal tests that are necessarily slower, more laborious, and far more expensive. The *Salmonella* test for mutagenicity is an outgrowth of studies of gene-protein relations in bacteria. It is a striking example of how fundamental research in molecular biology can lead directly to important advances in public health.

## 28.5 DNA Recombination Plays Important Roles in Replication, Repair, and Other Processes

Most processes associated with DNA replication function to copy the genetic message as faithfully as possible. However, several biochemical processes require the *recombination* of genetic material between two DNA molecules. In genetic recombination, two daughter molecules are formed by the exchange of genetic material between two parent molecules (Figure 28.43). Recombination is essential in the following processes.

**FIGURE 28.43 Recombination.** Two DNA molecules can recombine with each other to form new DNA molecules that have segments from both parent molecules.

1. When replication stalls, recombination processes can reset the replication machinery so that replication can continue.
2. Some double-stranded breaks in DNA are repaired by recombination.
3. In meiosis, the limited exchange of genetic material between paired chromosomes provides a simple mechanism for generating genetic diversity in a population.
4. As we shall see in Chapter 34, recombination plays a crucial role in generating molecular diversity for antibodies and some other molecules in the immune system.
5. Some viruses employ recombination pathways to integrate their genetic material into the DNA of a host cell.
6. Recombination is used to manipulate genes in, for example, the generation of “gene knockout” mice and other targeted genome modifications (Section 5.4).

Recombination is most efficient between DNA sequences that are similar in sequence. In homologous recombination, parent DNA duplexes align at regions of sequence similarity, and new DNA molecules are formed by the breakage and joining of homologous segments.

### RecA can initiate recombination by promoting strand invasion

In many recombination pathways, a DNA molecule with a free end recombines with a DNA molecule having no free ends available for interaction. DNA molecules with free ends are the common result of double-stranded DNA breaks, but they may also be generated in DNA replication if the replication complex stalls. This type of recombination has been studied extensively in *E. coli*, but it also takes place in other organisms through the action of proteins homologous to those of *E. coli*. Often dozens of proteins participate in the complete recombination process. However, the key protein is *RecA*, the homolog of which is called RAD51 in human cells. To accomplish the exchange, the single-stranded DNA displaces one of the strands of the double helix (Figure 28.44). The resulting three-stranded structure is called a *displacement loop* or *D-loop*. This process is often referred to as *strand invasion*. Because a free 3' end is now base-paired to a contiguous strand of DNA, the 3' end can act as a primer to initiate new DNA synthesis. Strand invasion can initiate many processes, including the repair of double-stranded breaks and the reinitiation of replication after the replication apparatus has come off its template. In the repair of a break, the recombination partner is an intact DNA molecule with an overlapping sequence.

**FIGURE 28.44 Strand invasion.** This process, promoted by proteins such as *RecA*, can initiate recombination.

**FIGURE 28.45 Recombination mechanism.** Recombination begins as two DNA molecules come together to form a recombination synapse. One strand from each duplex is cleaved by transesterification with the 3' end of each of the cleaved strands linked to a tyrosine residue on the recombinase enzyme. New phosphodiester bonds are formed when a 5' end of the other cleaved strand in the complex attacks these tyrosine–DNA adducts. After isomerization, these steps are repeated to form the recombined products.

### Some recombination reactions proceed through Holliday-junction intermediates

In recombination pathways for meiosis and some other processes, intermediates form that are composed of four polynucleotide chains in a crosslike structure. Intermediates with these crosslike structures are often referred to as *Holliday junctions*, after Robin Holliday, who proposed their role in recombination in 1964. Such intermediates have been characterized by a wide range of techniques, including x-ray crystallography.

Specific enzymes, termed *recombinases*, bind to these structures and resolve them into separated DNA duplexes. The Cre recombinase from bacteriophage P1 has been extensively studied. The mechanism begins with the recombinase binding to the DNA substrates (Figure 28.45).

Four molecules of the enzyme and two DNA molecules come together to form a *recombination synapse*. The reaction begins with the cleavage of one strand from each duplex via transesterification reactions with the 3'-phosphoryl groups becoming linked to specific tyrosine residues in the recombinase while the 5'-hydroxyl group of each cleaved strand remains free. The free 5' ends invade the other duplex and participate in transesterification reactions to form new phosphodiester bonds and free the tyrosine residues. These reactions result in the formation of a Holliday junction. This junction can then isomerize to form a structure in which the polynucleotide chains in the center of the structure are reoriented. From this junction, the processes of strand cleavage and phosphodiester-bond formation repeat. The result is a synapse containing the two recombined duplexes. Dissociation of this complex generates the final recombined products.

Cre catalyzes the formation of Holliday junctions as well as their resolution. In contrast, other proteins bind to Holliday junctions that have already been formed by other processes and resolve them into separate duplexes. In many cases, these proteins also promote the process of branch migration whereby a Holliday junction is moved along the two component double helices. Branch migration can affect which segments of DNA are exchanged in a recombination process.

Recombination can also occur during cell division between different, non-homologous chromosomes. These recombination events, termed translocations, can be harmless or can result in diseases, depending on the chromosomes involved and the genes that are modified or disrupted. The formation of the *bcr-abl* gene, which leads to chronic myelogenous leukemia, was discussed in section 14.5.

## SUMMARY

### 28.1 DNA Replication Proceeds by the Polymerization of Deoxyribonucleoside Triphosphates Along a Template

DNA polymerases are template-directed enzymes that catalyze the formation of phosphodiester bonds by nucleophilic attack by the 3'-hydroxyl group on the innermost phosphorus atom of a deoxyribonucleoside 5'-triphosphate. The complementarity of shape between correctly matched nucleotide bases is crucial to ensuring the fidelity of base incorporation. DNA polymerases cannot start chains *de novo*; a primer with a free 3'-hydroxyl group is required. Thus, DNA synthesis is initiated by the synthesis of an RNA primer, the task of a specialized primase enzyme. After serving as a primer, the RNA is degraded and replaced by DNA. DNA polymerases always synthesize a DNA strand in the 5'-to-3' direction. So that both strands of the double helix can be synthesized in the same direction simultaneously, one strand is synthesized continuously while the other is synthesized in fragments called Okazaki fragments. Gaps between the fragments are sealed by DNA ligases. ATP-driven helicases prepare the way for DNA replication by separating the strands of the double helix.

### 28.2 DNA Unwinding and Supercoiling Are Controlled by Topoisomerases

A key topological property of DNA is its linking number ( $Lk$ ), which is defined as the number of times one strand of DNA winds around the other in the right-hand direction when the DNA axis is constrained to lie in a plane. Molecules differing in linking number are topoisomers of one another and can be interconverted only by cutting one or both DNA strands; these reactions are catalyzed by topoisomerases. Changes in linking number generally lead to changes in both the number of turns of double helix and the number of turns of superhelix. Topoisomerase II catalyzes the ATP-driven introduction of negative supercoils, which leads to the compaction of DNA and renders it more susceptible to unwinding. Supercoiled DNA can be relaxed by topoisomerase I or topoisomerase II. Topoisomerase I acts by transiently cleaving one strand of DNA in a double helix, whereas topoisomerase II transiently cleaves both strands simultaneously.

### 28.3 DNA Replication Is Highly Coordinated

Replicative DNA polymerases are processive; that is, they catalyze the addition of many nucleotides without dissociating from the template. A major contributor to processivity is the DNA sliding clamp, such as the dimeric  $\beta$  subunit of the *E. coli* replicative polymerase. The sliding clamp has a ring structure that encircles the DNA double helix and keeps the enzyme and DNA associated. The DNA polymerase holoenzyme is a large DNA-copying machine formed by two DNA polymerase enzymes, one to act on each template strand, associated with other subunits including a sliding clamp and a clamp loader.

The synthesis of the leading and lagging strands of a double-stranded DNA template is coordinated. As a replicative polymerase

moves along a DNA template, the leading strand is copied smoothly while the lagging strand forms loops that change length in the course of the synthesis of each Okazaki fragment. The mode of action is referred to as the trombone model.

DNA replication is initiated at a single site within the *E. coli* genome. A set of specific proteins recognizes this origin of replication and assembles the enzymes needed for DNA synthesis, including a helicase that promotes strand separation. The initiation of replication in eukaryotes is more complex. DNA synthesis is initiated at thousands of sites throughout the genome. Complexes homologous to those in *E. coli*, but more complicated, are assembled at each eukaryotic origin of replication. A special polymerase called telomerase that relies on an RNA template synthesizes specialized structures called telomeres at the ends of linear chromosomes.

#### 28.4 Many Types of DNA Damage Can Be Repaired

A wide variety of DNA damage can occur. For example, mismatched bases may be incorporated in the course of DNA replication or individual bases may be damaged by oxidation or alkylation after DNA replication. Other forms of damage are the formation of cross-links and the introduction of single- or double-stranded breaks in the DNA backbone. Several different repair systems detect and repair DNA damage. Repair begins with the process of proofreading in DNA replication: mismatched bases that were incorporated in the course of synthesis are excised by exonuclease activity present in replicative polymerases. Some DNA lesions such as thymine dimers can be directly reversed through the action of specific enzymes. Other DNA-repair pathways act through the excision of single damaged bases (base-excision repair) or short segments of nucleotides (nucleotide-excision repair). Double-stranded breaks in DNA can be repaired by homologous or nonhomologous end-joining processes. Defects in DNA-repair components are associated with susceptibility to many different sorts of cancer. Such defects are a common target of cancer treatments. Many potential carcinogens can be detected by their mutagenic action on bacteria (the Ames test).

#### 28.5 DNA Recombination Plays Important Roles in Replication, Repair, and Other Processes

Recombination is the exchange of segments between two DNA molecules. Recombination is important in some types of DNA repair as well as other processes such as meiosis, the generation of antibody diversity, and the life cycles of some viruses. Some recombination pathways are initiated by strand invasion, in which a single strand at the end of a DNA double helix forms base pairs with one strand of DNA in another double helix and displaces the other strand. A common intermediate formed in other recombination pathways is the Holliday junction, which consists of four strands of DNA that come together to form a crosslike structure. Recombinases promote recombination reactions through the introduction of specific DNA breaks and the formation and resolution of Holliday-junction intermediates.

## PROBLEMS

1. *Activated intermediates.* DNA polymerase I, DNA ligase, and topoisomerase I catalyze the formation of phosphodiester bonds. What is the activated intermediate in the linkage reaction catalyzed by each of these enzymes? What is the leaving group?

2. *Life in a hot tub.* An archaeon (*Sulfolobus acidocaldarius*) found in acidic hot springs contains a topoisomerase that catalyzes the ATP-driven introduction of positive supercoils into DNA. How might this enzyme be advantageous to this unusual organism?

3. *Which way?* Provide a chemical explanation of why DNA synthesis proceeds in a 5'-to-3' direction.

4. *Nucleotide requirement.* DNA replication does not take place in the absence of the ribonucleotides ATP, CTP, GTP, and UTP. Propose an explanation.

5. *Close contact.* Examination of the structure of DNA polymerases bound to nucleotide analogs reveals that conserved residues come within van der Waals contact of C-2' of the bound nucleotide. What is the potential significance of this interaction?

6. *Molecular motors in replication.*

(a) How fast does template DNA spin (expressed in revolutions per second) at an *E. coli* replication fork?

(b) What is the velocity of movement (in micrometers per second) of DNA polymerase III holoenzyme relative to the template?

7. *Wound tighter than a drum.* Why would replication come to a halt in the absence of topoisomerase II?

8. *The missing link.* One form of a plasmid shows a twist of  $Tw = 48$  and a writhe of  $Wr = 3$ .

(a) What is the linking number?

(b) What would the value of writhe be for a form with twist  $Tw = 50$  if the linking number is the same as that for the preceding form?

9. *Telomeres and cancer.* Telomerase is not active in most human cells. Some cancer biologists have suggested that activation of the telomerase gene would be a requirement for a cell to become cancerous. Explain why this might be the case.

10. *Backward?* Bacteriophage T7 helicase moves along DNA in the 5'-to-3' direction. Other helicases have been reported to move in the 3'-to-5' direction. Is there any fundamental reason why you would expect helicases to move in one direction or the other?

11. *Nick translation.* Suppose that you wish to make a sample of DNA duplex highly radioactive to use as a DNA probe. You have a DNA endonuclease that cleaves the DNA internally to generate 3'-OH and 5'-phosphoryl groups, intact DNA polymerase I, and radioactive dNTPs. Suggest a means for making the DNA radioactive.

12. *Revealing tracks.* Suppose that replication is initiated in a medium containing *moderately* radioactive tritiated thymine. After a few minutes of incubation, the bacteria are transferred to a medium containing *highly* radioactive tritiated thymidine. Sketch the autoradiographic pattern that would be seen for (a) unidirectional replication and (b) bidirectional replication, each from a single origin.

13. *Mutagenic trail.* Suppose that the single-stranded RNA from tobacco mosaic virus was treated with a chemical mutagen, that mutants were obtained having serine or leucine instead of proline at a specific position, and that further treatment of these mutants with the same mutagen yielded phenylalanine at this position.

What are the plausible codon assignments for these four amino acids?

14. *Induced spectrum.* DNA photolyases convert the energy of light in the near-ultraviolet or visible region (300–500 nm)

into chemical energy to break the cyclobutane ring of pyrimidine dimers. In the absence of substrate, these photoreactivating enzymes do not absorb light of wavelengths longer than 300 nm. Why is the substrate-induced absorption band advantageous?

15. *Missing telomerase.* Cells lacking telomerase can grow for several cell divisions without obvious defects. However, after more cell divisions, such cells tend to show chromosomes that have fused together. Propose an explanation for the formation of the chromosomes.

16. *I need to unwind.* With the assumption that the energy required to break an average base pair in DNA is  $10 \text{ kJ mol}^{-1}$  ( $2.4 \text{ kcal mol}^{-1}$ ), estimate the maximum number of base pairs that could be broken per ATP hydrolyzed by a helicase operating under standard conditions.

17. *Triplet oxidation.* The oxidation of guanine bases in the context of triplet repeats such as CAGCAGCAG can lead to the expansion of the repeat. Explain.

#### Mechanism Problem

18. *A revealing analog.* AMP-PNP, the  $\beta,\gamma$ -imido analog of ATP (p. 833), is hydrolyzed very slowly by most ATPases. The addition of AMP-PNP to topoisomerase II and circular DNA leads to the negative supercoiling of a single molecule of DNA per enzyme. DNA remains bound to the enzyme in the presence of this analog. What does this finding reveal about the catalytic mechanism?

#### Data Interpretation and Chapter Integration Problems

19. *Like a ladder.* Circular DNA from SV40 virus was isolated and subjected to gel electrophoresis. The results are shown in lane A (the control) of the adjoining gel patterns.

[From W. Keller, *PNAS* 72:2553, 1975.]

(a) Why does the DNA separate in agarose gel electrophoresis? How does the DNA in each band differ?

The DNA was then incubated with topoisomerase I for 5 minutes and again analyzed by gel electrophoresis with the results shown in lane B.

(b) What types of DNA do the various bands represent?

Another sample of DNA was incubated with topoisomerase I for 30 minutes and again analyzed as shown in lane C.

(c) What is the significance of the fact that more of the DNA is in slower-moving forms?

20. *Ames test.* The illustration below shows four petri plates used for the Ames test. A piece of filter paper (white circle in the center of each plate) was soaked in one of four preparations and then placed on a petri plate. The four preparations contained (A) purified water (control), (B) a known mutagen, (C) a chemical whose mutagenicity is under investigation, and (D) the same chemical after treatment with liver homogenate. The number of revertants, visible as colonies on the petri plates, was determined in each case.

(a) What was the purpose of the control plate, which was exposed only to water?

(b) Why was it wise to use a known mutagen in the experimental system?

(c) How would you interpret the results obtained with the experimental compound?

(d) What liver components would you think are responsible for the effects observed in preparation D?

(a) Why does the DNA separate in agarose gel electrophoresis? How does the DNA in each band differ?

# RNA Synthesis and Processing

RNA synthesis is a key step in the expression of genetic information. For eukaryotic cells, the initial RNA transcript (the mRNA precursor) is often spliced, removing introns that do not encode protein sequences. Often, the same pre-mRNA is spliced differently in different cell types or at different developmental stages. In the image at the left, proteins associated with RNA splicing (stained with a fluorescent antibody) highlight regions of the new genome that are being actively transcribed. [(Left) Courtesy of Dr. Mark B. Roth and Dr. Joseph G. Gall.]

**D**NA stores genetic information in a stable form that can be readily replicated. The expression of this genetic information requires its flow from DNA to RNA and, usually, to protein, as was introduced in Chapter 4. This chapter examines RNA synthesis, or *transcription*, which is the process of synthesizing an RNA transcript with the transfer of sequence information from a DNA template. We begin with a discussion of RNA polymerases, the large and complex enzymes that carry out the synthetic process. We then turn to transcription in bacteria and focus on the three stages of transcription: promoter binding and initiation, elongation of the nascent RNA transcript, and termination. We then examine transcription in eukaryotes, focusing on the distinctions between bacterial and eukaryotic transcription.

RNA transcripts in eukaryotes are extensively modified, as exemplified by the capping of the 5' end of an mRNA precursor and the addition of a long poly(A) tail to its 3' end. One of the most striking examples of RNA modification is the splicing of mRNA precursors, which is catalyzed by spliceosomes, protein complexes consisting of small nuclear ribonucleoprotein particles (snRNPs). Remarkably, some RNA molecules can splice themselves in the absence of protein. This landmark discovery by Thomas Cech and Sidney Altman revealed that RNA molecules can serve as catalysts, greatly influencing our view of molecular evolution.

## OUTLINE

- 29.1 RNA Polymerases Catalyze Transcription
- 29.2 Transcription in Eukaryotes Is Highly Regulated
- 29.3 The Transcription Products of Eukaryotic Polymerases Are Processed
- 29.4 The Discovery of Catalytic RNA Was Revealing in Regard to Both Mechanism and Evolution

RNA splicing is not merely a curiosity. Many genetic diseases have been associated with mutations that affect RNA splicing. Moreover, the same pre-mRNA can be spliced differently in various cell types, at different stages of development, or in response to other biological signals. In addition, individual bases in some pre-mRNA molecules are changed in a process called RNA editing. One of the biggest surprises of the sequencing of the human genome was that only about 21,000 genes were identified compared with previous estimates of 100,000 or more. The ability of one gene to encode more than one distinct mRNA by alternative splicing and, hence, more than one protein may play a key role in expanding the repertoire of our genomes.

Furthermore, the investigation of different classes of RNA molecules has been one of the most productive areas of biochemical research in recent years. In the next chapter we will explore the long-known ribosomal and transfer RNA molecules that are central to protein synthesis. We have also encountered microRNAs, molecules for which our understanding is still rapidly expanding. Many other classes of RNAs have been discovered more recently, including long non-coding RNAs, the functions of which are still under active investigation.

### RNA synthesis comprises three stages: Initiation, elongation, and termination

RNA synthesis is catalyzed by large enzymes called *RNA polymerases*. The basic biochemistry of RNA synthesis is common to all organisms, commonality that has been beautifully illustrated by the three-dimensional structures of representative RNA polymerases from prokaryotes and eukaryotes (Figure 29.1). Despite substantial differences in size and number of polypeptide subunits, the overall structures of these enzymes are quite similar, revealing a common evolutionary origin.

RNA synthesis, like all biological polymerization reactions, takes place in three stages: *initiation*, *elongation*, and *termination*. RNA polymerases perform multiple functions in this process:

1. They search DNA for initiation sites, also called *promoter sites* or simply *promoters*. For instance, *E. coli* DNA has about 2000 promoter sites in its  $4.8 \times 10^6$  bp genome.
2. They unwind a short stretch of double-helical DNA to produce single-stranded DNA templates from which the sequence of bases can be easily read out.

**FIGURE 29.1 RNA polymerase structures.** The three-dimensional structures of RNA polymerases from a prokaryote (*Thermus aquaticus*) and a eukaryote (*Saccharomyces cerevisiae*). The two largest subunits for each structure are shown in dark red and dark blue. Notice that both structures contain a central metal ion (green) in their active sites, near a large cleft on the right. The similarity of these structures reveals that these enzymes have the same evolutionary origin and have many mechanistic features in common. [Drawn from 116V.pdb and 116H.pdb.]

Prokaryotic RNA polymerase

Eukaryotic RNA polymerase

3. They select the correct ribonucleoside triphosphate and catalyze the formation of a phosphodiester bond. This process is repeated many times as the enzyme moves along the DNA template. RNA polymerase is completely processive—a transcript is synthesized from start to end by a single RNA polymerase molecule.
4. They detect termination signals that specify where a transcript ends.
5. They interact with activator and repressor proteins that modulate the rate of transcription initiation over a wide range. Gene expression is controlled substantially at the level of transcription, as will be discussed in detail in Chapters 31 and 32.

The chemistry of RNA synthesis is identical for all forms of RNA, including messenger RNAs, transfer RNAs, ribosomal RNAs, and small regulatory RNAs. The basic steps just outlined apply to all forms. Their synthetic processes differ mainly in regulation, posttranscriptional processing, and the specific RNA polymerase that participates.

## 29.1 RNA Polymerases Catalyze Transcription

The fundamental reaction of RNA synthesis is the formation of a phosphodiester bond. The 3'-hydroxyl group of the last nucleotide in the chain nucleophilically attacks the  $\alpha$  phosphoryl group of the incoming nucleoside triphosphate with the concomitant release of a pyrophosphate.

This reaction is thermodynamically favorable, and the subsequent degradation of the pyrophosphate to orthophosphate locks the reaction in the direction of RNA synthesis. The catalytic sites of RNA polymerases include two metal ions, normally magnesium ions (Figure 29.2). One ion remains tightly bound to the enzyme, whereas the other ion comes in with the nucleoside triphosphate and leaves with the pyrophosphate. Three conserved aspartate residues participate in binding these metal ions.

RNA polymerases are very large, complex enzymes. For example, the core of the RNA polymerase of *E. coli* consists of 5 kinds of subunits with the composition  $\alpha_2\beta\beta'\omega$  (Table 29.1). A typical eukaryotic RNA polymerase is larger and more complex, having 12 subunits and a total molecular mass of more than 0.5 million daltons. Despite

**FIGURE 29.2 RNA polymerase active site.** A model of the transition state for phosphodiester-bond formation in the active site of RNA polymerase. The 3'-hydroxyl group of the growing RNA chain attacks the  $\alpha$ -phosphoryl group of the incoming nucleoside triphosphate, resulting in the release of pyrophosphate. This transition state is structurally similar to that in the active site of DNA polymerase (Figure 28.5).

**TABLE 29.1** Subunits of RNA polymerase from *E. coli*

Subunit	Gene	Number	Mass (kDa)
$\alpha$	<i>rpoA</i>	2	37
$\beta$	<i>rpoB</i>	1	151
$\beta'$	<i>rpoC</i>	1	155
$\omega$	<i>rpoZ</i>	1	10
$\sigma^{70}$	<i>rpoD</i>	1	70

**FIGURE 29.3** Transcription bubble. RNA polymerase separates a region of the double helix to form a structure called the “transcription bubble.” The red (template) and blue (nontemplate) strands of DNA are shown along with the RNA molecule being synthesized (shown in green). The position of the active site magnesium is indicated. The DNA enters from the left and exits at the bottom.

this complexity, the structures of RNA polymerases have been determined in detail by x-ray crystallography in work pioneered by Roger Kornberg and Seth Darst.

The polymerization reactions catalyzed by RNA polymerases take place within a complex in DNA termed a *transcription bubble* (Figure 29.3). This complex consists of double-stranded DNA that has been locally unwound in a region of approximately 17 base pairs. The edges of the bases that normally take part in Watson–Crick base pairs are exposed in the unwound region. We will begin with a detailed examination of the elongation process, including the role of the DNA template read by RNA polymerase and the reactions catalyzed by the polymerase, before returning to the more-complex processes of initiation and termination.

### RNA chains are formed de novo and grow in the 5'-to-3' direction

Let us begin our examination of transcription by considering the DNA template. The first nucleotide (the start site) of a DNA sequence to be transcribed is denoted as +1 and the second one as +2; the nucleotide preceding the start site is denoted as –1. These designations refer to the coding strand of DNA. Recall that the sequence of the *template strand of DNA* is the *complement* of that of the RNA transcript (Figure 29.4). In contrast, the *coding strand of DNA* has the *same* sequence as that of the RNA transcript except for thymine (T) in place of uracil (U). The coding strand is also known as the *sense (+) strand*, and the template strand as the *antisense (–) strand*.

In contrast with DNA synthesis, *RNA synthesis can start de novo, without the requirement for a primer*. Most newly synthesized RNA chains carry a highly distinctive tag on the 5' end: the first base at that end is either *pppG* or *pppA*.

The presence of the triphosphate moiety confirms that RNA synthesis starts at the 5' end.

The dinucleotide shown above is synthesized by RNA polymerase as part of the complex process of initiation, which will be discussed later in the chapter. After initiation takes place, RNA polymerase elongates the nucleic

**FIGURE 29.4** Template and coding strands. The template, or antisense (–), strand is complementary in sequence to the RNA transcript.

**FIGURE 29.5 Elongation mechanism.** A ribonucleoside triphosphate binds adjacent to the growing RNA chain and forms a Watson–Crick base pair with a base on the DNA template strand. The 3'-hydroxyl group at the end of the RNA chain attacks the newly bound nucleotide and forms a new phosphodiester bond, releasing pyrophosphate.

acid chain in the following manner (Figure 29.5). A ribonucleoside triphosphate binds in the active site of the RNA polymerase, directly adjacent to the growing RNA chain. The incoming ribonucleoside triphosphate forms a Watson–Crick base pair with the template strand. The 3'-hydroxyl group of the growing RNA chain, oriented and activated by the tightly bound metal ion, attacks the  $\alpha$ -phosphoryl group to form a new phosphodiester bond, displacing pyrophosphate.

To proceed to the next step, the RNA–DNA hybrid must move relative to the polymerase to bring the 3' end of the newly added nucleotide into proper position for the next nucleotide to be added (Figure 29.6). This translocation step does not include breaking any bonds between base pairs and is reversible but, once it has taken place, the addition of the next nucleotide, favored by the triphosphate cleavage and pyrophosphate release and cleavage, drives the polymerization reaction forward.

**FIGURE 29.6 Translocation.** After nucleotide addition, the RNA–DNA hybrid can translocate through the RNA polymerase, bringing a new DNA base into position to base-pair with an incoming nucleoside triphosphate.

The lengths of the RNA–DNA hybrid and of the unwound region of DNA stay rather constant as RNA polymerase moves along the DNA template. The length of the RNA–DNA hybrid is determined by a structure within the enzyme that forces the RNA–DNA hybrid to separate, allowing the RNA chain to exit from the enzyme and the DNA chain to rejoin its DNA partner (Figure 29.7).

**FIGURE 29.7 RNA–DNA hybrid separation.** A structure within RNA polymerase forces the separation of the RNA–DNA hybrid. Notice that the DNA strand exits in one direction and the RNA product exits in another. [Drawn from 116H.pdb.]

### RNA polymerases backtrack and correct errors

The RNA–DNA hybrid can also move in the direction opposite that of elongation (Figure 29.8). This backtracking is less favorable energetically than moving forward because it breaks the bonds between a base pair. However, backtracking is very important for *proofreading*. The incorporation of an incorrect nucleotide introduces a non-Watson–Crick base pair. In this case, breaking the bonds between this base pair and backtracking is less costly energetically. After the polymerase has backtracked, the phosphodiester bond one base pair before the one that has just formed is adjacent to the metal ion in the active site. In this position, a hydrolysis reaction in

**FIGURE 29.8 Backtracking.** The RNA–DNA hybrid can occasionally backtrack within the RNA polymerase. In the backtracked position, hydrolysis can take place, producing a configuration equivalent to that after translocation. Backtracking is more likely if a mismatched base is added, facilitating proofreading.

## Sigma subunits of RNA polymerase recognize promoter sites

To initiate transcription, the  $\alpha_2\beta\beta'\omega$  core of RNA polymerase must bind the promoter. However, it is the  $\sigma$  subunit that makes this binding possible by enabling RNA polymerase to recognize promoter sites. In the presence of the  $\sigma$  subunit, the RNA polymerase binds weakly to the DNA and slides along the double helix until it dissociates or encounters a promoter. The  $\sigma$  subunit recognizes the promoter through several interactions with the nucleotide bases of the promoter DNA. The structure of a bacterial RNA polymerase holoenzyme bound to a promoter site shows the  $\sigma$  subunit interacting with DNA at the  $-10$  and  $-35$  regions essential to promoter recognition (Figure 29.10). Therefore, the  $\sigma$  subunit is responsible for the specific binding of the RNA polymerase to a promoter site on the template DNA. The  $\sigma$  subunit is generally released when the nascent RNA chain reaches 9 or 10 nucleotides in length. After its release, it can assist initiation by another core enzyme. Thus, the  $\sigma$  subunit acts catalytically.

*E. coli* has seven distinct  $\sigma$  factors for recognizing several types of promoter sequences in *E. coli* DNA. The type that recognizes the consensus sequences described earlier is called  $\sigma^{70}$  because it has a mass of 70 kDa. A different  $\sigma$  factor comes into play when the temperature is raised abruptly. *E. coli* responds by synthesizing  $\sigma^{32}$ , which recognizes the promoters of heat-shock genes. These promoters exhibit  $-10$  sequences that are somewhat different from the  $-10$  sequence for standard promoters (Figure 29.11). The increased transcription of heat-shock genes leads to the coordinated synthesis of a series of protective proteins. Other  $\sigma$  factors respond to environmental conditions, such as nitrogen starvation. These findings demonstrate that  $\sigma$  plays the key role in determining where RNA polymerase initiates transcription.

Some other bacteria contain a much larger number of  $\sigma$  factors. For example, the genome of the soil bacterium *Streptomyces coelicolor* encodes more than 60  $\sigma$  factors recognized on the basis of their amino acid sequences. This repertoire allows these cells to adjust their gene-expression programs to the wide range of conditions, in regard to nutrients and competing organisms, that they may experience.

## RNA polymerases must unwind the template double helix for transcription to take place

Although RNA polymerases can search for promoter sites when bound to double-helical DNA, a segment of the DNA double helix must be unwound before synthesis can begin. The transition from the closed promoter complex

**FIGURE 29.10 RNA polymerase holoenzyme complex.** Notice that the  $\sigma$  subunit (blue) of the bacterial RNA polymerase holoenzyme makes sequence-specific contacts with the  $-10$  (green) and  $-35$  promoter elements (yellow). The active site of the polymerase is revealed by bound metal ion (purple). [Drawn from 1L9Z.pdb].

**FIGURE 29.11 Alternative promoter sequences.** A comparison of the consensus sequences of standard, heat-shock, and nitrogen-starvation promoters of *E. coli*. These promoters are recognized by  $\sigma^{70}$ ,  $\sigma^{32}$ , and  $\sigma^{54}$ , respectively.

**FIGURE 29.12 DNA unwinding.** The transition from the closed promoter complex to the open promoter complex requires the unwinding of approximately 17 base pairs of DNA.

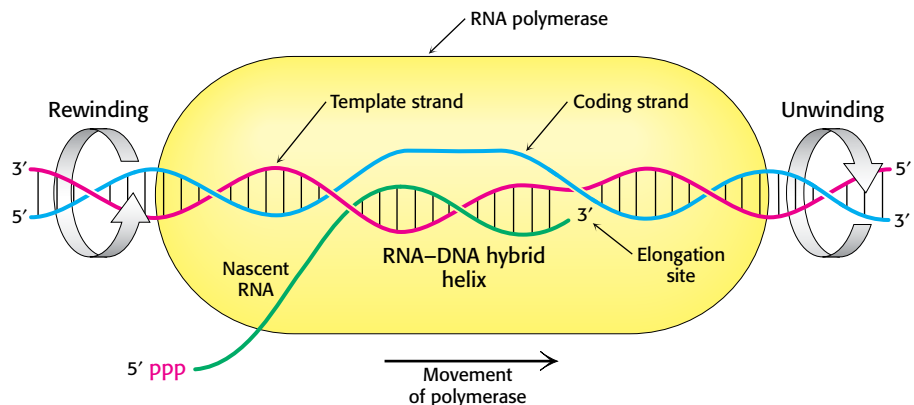

(in which DNA is double helical) to the *open promoter complex* (in which a DNA segment is unwound) is an essential event in transcription (Figure 29.12). The free energy necessary to break the bonds between approximately 17 base pairs in the double helix is derived from additional interactions that are possible when the DNA distorts to wrap around the RNA polymerase and from interactions between the single-stranded DNA regions and other parts of the enzyme. These interactions stabilize the open promoter complex and help pull the template strand into the active site. The  $-35$  element remains in a double-helical state, whereas the  $-10$  element is unwound. The stage is now set for the formation of the first phosphodiester bond of the new RNA chain.

### Elongation takes place at transcription bubbles that move along the DNA template

The elongation phase of RNA synthesis begins with the formation of the first phosphodiester bond. Repeated cycles of nucleotide addition can take place at this point. However, until about 10 nucleotides have been added, RNA polymerase sometimes releases the short RNA, which dissociates from the DNA. Once RNA polymerase passes this point, the enzyme stays bound to its template until a termination signal is reached. The region containing RNA polymerase, DNA, and nascent RNA corresponds to the transcription bubble (Figure 29.13). The newly synthesized RNA forms a hybrid helix with the template DNA strand. This RNA–DNA hybrid is about 8 bp long, which corresponds to nearly one turn of a double helix. The 3′-hydroxyl group of the RNA in this hybrid helix is positioned so that it can attack the  $\alpha$ -phosphorus atom of an incoming ribonucleoside triphosphate. The core enzyme also contains a binding site for the coding strand of DNA. About 17 bp of DNA are unwound throughout the elongation phase, as in the initiation phase. The transcription bubble moves a distance of 170 Å (17 nm) in a second, which corresponds to a rate of elongation of about 50 nucleotides per second. Although rapid, it is much slower than the rate of DNA synthesis, which is 800 nucleotides per second.

### Sequences within the newly transcribed RNA signal termination

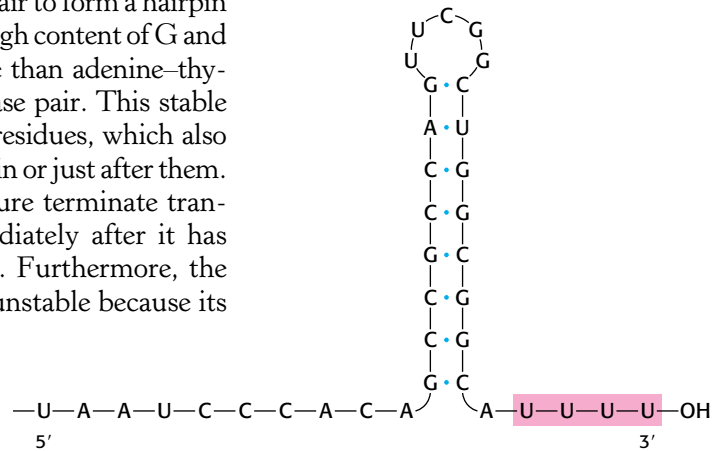

In bacteria, the termination of transcription is as precisely controlled as its initiation. In the termination phase of transcription, the formation of phosphodiester bonds ceases, the RNA–DNA hybrid dissociates, the unwound region of DNA rewinds, and RNA polymerase releases the DNA. What determines where transcription is terminated? *The transcribed regions of DNA*

**FIGURE 29.13 Transcription bubble.** A schematic representation of a transcription bubble in the elongation of an RNA transcript. Duplex DNA is unwound at the forward end of RNA polymerase and rewound at its rear end. The RNA–DNA hybrid rotates during elongation.

templates contain stop signals. The simplest one is a *palindromic GC-rich region followed by an AT-rich region*. The RNA transcript of this DNA palindrome is self-complementary (Figure 29.14). Hence, its bases can pair to form a hairpin structure with a stem and loop, a structure favored by its high content of G and C residues. Guanine–cytosine base pairs are more stable than adenine–thymine pairs because of the extra hydrogen bond in the base pair. This stable hairpin is followed by a sequence of four or more uracil residues, which also are crucial for termination. The RNA transcript ends within or just after them.

How does this combination hairpin–oligo(U) structure terminate transcription? First, RNA polymerase likely pauses immediately after it has synthesized a stretch of RNA that folds into a hairpin. Furthermore, the RNA–DNA hybrid helix produced after the hairpin is unstable because its rU–dA base pairs are the weakest of the four kinds. Hence, the pause in transcription caused by the hairpin permits the weakly bound *nascent RNA to dissociate from the DNA template and then from the enzyme*. The solitary DNA template strand rejoins its partner to re-form the DNA duplex, and the transcription bubble closes.

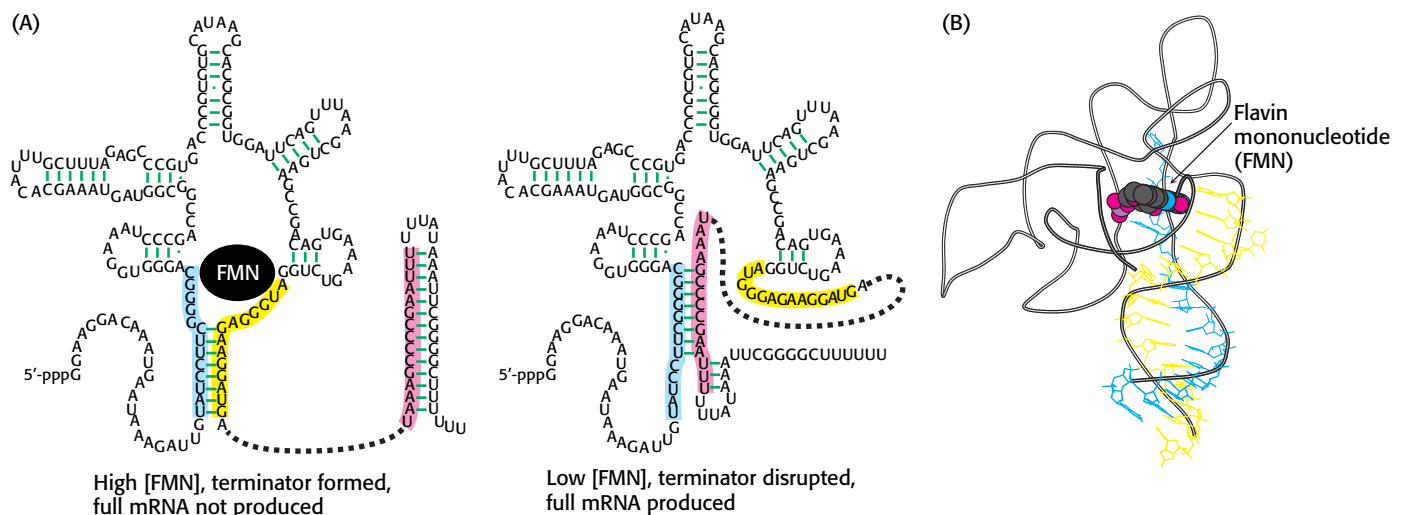

**FIGURE 29.14 Termination signal.** A termination signal found at the 3' end of an mRNA transcript consists of a series of bases that form a stable stem-loop structure and a series of U residues.

### Some messenger RNAs directly sense metabolite concentrations

As we shall explore in Chapters 31 and 32, the expression of many genes is controlled in response to the concentrations of metabolites and signaling molecules within cells. One set of control mechanisms depends on the remarkable ability of some mRNA molecules to form special secondary structures, some of which are capable of directly binding small molecules. These structures are termed *riboswitches*. Consider a riboswitch that controls the synthesis of genes that participate in the biosynthesis of riboflavin in *Bacillus subtilis* (Figure 29.15). When flavin mononucleotide (FMN), a key intermediate in riboflavin biosynthesis, is present at high concentration, it binds to a conformation of the RNA transcript with an FMN-binding pocket that also includes a hairpin structure that favors premature termination. By trapping the RNA transcript in this termination-favoring conformation, FMN prevents the production of functional mRNA. However, when FMN is present at low concentration, it does not readily bind to RNA, and an alternative conformation forms without the terminator, allowing the production of the full-length mRNA. The occurrence of riboswitches serves as a vivid illustration of how RNAs are capable of forming

**FIGURE 29.15 Riboswitch.** (A) The 5'-end of an mRNA that encodes proteins engaged in the production of flavin mononucleotide (FMN) folds to form a structure that is stabilized by binding FMN. This structure includes a terminator that leads to premature termination of the mRNA. At lower concentrations of FMN, an alternative structure that lacks the terminator is formed, leading to the production of full-length mRNA. (B) The three-dimensional structure of a related FMN-binding riboswitch bound to FMN. The blue and yellow stretches correspond to regions highlighted in the same colors in part A. Notice how the yellow strand contacts the bound FMN, stabilizing the structure. [Drawn from 3F2Q.pdb].

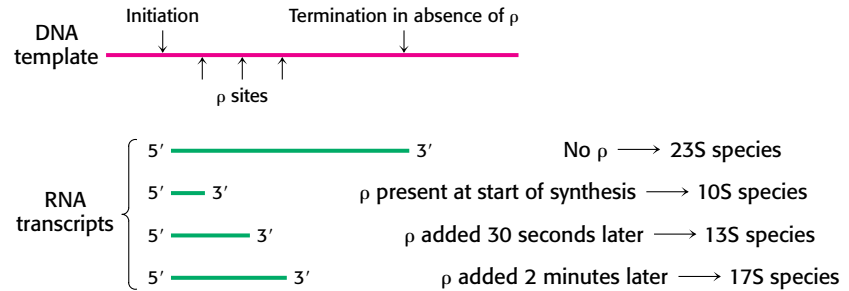

FIGURE 29.16 Effect of  $\rho$  protein on the size of RNA transcripts.

elaborate, functional structures, though we tend to depict them as simple lines in the absence of specific information.

### The *rho* protein helps to terminate the transcription of some genes

RNA polymerase needs no help to terminate transcription at a hairpin followed by several U residues. At other sites, however, termination requires the participation of an additional factor. This discovery was prompted by the observation that some RNA molecules synthesized *in vitro* by RNA polymerase acting alone are *longer* than those made *in vivo*. The missing factor, a protein that caused the correct termination, was isolated and named *rho* ( $\rho$ ). Additional information about the action of  $\rho$  was obtained by adding this termination factor to an incubation mixture at various times after the initiation of RNA synthesis (Figure 29.16). RNAs with sedimentation coefficients of 10S, 13S, and 17S were obtained when  $\rho$  was added at initiation, a few seconds after initiation, and 2 minutes after initiation, respectively. If no  $\rho$  was added, transcription yielded a 23S RNA product. It is evident that the template contains at least three termination sites that respond to  $\rho$  (yielding 10S, 13S, and 17S RNA) and one termination site that does not (yielding 23S RNA). Thus, specific termination at a site producing 23S RNA can take place in the absence of  $\rho$ . However,  $\rho$  detects additional termination signals that are not recognized by RNA polymerase alone.

How does  $\rho$  provoke the termination of RNA synthesis? A key clue is the finding that  $\rho$  hydrolyzes ATP in the presence of single-stranded RNA but not in the presence of DNA or duplex RNA. Hexameric  $\rho$  is a helicase, homologous to the helicases that we encountered in our consideration of DNA replication (Section 28.1). A stretch of nucleotides is bound in such a way that the RNA passes through the center of the structure (Figure 29.17). The  $\rho$  protein is brought into action by sequences located in the nascent RNA that are rich in cytosine and poor in guanine. The helicase activity of  $\rho$  enables the protein to pull the nascent RNA while pursuing RNA polymerase. When  $\rho$  catches RNA polymerase at the transcription bubble, it breaks the RNA–DNA hybrid helix by functioning as an RNA–DNA helicase.

Proteins in addition to  $\rho$  may provoke termination. For example, the *nusA* protein enables RNA polymerase in *E. coli* to recognize a characteristic class of termination sites. A common feature of protein-independent and protein-dependent termination is that the functioning signals lie in newly synthesized RNA rather than in the DNA template.

FIGURE 29.17 Mechanism for the termination of transcription by  $\rho$  protein. This protein is an ATP-dependent helicase that binds the nascent RNA chain and pulls it away from RNA polymerase and the DNA template.

## Some antibiotics inhibit transcription

Many antibiotics are highly specific inhibitors of biological processes in bacteria. Rifampicin and actinomycin are two antibiotics that inhibit bacterial transcription, although in quite different ways. *Rifampicin* is a semisynthetic derivative of *rifamycins*, which are derived from a strain of *Amycolatopsis* that is related to the bacterium that causes strep throat.

This antibiotic *specifically inhibits the initiation of RNA synthesis*. Rifampicin interferes with the formation of the first few phosphodiester bonds in the RNA chain. The structure of a complex between a prokaryotic RNA polymerase and rifampicin reveals that the antibiotic blocks the channel into which the RNA–DNA hybrid generated by the enzyme must pass (Figure 29.18). The binding site is 12 Å from the active site itself. Rifampicin can inhibit only the initiation of transcription, not elongation, because the RNA–DNA hybrid present in the enzyme during elongation prevents the antibiotic from binding. The pocket in which rifampicin binds is conserved among bacterial RNA polymerases, but not eukaryotic polymerases, and so rifampicin can be used as an antibiotic in antituberculosis therapy.

*Actinomycin D*, a peptide-containing antibiotic from a different strain of *Streptomyces*, inhibits transcription by an entirely different mechanism. *Actinomycin D binds tightly and specifically to double-helical DNA and thereby prevents it from being an effective template for RNA synthesis*. The results of spectroscopic, hydrodynamic, and structural studies of complexes of actinomycin D and DNA reveal that the phenoxazone ring of actinomycin slips in

**FIGURE 29.18 Antibiotic action.** Rifampicin binds to a pocket in the channel that is normally occupied by the newly formed RNA–DNA hybrid. Thus, the antibiotic blocks elongation after only two or three nucleotides have been added.

**FIGURE 29.19 Actinomycin–DNA complex structure.** (A) The structure of a complex between a DNA duplex (shown as a space-filling model) and actinomycin B (shown as a ball-and-stick model). Two actinomycin B molecules are bound in the complex. (B) The structure of actinomycin B showing the phenoxazone ring. Notice how the phenoxazone (yellow) slides between base pairs of the DNA. Abbreviation: Me, methyl. [Drawn from 1I3W.pdb]

between base pairs in DNA (Figure 29.19). This mode of binding is called *intercalation*. At low concentrations, actinomycin D inhibits transcription without significantly affecting DNA replication or protein synthesis. Hence, *actinomycin D* is extensively used as a highly specific inhibitor of the formation of new RNA in both prokaryotic and eukaryotic cells. Its ability to inhibit the growth of rapidly dividing cells makes it an effective therapeutic agent in the treatment of some cancers.

### Precursors of transfer and ribosomal RNA are cleaved and chemically modified after transcription in prokaryotes

**FIGURE 29.20 Primary transcript.** Cleavage of this transcript produces 5S, 16S, and 23S rRNA molecules and a tRNA molecule. Spacer regions are shown in yellow.

In prokaryotes, messenger RNA molecules undergo little or no modification after synthesis by RNA polymerase. Indeed, many mRNA molecules are translated while they are being transcribed. In contrast, *transfer RNA (tRNA)* and *ribosomal RNA (rRNA)* molecules are generated by cleavage and other modifications of nascent RNA chains. For example, in *E. coli*, the three rRNAs and a tRNA are excised from a single primary RNA transcript that also contains spacer regions (Figure 29.20). Other transcripts contain arrays of several kinds of tRNA or of several copies of the same tRNA. The nucleases that cleave and trim these precursors of rRNA and tRNA are highly precise. *Ribonuclease P* (RNase P), for example, generates the correct 5' terminus of all tRNA molecules in *E. coli*. Sidney Altman and his coworkers showed that this interesting enzyme contains a catalytically active RNA molecule. *Ribonuclease III* (RNase III) excises 5S, 16S, and 23S rRNA precursors from the primary transcript by cleaving double-helical hairpin regions at specific sites.

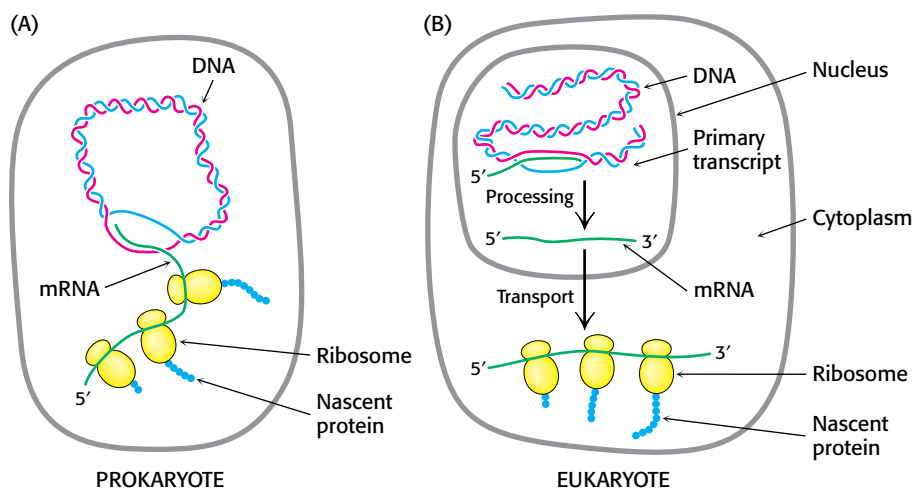

A second type of processing is the *addition of nucleotides to the termini of some RNA chains*. For example, CCA, a terminal sequence required for the function of all tRNAs, is added to the 3' ends of tRNA molecules for which this terminal sequence is not encoded in the DNA. The enzyme that catalyzes the addition of CCA is atypical for an RNA polymerase in that it does not use a DNA template. A third type of processing is the *modification of bases and ribose units of ribosomal RNAs*. In prokaryotes, some bases of rRNA are methylated. Unusual bases are found in all tRNA molecules. They are formed by the enzymatic modification of a standard ribonucleotide in a tRNA precursor. For example, uridylylate residues are modified after transcription to form *ribothymidylate* and *pseudouridylylate*. These modifications generate diversity, allowing greater structural and functional versatility.

## 29.2 Transcription in Eukaryotes Is Highly Regulated

We turn now to transcription in eukaryotes, a much more complex process than in bacteria. Eukaryotic cells have a remarkable ability to regulate precisely the time at which each gene is transcribed and how much RNA is produced. This ability has allowed some eukaryotes to evolve into multicellular organisms, with distinct tissues. *That is, multicellular eukaryotes use differential transcriptional regulation to create different cell types.* Gene expression is influenced by three important characteristics unique to eukaryotes: the nuclear membrane, complex transcriptional regulation, and RNA processing.

1. *The Nuclear Membrane.* In eukaryotes, transcription and translation take place in different cellular compartments: transcription takes place in the membrane-bounded nucleus, whereas translation takes place outside the nucleus in the cytoplasm. In bacteria, the two processes are closely coupled (Figure 29.21). Indeed, the translation of bacterial mRNA begins while

**FIGURE 29.21 Transcription and translation.** These two processes are closely coupled in prokaryotes whereas they are spatially and temporally separate in eukaryotes. (A) In prokaryotes, the primary transcript serves as mRNA and is used immediately as the template for protein synthesis. (B) In eukaryotes, mRNA precursors are processed and spliced in the nucleus before being transported to the cytoplasm for translation into protein. [Information from J. Darnell, H. Lodish, and D. Baltimore. *Molecular Cell Biology*, 2d ed. (Scientific American Books, 1990), p. 230.]

the transcript is still being synthesized. *The spatial and temporal separation of transcription and translation enables eukaryotes to regulate gene expression in much more intricate ways, contributing to the richness of eukaryotic form and function.*

2. *Complex Transcriptional Regulation.* Like bacteria, eukaryotes rely on conserved sequences in DNA to regulate the initiation of transcription. But bacteria have only three promoter elements (the  $-10$ ,  $-35$ , and UP elements), whereas eukaryotes use a variety of types of promoter elements, each identified by its own conserved sequence. Not all possible types will be present together in the same promoter. *In eukaryotes, elements that regulate transcription can be found at a variety of locations in DNA, upstream or downstream of the start site and sometimes at distances much farther from the start site than in prokaryotes.* For example, enhancer elements located on DNA far from the start site increase the promoter activity of specific genes.

3. *RNA Processing.* Although both bacteria and eukaryotes modify RNA, *eukaryotes very extensively process nascent RNA destined to become mRNA.* This processing includes modifications to both ends and, most significantly, splicing out segments of the primary transcript. RNA processing is described in Section 29.3.

### Three types of RNA polymerase synthesize RNA in eukaryotic cells

In bacteria, RNA is synthesized by a single kind of polymerase. In contrast, the nucleus of a typical eukaryotic cell contains three types of RNA polymerase differing in template specificity and location in the nucleus (Table 29.2). All these polymerases are large proteins, containing from 8 to 14 subunits and having total molecular masses greater than 500 kDa. *RNA polymerase I* is located in specialized structures within the nucleus called nucleoli, where it transcribes the tandem array of genes for 18S, 5.8S, and 28S rRNA. The other rRNA molecule (5S rRNA) and all the tRNA molecules are synthesized by *RNA polymerase III*, which is located in the nucleoplasm rather than in nucleoli. *RNA polymerase II*, which also is located in the nucleoplasm, synthesizes the precursors of mRNA as well as several small RNA molecules, such as those of the splicing apparatus and many of the precursors to small regulatory RNAs.

Although all eukaryotic RNA polymerases are homologous to one another and to prokaryotic RNA polymerases, RNA polymerase II contains a unique *carboxyl-terminal domain* on the 220-kDa subunit called the CTD; this domain is unusual because it contains multiple repeats of a YSPTSPS consensus sequence. The activity of RNA polymerase II is regulated by phosphorylation mainly on the serine residues of the CTD.

Another major distinction among the polymerases lies in their responses to the toxin  $\alpha$ -amanitin, a cyclic octapeptide that contains several modified amino acids.

**TABLE 29.2** Eukaryotic RNA polymerases

Type	Location	Cellular transcripts	Effects of $\alpha$ -amanitin
I	Nucleolus	18S, 5.8S, and 28S rRNA	Insensitive
II	Nucleoplasm	mRNA precursors and snRNA	Strongly inhibited
III	Nucleoplasm	tRNA and 5S rRNA	Inhibited by high concentrations

*Amanita phalloides*, also called the death cap.  
[Jacana/Science Source.]

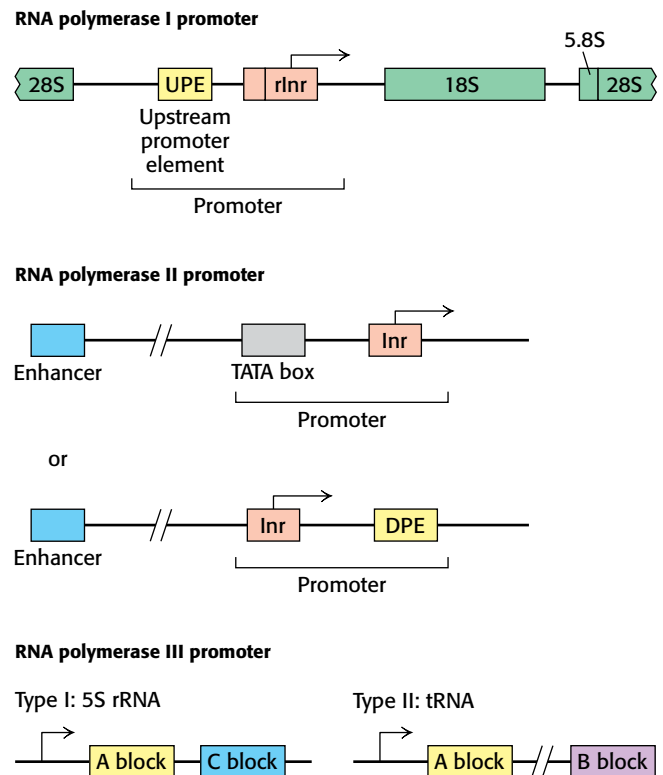

$\alpha$ -Amanitin is produced by the poisonous mushroom *Amanita phalloides*, which is also called the *death cap* or the *destroying angel*. More than a hundred deaths result worldwide each year from the ingestion of poisonous mushrooms.  $\alpha$ -Amanitin binds very tightly ( $K_d = 10$  nM) to RNA polymerase II and thereby blocks the elongation phase of RNA synthesis. Higher concentrations of  $\alpha$ -amanitin (1  $\mu$ M) inhibit polymerase III, whereas polymerase I is insensitive to this toxin. This pattern of sensitivity is highly conserved throughout the animal and plant kingdoms.

Eukaryotic polymerases also differ from each other in the promoters to which they bind. Eukaryotic genes, like prokaryotic genes, require promoters for transcription initiation. Like prokaryotic promoters, eukaryotic promoters consist of conserved sequences that attract the polymerase to the start site. However, eukaryotic promoters differ distinctly in sequence and position, depending on the type of RNA polymerase to which they bind (Figure 29.22).

1. *RNA Polymerase I*. The ribosomal DNA (rDNA) transcribed by polymerase I is arranged in several hundred tandem repeats, each containing a copy of each of three rRNA genes. The promoter sequences are located in stretches of DNA separating the genes. At the transcriptional start site lies a TATA-like sequence called the *ribosomal initiator element* (rInr). Farther upstream, 150 to 200 bp from the start site, is the *upstream promoter element* (UPE). Both elements aid transcription by binding proteins that recruit RNA polymerase I.

2. *RNA Polymerase II*. Promoters for RNA polymerase II, like prokaryotic promoters, include a set of consensus sequences that define the start site and recruit the polymerase. However, the promoter can contain any combination of a number of possible consensus sequences. Unique to eukaryotes, they also include enhancer elements that can be very distant (more than 1 kb) from the start site.

3. *RNA Polymerase III*. Promoters for RNA polymerase III are *within* the transcribed sequence, downstream of the start site. There are two types of intergenic promoters for RNA polymerase III. Type I promoters, found in the 5S rRNA

**FIGURE 29.22 Common eukaryotic promoter elements.** Each eukaryotic RNA polymerase recognizes a set of promoter elements—sequences in DNA that promote transcription. The RNA polymerase I promoter consists of a ribosomal initiator (rInr) and an upstream promoter element (UPE). The RNA polymerase II promoter likewise includes an initiator element (Inr) and may also include either a TATA box or a downstream promoter element (DPE). Separate from the promoter region, enhancer elements bind specific transcription factors. RNA polymerase III promoters consist of conserved sequences that lie within the transcribed genes.

gene, contain two short conserved sequences known as the A block and the C block. Type II promoters, found in tRNA genes, consist of two 11-bp sequences, the A block and the B block, situated about 15 bp from either end of the gene.

### Three common elements can be found in the RNA polymerase II promoter region

RNA polymerase II transcribes all of the protein-coding genes in eukaryotic cells. Promoters for RNA polymerase II, like those for bacterial polymerases, are generally located on the 5' side of the start site for transcription. Because these sequences are on the *same* molecule of DNA as the genes being transcribed, they are called *cis-acting elements*. The most commonly recognized *cis-acting element* for genes transcribed by RNA polymerase II is called the *TATA box* on the basis of its consensus sequence (Figure 29.23). The TATA box is usually found between positions  $-30$  and  $-100$ . Note that the eukaryotic TATA box closely resembles the prokaryotic  $-10$  sequence (TATAAT) but is farther from the start site. The mutation of a single base in the TATA box markedly impairs promoter activity. Thus, the precise sequence, not just a high content of AT pairs, is essential.

The TATA box is often paired with an *initiator element* (Inr), a sequence found at the transcriptional start site, between positions  $-3$  and  $+5$ . This sequence defines the start site because the other promoter elements are at variable distances from that site. Its presence increases transcriptional activity.

A third element, the *downstream core promoter element* (DPE), is commonly found in conjunction with the Inr in transcripts that lack the TATA box. In contrast with the TATA box, the DPE is found downstream of the start site, between positions  $+28$  and  $+32$ .

Additional regulatory sequences are located between  $-40$  and  $-150$ . Many promoters contain a *CAAT box*, and some contain a *GC box* (Figure 29.24). Constitutive genes (genes that are continuously expressed rather than regulated) tend to have GC boxes in their promoters. The positions of these upstream sequences vary from one promoter to another, in contrast with the quite constant location of the  $-35$  region in prokaryotes. Another difference is that the CAAT box and the GC box can be effective when present on the template (antisense) strand, unlike the  $-35$  region, which must be present on the coding (sense) strand. These differences between prokaryotes and eukaryotes correspond to fundamentally different mechanisms for the recognition of *cis-acting elements*. The  $-10$  and  $-35$  sequences in prokaryotic promoters are binding sites for RNA polymerase and its associated  $\sigma$  factor. In contrast, the TATA, CAAT, and GC boxes and other *cis-acting elements* in eukaryotic promoters are recognized by proteins other than by RNA polymerase itself.

### The TFIID protein complex initiates the assembly of the active transcription complex

*Cis-acting elements* constitute only part of the puzzle of eukaryotic gene expression. *Transcription factors* that bind to these elements also are required. For example, RNA polymerase II is guided to the start site by a set of transcription factors known collectively as *TFII* (*TF* stands for transcription factor, and *II* refers to RNA polymerase II). Individual *TFII* factors are called *TFIIA*, *TFIIB*, and so on.

In TATA-box promoters, the key initial event is the recognition of the TATA box by the TATA-box-binding protein (TBP), a 30-kDa component of the 700-kDa *TFIID* complex (Figure 29.25). In TATA-less promoters, other proteins in the *TFIID* complex bind the core promoter elements but, because less is known about these interactions, we will consider only the

**FIGURE 29.25 Transcription initiation.** Transcription factors TFIIA, B, D, E, F, and H are essential in initiating transcription by RNA polymerase II. The step-by-step assembly of these general transcription factors begins with the binding of TFIID (purple) to the TATA box. [The TATA-box-binding protein (TBP), a component of TFIID, recognizes the TATA box.] After assembly, TFIIH opens the DNA double helix and phosphorylates the carboxyl-terminal domain (CTD), allowing the polymerase to leave the promoter and begin transcription. The red arrow marks the transcription start site.

TATA-box–TBP binding interaction. TBP binds  $10^5$  times as tightly to the TATA box as to nonconsensus sequences; the dissociation constant of the TBP–TATA-box complex is approximately 1 nM. TBP is a saddle-shaped protein consisting of two similar domains (Figure 29.26). The TATA box of DNA binds to the concave surface of TBP. This binding induces large conformational changes in the bound DNA. The double helix is substantially unwound to widen its *minor groove*, enabling it to make extensive contact with the antiparallel  $\beta$  strands on the concave side of TBP. Hydrophobic interactions are prominent at this interface. Four phenylalanine residues, for example, are intercalated between base pairs of the TATA box. The flexibility of AT-rich sequences is generally exploited here in bending the DNA. Immediately outside the TATA box, classical B-DNA resumes. The TBP–TATA-box complex is distinctly asymmetric. The asymmetry is crucial for specifying a unique start site and ensuring that transcription proceeds unidirectionally.

*TBP bound to the TATA box is the heart of the initiation complex* (Figure 29.25). The surface of the TBP saddle provides docking sites for the binding of other components. Additional transcription factors assemble on this nucleus in a defined sequence. TFIIA is recruited, followed by TFIIB; then TFIIF, RNA polymerase II, TFIIE, and TFIIH join the other factors to form a complex called the *basal transcription apparatus*. During the formation of the basal transcription apparatus, the carboxyl-terminal domain (CTD) is unphosphorylated and plays a role in transcription regulation through its binding to an enhancer-associated complex called mediator (Section 32.2). The phosphorylated CTD stabilizes transcription elongation by RNA polymerase II and recruits RNA-processing enzymes that act in the course of elongation. *Phosphorylation of the CTD by TFIIH marks the transition from initiation to elongation.* The importance of the carboxyl-terminal domain is highlighted by the finding that yeast containing mutant polymerase II with fewer than 10 repeats in the CTD are not viable. Most of the factors are released before the polymerase leaves the promoter and can then participate in another round of initiation.

### Multiple transcription factors interact with eukaryotic promoters

The basal transcription complex described in the preceding section initiates transcription at a low frequency. Additional transcription factors that bind to other sites are required to achieve a high rate of mRNA synthesis. Their role is to selectively stimulate specific genes. Upstream stimulatory sites in eukaryotic genes are diverse in sequence and variable in position. Their variety suggests that they are recognized by many different specific proteins. Indeed, many transcription factors have been isolated, and their binding sites have been identified by footprinting experiments. For example, *heat-shock transcription factor* (HSTF) is expressed in *Drosophila* after an abrupt increase in temperature. This 93-kDa DNA-binding protein binds to the following consensus sequence:

Several copies of this sequence, known as the *heat-shock response element*, are present starting at a site 15 bp upstream of the TATA box.

**FIGURE 29.26 Complex formed by TATA-box-binding protein and DNA.** The saddlelike structure of the protein sits atop a DNA fragment. Notice that the DNA is significantly unwound and bent. [Drawn from 1CDW.pdb.]

HSTF differs from  $\sigma^{32}$ , a heat-shock protein of *E. coli* (p. 865), in binding directly to response elements in heat-shock promoters rather than first becoming associated with RNA polymerase.

### Enhancer sequences can stimulate transcription at start sites thousands of bases away

The activities of many promoters in higher eukaryotes are greatly increased by another type of cis-acting element called an *enhancer*. Enhancer sequences have no promoter activity of their own *yet can exert their stimulatory actions over distances of several thousand base pairs. They can be upstream, downstream, or even in the midst of a transcribed gene.* Moreover, enhancers are effective when present on *either the coding or non-coding DNA strand.*

A particular enhancer is effective only in certain cells. For example, the immunoglobulin enhancer functions in B lymphocytes but not elsewhere. Cancer can result if the relation between genes and enhancers is disrupted. In Burkitt lymphoma and B-cell leukemia, a chromosomal translocation brings the proto-oncogene *myc* (a transcription factor itself) under the control of a powerful immunoglobulin enhancer. The consequent dysregulation of the *myc* gene is believed to play a role in the progression of the cancer.

*Transcription factors and other proteins that bind to regulatory sites on DNA can be regarded as passwords that cooperatively open multiple locks, giving RNA polymerase access to specific genes.* The discovery of promoters and enhancers has allowed us to gain a better understanding of how genes are selectively expressed in eukaryotic cells. The regulation of gene transcription, discussed in Chapter 32, is the fundamental means of controlling gene expression.

Although bacteria lack TBP, archaea utilize a TBP molecule that is structurally quite similar to the eukaryotic protein. In fact, transcriptional control processes in archaea are, in general, much more similar to those in eukaryotes than are the processes in bacteria. Many components of the eukaryotic transcriptional machinery evolved from those in an ancestor of archaea.

## 29.3 The Transcription Products of Eukaryotic Polymerases Are Processed

Virtually all the initial products of transcription are further processed in eukaryotes. For example, primary transcripts (pre-mRNA molecules), the products of RNA polymerase II action, acquire a cap at their 5' ends and a poly(A) tail at their 3' ends. Most importantly, *nearly all mRNA precursors in higher eukaryotes are spliced.* Introns are precisely excised from primary transcripts, and exons are joined to form mature mRNAs with continuous messages. Some mature mRNAs are only a tenth the size of their precursors, which can be as large as 30 kb or more. The pattern of splicing can be regulated in the course of development to generate variations on a theme, such as membrane-bound or secreted forms of antibody molecules. Alternative splicing enlarges the repertoire of proteins in eukaryotes and is one clear illustration of why the proteome is more complex than the genome. The particular processing steps and the factors taking part vary according to the type of RNA polymerase.

**FIGURE 29.27 Processing of eukaryotic pre-rRNA.** The mammalian pre-rRNA transcript contains the RNA sequences destined to become the 18S, 5.8S, and 28S rRNAs of the small and large ribosomal subunits. First, nucleotides are modified: small nucleolar ribonucleoproteins methylate specific nucleoside groups and convert selected uridines into pseudouridines (indicated by red lines). Next, the pre-rRNA is cleaved and packaged to form mature ribosomes, in a highly regulated process in which more than 200 proteins take part.

### RNA polymerase I produces three ribosomal RNAs

Several RNA molecules are key components of ribosomes. RNA polymerase I transcription produces a single precursor (45S in mammals) that encodes three RNA components of the ribosome: the 18S rRNA, the 28S rRNA, and the 5.8S rRNA (Figure 29.27). The 18S rRNA is the RNA component of the small ribosomal subunit (40S), and the 28S and 5.8S rRNAs are two RNA components of the large ribosomal subunit (60S). The other RNA component of the large ribosomal subunit, the 5S rRNA, is transcribed by RNA polymerase III as a separate transcript.

The cleavage of the precursor into three separate rRNAs is actually the final step in its processing. First, the nucleotides of the pre-rRNA sequences destined for the ribosome undergo extensive modification, on both ribose and base components, directed by many *small nucleolar ribonucleoproteins* (snoRNPs), each of which consists of one snoRNA and several proteins. The pre-rRNA is assembled with ribosomal proteins, as guided by processing factors, in a large ribonucleoprotein. For instance, the small-subunit (SSU) processome is required for 18S rRNA synthesis and can be visualized in electron micrographs as a terminal knob at the 5' ends of the nascent rRNAs (Fig. 29.28). Finally, rRNA cleavage (sometimes coupled with additional processing steps) releases the mature rRNAs assembled with ribosomal proteins as ribosomes. Like those of RNA polymerase I transcription itself, most of these processing steps take place in the cell nucleolus, a nuclear subcompartment.

### RNA polymerase III produces transfer RNA

Eukaryotic tRNA transcripts are among the most processed of all RNA polymerase III transcripts. Like those of prokaryotic tRNAs, the 5' leader is cleaved by RNase P, the 3' trailer is removed, and CCA is added by the CCA-adding enzyme (Figure 29.29). Eukaryotic tRNAs are also heavily modified on base and ribose moieties; these modifications are important for function. In contrast with prokaryotic tRNAs, many eukaryotic pre-tRNAs are also spliced by an endonuclease and a ligase to remove an intron.

**FIGURE 29.28 Visualization of rRNA transcription and processing in eukaryotes.** Transcription of rRNA and its assembly into precursor ribosomes can be visualized by electron microscopy. The structures resemble Christmas trees: the trunk is the rDNA and each branch is a pre-rRNA transcript. Transcription starts at the top of the tree, where the shortest transcripts can be seen, and progresses down the rDNA to the end of the gene. The terminal knobs visible at the end of some pre-rRNA transcripts likely correspond to the SSU processome, a large ribonucleoprotein required for processing the pre-rRNA. [Reprinted by permission from Macmillan Publishers Ltd: *Nature* 417:967-970, F. Dragon et al. A large nucleolar U3 ribonucleoprotein required for 18S ribosomal RNA biogenesis, © 2002.]

**FIGURE 29.30 Capping the 5' end.** Caps at the 5' end of eukaryotic mRNA include 7-methylguanylate (red) attached by a triphosphate linkage to the ribose at the 5' end. None of the riboses are methylated in cap 0, one is methylated in cap 1, and both are methylated in cap 2.

**FIGURE 29.31 Polyadenylation of a primary transcript.** A specific endonuclease cleaves the RNA downstream of AAUAAA. Poly(A) polymerase then adds about 250 adenylate residues.

**FIGURE 29.29 Transfer RNA precursor processing.** The conversion of a yeast tRNA precursor into a mature tRNA requires the removal of a 14-nucleotide intron (yellow), the cleavage of a 5' leader (green), and the removal of UU and the attachment of CCA at the 3' end (red). In addition, several bases are modified.

### The product of RNA polymerase II, the pre-mRNA transcript, acquires a 5' cap and a 3' poly(A) tail

Perhaps the most extensively studied transcription product is the product of RNA polymerase II: most of this RNA will be processed to mRNA. The immediate product of RNA polymerase II is sometimes referred to as precursor-to-messenger RNA, or *pre-mRNA*. Most pre-mRNA molecules are spliced to remove the introns. Moreover, both the 5' and the 3' ends are modified, and both modifications are retained as the pre-mRNA is converted into mRNA.

As in prokaryotes, eukaryotic transcription usually begins with A or G. However, the 5' triphosphate end of the nascent RNA chain is immediately modified. First, a phosphoryl group is released by hydrolysis. The diphosphate 5' end then attacks the  $\alpha$ -phosphorus atom of GTP to form a very unusual 5'–5' triphosphate linkage. This distinctive terminus is called a *cap* (Figure 29.30). The N-7 nitrogen of the terminal guanine is then methylated by *S*-adenosylmethionine to form *cap 0*. The adjacent riboses may be methylated to form *cap 1* or *cap 2*. Transfer RNA and ribosomal RNA molecules, in contrast with messenger RNAs and with small RNAs that participate in

splicing, do not have caps. Caps contribute to the stability of mRNAs by protecting their 5' ends from phosphatases and nucleases. In addition, caps enhance the translation of mRNA by eukaryotic protein-synthesizing systems.

As mentioned earlier, pre-mRNA is also modified at the 3' end. Most eukaryotic mRNAs contain a polyadenylate, poly(A), tail at that end, added after transcription has ended. The DNA template does not encode this poly(A) tail. Indeed, the nucleotide preceding poly(A) is not the last nucleotide to be transcribed. Some primary transcripts contain hundreds of nucleotides beyond the 3' end of the mature mRNA.

How is the 3' end of the pre-mRNA given its final form? Eukaryotic primary transcripts are cleaved by a specific endonuclease that recognizes the sequence AAUAAA (Figure 29.31).

**FIGURE 29.32 Small regulatory RNA production.** A pathway from a transcription product including a microRNA to the mature microRNA bound to an Argonaute protein. The initial transcription product, a pri-microRNA, is first cleaved to a small double-stranded RNA called a pre-microRNA. One of the strands of the pre-microRNA, the mature microRNA, is then bound by an Argonaute protein.

Cleavage does not take place if this sequence or a segment of some 20 nucleotides on its 3' side is deleted. The presence of internal AAUAAA sequences in some mature mRNAs indicates that AAUAAA is only part of the cleavage signal; its context also is important. After cleavage of the pre-RNA by the endonuclease, a *poly(A) polymerase* adds about 250 adenylate residues to the 3' end of the transcript; ATP is the donor in this reaction.

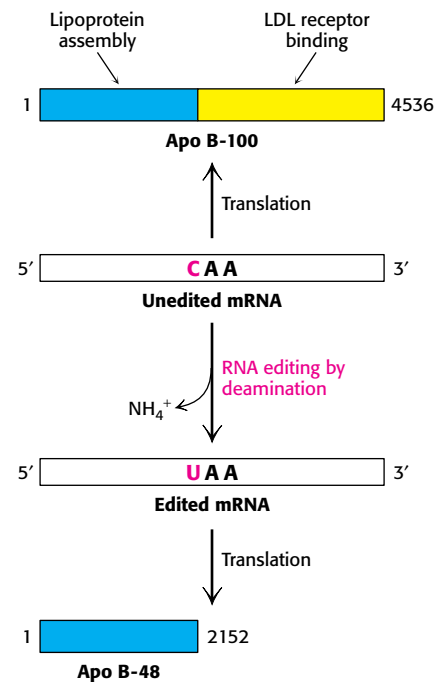

The role of the poly(A) tail is still not firmly established despite much effort. However, evidence is accumulating that it enhances translation efficiency and the stability of mRNA. Blocking the synthesis of the poly(A) tail by exposure to 3'-*deoxyadenosine* (*cordycepin*) does not interfere with the synthesis of the primary transcript. Messenger RNA devoid of a poly(A) tail can be transported out of the nucleus. However, an mRNA molecule devoid of a poly(A) tail is usually a much less effective template for protein synthesis than is one with a poly(A) tail. Indeed, some mRNAs are stored in an unadenylated form and receive the poly(A) tail only when translation is imminent. The half-life of an mRNA molecule may be determined in part by the rate of degradation of its poly(A) tail.

### Small regulatory RNAs are cleaved from larger precursors

Cleavage plays a role in the processing of small single-stranded RNAs (approximately 20–23 nucleotides) called *microRNAs*. MicroRNAs play key roles in gene regulation in eukaryotes, as we shall see in Chapter 32. They are generated from initial transcripts produced by RNA polymerase II and, in some cases, RNA polymerase III. These transcripts fold into hairpin structures that are cleaved by specific nucleases at various stages (Figure 29.32). The final single-stranded RNAs are bound by members of the Argonaute family of proteins where the RNAs help target the regulation of specific genes.

### RNA editing changes the proteins encoded by mRNA

Remarkably, the amino acid sequence information encoded by some mRNAs is altered after transcription. *RNA editing* is the term for a change in the nucleotide sequence of RNA after transcription by processes other than RNA splicing. RNA editing is prominent in some systems already discussed. *Apolipoprotein B* (apo B) plays an important role in the transport of triacylglycerols and cholesterol by forming an amphipathic spherical shell around the lipids carried in lipoprotein particles (Section 26.3). Apo B exists in two forms, a 512-kDa *apo B-100* and a 240-kDa *apo B-48*. The larger form, synthesized by the liver, participates in the transport of lipids synthesized in the cell. The smaller form, synthesized by the small intestine, carries dietary fat in the form of chylomicrons. Apo B-48 contains the 2152 N-terminal residues of the 4536-residue apo B-100. This truncated molecule can form lipoprotein particles but cannot bind to the low-density-lipoprotein receptor on cell surfaces. What is the relationship between these two forms of apo B? Experiments revealed that a totally unexpected mechanism for generating diversity is at work: *the changing of the nucleotide sequence of mRNA after its synthesis* (Figure 29.33). *A specific cytidine residue of mRNA is deaminated to uridine, which changes the codon at residue 2153*

**FIGURE 29.33 RNA editing.** Enzyme-catalyzed deamination of a specific cytidine residue in the mRNA for apolipoprotein B-100 changes a codon for glutamine (CAA) to a stop codon (UAA). Apolipoprotein B-48, a truncated version of the protein lacking the LDL receptor-binding domain, is generated by this posttranscriptional change in the mRNA sequence. [Information from P. Hodges and J. Scott, *Trends Biochem. Sci.* 17:77, 1992.]

from CAA (Gln) to UAA (stop). The deaminase that catalyzes this reaction is present in the small intestine, but not in the liver, and is expressed only at certain developmental stages.

RNA editing is not confined to apolipoprotein B. Glutamate opens cation-specific channels in the vertebrate central nervous system by binding to receptors in postsynaptic membranes. RNA editing changes a single glutamine codon (CAG) in the mRNA for the glutamate receptor to the codon for arginine (read as CGG). The substitution of Arg for Gln in the receptor prevents  $\text{Ca}^{2+}$ , but not  $\text{Na}^{+}$ , from flowing through the channel.

RNA editing is likely much more common than was formerly thought. The chemical reactivity of nucleotide bases, including the susceptibility to deamination that necessitates complex DNA-repair mechanisms, has been harnessed as an engine for generating molecular diversity at the RNA and, hence, protein levels.

In trypanosomes (parasitic protozoans), a different kind of RNA editing markedly changes several mitochondrial mRNAs. Nearly half the uridine residues in these mRNAs are inserted by RNA editing. A *guide RNA molecule* identifies the sequences to be modified, and a *poly(U) tail* on the guide donates uridine residues to the mRNAs undergoing editing. DNA sequences evidently do not always faithfully disclose the sequence of encoded proteins: functionally crucial changes to mRNA can take place.

### Sequences at the ends of introns specify splice sites in mRNA precursors

Most genes in higher eukaryotes are composed of exons and introns (Section 4.7). The introns must be excised and the exons must be linked to form the final mRNA in a process called *RNA splicing*. This splicing must be exquisitely sensitive: splicing just one nucleotide upstream or downstream of the intended site would create a one-nucleotide shift, which would alter the reading frame on the 3' side of the splice to give an entirely different amino acid sequence, likely including a premature stop codon. Thus, the correct splice site must be clearly marked. Does a particular sequence denote the splice site? The sequences of thousands of intron–exon junctions within RNA transcripts are known. In eukaryotes from yeast to mammals, these sequences have a common structural motif: *the intron begins with GU and ends with AG*. The consensus sequence at the 5' splice in vertebrates is AGGUAAGU, where the GU is invariant (Figure 29.34). At the 3' end of an intron, the consensus sequence is a stretch of 10 pyrimidines (U or C; termed the *polypyrimidine tract*), followed by any base and then by C, and ending with the invariant AG. Introns also have an important internal site located between 20 and 50 nucleotides upstream of the 3' splice site; it is called the *branch site* for reasons that will be evident shortly. In yeast, the branch-site sequence is nearly always UACUAAC, whereas, in mammals, a variety of sequences are found.

The 5' and 3' splice sites and the branch site are essential for determining where splicing takes place. Mutations in each of these three critical regions lead to aberrant splicing. Introns vary in length from 50 to 10,000 nucleotides, and so the splicing machinery may have to find the 3' site several

**FIGURE 29.34 Splice sites.** Consensus sequences for the 5' splice site and the 3' splice site are shown. Py stands for pyrimidine.

**FIGURE 29.35 Splicing mechanism used for mRNA precursors.** The upstream (5') exon is shown in blue, the downstream (3') exon in green, and the branch site in yellow. Y stands for a pyrimidine nucleotide, R for a purine nucleotide, and N for any nucleotide. The 5' splice site is attacked by the 2'-OH group of the branch-site adenosine residue. The 3' splice site is attacked by the newly formed 3'-OH group of the upstream exon. The exons are joined, and the intron is released in the form of a lariat. [Information from P. A. Sharp, *Cell* 42:397–408, 1985.]

thousand nucleotides away. Specific sequences near the splice sites (in both the introns and the exons) play an important role in splicing regulation, particularly in designating splice sites when there are many alternatives. Researchers are currently attempting to determine the factors that contribute to splice-site selection for individual mRNAs. Despite our knowledge of splice-site sequences, predicting pre-mRNAs and their protein products from genomic DNA sequence information remains a challenge.

### Splicing consists of two sequential transesterification reactions

The splicing of nascent mRNA molecules is a complicated process. It requires the cooperation of several small RNAs and proteins that form a large complex called a *spliceosome*. However, the chemistry of the splicing process is simple. Splicing begins with the cleavage of the phosphodiester bond between the upstream exon (exon 1) and the 5' end of the intron (Figure 29.35). The attacking group in this reaction is the 2'-OH group of an adenylate residue in the branch site. A 2'-5' phosphodiester bond is formed between this A residue and the 5' terminal phosphate of the intron. This reaction is a transesterification.

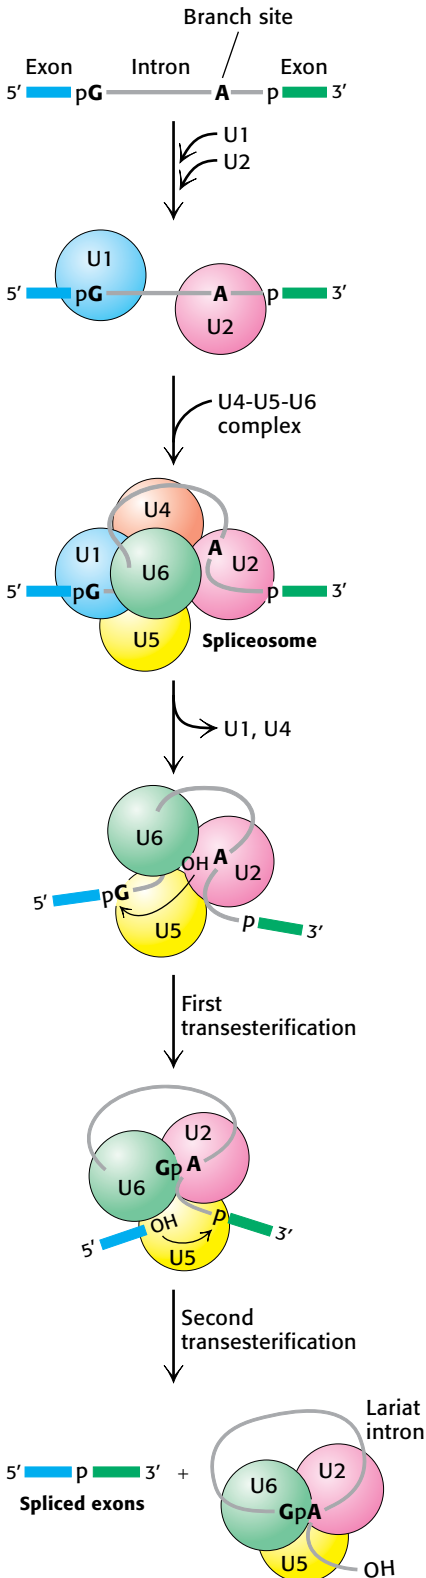

Note that this adenylate residue is also joined to two other nucleotides by normal 3'-5' phosphodiester bonds (Figure 29.36). Hence a *branch* is generated at this site, and a *lariat intermediate* is formed.

**FIGURE 29.36 Splicing branch point.** The structure of the branch point in the lariat intermediate in which the adenylate residue is joined to three nucleotides by phosphodiester bonds. The new 2'-to-5' linkage is shown in red, and the usual 3'-to-5' linkages are shown in blue.

**TABLE 29.3** Small nuclear ribonucleoprotein particles (snRNPs) in the splicing of mRNA precursors

snRNP	Size of snRNA (nucleotides)	Role
U1	165	Binds the 5' splice site
U2	185	Binds the branch site and forms part of the catalytic center
U5	116	Binds the 5' splice site and then the 3' splice site
U4	145	Masks the catalytic activity of U6
U6	106	Catalyzes splicing

The 3'-OH terminus of exon 1 then attacks the phosphodiester bond between the intron and exon 2. Exons 1 and 2 become joined, and the intron is released in lariat form. Again, this reaction is a transesterification. Splicing is thus accomplished by two *transesterification reactions* rather than by hydrolysis followed by ligation. The first reaction generates a free 3'-OH group at the 3' end of exon 1, and the second reaction links this group to the 5'-phosphate of exon 2. *The number of phosphodiester bonds stays the same during these steps*, which is crucial because it allows the splicing reaction itself to proceed without an energy source such as ATP or GTP.

### Small nuclear RNAs in spliceosomes catalyze the splicing of mRNA precursors

The nucleus contains many types of small RNA molecules with fewer than 300 nucleotides, referred to as *snRNAs* (small nuclear RNAs). A few of them—designated U1, U2, U4, U5, and U6—are essential for splicing mRNA precursors. The secondary structures of these RNAs are highly conserved in organisms ranging from yeast to human beings. These RNA molecules are associated with specific proteins to form complexes termed *snRNPs* (small nuclear ribonucleoprotein particles); investigators often speak of them as “snurps.” Spliceosomes are large (60S) dynamic assemblies composed of snRNPs, hundreds of other proteins called *splicing factors*, and the mRNA precursors being processed (Table 29.3).

In mammalian cells, splicing begins with the recognition of the 5' splice site by the U1 snRNP (Figure 29.37). U1 snRNA contains a highly conserved six-nucleotide sequence, not covered by protein in the snRNP, that base-pairs to the 5' splice site of the pre-mRNA. This binding initiates spliceosome assembly on the pre-mRNA molecule.

U2 snRNP then binds the branch site in the intron by base-pairing between a highly conserved sequence in U2 snRNA and the pre-mRNA.

**FIGURE 29.37 Spliceosome assembly and action.** U1 binds the 5' splice site and U2 binds to the branch point. A preformed U4-U5-U6 complex then joins the assembly to form the complete spliceosome. The U6 snRNA re-folds and binds the 5' splice site, displacing U1. Extensive interactions between U6 and U2 displace U4. Then, in the first transesterification step, the branch-site adenosine attacks the 5' splice site, making a lariat intermediate. U5 holds the two exons in close proximity, and the second transesterification takes place, with the 5' splice-site hydroxyl group attacking the 3' splice site. These reactions result in the mature spliced mRNA and a lariat form of the intron bound by U2, U5, and U6. [Information from T. Villa, J. A. Pleiss, and C. Guthrie, *Cell* 109:149–152, 2002.]

**FIGURE 29.38 Splicing catalytic center.** The catalytic center of the spliceosome is formed by U2 snRNA (red) and U6 snRNA (green), which are base paired. U2 is also base paired to the branch site of the mRNA precursor. [Information from H. D. Madhani and C. Guthrie, *Cell* 71:803–817, 1992.]

U2 snRNP binding requires ATP hydrolysis. A preassembled U4-U5-U6 tri-snRNP joins this complex of U1, U2, and the mRNA precursor to form the spliceosome. This association also requires ATP hydrolysis.

A revealing view of the interplay of RNA molecules in this assembly came from examining the pattern of cross-links formed by *psoralen*, a reagent that joins neighboring pyrimidines in base-paired regions on treatment with light. These cross-links suggest that splicing takes place in the following way. First, U5 interacts with exon sequences in the 5' splice site and subsequently with the 3' exon. Next, U6 disengages from U4 and undergoes an intramolecular rearrangement that permits base-pairing with U2 as well as interaction with the 5' end of the intron, displacing U1 from the spliceosome. The U2-U6 helix is indispensable for splicing, suggesting that *U2 and U6 snRNAs probably form the catalytic center of the spliceosome* (Figure 29.38). U4 serves as an inhibitor that masks U6 until the specific splice sites are aligned. These rearrangements result in the first transesterification reaction, cleaving the 5' exon and generating the lariat intermediate.

Further rearrangements of RNA in the spliceosome facilitate the second transesterification. In these rearrangements, U5 aligns the free 5' exon with the 3' exon such that the 3'-hydroxyl group of the 5' exon is positioned to nucleophilically attack the 3' splice site to generate the spliced product. U2, U5, and U6 bound to the excised lariat intron are released to complete the splicing reaction.

Many of the steps in the splicing process require ATP hydrolysis. How is the free energy associated with ATP hydrolysis used to power splicing? To achieve the well-ordered rearrangements necessary for splicing, ATP-powered RNA helicases must unwind RNA helices and allow alternative base-pairing arrangements to form. Thus, two features of the splicing process are noteworthy. First, *RNA molecules play key roles in directing the alignment of splice sites and in carrying out catalysis*. Second, *ATP-powered helicases unwind RNA duplex intermediates that facilitate catalysis and induce the release of snRNPs from the mRNA*.

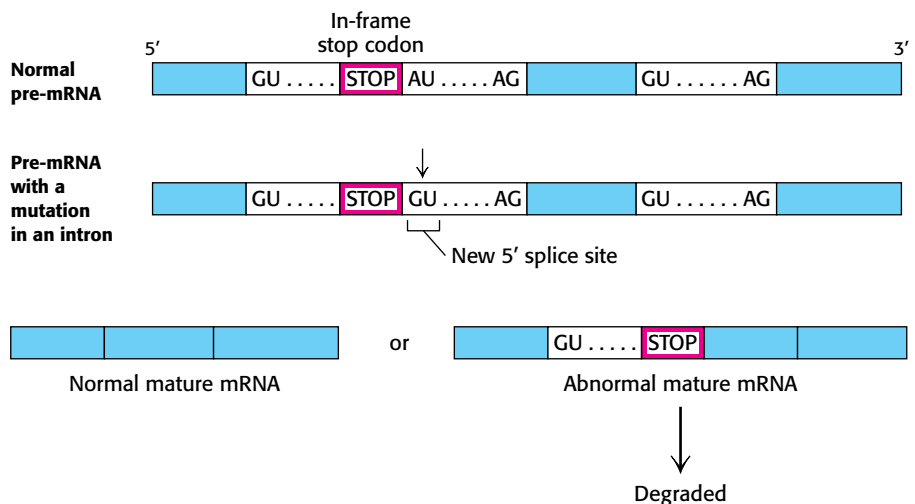

### Transcription and processing of mRNA are coupled

Although the transcription and processing of mRNAs have been described herein as separate events in gene expression, experimental evidence suggests that the two steps are coordinated by the carboxyl-terminal domain of RNA polymerase II. We have seen that the CTD consists of a unique repeated seven-amino-acid sequence, YSPTSPS. Either S<sub>2</sub> or S<sub>5</sub> or both may be phosphorylated in the various repeats. The phosphorylation state of the CTD is controlled by a number of kinases and phosphatases and leads the CTD to bind many of

**FIGURE 29.39 The CTD: Coupling transcription to pre-mRNA processing.** The transcription factor TFIIF phosphorylates the carboxyl-terminal domain (CTD) of RNA polymerase II, signaling the transition from transcription initiation to elongation. The phosphorylated CTD binds factors required for pre-mRNA capping, splicing, and polyadenylation. These proteins are brought in close proximity to their sites of action on the nascent pre-mRNA as it is transcribed during elongation. [Information from P. A. Sharp, *TIBS* 30:279–281, 2005.]

**FIGURE 29.40 A splicing mutation that causes thalassemia.** An A-to-G mutation within the first intron of the gene for the human hemoglobin  $\beta$  chain creates a new 5' splice site (GU). Both 5' splice sites are recognized by the U1 snRNP; thus splicing may sometimes create a normal mature mRNA and an abnormal mature mRNA that contains intron sequences. The normal mature mRNA is translated into a hemoglobin  $\beta$  chain. Because it includes intron sequences, the abnormal mature mRNA now has a premature stop codon and is degraded.

the proteins having roles in RNA transcription and processing. The CTD contributes to efficient transcription by recruiting these proteins to the pre-mRNA (Figure 29.39), including:

1. capping enzymes, which methylate the 5' guanine on the pre-mRNA immediately after transcription begins;
2. components of the splicing machinery, which initiate the excision of each intron as it is synthesized; and
3. an endonuclease that cleaves the transcript at the poly(A) addition site, creating a free 3'-OH group that is the target for 3' adenylation.

These events take place sequentially, directed by the phosphorylation state of the CTD.

### Mutations that affect pre-mRNA splicing cause disease

 Mutations in either the pre-mRNA (cis-acting) or the splicing factors (trans-acting) can cause defective pre-mRNA splicing. Mutations in the pre-mRNA cause some forms of thalassemia, a group of hereditary anemias characterized by the defective synthesis of hemoglobin (Section 7.4). Cis-acting mutations that cause aberrant splicing can occur at the 5' or 3' splice sites in either of the two introns of the hemoglobin  $\beta$  chain or in its exons. The mutations usually result in an incorrectly spliced pre-mRNA that, because of a premature stop codon, cannot encode a full-length protein. The defective mRNA is normally degraded rather than translated. Mutations in the 5' splice site may alter that site such that the splicing machinery cannot recognize it, forcing the machinery to find another 5' splice site in the intron and introducing the potential for a premature stop codon. Mutations in the intron itself may create a new 5' splice site; in this case, either one of the two splice sites may be recognized (Figure 29.40). Consequently, some normal protein can be made, and so the disease is less severe. *Mutations affecting splicing have been estimated to cause at least 15% of all genetic diseases.*

Disease-causing mutations may also appear in splicing factors. Retinitis pigmentosa is a disease of acquired blindness, first described in 1857, with an incidence of 1/3500. About 5% of the autosomal dominant form of retinitis

pigmentosa is likely due to mutations in the hPrp8 protein, a pre-mRNA splicing factor that is a component of the U4-U5-U6 tri-snRNP. How a mutation in a splicing factor that is present in all cells causes disease only in the retina is not clear; nevertheless, retinitis pigmentosa is a good example of how mutations that disrupt spliceosome function can cause disease.

### Most human pre-mRNAs can be spliced in alternative ways to yield different proteins

*Alternative splicing* is a widespread mechanism for generating protein diversity. Different combinations of exons from the same gene may be spliced into a mature RNA, producing distinct forms of a protein for specific tissues, developmental stages, or signaling pathways. What controls which splicing sites are selected? The selection is determined by the binding of trans-acting splicing factors to cis-acting sequences in the pre-mRNA. Most alternative splicing leads to changes in the coding sequence, resulting in proteins with different functions. *Alternative splicing provides a powerful mechanism for expanding the versatility of genomic sequences through combinatorial control.* Consider a gene with five positions at which splicing can take place. With the assumption that these alternative splicing pathways can be regulated independently, a total of  $2^5 = 32$  different mRNAs can be generated.

Sequencing of the human genome has revealed that most pre-mRNAs are alternatively spliced, leading to a much greater number of proteins than would be predicted from the number of genes. An example of alternative splicing leading to the expression of two different proteins, each in a different tissue, is provided by the gene encoding both calcitonin and calcitonin-gene-related peptide (CGRP; Figure 29.41). In the thyroid gland, the inclusion of exon 4 in one splicing pathway produces calcitonin, a peptide hormone that regulates calcium and phosphorus metabolism. In neuronal cells, the exclusion of exon 4 in another splicing pathway produces CGRP, a peptide hormone that acts as a vasodilator. A single pre-mRNA thus yields two very different peptide hormones, depending on cell type. In this case, only two proteins result from alternative splicing; however, in other cases, many more can be produced. An extreme example is the *Drosophila* pre-mRNA that encodes DSCAM, a neuronal protein affecting axon connectivity. Alternative splicing of this pre-mRNA has the potential to produce 38,016 different combinations of exons, a greater number than the total number of genes in the *Drosophila* genome. However, only a fraction of these potential mRNAs appear to be produced, owing to regulatory mechanisms that are not yet well understood. Several human diseases that can be attributed to defects in alternative splicing are listed in Table 29.4.

**FIGURE 29.41 An example of alternative splicing.** In human beings, two very different hormones are produced from a single calcitonin/CGRP pre-mRNA. Alternative splicing produces the mature mRNA for either calcitonin or CGRP (calcitonin-gene-related protein), depending on the cell type in which the gene is expressed. Each alternative transcript incorporates one of two alternative polyadenylation signals (A) present in the pre-mRNA.

**TABLE 29.4** Selected human diseases attributed to defects in alternative splicing

Disorder	Gene or its product
Acute intermittent porphyria	Porphobilinogen deaminase
Breast and ovarian cancer	BRCA1
Cystic fibrosis	CFTR
Frontotemporal dementia	$\tau$ protein
Hemophilia A	Factor VIII
HGPRT deficiency (Lesch–Nyhan syndrome)	Hypoxanthine-guanine phosphoribosyltransferase
Leigh encephalomyelopathy	Pyruvate dehydrogenase E1 $\alpha$
Severe combined immunodeficiency	Adenosine deaminase
Spinal muscle atrophy	SMN1 or SMN2

Further understanding of alternative splicing and the mechanisms of splice-site selection will be crucial to understanding how the proteome represented by the human genome is expressed.

## 29.4 The Discovery of Catalytic RNA Was Revealing in Regard to Both Mechanism and Evolution

RNAs form a surprisingly versatile class of molecules. As we have seen, splicing is catalyzed largely by RNA molecules, with proteins playing a secondary role. Another enzyme that contains a key RNA component is ribonuclease P, which catalyzes the maturation of tRNA by endonucleolytic cleavage of nucleotides from the 5' end of the precursor molecule. Finally, as we shall see in Chapter 30, the RNA component of ribosomes is the catalyst that carries out protein synthesis.

The versatility of RNA first became clear from observations of the processing of ribosomal RNA in a single-cell eukaryote. In *Tetrahymena* (a ciliated protozoan), a 414-nucleotide intron is removed from a 6.4-kb precursor to yield the mature 26S rRNA molecule (Figure 29.42). In an elegant series of studies of this splicing reaction, Thomas Cech and his coworkers established that the RNA spliced itself to precisely excise the intron. These remarkable experiments demonstrated that an RNA molecule can *splice itself* in the absence of protein. Indeed, the RNA alone is catalytic and, under certain conditions, is thus a *ribozyme*. More than 1500 similar introns have since been found in species as widely dispersed as bacteria and eukaryotes, though not in vertebrates. Collectively, they are referred to as *group I introns*.

The *self-splicing* reaction in the group I intron requires an added guanosine nucleotide. Nucleotides were originally included in the reaction mixture because it was thought that ATP or GTP might be needed as an energy source. Instead, the nucleotides were found to be necessary as cofactors. The required cofactor proved to be a guanosine unit, in the form of guanosine, GMP, GDP, or GTP. G (denoting any one of these species) serves not as an energy source but as an attacking group that becomes transiently incorporated into the RNA (Figure 29.42). G binds to the RNA and then attacks the 5' splice site to form a phosphodiester bond with the 5' end of

**FIGURE 29.43 Structure of a self-splicing intron.** The structure of a large fragment of the self-splicing intron from *Tetrahymena* reveals a complex folding pattern of helices and loops. Bases are shown in green, A; yellow, C; purple, G; and orange, U. [Drawn from 1GRZ.pdb].

the intron. This transesterification reaction generates a 3'-OH group at the end of the upstream exon. This newly attached 3'-OH group then attacks the 3' splice site. This second transesterification reaction joins the two exons and leads to the release of the 414-nucleotide intron.

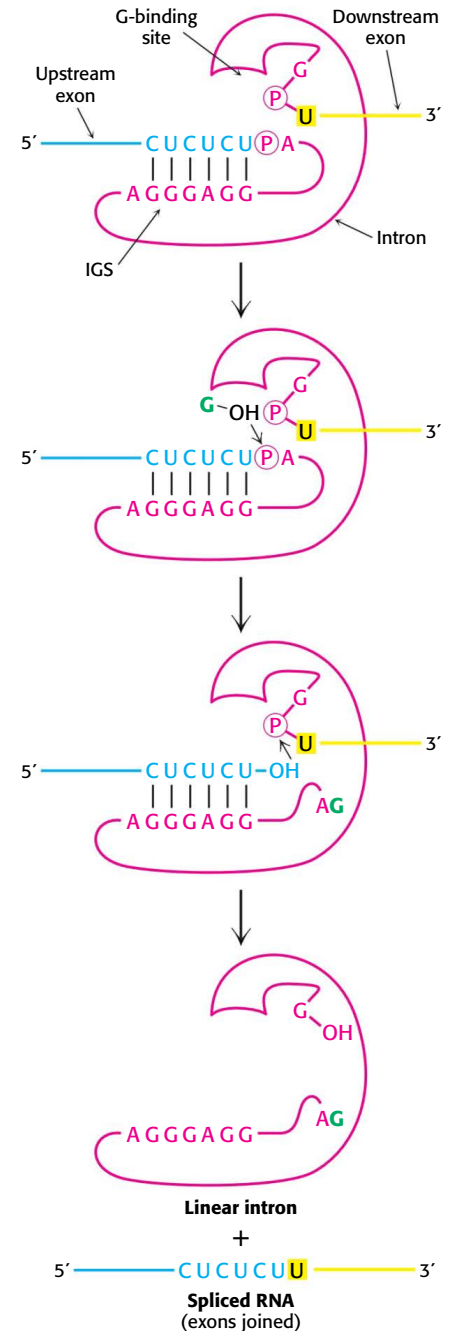

Self-splicing depends on the structural integrity of the RNA precursor. Much of the group I intron is needed for self-splicing. This molecule, like many RNAs, has a folded structure formed by many double-helical stems and loops (Figure 29.43), with a well-defined pocket for binding the guanosine. Examination of the three-dimensional structure of a catalytically active group I intron determined by x-ray crystallography reveals the coordination of magnesium ions in the active site analogous to that observed in protein enzymes such as DNA polymerase.

Analysis of the base sequence of the rRNA precursor suggested that the splice sites are aligned with the catalytic residues by base-pairing between the *internal guide sequence* (IGS) in the intron and the 5' and 3' exons (Figure 29.44). The IGS first brings together the guanosine cofactor and the 5' splice site so that the 3'-OH group of G can nucleophilically attack the phosphorus atom at this splice site. The IGS then holds the downstream exon in position for attack by the newly formed 3'-OH group of the upstream exon. A phosphodiester bond is formed between the two exons, and the intron is released as a linear molecule. Like catalysis by protein enzymes, self-catalysis of bond formation and breakage in this rRNA precursor is highly specific.

The finding of enzymatic activity in the self-splicing intron and in the RNA component of RNase P has opened new areas of inquiry and changed the way in which we think about molecular evolution. As mentioned in an earlier chapter, the discovery that RNA can be a catalyst as well as an information carrier suggests that an RNA world may have existed early in the evolution of life, before the appearance of DNA and protein.

Messenger RNA precursors in the mitochondria of yeast and fungi also undergo self-splicing, as do some RNA precursors in the chloroplasts of unicellular organisms such as *Chlamydomonas*. Self-splicing reactions can be classified according to the nature of the unit that attacks the upstream splice site. Group I self-splicing is mediated by a guanosine cofactor, as in *Tetrahymena*. The attacking moiety in group II splicing is the 2'-OH group of a specific adenylate of the intron (Figure 29.45).

Group I and group II self-splicing resembles spliceosome-catalyzed splicing in two respects. First, in the initial step, a ribose hydroxyl group

**FIGURE 29.44 Self-splicing mechanism.**

The catalytic mechanism of the group I intron includes a series of transesterification reactions. [Information from T. Cech. RNA as an enzyme. Copyright © 1986 by Scientific American, Inc. All rights reserved.]

## SELF-SPLICING INTRONS

## SPliceosome-CATALYZED SPLICING OF NUCLEAR mRNA

**FIGURE 29.45 Comparison of splicing pathways.** The exons being joined are shown in blue and yellow and the attacking unit is shown in green. The catalytic site is formed by the intron itself (red) in group I and group II splicing. In contrast, the splicing of nuclear mRNA precursors is catalyzed by snRNAs and their associated proteins in the spliceosome. [Information from P. A. Sharp, *Science* 235:766–771, 1987.]

attacks the 5' splice site. The newly formed 3'-OH terminus of the upstream exon then attacks the 3' splice site to form a phosphodiester bond with the downstream exon. Second, both reactions are transesterifications in which the phosphate moieties at each splice site are retained in the products. The number of phosphodiester bonds stays constant. Group II splicing is like the spliceosome-catalyzed splicing of mRNA precursors in several additional ways. The attack at the 5' splice site is carried out by a part of the intron itself (the 2'-OH group of adenosine) rather than by an external cofactor (G). In both cases, the intron is released in the form of a lariat. Moreover, in some instances, the group II intron is transcribed in pieces that assemble through hydrogen bonding to the catalytic intron, in a manner analogous to the assembly of the snRNAs in the spliceosome.

 These similarities have led to the suggestion that the spliceosome-catalyzed splicing of mRNA precursors evolved from RNA-catalyzed self-splicing. Group II splicing may well be an intermediate between group I splicing and the splicing in the nuclei of higher eukaryotes. A major step in this transition was the transfer of catalytic power from the intron itself to other molecules. The formation of spliceosomes gave genes a new freedom because introns were no longer constrained to provide the catalytic center for splicing. Another advantage of external catalysts for splicing is that they can be more readily regulated. However, it is important to note that similarities do

not establish ancestry. The similarities between group II introns and mRNA splicing may be a result of convergent evolution. Perhaps there are only a limited number of ways to carry out efficient, specific intron excision. The determination of whether these similarities stem from ancestry or from chemistry will require expanding our understanding of RNA biochemistry.

## SUMMARY

### 29.1 RNA Polymerases Catalyze Transcription

All cellular RNA molecules are synthesized by RNA polymerases according to instructions given by DNA templates. The activated monomer substrates are ribonucleoside triphosphates. The direction of RNA synthesis is  $5' \rightarrow 3'$ , as in DNA synthesis. RNA polymerases, unlike DNA polymerases, do not need a primer.

RNA polymerase in *E. coli* is a multisubunit enzyme. The subunit composition of the  $\sim 500$ -kDa holoenzyme is  $\alpha_2\beta\beta'\omega\sigma$  and that of the core enzyme is  $\alpha_2\beta\beta'\omega$ . Transcription is initiated at promoter sites consisting of two sequences, one centered near  $-10$  and the other near  $-35$ ; that is, 10 and 35 nucleotides away from the start site in the  $5'$  (upstream) direction. The consensus sequence of the  $-10$  region is TATAAT. The  $\sigma$  subunit enables the holoenzyme to recognize promoter sites. When the growth temperature is raised, *E. coli* expresses a special  $\sigma$  subunit that selectively binds the distinctive promoter of heat-shock genes. RNA polymerase must unwind the template double helix for transcription to take place. Unwinding exposes some 17 bases on the template strand and sets the stage for the formation of the first phosphodiester bond. Newly synthesized RNA chains usually start with pppG or pppA. The  $\sigma$  subunit usually dissociates from the holoenzyme after the initiation of the new chain.

Elongation takes place at transcription bubbles that move along the DNA template at a rate of about 50 nucleotides per second. RNA polymerase occasionally backtracks, a process that can facilitate proof-reading of the RNA transcript. The nascent RNA chain contains stop signals that end transcription. One stop signal is an RNA hairpin, which is followed by several U residues. A different stop signal is read by the *rho* protein, an ATPase. Some genes are regulated by riboswitches, structures that form in RNA transcripts and bind specific metabolites. In *E. coli*, precursors of transfer RNA and ribosomal RNA are cleaved and chemically modified after transcription, whereas messenger RNA is used unchanged as a template for protein synthesis.

### 29.2 Transcription in Eukaryotes Is Highly Regulated

RNA synthesis in eukaryotes takes place in the nucleus, whereas protein synthesis takes place in the cytoplasm. There are three types of RNA polymerase in the nucleus: RNA polymerase I makes ribosomal RNA precursors, II makes messenger RNA precursors, and III makes transfer RNA precursors. Eukaryotic promoters are complex, being composed of several different elements. Promoters for RNA polymerase II may be located on the  $5'$  side or the  $3'$  side of the start site for transcription. A common type of eukaryotic promoter consists of a TATA box centered between  $-30$  and  $-100$  and paired with an initiator element. Eukaryotic promoter elements are recognized by proteins called transcription factors rather than by RNA polymerase II. The saddle-shaped TATA-box-binding protein unwinds and sharply bends DNA at TATA-box sequences and serves as a focal point for the assembly of transcription complexes. The TATA-box-binding protein initiates the assembly of

the active transcription complex. The activity of many promoters is greatly increased by enhancer sequences that have no promoter activity of their own. Enhancer sequences can act over distances of several kilobases, and they can be located either upstream or downstream of a gene.

### 29.3 The Transcription Products of Eukaryotic Polymerases Are Processed

The 5' ends of mRNA precursors become capped and methylated in the course of transcription. A 3' poly(A) tail is added to most mRNA precursors after the nascent chain has been cleaved by an endonuclease. RNA editing alters the nucleotide sequence of some mRNAs, such as the one for apolipoprotein B.

The splicing of mRNA precursors is carried out by spliceosomes, which consist of small nuclear ribonucleoprotein particles. Splice sites in mRNA precursors are specified by sequences at ends of introns and by branch sites near their 3' ends. The 2'-OH group of an adenosine residue in the branch site attacks the 5' splice site to form a lariat intermediate. The newly generated 3'-OH terminus of the upstream exon then attacks the 3' splice site to become joined to the downstream exon. Splicing thus consists of two transesterification reactions, with the number of phosphodiester bonds remaining constant during reactions. Small nuclear RNAs in spliceosomes catalyze the splicing of mRNA precursors. In particular, U2 and U6 snRNAs form the active centers of spliceosomes.

The events in posttranscriptional processing of mRNA are controlled by the phosphorylation state of the carboxy-terminal domain, part of RNA polymerase II.

### 29.4 The Discovery of Catalytic RNA Was Revealing in Regard to Both Mechanism and Evolution

Some RNA molecules, such as those containing the group I intron, undergo self-splicing in the absence of protein. A self-modified version of this rRNA intron displays true catalytic activity and is thus a ribozyme. Spliceosome-catalyzed splicing may have evolved from self-splicing. The discovery of catalytic RNA has opened new vistas in our exploration of early stages of molecular evolution and the origins of life.

## PROBLEMS

- Complements.* The sequence of part of an mRNA is 5'-AUGGGGAACAGCAAGAGUGGGGCCUGUCCAAGGAG-3'. What is the sequence of the DNA coding strand? Of the DNA template strand?
- Checking for errors.* Why is RNA synthesis not as carefully monitored for errors as is DNA synthesis?
- Speed is not of the essence.* Why is it advantageous for DNA synthesis to be more rapid than RNA synthesis?

4. *Active sites.* The overall structures of RNA polymerase and DNA polymerase are very different, yet their active sites show considerable similarities. What do the similarities suggest about the evolutionary relationship between these two important enzymes?

5. *Potent inhibitor.* Heparin inhibits transcription by binding to RNA polymerase. What properties of heparin allow it to bind so effectively to RNA polymerase?

6. *A loose cannon.* Sigma protein by itself does not bind to promoter sites. Predict the effect of a mutation enabling  $\sigma$  to bind to the  $-10$  region in the absence of other subunits of RNA polymerase.

7. *Stuck sigma.* What would be the likely effect of a mutation that prevents  $\sigma$  from dissociating from the RNA polymerase core?

8. *Transcription time.* What is the minimum length of time required for the synthesis by *E. coli* polymerase of an mRNA encoding a 100-kDa protein?

9. *Rapid search.* RNA polymerase finds promoter sites very rapidly. The observed rate constant for the binding of the RNA polymerase holoenzyme to promoter sequences is  $10^{10} \text{ M}^{-1}\text{s}^{-1}$ . The rate constant for two macromolecules encountering each other is typically  $10^8 \text{ M}^{-1}\text{s}^{-1}$ . Propose an explanation for the 100-fold larger rate for a protein finding a particular site along a DNA molecule.

10. *Where to begin?* Identify the likely transcription start site in the following DNA sequence:

5'-GCCGTTGACACCGTTTCGGCGATCGATCCGCTATAATGTGTGGATCCGCTT-3'  
3'-CGGCAACTGTGGCAAGCCGCTAGCTAGGCGATATTACACACCTAGGCGAA-5'

11. *Between bubbles.* How far apart are transcription bubbles on *E. coli* genes that are being transcribed at a maximal rate?

12. *A revealing bubble.* Consider the synthetic RNA-DNA transcription bubble illustrated here. Refer to the coding DNA strand, the template strand, and the RNA strand as strands 1, 2, and 3, respectively.

(a) Suppose that strand 3 is labeled with  $^{32}\text{P}$  at its 5' end and that polyacrylamide gel electrophoresis is carried out under nondenaturing conditions. Predict the autoradiographic pattern for (i) strand 3 alone, (ii) strands 1 and 3,

(iii) strands 2 and 3, (iv) strands 1, 2, and 3, and (v) strands 1, 2, and 3 and core RNA polymerase.

(b) What is the likely effect of rifampicin on RNA synthesis in this system?

(c) Heparin blocks elongation of the RNA primer if it is added to core RNA polymerase before the onset of transcription but not if added after transcription starts. Account for this difference.

(d) Suppose that synthesis is carried out in the presence of ATP, CTP, and UTP. Compare the length of the longest product obtained with that expected when all four ribonucleoside triphosphates are present.

13. *Proofreading marks.* The major products of proofreading by RNA polymerase are dinucleotides rather than mononucleotides. Why?

14. *Abortive cycling.* Di- and trinucleotides are occasionally released from RNA polymerase at the very start of transcription, a process called abortive cycling. This process requires the restart of transcription. Suggest a plausible explanation for abortive cycling.

15. *Polymerase inhibition.* Cordycepin inhibits poly(A) synthesis at low concentrations and RNA synthesis at higher concentrations.

(a) What is the basis of inhibition by cordycepin?

(b) Why is poly(A) synthesis more sensitive than the synthesis of other RNAs to the presence of cordycepin?

(c) Does cordycepin need to be modified to exert its effect?

16. *Alternative splicing.* A gene contains eight sites where alternative splicing is possible. Assuming that the splicing pattern at each site is independent of that at all other sites, how many splicing products are possible?

17. *Supercoiling.* Negative supercoiling of DNA favors the transcription of genes because it facilitates unwinding. However, not all promoter sites are stimulated by negative supercoiling. The promoter site for topoisomerase II itself is a noteworthy exception. Negative supercoiling decreases the rate of transcription of this gene. Propose a possible mechanism for this effect and suggest a reason why it may occur.

18. *An extra piece.* In one type of mutation leading to a form of thalassemia, the mutation of a single base (G to A) generates a new 3' splice site (blue in the illustration below) akin to the normal one (yellow) but farther upstream.

What is the amino acid sequence of the extra segment of protein synthesized in a thalassemic patient having a mutation leading to aberrant splicing? The reading frame after the splice site begins with TCT.

19. *A long-tailed messenger.* Another thalassemic patient had a mutation leading to the production of an mRNA for the  $\beta$  chain of hemoglobin that was 900 nucleotides longer than the normal one. The poly(A) tail of this mutant mRNA was located a few nucleotides after the only AAUAAA sequence in the additional sequence. Propose a mutation that would lead to the production of this altered mRNA.

### Mechanism Problem

20. *RNA editing.* Many uridine molecules are inserted into some mitochondrial mRNAs in trypanosomes. The uridine residues come from the poly(U) tail of a donor strand. Nucleoside triphosphates do not participate in this reaction. Propose a reaction mechanism that accounts for these findings. (Hint: Relate RNA editing to RNA splicing.)

### Chapter Integration Problems

21. *Proteome complexity.* What processes considered in this chapter make the proteome more complex than the genome? What processes might further enhance this complexity?

22. *Separation technique.* Suggest a means by which you could separate mRNA from the other types of RNA in a eukaryotic cell.

### Data Interpretation Problems

23. *Run-off experiment.* Nuclei were isolated from brain, liver, and muscle. The nuclei were then incubated with  $\alpha$ - $^{32}\text{P}$ UTP under conditions that allow RNA synthesis, except that an inhibitor of RNA initiation was present. The

radioactive RNA was isolated and annealed to various DNA sequences that had been attached to a gene chip. In the adjoining graphs, the intensity of the shading indicates roughly how much mRNA was attached to each DNA sequence.

(a) Why does the intensity of hybridization differ between genes?

(b) What is the significance of the fact that some of the RNA molecules display different hybridization patterns in different tissues?

(c) Some genes are expressed in all three tissues. What would you guess is the nature of these genes?

(d) Suggest a reason why an initiation inhibitor was included in the reaction mixture.

24. *Christmas trees.* The adjoining autoradiograph depicts several bacterial genes undergoing transcription. Identify the DNA. What are the strands of increasing length? Where is the beginning of transcription? The end of transcription? On the page, what is the direction of RNA synthesis? What can you conclude about the number of enzymes participating in RNA synthesis on a given gene?

[Thomas Broker/Phototake.]

# Protein Synthesis

The ribosome, shown at the right, is a factory for the manufacture of polypeptides. Amino acids are carried into the ribosome, one at a time, connected to transfer RNA molecules. Each amino acid is joined to the growing polypeptide chain, which detaches from the ribosome only after the polypeptide has been completed. This assembly-line approach allows even very long polypeptide chains to be assembled rapidly and with impressive accuracy. [(Left) Images of Birmingham Premium/Alamy.]

The genes that encode proteins are key components of the genetic information because proteins play most of the functional roles in cells. In Chapters 28 and 29, we examined how DNA is replicated and transcribed into RNA. We now turn to the mechanism of protein synthesis, a process called *translation* because the four-letter alphabet of nucleic acids is translated into the entirely different twenty-letter alphabet of proteins. Translation is a conceptually more complex process than either replication or transcription, both of which take place within the framework of a common base-pairing language. As befits its position linking the nucleic acid and protein languages, the process of protein synthesis critically depends on both nucleic acid and protein factors. Protein synthesis takes place on *ribosomes*—enormous complexes containing three large RNA molecules and more than 50 proteins. Interestingly, *the ribosome is a ribozyme*; that is, the RNA components catalyze protein synthesis. This observation strongly supports the notion that life evolved through an RNA world, and the ribosome is a surviving inhabitant of that world.

Transfer RNA molecules (tRNAs) and messenger RNA (mRNA) also are key participants in protein synthesis. The link between amino acids and nucleic acids is first made by enzymes called aminoacyl-tRNA synthetases. By specifically linking a particular amino acid to each tRNA, these enzymes translate the genetic code.

Although RNA is paramount in the process of translation, protein factors also are required for the efficient synthesis of a protein. Protein factors participate in the initiation, elongation, and termination of protein synthesis.

## OUTLINE

- 30.1** Protein Synthesis Requires the Translation of Nucleotide Sequences into Amino Acid Sequences
- 30.2** Aminoacyl Transfer RNA Synthetases Read the Genetic Code
- 30.3** The Ribosome Is the Site of Protein Synthesis
- 30.4** Eukaryotic Protein Synthesis Differs from Bacterial Protein Synthesis Primarily in Translation Initiation
- 30.5** A Variety of Antibiotics and Toxins Can Inhibit Protein Synthesis
- 30.6** Ribosomes Bound to the Endoplasmic Reticulum Manufacture Secretory and Membrane Proteins

This chapter focuses primarily on protein synthesis in bacteria because it illustrates many general principles and is well understood. Some distinctive features of protein synthesis in eukaryotes also are presented.

### 30.1 Protein Synthesis Requires the Translation of Nucleotide Sequences into Amino Acid Sequences

The basics of protein synthesis are the same across all kingdoms of life—evidence that the protein-synthesis system arose very early in evolution. An mRNA is decoded, or read, in the 5′-to-3′ direction, one codon at a time, and the corresponding protein is synthesized in the amino-to-carboxyl direction by the sequential addition of amino acids to the carboxyl end of the growing peptide chain (Figure 30.1). The amino acids arrive at the growing chain in activated form as aminoacyl-tRNAs, created by joining the carboxyl group of an amino acid to the 3′ end of a tRNA molecule. The linking of an amino acid to its corresponding tRNA is catalyzed by an *aminoacyl-tRNA synthetase*. For each amino acid, there is usually one activating enzyme and at least one kind of tRNA.

**FIGURE 30.1 Polypeptide-chain growth.**

Proteins are synthesized by the successive addition of amino acids to the carboxyl terminus.

#### The synthesis of long proteins requires a low error frequency

The process of transcription is analogous to copying, word for word, a page of a book. There is no change of alphabet or vocabulary; so the likelihood of a change in meaning is small. Translating the base sequence of an mRNA molecule into a sequence of amino acids is analogous to translating the page of a book into another language. Translation is a complex process, entailing many steps and dozens of molecules. The potential for error exists at each step. The complexity of translation creates a conflict between two requirements: the process must be both accurate and fast enough to meet a cell's needs. In *E. coli*, translation can take place at a rate of 20 amino acids per second, a truly impressive speed considering the complexity of the process.

How accurate must protein synthesis be? Let us consider error rates. The probability of forming a protein with no errors depends on the number of amino acid residues and on the frequency ( $\epsilon$ ) of insertion of a wrong amino acid. As Table 30.1 shows, an error frequency of  $10^{-2}$  is intolerable, even for quite small proteins. An  $\epsilon$  value of  $10^{-3}$  usually leads to the error-free synthesis of a 300-residue protein ( $\sim 33$  kDa) but not of a 1000-residue protein ( $\sim 110$  kDa). Thus, the error frequency must not exceed approximately

**TABLE 30.1** Accuracy of protein synthesis

Frequency of inserting an incorrect amino acid	Probability of synthesizing an error-free protein		
	Number of amino acid residues		
	100	300	1000
$10^{-2}$	0.366	0.049	0.000
$10^{-3}$	0.905	0.741	0.368
$10^{-4}$	0.990	0.970	0.905
$10^{-5}$	0.999	0.997	0.990

Note: The probability  $p$  of forming a protein with no errors depends on  $n$ , the number of amino acids, and  $\epsilon$ , the frequency of insertion of a wrong amino acid:  $p = (1 - \epsilon)^n$ .

$10^{-4}$  to produce the larger proteins effectively. Lower error frequencies are conceivable; however, except for the largest proteins, they will not dramatically increase the percentage of proteins with accurate sequences. In addition, such lower error rates are likely to be possible only by a reduction in the rate of protein synthesis because additional time for proofreading is required. *In fact, the observed values of  $\epsilon$  are close to  $10^{-4}$ .* An error frequency of about  $10^{-4}$  per amino acid residue was selected in the course of evolution to accurately produce proteins consisting of as many as 1000 amino acids while maintaining a remarkably rapid rate for protein synthesis.

### Transfer RNA molecules have a common design

The fidelity of protein synthesis requires accurate recognition of three-base *codons* on messenger RNA. Recall that the genetic code relates each amino acid to a three-letter codon (Section 4.6). An amino acid cannot itself recognize a codon. Consequently, an amino acid is attached to a specific tRNA molecule that recognizes the codon by Watson–Crick base-pairing. *Transfer RNA serves as the adapter molecule that binds to a specific codon and brings with it an amino acid for incorporation into the polypeptide chain.*

Consider yeast alanyl-tRNA, so called because it will carry the amino acid alanine. This adapter molecule is a single chain of 76 ribonucleotides (Figure 30.2). The 5' terminus is phosphorylated (pG), whereas the 3' terminus has a free hydroxyl group. The *amino acid-attachment site* is the 3'-hydroxyl group of the adenosine residue at the 3' terminus of the molecule. The sequence 5'-IGC-3' in the middle of the molecule is the *anticodon*, where I is the purine base inosine. It is complementary to 5'-GCC-3', one of the codons for alanine.

Thousands of tRNA sequences are known. The striking finding is that all of them can be arranged in a cloverleaf pattern in which about half the residues are base-paired (Figure 30.3). Hence, *tRNA molecules have many common structural features*. This finding is not unexpected, because all tRNA molecules must be able to interact in nearly the same way with the ribosomes, mRNAs, and protein factors that participate in translation.

**FIGURE 30.2 Alanyl-tRNA sequence.** The base sequence of yeast alanyl-tRNA and the deduced cloverleaf secondary structure are shown. Modified nucleosides are abbreviated as follows: methylinosine (ml), dihydrouridine ( $\text{UH}_2$ ), ribothymidine (T), pseudouridine ( $\psi$ ), methylguanosine (mG), and (dimethylguanosine ( $\text{m}_2\text{G}$ ). Inosine (I), another modified nucleoside, is part of the anticodon.

**FIGURE 30.3 General structure of tRNA molecules.** Comparison of the base sequences of many tRNAs reveals a number of conserved features.

All known transfer RNA molecules have the following features:

1. Each is a single chain containing between 73 and 93 ribonucleotides (~25 kDa).

2. The molecule is L-shaped (Figure 30.4).

3. They contain *many unusual bases*, typically between 7 and 15 per molecule. Some of these bases are methylated or dimethylated derivatives of A, U, C, and G formed by enzymatic modification of a precursor tRNA. Some methylations prevent the formation of certain base pairs, thereby rendering such bases accessible for interactions with other bases. In addition, methylation imparts a hydrophobic character to some regions of tRNAs, which may be important for their interaction with synthetases and ribosomal proteins. Other modifications alter codon recognition, as will be described shortly.

4. About half the nucleotides in tRNAs are base-paired to form double helices. The four helical regions are arranged to form two apparently continuous segments of double helix. These segments are like A-form DNA, as expected for an RNA helix (Section 4.2). One helix, containing the 5' and 3' ends, runs horizontally in the model shown in Figure 30.5. The other helix, which contains the anticodon and runs vertically in Figure 30.5, forms the other arm of the L.

Five groups of bases are not base-paired in this way: the 3' *CCA terminal region*, which is part of a region called the *acceptor stem*; the *T $\psi$ C loop*, which acquired its name from the sequence ribothymine-pseudouracil-cytosine; the "*extra arm*," which contains a variable number of residues; the *DHU loop*, which contains several dihydrouracil residues; and the *anticodon loop*. Most of the bases in the nonhelical regions participate in hydrogen-bonding interactions, even if the interactions are not like those in Watson-Crick base pairs. The structural diversity generated by this combination of helices and loops containing modified bases ensures that the tRNAs can be uniquely distinguished, though they are structurally similar overall.

5. The 5' end of a tRNA is phosphorylated. The 5' terminal residue is usually pG.

6. An activated amino acid is attached to a hydroxyl group of the adenosine residue in the amino acid-attachment site, located at the end of the 3' CCA

**FIGURE 30.4 Transfer RNA structure.** Notice the L-shaped structure revealed by this skeletal model of yeast phenylalanyl-tRNA. The CCA region is at the end of one arm, and the anticodon loop is at the end of the other. [Drawn from 1EHZ.pdb.]

**FIGURE 30.5 Helix stacking in tRNA.** The four double-stranded regions of the tRNA (Figure 30.3) stack to form an L-shaped structure. [Drawn from 1EHZ.pdb.]

component of the acceptor stem (Figure 30.6). This single-stranded region can change conformation in the course of amino acid activation and protein synthesis.

7. The anticodon loop, which is present in a loop near the center of the sequence, is at the other end of the L, making accessible the three bases that constitute the anticodon.

Thus, the architecture of the tRNA molecule is well suited to its role as adaptor: the anticodon is available to interact with an appropriate codon on mRNA while the end that is linked to an activated amino acid is well positioned to participate in peptide-bond formation.

### Some transfer RNA molecules recognize more than one codon because of wobble in base-pairing

What are the rules that govern the recognition of a codon by the anticodon of a tRNA? A simple hypothesis is that each of the bases of the codon forms a Watson–Crick type of base pair with a complementary base on the anticodon of the tRNA. The codon and anticodon would then be lined up in an antiparallel fashion. In the diagram in the margin, the prime denotes the complementary base. Thus X and X' would be either A and U (or U and A) or G and C (or C and G). According to this model, a particular anticodon can recognize only one codon.

The facts are otherwise. As found experimentally, *some tRNA molecules can recognize more than one codon*. For example, the yeast alanyl-tRNA binds to *three* codons: GCU, GCC, and GCA. The first two bases of these codons are the same, whereas the third is different. Could it be that recognition of the third base of a codon is sometimes less discriminating than recognition of the other two? The pattern of degeneracy of the genetic code indicates that it might be so. XYU and XYC always encode the same amino acid; XYA and XYG usually do. These data suggest that the steric criteria might be less stringent for pairing of the third base than for the other two. In other words, there is some steric freedom (“wobble”) in the pairing of the third base of the codon.

The *wobble hypothesis* is now firmly established (Table 30.2). The anticodons of tRNAs of known sequence bind to the codons predicted by this hypothesis. For example, the anticodon of yeast alanyl-tRNA is IGC. This tRNA recognizes the codons GCU, GCC, and GCA. Recall that, by convention, nucleotide sequences are written in the 5' → 3' direction unless otherwise noted. Hence, I (the 5' base of this anticodon) pairs with U, C, or A (the 3' base of the codon), as predicted.

**FIGURE 30.6 Aminoacyl-tRNA.** Amino acids are coupled to tRNAs through ester linkages to either the 2'- or the 3'-hydroxyl group of the 3'-adenosine residue. A linkage to the 3'-hydroxyl group is shown.

**TABLE 30.2** Allowed pairings at the third base of the codon according to the wobble hypothesis

First base of anticodon	Third base of codon
C	G
A	U
U	A or G
G	U or C
I	U, C, or A

**FIGURE 30.7** 16S rRNA monitors base-pairing between the codon and the anticodon. Adenine 1493, one of three universally conserved bases in 16S rRNA, forms hydrogen bonds with the bases in both the codon and the anticodon only if the codon and anticodon are correctly paired. [Information from J. M. Ogle and V. Ramakrishnan, *Annu. Rev. Biochem.* 74: 129–177, 2005, Fig. 2a.]

Two generalizations concerning the codon–anticodon interaction can be made:

1. The first two bases of a codon pair in the standard way. Recognition is precise. Hence, *codons that differ in either of their first two bases must be recognized by different tRNAs*. For example, both UUA and CUA encode leucine but are read by different tRNAs.
2. The first base of an anticodon determines whether a particular tRNA molecule reads one, two, or three kinds of codons: C or A (one codon), U or G (two codons), or I (three codons). Thus, *part of the degeneracy of the genetic code arises from imprecision (wobble) in the pairing of the third base of the codon with the first base of the anticodon*. We see here a strong reason for the frequent appearance of inosine, one of the unusual nucleosides, in anticodons. *Inosine maximizes the number of codons that can be read by a particular tRNA molecule*. The inosine bases in tRNA are formed by the deamination of adenosine after the synthesis of the primary transcript.

Why is wobble tolerated in the third position of the codon but not in the first two? This question is answered by considering the interaction of the tRNA with the ribosome. As we will see, ribosomes are huge RNA–protein complexes consisting of two subunits, the 30S and 50S subunits. The 30S subunit has an RNA molecule, the 16S rRNA, that has three universally conserved bases—adenine 1492, adenine 1493, and guanine 530—that form hydrogen bonds on the minor-groove side but only with correctly formed base pairs of the codon–anticodon duplex (Figure 30.7). These interactions check whether Watson–Crick base pairs are present in the first two positions of the codon–anticodon duplex, but not the third position, so more-varied base pairs are tolerated. *Thus, the ribosome plays an active role in decoding the codon–anticodon interactions.*

## 30.2 Aminoacyl Transfer RNA Synthetases Read the Genetic Code

Before codon and anticodon meet, the amino acids required for protein synthesis must first be attached to specific tRNA molecules, linkages that are crucial for two reasons. *First, the attachment of a given amino acid to a particular tRNA establishes the genetic code*. When an amino acid has been linked to a tRNA, it will be incorporated into a growing polypeptide chain at a position dictated by the anticodon of the tRNA. *Second, because the formation of a peptide bond between free amino acids is not thermodynamically favorable, the amino acid must first be activated in order for protein synthesis to proceed*. The activated intermediates in protein synthesis are amino acid esters, in which the carboxyl group of an amino acid is linked to either the 2'- or the 3'-hydroxyl group of the ribose unit at the 3' end of tRNA. An amino acid ester of tRNA is called an *aminoacyl-tRNA* or sometimes a *charged tRNA* (Figure 30.6). For a specific amino acid attached to its cognate tRNA—for instance, threonine—the charged tRNA is designated Thr-tRNA<sup>Thr</sup>.

### Amino acids are first activated by adenylation

The activation reaction is catalyzed by specific *aminoacyl-tRNA synthetases*. The first step is the formation of an *aminoacyl adenylate* from an amino acid and ATP.

This activated species is a mixed anhydride in which the carboxyl group of the amino acid is linked to the phosphoryl group of AMP; hence, it is also known as *aminoacyl-AMP*.

The next step is the transfer of the aminoacyl group of aminoacyl-AMP to a particular tRNA molecule to form *aminoacyl-tRNA*.

The sum of these activation and transfer steps is

The  $\Delta G^\circ$  of this reaction is close to 0, because the free energy of hydrolysis of the ester bond of aminoacyl-tRNA is similar to that for the hydrolysis of ATP to AMP and  $\text{PP}_i$ . As we have seen many times, the reaction is driven by the hydrolysis of pyrophosphate. The sum of these three reactions is highly exergonic:

Thus, *the equivalent of two molecules of ATP is consumed in the synthesis of each aminoacyl-tRNA*. One of them is consumed in forming the ester linkage of aminoacyl-tRNA, whereas the other is consumed in driving the reaction forward.

The activation and transfer steps for a particular amino acid are catalyzed by the same aminoacyl-tRNA synthetase. Indeed, *the aminoacyl-AMP intermediate does not dissociate from the synthetase*. Rather, it is tightly bound to the active site of the enzyme by noncovalent interactions.

We have already encountered an acyl adenylate intermediate in fatty acid activation (Section 22.2). The major difference between these reactions is that the acceptor of the acyl group is CoA in fatty acid activation and tRNA in amino acid activation. The energetics of these biosyntheses are very similar: both are made irreversible by the hydrolysis of pyrophosphate.

### Aminoacyl-tRNA synthetases have highly discriminating amino acid activation sites

Each aminoacyl-tRNA synthetase is highly specific for a given amino acid. Indeed, a synthetase will incorporate the incorrect amino acid only once in  $10^4$  or  $10^5$  reactions. How is this level of specificity achieved? Each aminoacyl-tRNA synthetase takes advantage of the properties of its amino acid substrate. Let us consider the challenge faced by threonyl-tRNA synthetase. Threonine is especially similar to two other amino acids—namely, valine and serine. Valine has almost exactly the same shape as that of threonine, except that valine has a methyl group in place of a hydroxyl group. Serine has a hydroxyl group, as does threonine, but lacks the methyl group. How can the threonyl-tRNA synthetase avoid coupling these incorrect amino acids to threonyl-tRNA?

**FIGURE 30.9** Editing site.

Mutagenesis studies revealed the position of the editing site (shown in green) in threonyl-tRNA synthetase. The activation site is shown in yellow. Only one subunit of the dimeric enzyme is shown here and in subsequent illustrations. [Drawn from 1QF6.pdb.]

**FIGURE 30.10** Editing of aminoacyl-tRNA.

The flexible CCA arm of an aminoacyl-tRNA can move the amino acid between the activation site and the editing site. If the amino acid fits well into the editing site, the amino acid is removed by hydrolysis.

**FIGURE 30.8** Active site of threonyl-tRNA synthetase. Notice that the amino acid-binding site includes a zinc ion (green ball) that binds threonine through its amino and hydroxyl groups.

The structure of the amino acid-binding site of threonyl-tRNA synthetase reveals how valine is avoided (Figure 30.8). The synthetase contains a zinc ion, bound to the enzyme by two histidine residues and one cysteine residue. The remaining coordination sites are available for substrate binding. Threonine binds to the zinc ion through its amino group and its side-chain hydroxyl group. The side-chain hydroxyl group is further recognized by an aspartate residue that hydrogen bonds to it. The methyl group present in valine in place of this hydroxyl group cannot participate in these interactions; it is excluded from this active site and, hence, does not become adenylated and transferred to threonyl-tRNA (abbreviated tRNA<sup>Thr</sup>). The use of a zinc ion appears to be unique to threonyl-tRNA synthetase; other aminoacyl-tRNA synthetases have different strategies for recognizing their cognate amino acids. The carboxylate group of the correctly positioned threonine is available to attack the  $\alpha$  phosphoryl group of ATP to form the aminoacyl adenylate.

The zinc site is less able to discriminate against serine because this amino acid does have a hydroxyl group that can bind to the zinc ion. Indeed, with only this mechanism available, threonyl-tRNA synthetase does mistakenly couple serine to threonyl-tRNA at a rate  $10^{-2}$  to  $10^{-3}$  times that for threonine. As noted on page 894, this error rate is likely to lead to many translation errors. How is a higher level of specificity achieved?

### Proofreading by aminoacyl-tRNA synthetases increases the fidelity of protein synthesis

Threonyl-tRNA synthetase can be incubated with tRNA<sup>Thr</sup> that has been covalently linked with serine (Ser-tRNA<sup>Thr</sup>); the tRNA has been “mis-charged.” The reaction is immediate: a rapid hydrolysis of the aminoacyl-tRNA forms serine and free tRNA. In contrast, incubation with correctly charged Thr-tRNA<sup>Thr</sup> results in no reaction. Thus, threonyl-tRNA synthetase contains an additional functional site that hydrolyzes Ser-tRNA<sup>Thr</sup> but not Thr-tRNA<sup>Thr</sup>. This editing site provides an opportunity for the synthetase to correct its mistakes and improve its fidelity to less than one mistake in  $10^4$ . The results of structural and mutagenesis studies revealed that the editing site is more than 20 Å from the activation site (Figure 30.9). This editing site readily accepts and cleaves Ser-tRNA<sup>Thr</sup> but does not cleave Thr-tRNA<sup>Thr</sup>. The discrimination of serine from threonine is easy because threonine contains an *extra* methyl group; a site that conforms to the structure of serine will sterically exclude threonine. The structure of the complex between threonyl-tRNA synthetase and its substrate reveals that the aminoacylated CCA can swing out of the activation site and into the editing site (Figure 30.10). Thus, the aminoacyl-tRNA can be edited

without dissociating from the synthetase. This proofreading depends on the conformational flexibility of a short stretch of polynucleotide sequence.

Most aminoacyl-tRNA synthetases contain editing sites in addition to activation sites. These complementary pairs of sites function as a *double sieve* to ensure very high fidelity. In general, the acylation site rejects amino acids that are *larger* than the correct one because there is insufficient room for them, whereas the hydrolytic site cleaves activated species that are *smaller* than the correct one.

A few synthetases achieve high accuracy without editing. For example, tyrosyl-tRNA synthetase has no difficulty discriminating between tyrosine and phenylalanine; the hydroxyl group on the tyrosine ring enables tyrosine to bind to the enzyme  $10^4$  times as strongly as phenylalanine. *Proofreading has been selected in evolution only when fidelity must be enhanced beyond what can be obtained through an initial binding interaction.*

### Synthetases recognize various features of transfer RNA molecules

How do synthetases choose their tRNA partners? This enormously important step is the point at which “translation” takes place—at which the correlation between the amino acid and the nucleic acid worlds is made. In a sense, aminoacyl-tRNA synthetases are the only molecules in biology that “know” the genetic code. Their precise recognition of tRNAs is as important for high-fidelity protein synthesis as is the accurate selection of amino acids. In general, tRNA recognition by the synthetase is different for each synthetase and tRNA pair. Consequently, generalities are difficult to make.

*Some synthetases recognize their tRNA partners primarily on the basis of their anticodons*, although they may also recognize other aspects of tRNA structure that vary among different tRNAs. The most direct evidence comes from crystallographic studies of complexes formed between synthetases and their cognate tRNAs. Consider, for example, the structure of the complex between threonyl-tRNA synthetase and tRNA<sup>Thr</sup> (Figure 30.11). As expected, the CCA arm extends into the zinc-containing activation site, where it is well positioned to accept threonine from threonyl adenylate. The enzyme interacts extensively not only with the acceptor stem of the tRNA, but also with the anticodon loop. The interactions with the anticodon loop are particularly revealing. Each base within the sequence 5′-CGU-3′ of the anticodon participates in hydrogen bonds with the enzyme; those with the second two bases (G and U) appear to be more important because the synthetase interacts just as efficiently with the anticodons GGU and UGU. Although interactions between the enzyme and the anticodon are often crucial for correct recognition, Figure 30.12 shows that many aspects of tRNA molecules are recognized by synthetases. Note that many of the recognition sites are loops rich in unusual bases that can provide structural identifiers.

### Aminoacyl-tRNA synthetases can be divided into two classes

At least one aminoacyl-tRNA synthetase exists for each amino acid. The diverse sizes, subunit composition, and

**FIGURE 30.11 Threonyl-tRNA synthetase complex.** The structure shows the complex between threonyl-tRNA synthetase (blue) and tRNA<sup>Thr</sup> (red). Notice that the synthetase binds to both the acceptor stem and the anticodon loop. [Drawn from 1QF6.pdb.]

**FIGURE 30.12 Recognition sites on tRNA.** Circles represent nucleotides, and the sizes of the circles are proportional to the frequency with which they are used as recognition sites by aminoacyl-tRNA synthetases. The numbers indicate the positions of the nucleotides in the base sequence, beginning from the 5′ end of the tRNA molecule. [Information from M. Ibba, and D. Söll, *Annu. Rev. Biochem.* 69:617–650, 1981, p. 636.]

**FIGURE 30.13** Classes of aminoacyl-tRNA synthetases. Notice that class I and class II synthetases recognize different faces of the tRNA molecule. The CCA arm of tRNA adopts different conformations in complexes with the two classes of synthetase. Note that the CCA arm of the tRNA is turned toward the viewer (Figures 30.4 and 30.5). [Drawn from 1EUY.pdb and 1QF6.pdb.]

**TABLE 30.3** Classification and subunit structure of aminoacyl-tRNA synthetases in *E. coli*

Class I	Class II
Arg ( $\alpha$ )	Ala ( $\alpha 4$ )
Cys ( $\alpha$ )	Asn ( $\alpha 2$ )
Gln ( $\alpha$ )	Asp ( $\alpha 2$ )
Glu ( $\alpha$ )	Gly ( $\alpha 2\beta 2$ )
Ile ( $\alpha$ )	His ( $\alpha 2$ )
Leu ( $\alpha$ )	Lys ( $\alpha 2$ )
Met ( $\alpha$ )	Phe ( $\alpha 2\beta 2$ )
Trp ( $\alpha 2$ )	Ser ( $\alpha 2$ )
Tyr ( $\alpha 2$ )	Pro ( $\alpha 2$ )
Val ( $\alpha$ )	Thr ( $\alpha 2$ )

sequences of these enzymes were bewildering for many years. Could it be that essentially all synthetases evolved independently? The determination of the three-dimensional structures of several synthetases followed by more-refined sequence comparisons revealed that different synthetases are, in fact, related. Specifically, synthetases fall into two classes, termed *class I* and *class II*, each of which includes enzymes specific for 10 of the 20 amino acids (Table 30.3). Intriguingly, synthetases from the two classes bind to different faces of the tRNA molecule (Figure 30.13). The CCA arm of tRNA adopts different conformations to accommodate these interactions; the arm is in the helical conformation observed for free tRNA (Figures 30.4 and 30.5) for class II enzymes and in a hairpin conformation for class I enzymes. These two classes also differ in other ways.

1. Class I enzymes acylate the 2'-hydroxyl group of the terminal adenosine of tRNA, whereas class II enzymes (except the enzyme for Phe-tRNA) acylate the 3'-hydroxyl group.
2. The two classes bind ATP in different conformations.
3. Most class I enzymes are monomeric, whereas most class II enzymes are dimeric.

Why did two distinct classes of aminoacyl-tRNA synthetases evolve? The observation that the two classes bind to distinct faces of tRNA suggests a possibility. Recognition sites on both faces of tRNA may have been required to allow the recognition of 20 different tRNAs.

### 30.3 The Ribosome Is the Site of Protein Synthesis

We turn now to ribosomes, the molecular machines that coordinate the interplay of aminoacyl-tRNAs, mRNA, and proteins that leads to protein synthesis. An *E. coli* ribosome is a ribonucleoprotein assembly with a mass of about 2500 kDa, a diameter of approximately 250 Å, and a sedimentation coefficient (Section 3.1) of 70S. The 20,000 ribosomes in a bacterial cell constitute nearly a fourth of its mass.

A ribosome can be dissociated into a *large subunit* (50S) and a *small subunit* (30S). These subunits can be further split into their constituent proteins and RNAs. The 30S subunit contains 21 different proteins (referred to as S1 through S21) and a 16S RNA molecule. The 50S subunit contains 34 different proteins (L1 through L34) and two RNA molecules, a 23S and a 5S

**FIGURE 30.14 The ribosome at high resolution.** Detailed models of the ribosome based on the results of x-ray crystallographic studies of the 70S ribosome and the 30S and 50S subunits: (left) view of the part of the 50S subunit that interacts with the 30S subunit; (center) side view of the 70S ribosome; (right) view of the part of the 30S subunit that interacts with the 50S subunit. 23S RNA is shown in yellow, 5S RNA in orange, 16S RNA in green, proteins of the 50S subunit in red, and proteins of the 30S subunit in blue. *Notice that the interface between the 50S and the 30S subunits consists entirely of RNA.* [Drawn from 1GIX.pdb and 1GIY.pdb.]

species. A ribosome contains one copy of each RNA molecule, two copies each of the L7 and L12 proteins, and one copy of each of the other proteins. The L7 protein is identical with L12 except that its amino terminus is acetylated (Section 10.3). Both the 30S and the 50S subunits can be reconstituted *in vitro* from their constituent proteins and RNA. *This reconstitution is an outstanding example of the principle that supramolecular complexes can form spontaneously from their macromolecular constituents.*

The structures of both the 30S and the 50S subunits as well as the complete 70S ribosome have been determined (Figure 30.14). The features of these structures are in remarkable agreement with interpretations of less-direct experimental probes. These structures provide an invaluable framework for examining the mechanism of protein synthesis.

### Ribosomal RNAs (5S, 16S, and 23S rRNA) play a central role in protein synthesis

The prefix *ribo* in the name *ribosome* is apt because RNA constitutes nearly two-thirds of the mass of these large molecular assemblies. The three RNAs present—5S, 16S, and 23S—are critical for ribosomal architecture and function. They are formed by the cleavage of primary 30S transcripts and further processing. These molecules fold into structures that allow them to form internal base pairs. Their base-pairing patterns were deduced by comparing the nucleotide sequences of many species to detect conserved sequences as well as conserved base pairings. For instance, the 16S RNA of one species may have a G–C base pair, whereas another may have an A–U base pair, but the location of the base pair is the same in both molecules. Chemical modification and digestion experiments supported the structures deduced from sequence comparisons (Figure 30.15). The striking finding is that across all species, *ribosomal RNAs (rRNAs) are folded into defined structures that have many short duplex regions.*

For many years, ribosomal proteins were presumed to orchestrate protein synthesis and ribosomal RNAs were presumed to serve primarily as structural scaffolding. The current view is almost the reverse. The discovery of catalytic RNA (Section 29.4) made biochemists receptive to the possibility that RNA plays a much more active role in ribosomal function. The detailed structures make it clear that the key sites in the ribosome, such as those that catalyze the formation of the peptide bond and interact with mRNA and tRNA, are composed almost entirely of RNA. Contributions from the proteins are minor. The almost inescapable conclusion is that the ribosome initially consisted only of RNA and that the proteins were added later to fine-tune

**FIGURE 30.15 Ribosomal RNA folding pattern.** (A) The secondary structure of 16S ribosomal RNA deduced from sequence comparison and the results of chemical studies. (B) The tertiary structure of 16S RNA determined by x-ray crystallography. [(A) Courtesy of Dr. Bryn Weiser and Dr. Harry Noller; (B) drawn from 1FJG.pdb.]

**FIGURE 30.16 Transfer RNA-binding sites.** (A) Three tRNA-binding sites are present on the 70S ribosome. They are called the A (for aminoacyl), P (for peptidyl), and E (for exit) sites. Each tRNA molecule contacts both the 30S and the 50S subunit. (B) The tRNA molecules in sites A and P are base-paired with mRNA. [(B) Drawn from 1JGP. pdb.]

its functional properties. This conclusion has the pleasing consequence of dodging a “chicken and egg” question: How can complex proteins be synthesized if complex proteins are required for protein synthesis?

### Ribosomes have three tRNA-binding sites that bridge the 30S and 50S subunits

Three tRNA-binding sites in ribosomes are arranged to allow the formation of peptide bonds between amino acids encoded by the codons on mRNA (Figure 30.16). The mRNA fragment being translated at a given moment is bound within the 30S subunit. Each of the tRNA molecules is in contact with both the 30S subunit and the 50S subunit. At the 30S end, two of the three tRNA molecules are bound to the mRNA through anticodon–codon base pairs. These binding sites are called the A site (for *aminoacyl*) and the P site (for *peptidyl*). The third tRNA molecule is bound to an adjacent site called the E site (for *exit*).

The other end of each tRNA molecule, the end without the anticodon, interacts with the 50S subunit. The acceptor stems of the tRNA molecules occupying the A site and the P site converge at a site where a peptide bond is formed. A tunnel connects this site to the back of the ribosome, through which the polypeptide chain passes during synthesis (Figure 30.17).

### The start signal is usually AUG preceded by several bases that pair with 16S rRNA

How does protein synthesis start? The simplest possibility would be for the first 3 nucleotides of each mRNA to serve as the first codon; no special start signal would then be needed. However, experiments show that translation in bacteria does not begin immediately at the 5′ terminus of mRNA. Indeed, the first translated codon is nearly always more than 25 nucleotides away from the 5′ end. Furthermore, in bacteria, many mRNA molecules are *polycistronic*—that is, they encode two or more polypeptide chains. For example, a single mRNA molecule about 7000-nucleotides long specifies five enzymes in the biosynthetic pathway for tryptophan in *E. coli*. Each of these five proteins has its own start and stop signals on the mRNA. In fact, *all known mRNA molecules contain signals that define the beginning and end of each encoded polypeptide chain.*

A clue to the mechanism of initiation was the finding that nearly half the amino-terminal residues of proteins in *E. coli* are methionine. In fact, the

**FIGURE 30.17 An active ribosome.** This schematic representation shows the relations among the key components of the translation machinery.

**FIGURE 30.18 Initiation sites.**

Sequences of mRNA initiation sites for protein synthesis in some bacterial and viral mRNA molecules. Comparison of these sequences reveals some recurring features.

initiating codon in mRNA is AUG (methionine) or, less frequently, GUG (valine) or, rarely UUG (leucine). What additional signals are necessary to specify a translation start site? The first step toward answering this question was the isolation of initiator regions from a number of mRNAs. This isolation was accomplished by using ribonuclease to digest mRNA–ribosome complexes (formed under conditions in which protein synthesis could begin but elongation could not take place). As expected, each initiator region usually displays an AUG codon (Figure 30.18). In addition, each initiator region contains a purine-rich sequence centered about 10 nucleotides on the 5' side of the initiator codon.

The role of this purine-rich region, called the *Shine–Dalgarno sequence*, (named after John Shine and Lynn Dalgarno, who first described the sequence), became evident when the sequence of 16S rRNA was elucidated. The 3' end of this rRNA component of the 30S subunit contains a sequence of several bases that is complementary to the purine-rich region in the initiator sites of mRNA. Mutagenesis of the CCUCC sequence near the 3' end of 16S rRNA to ACACA markedly interferes with the recognition of start sites in mRNA. This result and other evidence show that the initiator region of mRNA binds very near the 3' end of the 16S rRNA. The number of base pairs linking mRNA and 16S rRNA ranges from three to nine. Thus, *two kinds of interactions determine where protein synthesis starts: (1) the pairing of mRNA bases with the 3' end of 16S rRNA and (2) the pairing of the initiator codon on mRNA with the anticodon of an initiator tRNA molecule.*

### Bacterial protein synthesis is initiated by formylmethionyl transfer RNA

As stated earlier, methionine is the first amino acid in many *E. coli* proteins. However, the methionine residue found at the amino-terminal end of *E. coli* proteins is usually modified. In fact, *protein synthesis in bacteria starts with the modified amino acid N-formylmethionine (fMet)*. A special tRNA brings formylmethionine to the ribosome to initiate protein synthesis. This *initiator tRNA* (abbreviated as tRNA<sub>f</sub>) differs from the tRNA that inserts methionine in internal positions (abbreviated as tRNA<sub>m</sub>). The subscript “f” indicates that methionine attached to the initiator tRNA can be formylated, whereas it cannot be formylated when attached to tRNA<sub>m</sub>. Although virtually all proteins synthesized in *E. coli* begin with formylmethionine, in approximately one-half of the proteins, N-formylmethionine is removed when the nascent chain is 10 amino acids long.

Methionine is linked to these two kinds of tRNAs by the same aminoacyl-tRNA synthetase. A specific enzyme then formylates the amino group of the methionine molecule that is attached to tRNA<sub>f</sub> (Figure 30.19). The activated formyl donor in this reaction is N<sup>10</sup>-formyltetrahydrofolate, a folate derivative that carries activated one-carbon units (Section 24.2). Free methionine and methionyl-tRNA<sub>m</sub> are not substrates for this transformylase.

**FIGURE 30.19 Formylation of methionyl-tRNA.** Initiator tRNA (tRNA<sub>f</sub>) is first charged with methionine, and then a formyl group is transferred to the methionyl-tRNA<sub>f</sub> from N<sup>10</sup>-formyltetrahydrofolate.

## Formylmethionyl-tRNA<sub>f</sub> is placed in the P site of the ribosome in the formation of the 70S initiation complex

Messenger RNA and formylmethionyl-tRNA<sub>f</sub> must be brought to the ribosome for protein synthesis to begin. How is this task accomplished? Three protein *initiation factors* (IF1, IF2, and IF3) are essential. The 30S ribosomal subunit first forms a complex with IF1 and IF3 (Figure 30.20). The binding of these factors to the 30S subunit prevents it from prematurely joining the 50S subunit to form a dead-end 70S complex, devoid of mRNA and fMet-tRNA<sub>f</sub>. IF1 binds near the A site and directs the fMet-tRNA<sub>f</sub> to the P site. Initiation factor 2, a member of the G-protein family, binds GTP, and the concomitant conformational change enables IF2 to associate with fMet-tRNA<sub>f</sub>. The IF2–GTP–initiator-tRNA complex binds with mRNA (correctly positioned by the interaction of the Shine–Dalgarno sequence with the 16S rRNA) and the 30S subunit to form the *30S initiation complex*. Structural changes then lead to the ejection of IF1 and IF3. IF2 stimulates the association of the 50S subunit to the complex. The GTP bound to IF2 is hydrolyzed upon arrival of the 50S subunit, releasing IF2. The result is a *70S initiation complex*. The formation of the 70S initiation complex is the rate-limiting step in protein synthesis.

When the 70S initiation complex has been formed, the ribosome is ready for the elongation phase of protein synthesis. The fMet-tRNA<sub>f</sub> molecule occupies the P site on the ribosome, positioned so that its anticodon pairs with the initiating codon on mRNA. The other two sites for tRNA molecules, the A site and the E site, are empty. This interaction establishes the *reading frame* for the translation of the entire mRNA. After the initiator codon has been located, groups of three nonoverlapping nucleotides are defined.

## Elongation factors deliver aminoacyl-tRNA to the ribosome

At this point, fMet-tRNA<sub>f</sub> occupies the P site, and the A site is vacant. The particular species inserted into the empty A site depends on the mRNA codon in the A site. However, the appropriate aminoacyl-tRNA does not simply leave the synthetase and diffuse to the A site. Rather, it is delivered to the A site in association with a 43-kDa protein called *elongation factor Tu* (EF-Tu), another member of the G-protein family. EF-Tu, the most abundant bacterial protein, binds aminoacyl-tRNA only in its GTP form (Figure 30.21). The binding of EF-Tu to aminoacyl-tRNA serves two functions. First, EF-Tu protects the delicate ester linkage in aminoacyl-tRNA from hydrolysis. Second, EF-Tu contributes to the accuracy of protein synthesis because GTP hydrolysis and expulsion of the EF-Tu-GDP complex from the ribosome occurs only if the pairing between the anticodon and the codon is correct. EF-Tu interacts with the 16S rRNA, which monitors the accuracy of the base pairing of position 1 and 2 of the codon (p. 898). Correct codon recognition induces structural changes in the 30S subunit that activate the GTPase activity of EF-Tu, releasing EF-Tu-GDP from the ribosome. These same structural changes also rotate the aminoacyl-tRNA in the A site so that the amino acid is brought into proximity with the aminoacyl-tRNA in the P site, a process called *accommodation*. Accommodation aligns the amino acids for peptide bond formation.

Released EF-Tu is then reset to its GTP form by a second elongation factor, *elongation factor Ts*. EF-Ts induces the dissociation of GDP. GTP binds to EF-Tu, and EF-Ts concomitantly departs. It is noteworthy that *EF-Tu does not interact with fMet-tRNA<sub>f</sub>*. Hence, this initiator tRNA is not

**FIGURE 30.20 Translation initiation in bacteria.** Initiation factors aid the assembly first of the 30S initiation complex and then of the 70S initiation complex.

**FIGURE 30.21 Structure of elongation factor Tu.** The structure of a complex between elongation factor Tu (EF-Tu) and an aminoacyl-tRNA. Notice the P-loop NTPase domain (purple shading) at the amino-terminal end of EF-Tu. This NTPase domain is similar to those in other G proteins. [Drawn from 1B23. pdb.]

delivered to the A site. In contrast, Met-tRNA<sub>m</sub>, like all other aminoacyl-tRNAs, does bind to EF-Tu. These findings account for the fact that *internal AUG codons are not read by the initiator tRNA*. Conversely, IF2 recognizes fMet-tRNA<sub>f</sub> but no other tRNA. The cycle of elongation continues until a termination codon is met.

This GTP–GDP cycle of EF-Tu is reminiscent of those of the heterotrimeric G proteins in signal transduction (Section 14.1) and the Ras proteins in growth control (Section 14.3). This similarity is due to their shared evolutionary heritage, seen in the homology of the amino-terminal domain of EF-Tu to the P-loop NTPase domains in the other G proteins. In all these related enzymes, the change in conformation between the GTP and the GDP forms leads to a change in interaction partners. A further similarity is the requirement that an additional protein catalyzes the exchange of GTP for GDP; EF-Ts catalyzes the exchange for EF-Tu, just as an activated receptor does for a heterotrimeric G protein.

### Peptidyl transferase catalyzes peptide-bond synthesis

With both the P site and the A site occupied by aminoacyl-tRNA, the stage is set for the formation of a peptide bond: the formylmethionine molecule linked to the initiator tRNA will be transferred to the amino group of the amino acid in the A site. The formation of the peptide bond, one of the most important reactions in life, is a thermodynamically spontaneous reaction catalyzed by a site on the 23S rRNA of the 50S subunit called the *peptidyl transferase center*. This catalytic center is located deep in the 50S subunit near the tunnel that allows the nascent peptide to leave the ribosome.

The ribosome, which enhances the rate of peptide bond synthesis by a factor of  $10^7$  over the uncatalyzed reaction ( $\sim 10^{-4} \text{ M}^{-1} \text{ s}^{-1}$ ), derives much of its catalytic power from *catalysis by proximity and orientation*. The ribosome positions and orients the two substrates so that they are situated to take advantage of the inherent reactivity of an amine group (on the aminoacyl-tRNA in the A site) with an ester (on the initiator tRNA in the P site). The amino group of the aminoacyl-tRNA in the A site, in its unprotonated state, makes a nucleophilic attack on the ester linkage between the initiator tRNA and the formylmethionine molecule in the P site (Figure 30.22A). The nature

**FIGURE 30.22 Peptide-bond formation.**

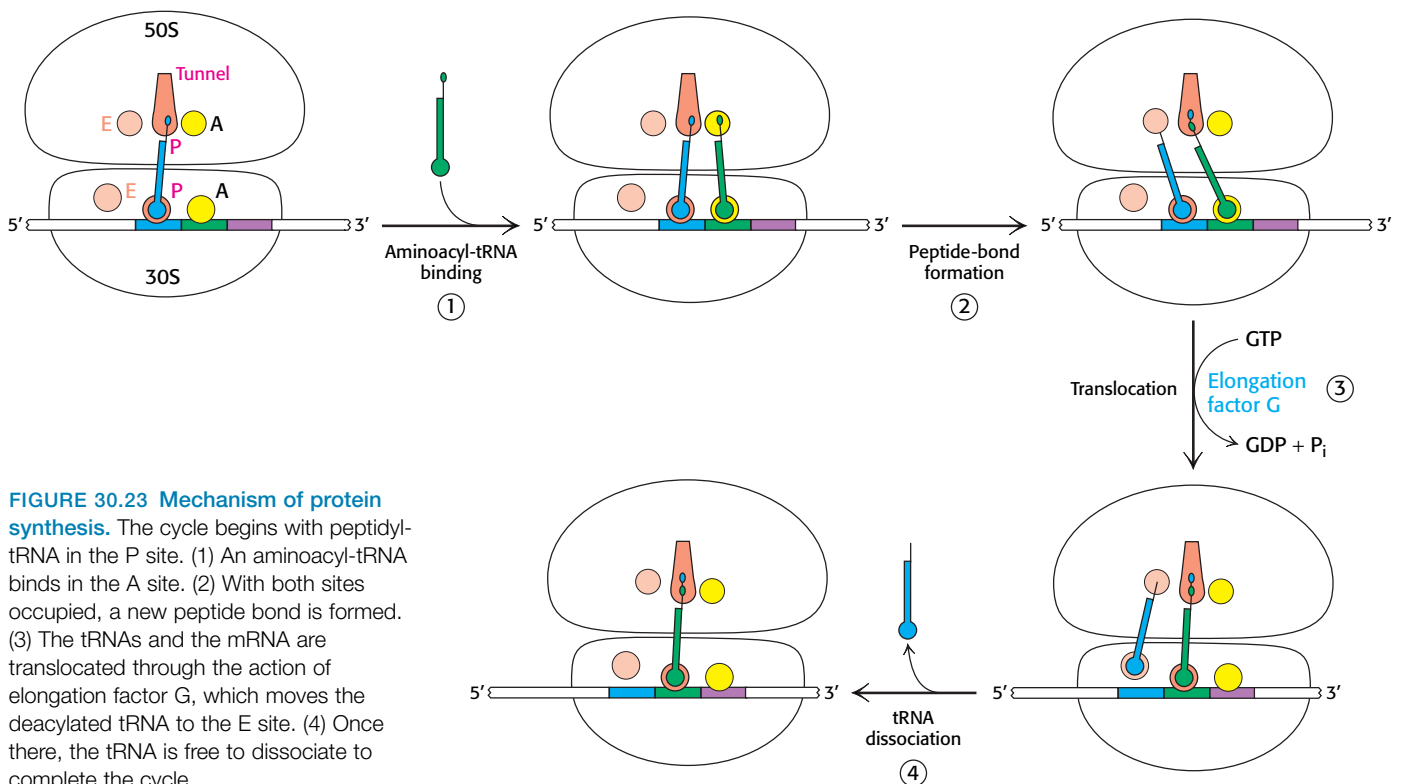

(A) The amino group of the aminoacyl-tRNA attacks the carbonyl group of the ester linkage of the peptidyl-tRNA. (B) An eight-membered transition state is formed. Note: Not all atoms are shown and some bond lengths are exaggerated for clarity. (C) This transition state collapses to form the peptide bond and release the deacylated tRNA.

of the transition state that follows the attack is not established and several models are plausible. One model proposes roles for the 2'OH of the adenosine of the tRNA in the P site and a molecule of water at the peptidyl transferase center (Figure 30.22B). The nucleophilic attack of the  $\alpha$ -amino group generates an eight-membered transition state in which three protons are shuttled about in a concerted manner. The proton of the attacking amino group hydrogen bonds to the 2' oxygen of ribose of the tRNA. The hydrogen of 2'OH in turn interacts with the oxygen of the water molecule at the center, which then donates a proton to the carbonyl oxygen. Collapse of the transition state with the formation of the peptide bond allows protonation of the 3'OH of the now empty tRNA in the P site (Figure 30.22C). The stage is now set for translocation and formation of the next peptide bond.

### The formation of a peptide bond is followed by the GTP-driven translocation of tRNAs and mRNA

With the formation of the peptide bond, the peptide chain is now attached to the tRNA whose anticodon is in the A site on the 30S subunit. The two subunits rotate with respect to one another, and this structural change places the CCA end of the same tRNA and its peptide in the P site of the large subunit (Figure 30.23). Another aminoacyl-tRNA arrives and binds at the A site (1). Again, peptide bond synthesis occurs (2). However, protein synthesis cannot continue without the translocation of the mRNA and the tRNAs within the ribosome. *Elongation factor G* (EF-G, also called *translocase*) catalyzes the movement of mRNA, at the expense of GTP hydrolysis, by a distance of three nucleotides. Now, the next codon is positioned in the A site for interaction with the incoming aminoacyl-tRNA (3). The peptidyl-tRNA moves out of the A site into the P site on the 30S subunit and at the same time, the deacylated tRNA moves out of the P site into the E site and is subsequently released from the ribosome (4). The movement of the peptidyl-tRNA into the P site shifts the mRNA by one codon, exposing the next codon to be translated in the A site.

**FIGURE 30.23 Mechanism of protein synthesis.** The cycle begins with peptidyl-tRNA in the P site. (1) An aminoacyl-tRNA binds in the A site. (2) With both sites occupied, a new peptide bond is formed. (3) The tRNAs and the mRNA are translocated through the action of elongation factor G, which moves the deacylated tRNA to the E site. (4) Once there, the tRNA is free to dissociate to complete the cycle.

**FIGURE 30.24 Translocation mechanism.** In the GTP form, EF-G binds to the A site on the 50S subunit. This binding stimulates GTP hydrolysis, inducing a conformational change in EF-G that forces the tRNAs and mRNA to move through the ribosome by a distance corresponding to one codon.

The three-dimensional structure of the ribosome undergoes significant change during translocation, and evidence suggests that translocation may result from properties of the ribosome itself. However, EF-G accelerates the process. A possible mechanism for accelerating the translocation process is shown in Figure 30.24. First, EF-G in the GTP form binds to the ribosome near the A site, interacting with the 23S rRNA of the 50S subunit. The binding of EF-G to the ribosome stimulates the GTPase activity of EF-G. On GTP hydrolysis, EF-G undergoes a conformational change that displaces the peptidyl-tRNA in the A site to the P site, which carries the mRNA and the deacylated tRNA with it. The dissociation of EF-G leaves the ribosome ready to accept the next aminoacyl-tRNA into the A site.

Note that *the peptide chain remains in the P site on the 50S subunit throughout this cycle*, growing into the exit tunnel. This cycle is repeated, with mRNA translation taking place in the 5' → 3' direction, as new aminoacyl-tRNAs move into the A site, allowing the polypeptide to be elongated until a stop signal is found.

The direction of translation has important consequences. Recall that transcription also is in the 5' → 3' direction (Section 29.1). If the direction of translation were opposite that of transcription, only fully synthesized mRNA could be translated. In contrast, because the directions are the same, mRNA can be translated while it is being synthesized. In bacteria, almost no time is lost between transcription and translation. The 5' end of mRNA interacts with ribosomes very soon after it is made, well before the 3' end of the mRNA molecule is finished. *An important feature of bacterial gene expression is that translation and transcription are closely coupled in space and time.*

Many ribosomes can be translating an mRNA molecule simultaneously. The group of ribosomes bound to an mRNA molecule is called a *polyribosome* or a *polysome* (Figure 30.25). Recent work shows that the ribosomes are arranged so as to protect the mRNA and to facilitate easy exchange of the substrates and products with the cytoplasm. The ribosomes in the polysome are in a helical array around the mRNA with the tRNA binding sites and peptide exit tunnel exposed to the cytoplasm.

### Protein synthesis is terminated by release factors that read stop codons

The final phase of translation is termination. How does the synthesis of a polypeptide chain come to an end when a stop codon is encountered? No tRNAs with anticodons complementary to the stop codons—UAA, UGA, or UAG—exist in normal cells. Instead, these *stop codons are recognized by proteins called release factors (RFs)*. One of these release factors, RF1, recognizes UAA or UAG. A second factor, RF2, recognizes UAA or UGA.

**FIGURE 30.25 Polysomes.** Transcription of a segment of DNA from *E. coli* generates mRNA molecules that are immediately translated by multiple ribosomes. [From O. L. Miller, Jr., B. A. Hamkalo, and C. A. Thomas, Jr. *Science* 169 (1970):392. Reprinted with permission from AAAS.]

**FIGURE 30.26 Termination of protein synthesis.** A release factor recognizes a stop codon in the A site and stimulates the release of the completed protein from the tRNA in the P site.

A third factor, RF3, another GTPase, catalyzes the removal of RF1 or RF2 from the ribosome upon release of the newly synthesized protein.

RF1 and RF2 are compact proteins that, in eukaryotes, resemble a tRNA molecule. When bound to the ribosome, the proteins unfold to bridge the gap between the stop codon on the mRNA and the peptidyl transferase center on the 50S subunit (Figure 30.26). The RF interacts with the peptidyl transferase center using a loop containing a highly conserved glycine-glycine-glutamine (GGQ) sequence, with the glutamine methylated on the amide nitrogen atom of the R group. This modified glutamine (assisted by the peptidyl transferase) is crucial in promoting a water molecule's attack on the ester linkage between the tRNA and the polypeptide chain, freeing the polypeptide chain. The detached polypeptide leaves the ribosome. Transfer RNA and messenger RNA remain briefly attached to the 70S ribosome until the entire complex is dissociated through the hydrolysis of GTP in response to the binding of EF-G and another factor, called the *ribosome release factor* (RRF).

### 30.4 Eukaryotic Protein Synthesis Differs from Bacterial Protein Synthesis Primarily in Translation Initiation

The basic plan of protein synthesis in eukaryotes and archaea is similar to that in bacteria. The major structural and mechanistic themes recur in all domains of life. However, eukaryotic protein synthesis entails more protein components than does bacterial protein synthesis, and some steps are more intricate. Some noteworthy similarities and differences are as follows:

1. *Ribosomes.* Eukaryotic ribosomes are larger. They consist of a 60S large subunit and a 40S small subunit, which come together to form an 80S particle having a mass of 4200 kDa, compared with 2700 kDa for the bacterial 70S ribosome. The 40S subunit contains an 18S RNA that is homologous to the bacterial 16S RNA. The 60S subunit contains three RNAs: the 5S RNA, which is homologous to the bacterial 5S rRNA; the 28S RNA, which is homologous to the bacterial 23S molecules; and the 5.8S RNA, which is homologous to the 5' end of the 23S RNA of bacteria.
2. *Initiator tRNA.* In eukaryotes, the initiating amino acid is methionine rather than *N*-formylmethionine. However, as in bacteria, a special tRNA participates in initiation. This aminoacyl-tRNA is called Met-tRNA<sub>i</sub> (the subscript "i" stands for initiation).
3. *Initiation.* The initiating codon in eukaryotes is always AUG. Eukaryotes, in contrast with bacteria, do not have a specific purine-rich sequence on the 5' side to distinguish initiator AUGs from internal ones.

**FIGURE 30.27 Eukaryotic translation initiation.** In eukaryotes, translation initiation starts with the assembly of a complex on the 5' cap that includes the 40S subunit and Met-tRNA<sub>i</sub>. Driven by ATP hydrolysis, this complex scans the mRNA until the first AUG is reached. The 60S subunit is then added to form the 80S initiation complex.

Instead, the AUG nearest the 5' end of mRNA is usually selected as the start site. Eukaryotes utilize many more initiation factors than do bacteria, and their interplay is much more complex. The prefix *eIF* denotes a eukaryotic initiation factor.

Initiation begins with the formation of a ternary complex consisting of the 40S ribosome and Met-tRNA<sub>i</sub> in association with eIF-2. The complex is called the 43S preinitiation complex (PIC). The PIC binds to the 5' end of mRNA and begins searching for an AUG codon by moving step-by-step in the 3' direction. Initiation factor eIF-4E binds to the 5'-cap of the mRNA (Section 29.3) and facilitates binding of PIC to the mRNA (Figure 30.27). This scanning process is catalyzed by helicases that move along the mRNA powered by ATP hydrolysis. Pairing of the anticodon of Met-tRNA<sub>i</sub> with the AUG codon of mRNA signals that the target has been found. In almost all cases, eukaryotic mRNA has only one start site and hence is the template for only a single protein. In contrast, a bacterial mRNA can have multiple Shine–Dalgarno sequences and, hence, start sites, and it can serve as a template for the synthesis of several proteins.

The difference in initiation mechanism between bacteria and eukaryotes is, in part, a consequence of the difference in RNA processing. The 5' end of mRNA is readily available to ribosomes immediately after transcription in bacteria. In contrast, in eukaryotes pre-mRNA must be processed and transported to the cytoplasm before translation is initiated. The 5' cap provides an easily recognizable starting point. In addition, the complexity of eukaryotic translation initiation provides another mechanism for regulation of gene expression that we shall explore further in Chapter 31.

Although most eukaryotic mRNA molecules rely on the 5' cap to initiate protein synthesis, recent work has established that some mRNA molecules can recruit ribosomes for initiation without the use of a 5'-cap and cap-binding proteins. In these mRNAs, highly structured RNA sequences called *internal ribosome entry sites* (IRES) facilitate 40S ribosome binding to the mRNA. IRES were first discovered in the genomes of RNA viruses and have since been found in other viruses, as well as in a subset of cellular mRNA that appears to take part in development and cell stress. The molecular mechanism by which IRES function to initiate protein synthesis remains to be determined.

4. *The Structure of mRNA.* Soon after the PIC binds the mRNA, eIF-4G links eIF-4E to a protein associated with the poly(A) tail, the poly(A)-binding protein I (PABPI; Figure 30.28). Cap and tail are thus brought together to form a circle of mRNA. The benefits of circularization of mRNA remain to be determined, but a requirement for circularization may prevent translation of mRNA molecules that have lost their poly(A) tails (Section 29.3).

**FIGURE 30.28 Protein interactions circularize eukaryotic mRNA.** [Information from H. Lodish et al., *Molecular Cell Biology*, 5th ed. (W. H. Freeman and Company, 2004), Fig. 4.31.]

**FIGURE 30.29** The effects of vanishing white matter disease. (A) In the normal brain, magnetic resonance imaging (MRI) visualizes the white matter as dark gray. (B) In the diseased brain, this MRI reveals that white matter is replaced by cerebrospinal fluid, seen as white. [(A) Macmillan Publishers Ltd: NATURE Ainsworth, Claire. "Molecular Medicine: Lost in Translation." *Nature* 435 (2005): 5556-558, © 2005. (B) Reprinted from *Lancet Neurology*, 5, M. C. van der Knaap, M. S., Pronk, J. C., Scheper, G. C., "Vanishing white matter disease" Fig. B, p. 414 © 2006, with permission from Elsevier.]

5. *Elongation and Termination.* Eukaryotic elongation factors EF1 $\alpha$  and EF1 $\beta\gamma$  are the counterparts of bacterial EF-Tu and EF-Ts. The GTP form of EF1 $\alpha$  delivers aminoacyl-tRNA to the A site of the ribosome, and EF1 $\beta\gamma$  catalyzes the exchange of GTP for bound GDP. Eukaryotic EF2 mediates GTP-driven translocation in much the same way as does bacterial EF-G. Termination in eukaryotes is carried out by a single release factor, eRF1, compared with two in bacteria. Release factor eIF-3 accelerates the activity of eRF-1.

6. *Organization.* The components of the translation machinery in higher eukaryotes are organized into large complexes associated with the cytoskeleton. This association is believed to facilitate the efficiency of protein synthesis. Recall that organization of elaborate biochemical processes into physical complexes is a reoccurring theme in biochemistry (Section 18.5 and Section 25.2).

#### Mutations in initiation factor 2 cause a curious pathological condition

 Mutations in eukaryotic initiation factor 2 result in a mysterious disease, called *vanishing white matter (VWM) disease*, in which nerve cells in the brain disappear and are replaced by cerebrospinal fluid (Figure 30.29). The white matter of the brain consists predominantly of nerve axons that connect the gray matter of the brain to the rest of the body. Death, resulting from fever or extended coma, can occur anywhere from a few years to decades after the onset of the disease. Symptoms usually appear in young children but can develop shortly after birth or even in adulthood. An especially puzzling aspect of the disease is its tissue specificity. A mutation in a biochemical process as fundamental to life as protein-synthesis initiation would be predicted to be lethal or at least to affect all tissues of the body. Diseases such as VWM graphically show that, although much progress has been made in biochemistry, much more research will be required to understand the complexities of health and disease.

### 30.5 A Variety of Antibiotics and Toxins Can Inhibit Protein Synthesis

Many chemicals that inhibit various aspects of protein synthesis have been identified. These chemicals are powerful experimental tools and clinically useful drugs.

**TABLE 30.4** Antibiotic inhibitors of protein synthesis

Antibiotic	Action
Streptomycin and other aminoglycosides	Inhibit initiation and cause the misreading of mRNA (bacteria)
Tetracycline	Binds to the 30S subunit and inhibits the binding of aminoacyl-tRNAs (bacteria)
Chloramphenicol	Inhibits the peptidyl transferase activity of the 50S ribosomal subunit (bacteria)
Cycloheximide	Inhibits translocation (eukaryotes)
Erythromycin	Binds to the 50S subunit and inhibits translocation (bacteria)
Puromycin	Causes premature chain termination by acting as an analog of aminoacyl-tRNA (bacteria and eukaryotes)

### Some antibiotics inhibit protein synthesis

 The differences between eukaryotic and bacterial ribosomes can be exploited for the development of antibiotics (Table 30.4). For example, the antibiotic *streptomycin*, a highly basic trisaccharide, interferes with the binding of fMet-tRNA to ribosomes in bacteria and thereby prevents the correct initiation of protein synthesis. Other *aminoglycoside antibiotics* such as neomycin, kanamycin, and gentamycin interfere with the interaction between tRNA and the 16S rRNA of the 30S subunit (p. 906) of bacterial ribosomes. *Chloramphenicol* acts by inhibiting peptidyl transferase activity. *Erythromycin* binds to the 50S subunit and blocks translocation.

The antibiotic *puromycin* inhibits protein synthesis in both bacteria and eukaryotes by causing nascent polypeptide chains to be released before their synthesis is completed. Puromycin is an analog of the terminal part of aminoacyl-tRNA (Figure 30.30). It binds to the A site on the ribosome and blocks the entry of aminoacyl-tRNA. Furthermore, puromycin contains an  $\alpha$ -amino group. This amino group, like the one on aminoacyl-tRNA, forms a peptide bond with the carboxyl group of the growing peptide chain. The product, a peptide having a covalently attached puromycin residue at its carboxyl end, dissociates from the ribosome. No longer used medicinally, puromycin remains an experimental tool for the investigation of protein synthesis. *Cycloheximide*, another antibiotic, blocks translocation in eukaryotic ribosomes, making a useful laboratory tool for blocking protein synthesis in eukaryotic cells.

### Diphtheria toxin blocks protein synthesis in eukaryotes by inhibiting translocation

 Many antibiotics, harvested from bacteria for medicinal purposes, are inhibitors of bacterial protein synthesis. However, some bacteria produce protein-synthesis inhibitors that inhibit eukaryotic protein synthesis, leading to diseases such as diphtheria, which was a major cause of death in childhood before the advent of effective immunization. Symptoms include painful sore throat, hoarseness, fever, and difficulty breathing. The

**FIGURE 30.30 Antibiotic action of puromycin.** Puromycin resembles the aminoacyl terminus of an aminoacyl-tRNA. Its amino group joins the carboxyl group of the growing polypeptide chain to form peptidyl-puromycin that dissociates from the ribosome. Peptidyl-puromycin is stable because puromycin has an amide (shown in red) rather than an ester linkage.

lethal effects of this disease are due mainly to a protein toxin produced by a phage infecting *Corynebacterium diphtheriae*, a bacterium that grows in the upper respiratory tract of an infected person. A few micrograms of diphtheria toxin is usually lethal in an unimmunized person because it inhibits protein synthesis. The toxin consists of a single polypeptide chain that is cleaved into a 21-kDa A fragment and a 40-kDa B fragment shortly after entering the cell. The role of the B-fragment in the intact protein is to bind to the cell, enabling the toxin to enter the cytoplasm of its target cell. The A fragment catalyzes the covalent modification of EF2, the elongation factor catalyzing translocation in eukaryotic protein synthesis, resulting in protein synthesis inhibition and cell death.

A single A fragment of the toxin in the cytoplasm can kill a cell. Why is it so lethal? EF2 contains *diphthamide*, an unusual amino acid residue that enhances the fidelity of codon shifting during translocation. Diphthamide is formed by a highly conserved complicated pathway that posttranslationally modifies histidine. The A fragment of the diphtheria toxin catalyzes the transfer of the ADP ribose unit of  $\text{NAD}^+$  to the diphthamide ring (Figure 30.31). This ADP ribosylation of a single side chain of EF2 blocks EF2's capacity to carry out the translocation of the growing polypeptide chain. Protein synthesis ceases, accounting for the remarkable toxicity of diphtheria toxin.

### Ricin fatally modifies 28S ribosomal RNA

Ricin is a small protein (65 kDa) found in the seeds of the castor oil plant, *Ricinus communis* (Figure 30.32). It is indeed a deadly molecule because as little as 500  $\mu\text{g}$  is lethal for an adult human being, and a single molecule can inhibit all protein synthesis in a cell, resulting in cell death.

Ricin is a heterodimeric protein composed of a catalytic A chain joined by a single disulfide bond to a B chain. The B chain allows the toxin to bind to the target cell, and this binding leads to an endocytotic uptake of the dimer and the eventual release of the A chain into the cytoplasm. The A chain, an N-glycoside hydrolyase, cleaves adenine from a particular adenosine nucleotide on the 28S rRNA that is found in all eukaryotic ribosomes. Removal of the adenine base completely inactivates the ribosome by preventing the binding of elongation factors. Thus, ricin and diphtheria toxin both act by inhibiting protein-synthesis elongation; ricin does so by covalently modifying rRNA, and diphtheria toxin does so by covalently modifying the elongation factor.

## 30.6 Ribosomes Bound to the Endoplasmic Reticulum Manufacture Secretory and Membrane Proteins

Not all newly synthesized proteins are destined to function in the cytoplasm. Eukaryotic cells can direct proteins to internal sites such as mitochondria, the nucleus and the endoplasmic reticulum, a process called *protein targeting* or *protein sorting*. How is sorting accomplished? There are two general mechanisms by which sorting takes place. In one mechanism, the protein is synthesized in the cytoplasm, and then the completed protein is delivered to its intracellular location posttranslationally. Proteins destined for the nucleus, chloroplasts, mitochondria, and peroxisomes are delivered by this general process. The other mechanism, termed the *secretory pathway*, directs proteins into the *endoplasmic reticulum* (ER), the extensive membrane system

**FIGURE 30.31 Blocking of translocation by diphtheria toxin.** Diphtheria toxin blocks protein synthesis in eukaryotes by catalyzing the transfer of an ADP-ribose unit from  $\text{NAD}^+$  to diphthamide, a modified amino acid residue in EF2 (translocase). Diphthamide is formed by the posttranslational modification (blue) of a histidine residue.

On September 7, 1978, an agent of the Soviet Union State Security Department (KGB), using a weapon built into an umbrella, embedded a small pellet containing ricin into the thigh of Bulgarian dissident Georgi Markov as he crossed Waterloo Bridge in London. Mr. Markov felt a sharp sting, as if from a bug bite. He died four days later.

**FIGURE 30.32 Castor beans.** The seeds of castor beans from *Ricinus communis* are a rich source of oils with a wide variety of uses, including the production of biodiesel fuels. The seeds are also rich in the toxin ricin. [Ted Kinsman/Science Source.]

**FIGURE 30.33 Ribosomes are bound to the endoplasmic reticulum.** In this electron micrograph, ribosomes appear as small black dots binding to the cytoplasmic side of the endoplasmic reticulum to give a rough appearance. In contrast, the smooth endoplasmic reticulum is devoid of ribosomes. [Don W. Fawcett/Science Source]

that comprises about half the total membrane of a cell, cotranslationally—that is, while the protein is being synthesized. Approximately 30% of all proteins are sorted by the secretory pathway, including secreted proteins, residents of the ER, the Golgi complex, lysosomes, and integral membrane proteins of these organelles as well as integral plasma-membrane proteins. We will focus our attention on the secretory pathway only.

In eukaryotic cells, a ribosome remains free in the cytoplasm unless it is directed to the ER. The region that binds ribosomes is called the *rough ER* because of its studded appearance in contrast with the *smooth ER*, which is devoid of ribosomes (Figure 30.33).

### Protein Synthesis Begins on Ribosomes That Are Free in the Cytoplasm

The synthesis of proteins sorted by the secretory pathway begins on free ribosomes that soon associate with the ER. Free ribosomes that are synthesizing proteins for use in the cell are identical with those attached to the ER. What is the process that directs the ribosome synthesizing a protein destined to enter the ER to bind to the ER?

### Signal sequences mark proteins for translocation across the endoplasmic reticulum membrane

The synthesis of proteins destined to leave the cell or become embedded in the plasma membrane begins on a free ribosome but, shortly after synthesis begins, it is halted until the ribosome is directed to the cytoplasmic side of the ER. When the ribosome docks with the ER membrane, protein synthesis begins again. As the newly forming peptide chain exits the ribosome, it is transported, cotranslationally, through the membrane into the lumen of the ER. The translocation consists of four components.

1. *The Signal Sequence.* The signal sequence is a sequence of 9 to 12 hydrophobic amino acid residues, sometimes containing positively charged amino acids (Figure 30.34). This sequence, which adopts an  $\alpha$ -helical structure, is usually near the amino terminus of the nascent polypeptide chain. The presence of the signal sequence identifies the nascent peptide as one that must cross the ER membrane. Some signal sequences are maintained in the mature protein, whereas others are cleaved by a *signal peptidase* on the luminal side of the ER membrane.
2. *The Signal-Recognition Particle (SRP).* The signal-recognition particle recognizes the signal sequence and binds the sequence and the ribosome as soon as the signal sequence exits the ribosome. SRP then shepherds

the ribosome and its nascent polypeptide chain to the ER membrane. SRP is a ribonucleoprotein consisting of a 7S RNA and six different proteins (Figure 30.35). One protein, SRP54, is a GTPase that is crucial for SRP function. SRP samples all ribosomes until it locates one exhibiting a signal sequence. After SRP is bound to the signal sequence, interactions between the ribosome and the SRP occlude the elongation-factor-binding site, thereby halting protein synthesis.

3. *The SRP Receptor (SR)*. The SRP-ribosome complex diffuses to the ER, where SRP binds the SRP receptor, an integral membrane protein consisting of two subunits, SR $\alpha$  and SR $\beta$ . SR $\alpha$  is, like SRP54, a GTPase.

4. *The Translocon*. The SRP-SR complex delivers the ribosome to the translocation machinery, called the *translocon*, a multisubunit assembly of integral and peripheral membrane proteins. The translocon is a protein-conducting channel. This channel opens when the translocon and ribosome bind to each other. Protein synthesis resumes with the growing polypeptide chain passing through the translocon channel into the lumen of the ER.

The interactions of the components of the translocation machinery are shown in Figure 30.36. Both the SRP54 and the SR $\alpha$  subunits of SR must bind GTP to facilitate the formation of the SRP-SR complex. For the SRP-SR complex to then deliver the ribosome to the translocon, the two GTP molecules—one in SRP and the other in SR—are aligned in what is

**FIGURE 30.35 The signal-recognition particle.** The signal-recognition particle (SRP) consists of six proteins and one 300-nucleotide RNA molecule. The RNA has a complex structure with many double-helical stretches punctuated by single-stranded regions, shown as circles. [Information from H. Lodish et al., *Molecular Cell Biology*, 5th ed. (W. H. Freeman and Company, 2004). Data from K. Strub et al., *Mol. Cell Biol.* 11:3949–3959, 1991, and S. High and B. Dobberstein, *J. Cell Biol.* 113:229–233, 1991.]

**FIGURE 30.36 The SRP targeting cycle.** (1) Protein synthesis begins on free ribosomes. (2) After the signal sequence has exited the ribosome, it is bound by the SRP, and protein synthesis halts. (3) The SRP-ribosome complex docks with the SRP receptor in the ER membrane. (4) The SRP and the SRP receptor simultaneously hydrolyze bound GTPs. Protein synthesis resumes and the SRP is free to bind another signal sequence. (5) The signal peptidase may remove the signal sequence as it enters the lumen of the ER. (6) Protein synthesis continues as the protein is synthesized directly into the ER. (7) On completion of protein synthesis, the ribosome is released. (8) The protein tunnel in the translocon closes. [Information from H. Lodish et al., *Molecular Cell Biology*, 5th ed. (W. H. Freeman and Company, 2004), Fig. 16.6.]

essentially an active site shared by the two proteins. The formation of the alignment is catalyzed by the 7S RNA of the SRP. After the ribosome has been passed along to the translocon, the GTPs are hydrolyzed, SRP and SR dissociate, and SRP is free to search for another signal sequence to begin the cycle anew. Thus, SRP acts catalytically. The signal peptidase, which is associated with the translocon in the lumen of the ER, removes the signal sequence from most proteins.

### Transport vesicles carry cargo proteins to their final destination

As the proteins are synthesized, they fold to form their three-dimensional structures in the lumen of the ER. Some proteins are modified by the attachment of N-linked carbohydrates (Section 11.3). Finally, the proteins must be sorted and transported to their final destinations. Regardless of the destination, the principles of transport are the same. Transport is mediated by *transport vesicles* that bud off the ER (Figure 30.37). Transport vesicles from the ER carry their cargo (the proteins) to the Golgi complex, where the vesicles fuse and deposit the cargo inside the complex. There the cargo proteins are further modified—for instance, by the attachment of O-linked carbohydrates. From the Golgi complex, transport vesicles carry the cargo proteins to their final destinations, as shown in Figure 30.37.

**FIGURE 30.37 Protein-sorting pathways.** Newly synthesized proteins in the lumen of the ER are collected into membrane buds. These buds pinch off to form transport vesicles. The transport vesicles carry the cargo proteins to the Golgi complex, where the cargo proteins are modified. Transport vesicles then carry the cargo to the final destination as directed by the v-SNARE and t-SNARE proteins.

How does a protein end up at the correct destination? A newly synthesized protein will float inside the ER lumen until it binds to an integral membrane protein called a *cargo receptor*. This binding sequesters the cargo protein into a small region of the membrane that can subsequently form a membrane bud. The bud will carry the protein to a specific destination—plasma membrane, lysosome, or cell exterior. The key to ensuring that the protein reaches the proper destination is that the protein must bind to a receptor in the ER region associated with the protein's destination. To ensure the proper match of protein with ER region, cargo receptors recognize various characteristics of the cargo protein, such as a particular amino acid sequence or an added carbohydrate.

The formation of buds is facilitated by the binding of *coat proteins* (COPs) to the cytoplasmic side of the bud. The coat proteins associate with one another to pinch off the vesicle. After the transport vesicle has formed and is released, the coat proteins are shed to reveal another integral protein called *v-SNARE* ("v" for vesicle). *v-SNARE* will bind to a particular *t-SNARE* ("t" for target) in the target membrane. This binding leads to the fusion of the transport vesicle to the target membrane, and the cargo is delivered. Thus, the assignment of identical *v-SNARE* proteins to the same region of the ER membrane causes an ER region to be associated with a particular destination.

## SUMMARY

### 30.1 Protein Synthesis Requires the Translation of Nucleotide Sequences into Amino Acid Sequences

Protein synthesis is called translation because information present as a nucleic acid sequence is translated into a different language, the sequence of amino acids in a protein. This complex process is mediated by the coordinated interplay of more than a hundred macromolecules, including mRNA, rRNAs, tRNAs, aminoacyl-tRNA synthetases, and protein factors. Given that a protein typically comprises from 100 to 1000 amino acids, the frequency at which an incorrect amino acid is incorporated in the course of protein synthesis must be less than  $10^{-4}$ . Transfer RNAs are the adaptors that make the link between a nucleic acid and an amino acid. These molecules, single chains of about 80 nucleotides, have an L-shaped structure.

### 30.2 Aminoacyl Transfer RNA Synthetases Read the Genetic Code

Each amino acid is activated and linked to a specific transfer RNA by an enzyme called an aminoacyl-tRNA synthetase. The synthetase links the carboxyl group of an amino acid to the 2' - or 3' -hydroxyl group of the adenosine unit of a CCA sequence at the 3' end of the tRNA by an ester linkage. There is at least one specific aminoacyl-tRNA synthetase and at least one specific tRNA for each amino acid. A synthetase utilizes both the functional groups and the shape of its cognate amino acid to prevent the attachment of an incorrect amino acid to a tRNA. Some synthetases have a separate active site at which incorrectly linked amino acids are removed by hydrolysis. A synthetase recognizes the anticodon, the acceptor stem, and sometimes other parts of its tRNA substrate. By specifically recognizing both amino acids and tRNAs, aminoacyl-tRNA synthetases implement the instructions of the genetic code.

The codons of messenger RNA recognize the anticodons of transfer RNAs rather than the amino acids attached to the tRNAs. A codon on mRNA forms base pairs with the anticodon of the tRNA. Some tRNAs are recognized by more than one codon because pairing of the third base of a codon is less crucial than that of the other two (the wobble mechanism). There are two evolutionary distinct classes of

synthetases, each recognizing 10 amino acids. The two classes recognize opposite faces of tRNA molecules.

### 30.3 The Ribosome Is the Site of Protein Synthesis

Protein synthesis takes place on ribosomes—ribonucleoprotein particles (about two-thirds RNA and one-third protein) consisting of large and small subunits. In *E. coli*, the 70S ribosome (2500 kDa) is made up of 30S and 50S subunits. The 30S subunit consists of 16S ribosomal RNA and 21 different proteins; the 50S subunit consists of 23S and 5S rRNA and 34 different proteins. The ribosome includes three sites for tRNA binding called the A (aminoacyl) site, the P (peptidyl) site, and the E (exit) site.

Protein synthesis takes place in three phases: initiation, elongation, and termination. In bacteria, mRNA, formylmethionyl-tRNA<sub>f</sub> (the special initiator tRNA that recognizes AUG), and a 30S ribosomal subunit come together with the assistance of initiation factors to form a 30S initiation complex. A 50S ribosomal subunit then joins this complex to form a 70S initiation complex, in which fMet-tRNA<sub>f</sub> occupies the P site of the ribosome.

Elongation factor Tu delivers the appropriate aminoacyl-tRNA to the ribosome's A site as an EF-Tu-aminoacyl-tRNA-GTP ternary complex. EF-Tu serves both to protect the aminoacyl-tRNA from premature cleavage and to increase the fidelity of protein synthesis by ensuring that the correct anticodon-codon pairing has taken place before hydrolyzing GTP and releasing aminoacyl-tRNA into the A site. A peptide bond is formed when the amino group of the aminoacyl-tRNA nucleophilically attacks the ester linkage of the peptidyl-tRNA. On peptide-bond formation, the tRNAs and mRNA are translocated for the next cycle to begin. The deacylated tRNA moves to the E site and then leaves the ribosome, and the peptidyl-tRNA moves from the A site into the P site. Elongation factor G uses the free energy of GTP hydrolysis to drive translocation. Protein synthesis is terminated by release factors, which recognize the termination codons UAA, UGA, and UAG and cause the hydrolysis of the ester bond between the polypeptide and tRNA.

### 30.4 Eukaryotic Protein Synthesis Differs from Bacterial Protein Synthesis Primarily in Translation Initiation

The basic plan of protein synthesis in eukaryotes is similar to that in bacteria, but there are some significant differences between them. Eukaryotic ribosomes (80S) consist of a 40S small subunit and a 60S large subunit. The initiating amino acid is again methionine, but it is not formylated. The initiation of protein synthesis is more complex in eukaryotes than in bacteria. In eukaryotes, the AUG closest to the 5' end of mRNA is nearly always the start site. The 40S ribosome finds this site by binding to the 5' cap and then scanning the RNA until AUG is reached. The regulation of translation in eukaryotes provides a means for regulating gene expression.

### 30.5 A Variety of Antibiotics and Toxins Can Inhibit Protein Synthesis

Many clinically important antibiotics function by inhibiting protein synthesis. All steps of protein synthesis are susceptible to inhibition by one antibiotic or another. Diphtheria toxin inhibits protein synthesis by covalently modifying an elongation factor, thereby preventing elongation. Ricin, a toxin from castor beans, inhibits elongation by removing a crucial adenine residue from rRNA.

### 30.6 Ribosomes Bound to the Endoplasmic Reticulum Manufacture Secretory and Membrane Proteins

Proteins contain signals that determine their ultimate destination. The synthesis of all proteins begins on free ribosomes in the cytoplasm. In

eukaryotes, protein synthesis continues in the cytoplasm unless the nascent chain contains a signal sequence that directs the ribosome to the endoplasmic reticulum. Amino-terminal signal sequences consist of a hydrophobic segment of 9 to 12 residues preceded by a positively charged amino acid. The signal-recognition particle, a ribonucleoprotein assembly, recognizes signal sequences and brings ribosomes bearing them to the ER. A GTP–GDP cycle releases the signal sequence from SRP and then detaches SRP from its receptor. The nascent chain is then translocated across the ER membrane. Proteins are transported throughout the cell in transport vesicles.

## KEY TERMS

translation (p. 893)	initiation factor (p. 907)	signal peptidase (p. 916)
ribosome (p. 893)	elongation factor Tu (EF-Tu) (p. 907)	signal-recognition particle (SRP) (p. 916)
aminoacyl-tRNA synthetase (p. 894)	accommodation (p. 907)	SRP receptor (SR) (p. 917)
codon (p. 895)	elongation factor Ts (EF-Ts) (p. 907)	translocon (p. 917)
transfer RNA (tRNA) (p. 895)	peptidyl transferase center (p. 908)	transport vesicle (p. 918)
anticodon (p. 895)	elongation factor G (EF-G) (translocase) (p. 909)	coat proteins (p. 919)
wobble hypothesis (p. 897)	polysome (p. 910)	v-SNARE (p. 919)
30S subunit (p. 902)	release factor (RF) (p. 910)	t-SNARE (p. 919)
50S subunit (p. 902)	signal sequence (p. 916)	
Shine–Dalgarno sequence (p. 906)		

## PROBLEMS

- Babel fish.* Why is protein synthesis also called translation?
- Careful, but not too careful.* Why is it crucial that protein synthesis has an error frequency of  $10^{-4}$ ?
- Commonalities.* What features are common to all tRNA molecules?
- The ol' two step.* What two reaction steps are required for the formation of an aminoacyl-tRNA?
- The same but different.* Why must tRNA molecules have both unique structural features and common structural features?
- Charge it.* In the context of protein synthesis, what is meant by an activated amino acid?
- Synthetase mechanism.* The formation of isoleucyl-tRNA proceeds through the reversible formation of an enzyme-bound Ile-AMP intermediate. Predict whether  $^{32}\text{P}$ -labeled ATP is formed from  $^{32}\text{PP}_i$  when each of the following sets of components is incubated with the specific activating enzyme:
  - ATP and  $^{32}\text{PP}_i$
  - tRNA, ATP, and  $^{32}\text{PP}_i$
  - Isoleucine, ATP, and  $^{32}\text{PP}_i$
- 1 = 2, for sufficiently large values of 1.* The energetic equivalent of two molecules of ATP is used to activate an amino acid, yet only one molecule of ATP is used. Explain.
- Sieves.* Using threonyl-tRNA synthetase as an example, account for the specificity of threonyl-tRNA formation.
- Use all available information.* Suggest a reason why there are two classes of aminoacyl-tRNA synthetases, with each class recognizing a different face of the tRNA.
- Going wobbly.* Explain how it is possible that some tRNA molecules recognize more than one codon.
- Light and heavy ribosomes.* Ribosomes were isolated from bacteria grown in a “heavy” medium ( $^{13}\text{C}$  and  $^{15}\text{N}$ ) and from bacteria grown in a “light” medium ( $^{12}\text{C}$  and  $^{14}\text{N}$ ). These 60S ribosomes were added to an in vitro system engaged in protein synthesis. An aliquot removed several hours later was analyzed by density-gradient centrifugation. How many bands of 70S ribosomes would you expect to see in the density gradient?
- The price of protein synthesis.* What is the smallest number of molecules of ATP and GTP consumed in the synthesis of a 200-residue protein, starting from amino acids? Assume that the hydrolysis of  $\text{PP}_i$  is equivalent to the hydrolysis of ATP for this calculation.
- Correct phasing.* What is meant by the phrase *reading frame*?
- Suppressing frameshifts.* The insertion of a base in a coding sequence leads to a shift in the reading frame, which in

most cases produces a nonfunctional protein. Propose a mutation in a tRNA that might suppress frameshifting.

16. *Tagging a ribosomal site.* Design an affinity-labeling reagent for one of the tRNA-binding sites in *E. coli* ribosomes.

17. *Viral mutation.* An mRNA transcript of a T7 phage gene contains the base sequence

↓

5'–AACUGCACGAGGUAACACAAGAUGGCU–3'

Predict the effect of a mutation that changes the red G to A.

18. *A new translation.* A transfer RNA with a UGU anticodon is enzymatically conjugated to  $^{14}\text{C}$ -labeled cysteine. The cysteine unit is then chemically modified to alanine. The altered aminoacyl-tRNA is added to a protein-synthesizing system containing normal components except for this tRNA. The mRNA added to this mixture contains the following sequence:

5'–UUUUGCCAUGUUUGUGCU–3'

What is the sequence of the corresponding radiolabeled peptide?

19. *Two synthetic modes.* Compare and contrast protein synthesis by ribosomes with protein synthesis by the solid-phase method (Section 3.4).

20. *Triggered GTP hydrolysis.* Ribosomes markedly accelerate the hydrolysis of GTP bound to the complex of EF-Tu and aminoacyl-tRNA. What is the biological significance of this enhancement of GTPase activity by ribosomes?

21. *Blocking translation.* Devise an experimental strategy for switching off the expression of a specific mRNA without changing the gene encoding the protein or the gene's control elements.

22. *Directional problem.* Suppose that you have a protein-synthesis system that is synthesizing a protein designated A. Furthermore, you know that protein A has four trypsin-sensitive sites, equally spaced in the protein, that, on digestion with trypsin, yield the peptides  $A_1$ ,  $A_2$ ,  $A_3$ ,  $A_4$ , and  $A_5$ . Peptide  $A_1$  is the amino-terminal peptide, and  $A_5$  is the carboxyl-terminal peptide. Finally, you know that your system requires 4 minutes to synthesize a complete protein A. At  $t = 0$ , you add all 20 amino acids, each carrying a  $^{14}\text{C}$  label.

(a) At  $t = 1$  minute, you isolate intact protein A from the system, cleave it with trypsin, and isolate the five peptides. Which peptide is most heavily labeled?

(b) At  $t = 3$  minutes, what will be the order of the labeling of peptides from greatest to least?

(c) What does this experiment tell you about the direction of protein synthesis?

23. *Translator.* Aminoacyl-tRNA synthetases are the only component of gene expression that decodes the genetic code. Explain.

24. *A timing device.* EF-Tu, a member of the G-protein family, plays a crucial role in the elongation process of translation. Suppose that a slowly hydrolyzable analog of GTP were added to an elongating system. What would be the effect on the rate of protein synthesis?

25. *Not just RNA.* What are the roles of the protein factors required for protein synthesis?

26. *Membrane transport.* What four components are required for the translocation of proteins across the endoplasmic reticulum membrane?

27. *Push. Don't pull.* What is the energy source that powers the cotranslational movement of proteins across the endoplasmic reticulum?

28. *You have to know where to look.* Bacterial messenger RNAs usually contain many AUG codons. How does the ribosome identify the AUG specifying initiation?

29. *Fundamentally the same, yet ...* List the differences between bacterial and eukaryotic protein synthesis.

30. *Like a border collie.* What is the role of the signal-recognition particle in protein translocation?

31. *An assembly line.* Why is the fact that protein synthesis takes place on polysomes advantageous?

32. *Match 'em*

|                       | 10. Transformylase      |

33. *Wasted effort?* Transfer RNA molecules are quite large, given that the anticodon consists of only three nucleotides. What is the purpose of the rest of the tRNA molecule?

### Mechanism Problems

34. *Evolutionary amino acid choice.* Ornithine is structurally similar to lysine except ornithine's side chain is one methylene group shorter than that of lysine. Attempts

to chemically synthesize and isolate ornithinyl-tRNA proved unsuccessful. Propose a mechanistic explanation. (Hint: Six-membered rings are more stable than seven-membered rings.)

### Chapter Integration Problems

35. *Contrasting modes of elongation.* The two basic mechanisms for the elongation of biomolecules are represented in the adjoining illustration. In type 1, the activating group (X) is released from the growing chain. In type 2, the activating group is released from the incoming unit as it is added to the growing chain. Indicate whether each of the following biosyntheses is by means of a type 1 or a type 2 mechanism:

- Glycogen synthesis
- Fatty acid synthesis
- $C_5 \rightarrow C_{10} \rightarrow C_{15}$  in cholesterol synthesis
- DNA synthesis
- RNA synthesis
- Protein synthesis

36. *Enhancing fidelity.* Compare the accuracy of DNA replication, RNA synthesis, and protein synthesis. Which mechanisms are used to ensure the fidelity of each of these processes?

37. *Déjà vu.* Which protein in G-protein cascades plays a role similar to that of elongation factor Ts?

38. *Family resemblance.* Eukaryotic elongation factor 2 is inhibited by ADP ribosylation catalyzed by diphtheria toxin. What other G proteins are sensitive to this mode of inhibition?

39. *The exceptional E. coli.* In contrast with *E. coli*, most bacteria do not have a full complement of aminoacyl-tRNA synthetases. For instance, *Helicobacter pylori*, the cause of stomach ulcers, has tRNA<sup>Gln</sup>, but no Gln-tRNA synthetase. However, glutamine is a common amino acid in *H. pylori* proteins. Suggest a means by which glutamine can be incorporated into proteins in *H. pylori*. (Hint: Glu-tRNA synthetase can misacylate tRNA<sup>Gln</sup>.)

40. *The final step.* What aspect of primary structure allows the transfer of linear nucleic acid information into the functional three-dimensional structure of proteins?

### Data Interpretation Problems

41. *Helicase helper.* The initiation factor eIF-4 displays ATP-dependent RNA helicase activity. Another initiation factor, eIF-4H, has been proposed to assist the action of eIF-4. Graph A shows some of the experimental results from an assay that can measure the activity of eIF-4 helicase in the presence of eIF-4H.

(a) What are the effects on eIF-4 helicase activity in the presence of eIF-4H?

(b) Why did measuring the helicase activity of eIF-4H alone serve as an important control?

(c) The initial rate of helicase activity of 0.2 μM of eIF-4 was then measured with varying amounts of eIF-4H (graph B). What ratio of eIF-4H to eIF-4 yielded optimal activity?

[Data from N. J. Richter, G. W. Rodgers, Jr., J. O. Hensold, and W. C. Merrick. Further biochemical and kinetic characterization of human eukaryotic initiation factor 4H., *J. Biol. Chem.* 274:35415–35424, 1999.]

(d) Next, the effect of RNA–RNA helix stability on the initial rate of unwinding in the presence and absence of eIF-4H was tested (graph C). How does the effect of eIF-4H vary with helix stability?

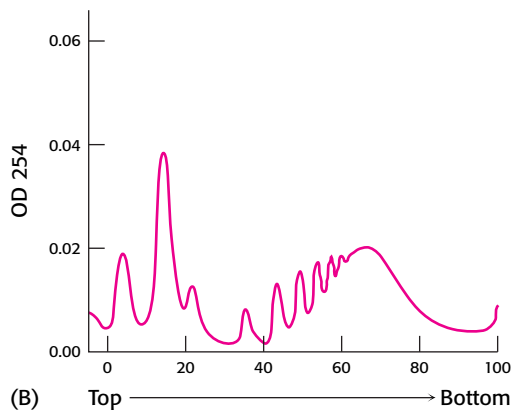

(e) How might eIF-4H affect the helicase activity of eIF-4A?

42. *Size separation.* The protein-synthesizing machinery was isolated from eukaryotic cells and briefly treated with a low concentration of RNase. The sample was then subjected to sucrose gradient centrifugation. The gradient was fractionated and the absorbance, or optical density (OD), at 254 nm was recorded for each fraction. The following plot was obtained.

(a) What do the three peaks of absorbance in graph A represent?

The experiment was repeated except that, this time, the RNase treatment was omitted.

(b) Why is the centrifugation pattern in graph B more complex? What do the series of peaks near the bottom of the centrifuge tube represent?

Before the isolation of the protein-synthesizing machinery, the cells were grown in low concentrations of oxygen (hypoxic conditions). Again the experiment was repeated without RNase treatment (graph C).

[Data from M. Koritzinsky et al., *EMBO J.* 25:1114–1125, 2006.]

(c) What is the effect of growing cells under hypoxic conditions?

# The Control of Gene Expression in Prokaryotes

Bacteria respond to changes in their environments. A micrograph of the light organ of a newly hatched squid (*Euprymna scolopes*) is shown on the left. The light spots are due to colonies of the bacteria *Vibrio fischeri* that live symbiotically within these organs. These bacteria become luminescent when they reach an appropriately high density. The density is sensed by the circuit shown on the right in which each bacterium releases a small molecule into the environment. The molecule is subsequently taken up by other bacterial cells, which start a signaling cascade that stimulates the expression of specific genes. [Spencer V. Nyholm, Eric V. Stabb, Edward G. Ruby, and Margaret J. McFall-Ngai, "Establishment of an animal–bacterial association: Recruiting symbiotic vibrios from the environment." *PNAS* 97(2000): 10231–10235. Copyright 2000 National Academy of Sciences.]

Even simple prokaryotic cells must respond to changes in their metabolism or in their environments. Much of this response takes place through changes in gene expression. A gene is *expressed* when it is transcribed into RNA and, for most genes, translated into proteins. Genomes comprise thousands of genes. Some of these genes are expressed all the time. These genes are subject to *constitutive expression*. Many other genes are expressed only under some circumstances—that is, under a particular set of physiological conditions. These genes are subject to *regulated expression*. For example, the level of expression of some genes in bacteria may vary more than a 1000-fold in response to the supply of nutrients or to environmental challenges.

In this chapter, we will examine gene-regulation mechanisms in prokaryotes, particularly *E. coli*, because many of these processes were first discovered in this organism. In Chapter 32, we will turn to gene-regulation mechanisms in eukaryotes. We shall see both substantial similarities and fundamental differences in comparing gene-regulatory mechanisms of the two types of organisms.

How is gene expression controlled? *Gene activity is controlled first and foremost at the level of transcription.* Whether a gene is transcribed is determined

## OUTLINE

- 31.1 Many DNA-Binding Proteins Recognize Specific DNA Sequences
- 31.2 Prokaryotic DNA-Binding Proteins Bind Specifically to Regulatory Sites in Operons
- 31.3 Regulatory Circuits Can Result in Switching Between Patterns of Gene Expression
- 31.4 Gene Expression Can Be Controlled at Posttranscriptional Levels

largely by the interplay between specific DNA sequences and certain proteins that bind to these sequences. Most often, these proteins repress the expression of specific genes by blocking the access of RNA polymerase to their promoters. In some cases, however, the proteins can activate the expression of specific genes. We shall learn about several different strategies that allow the coordinated regulation of sets of genes. Some genes are also controlled at stages beyond the level of transcription and we shall examine several mechanisms at these stages. Finally, we will examine several important examples of how gene expression is regulated in response to changes in the concentrations of specific molecules in the environment of prokaryotic cells.

### 31.1 Many DNA-Binding Proteins Recognize Specific DNA Sequences

How do regulatory systems distinguish the genes that need to be activated or repressed from genes that are constitutive? After all, the DNA sequences of genes themselves do not have any distinguishing features that would allow regulatory systems to recognize them. Instead, gene regulation depends on other sequences in the genome. In prokaryotes, these regulatory sites are close to the region of the DNA that is transcribed. Regulatory sites are usually binding sites for specific DNA-binding proteins, which can stimulate or repress gene expression. These regulatory sites were first identified in *E. coli* in studies of changes in gene expression. In the presence of the sugar lactose, the bacterium starts to express a gene encoding  $\beta$ -galactosidase, an enzyme that can process lactose for use as a carbon and energy source. The sequence of the regulatory site for this gene is shown in Figure 31.1. The nucleotide sequence of this site shows a nearly perfect inverted repeat, indicating that the DNA in this region has an approximate twofold axis of symmetry. Recall that cleavage sites for restriction enzymes such as EcoRV have similar symmetry properties (Section 9.3). Symmetry in such regulatory sites usually corresponds to symmetry in the protein that binds the site. *Symmetry matching is a recurring theme in protein–DNA interactions.*

**FIGURE 31.1** Sequence of the *lac* regulatory site. The nucleotide sequence of this regulatory site shows a nearly perfect inverted repeat, corresponding to twofold rotational symmetry in the DNA. Parts of the sequences that are related by this symmetry are shown in the same color.

To understand these protein–DNA interactions in detail, scientists examined the structure of the complex between an oligonucleotide that includes this site and the DNA-binding unit that recognizes it (Figure 31.2).

**FIGURE 31.2** The *lac* repressor–DNA complex. The DNA-binding domain from a gene-regulatory protein, the *lac* repressor, binds to a DNA fragment containing its preferred binding site (referred to as operator DNA) by inserting an  $\alpha$  helix into the major groove of operator DNA. Notice that a specific contact forms between an arginine residue of the repressor and a G–C base pair in the binding site. [Drawn from 1EFA.pdb.]

**FIGURE 31.3 Helix-turn-helix motif.** These structures show three sequence-specific DNA-binding proteins that interact with DNA through a helix-turn-helix motif (highlighted in yellow). Notice that, in each case, the helix-turn-helix units within a protein dimer are approximately 34 Å apart, corresponding to one full turn of DNA. [Drawn from 1EFA, 1RUN, and 1TRO.pdb.]

The DNA-binding unit comes from a protein called the *lac repressor*, which represses the expression of the lactose-processing gene. As expected, this DNA-binding unit binds as a dimer, and the twofold axis of symmetry of the dimer matches the symmetry of the DNA. An  $\alpha$  helix from each monomer of the protein is inserted into the major groove of the DNA, where amino acid side chains make specific contacts with exposed edges of the base pairs. For example, the side chain of an arginine residue of the protein forms a pair of hydrogen bonds with a guanine residue of the DNA, which would not be possible with any other base. This interaction and similar ones allow the *lac* repressor to bind more tightly to this site than to the wide range of other sites present in the *E. coli* genome.

### The helix-turn-helix motif is common to many prokaryotic DNA-binding proteins

Are similar strategies utilized by other prokaryotic DNA-binding proteins? The structures of many such proteins have now been determined, and amino acid sequences are known for many more. Strikingly, the DNA-binding surfaces of many, but not all, of these proteins consist of a pair of  $\alpha$  helices separated by a tight turn (Figure 31.3). In complexes with DNA, the second of these two helices (often called the *recognition helix*) lies in the major groove, where amino acid side chains make contact with the edges of base pairs. In contrast, residues of the first helix participate primarily in contacts with the DNA backbone. *Helix-turn-helix motifs* are present on many proteins that bind DNA as dimers, and thus two of the units will be present, one on each monomer.

Although the helix-turn-helix motif is the most commonly observed DNA-binding unit in prokaryotes, not all regulatory proteins bind DNA through such units. A striking example is provided by the *E. coli* methionine repressor (Figure 31.4). This protein binds DNA through the insertion of a pair of  $\beta$  strands into the major groove.

**FIGURE 31.4 DNA recognition through  $\beta$  strands.** A methionine repressor is shown bound to DNA. Notice that residues in  $\beta$  strands, rather than in  $\alpha$  helices, participate in the crucial interactions between the protein and the DNA. [Drawn from 1CMA.pdb.]

## 31.2 Prokaryotic DNA-Binding Proteins Bind Specifically to Regulatory Sites in Operons

A historically important example reveals many common principles of gene regulation by DNA-binding proteins. Bacteria such as *E. coli* usually rely on glucose as their source of carbon and energy, even when other sugars are available. However, when glucose is scarce, *E. coli* can use lactose as their carbon source, even though this disaccharide does not lie on any major metabolic pathways. An essential enzyme in the metabolism of lactose is

**FIGURE 31.5 Monitoring the  $\beta$ -galactosidase reaction.** The galactoside substrate X-Gal produces a colored product on cleavage by  $\beta$ -galactosidase. The appearance of this colored product provides a convenient means for monitoring the amount of the enzyme both in vitro and in vivo.

$\beta$ -galactosidase, which hydrolyzes lactose into galactose and glucose. These products are then metabolized by pathways discussed in Chapter 16.

**FIGURE 31.6  $\beta$ -Galactosidase induction.** The addition of lactose to an *E. coli* culture causes the production of  $\beta$ -galactosidase to increase from very low amounts to much larger amounts. The increase in the amount of enzyme parallels the increase in the number of cells in the growing culture.  $\beta$ -Galactosidase constitutes 6.6% of the total protein synthesized in the presence of lactose.

This reaction can be conveniently followed in the laboratory through the use of alternative galactoside substrates that form colored products such as X-Gal (Figure 31.5). An *E. coli* cell growing on a carbon source such as glucose or glycerol contains fewer than 10 molecules of  $\beta$ -galactosidase. In contrast, the same cell will contain several thousand molecules of the enzyme when grown on lactose (Figure 31.6). The presence of lactose in the culture medium induces a large increase in the amount of  $\beta$ -galactosidase by eliciting the synthesis of new enzyme molecules rather than by activating a preexisting but inactive precursor.

A crucial clue to the mechanism of gene regulation was the observation that two other proteins are synthesized in concert with  $\beta$ -galactosidase—namely, *galactoside permease* and *thiogalactoside transacetylase*. The permease is required for the transport of lactose across the bacterial cell membrane (Section 13.3). The transacetylase is not essential for lactose metabolism but appears to play a role in the detoxification of compounds that also may be transported by the permease. Thus, *the expression levels of a set of enzymes that all contribute to the adaptation to a given change in the environment change together*. Such a coordinated unit of gene expression is called an *operon*.

### An operon consists of regulatory elements and protein-encoding genes

The parallel regulation of  $\beta$ -galactosidase, the permease, and the transacetylase suggested that the expression of genes encoding these enzymes is controlled by a common mechanism. François Jacob and Jacques Monod proposed the *operon model* to account for this parallel regulation as well as the results of other genetic experiments. The genetic elements of the model are a *regulator gene* that encodes a regulatory protein, a regulatory DNA sequence called an *operator site*, and a *set of structural genes* (Figure 31.7).

The regulator gene encodes a *repressor* protein that binds to the operator site. The binding of the repressor to the operator prevents transcription of the structural genes. The operator and its associated structural genes constitute

**FIGURE 31.7 Operons.** (A) The general structure of an operon as conceived by Jacob and Monod. (B) The structure of the lactose operon. In addition to the promoter,  $p$ , in the operon, a second promoter is present in front of the regulator gene,  $i$ , to drive the synthesis of the regulator.

the operon. For the *lactose (lac) operon*, the  $i$  gene encodes the repressor,  $o$  is the operator site, and the  $z$ ,  $y$ , and  $a$  genes are the structural genes for  $\beta$ -galactosidase, the permease, and the transacetylase, respectively. The operon also contains a promoter site (denoted by  $p$ ), which directs the RNA polymerase to the correct transcription initiation site. The  $z$ ,  $y$ , and  $a$  genes are transcribed to give a single mRNA molecule that encodes all three proteins. An mRNA molecule encoding more than one protein is known as a *polygenic* or *polycistronic* transcript.

### The *lac* repressor protein in the absence of lactose binds to the operator and blocks transcription

In the absence of lactose, the lactose operon is repressed. How does the *lac* repressor mediate this repression? The *lac repressor* exists as a tetramer of 37-kDa subunits with two pairs of subunits coming together to form the DNA-binding unit previously discussed. In the absence of lactose, the repressor binds very tightly and rapidly to the operator. When the *lac* repressor is bound to DNA, the repressor prevents RNA polymerase from transcribing the protein-coding genes inasmuch as the operator site is directly adjacent to and downstream of the promoter site where the repressor would block the progress of RNA polymerase.

How does the *lac* repressor locate the operator site in the *E. coli* chromosome? The *lac* repressor binds  $4 \times 10^6$  times as strongly to operator DNA as it does to random sites in the genome. This high degree of selectivity allows the repressor to find the operator efficiently even with a large excess ( $4.6 \times 10^6$ ) of other sites within the *E. coli* genome. The dissociation constant for the repressor–operator complex is approximately 0.1 pM ( $10^{-13}$  M). The rate constant for association ( $\approx 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ ) is strikingly high, indicating that the repressor finds the operator primarily by diffusing along a DNA molecule (a one-dimensional search) rather than encountering it from the aqueous medium (a three-dimensional search). This diffusion has been confirmed by studies that monitored the behavior of fluorescently labeled single molecules of *lac* repressor inside living *E. coli* cells.

Inspection of the complete *E. coli* genome sequence reveals two sites within 500 bp of the primary operator site that approximate the sequence of the operator. When one dimeric DNA-binding unit binds to the operator site, the other DNA-binding unit of the *lac* repressor tetramer can bind to one of these sites with similar sequences. The DNA between the two bound sites forms a loop. No other sites that closely match the sequence of the *lac* operator site are present in the rest of the *E. coli* genome sequence. Thus, the *DNA-binding specificity of the lac repressor is sufficient to specify a nearly unique site within the E. coli genome.*

The three-dimensional structure of the *lac* repressor has been determined in various forms. Each monomer consists of a small amino-terminal domain that binds DNA and a larger domain that mediates the formation of the dimeric DNA-binding unit and the tetramer (Figure 31.8). A pair of the amino-terminal domains come together to form the functional DNA-binding unit. Each monomer has a helix-turn-helix unit that interacts with the major groove of the bound DNA.

**FIGURE 31.8 Structure of the *lac* repressor.** A *lac* repressor dimer is shown bound to DNA. Notice that the amino-terminal domain binds to DNA, whereas the carboxyl-terminal domain forms a separate structure. A part of the structure that mediates the formation of *lac* repressor tetramers is not shown. [Drawn from 1EFA.pdb.]

**FIGURE 31.9 Effects of IPTG on *lac* repressor structure.** The structure of the *lac* repressor bound to the inducer isopropylthiogalactoside (IPTG), shown in orange, is superimposed on the structure of the *lac* repressor bound to DNA, shown in purple. Notice that the binding of IPTG induces structural changes that alter the relation between the two DNA-binding domains so that they cannot interact effectively with DNA. The DNA-binding domains of the *lac* repressor bound to IPTG are not shown, because these regions are not well ordered in the crystals studied.

## Ligand binding can induce structural changes in regulatory proteins

In the situation just described, glucose is present and lactose is absent, and the *lac* operon is repressed. How does the presence of lactose trigger the relief of this repression and, hence, the expression of the *lac* operon? Interestingly, lactose itself does not have this effect; rather, *allolactose*, a combination of galactose and glucose with an  $\alpha$ -1,6 rather than an  $\alpha$ -1,4 linkage, does. Allolactose is thus referred to as the *inducer* of the *lac* operon. Allolactose is a side product of the  $\beta$ -galactosidase reaction and is produced at low levels by the few molecules of  $\beta$ -galactosidase that are present before induction. Some other  $\beta$ -galactosides such as *isopropylthiogalactoside* (IPTG) are potent inducers of  $\beta$ -galactosidase expression, although they are not substrates of the enzyme. IPTG is useful in the laboratory as a tool for inducing gene expression in engineered bacterial strains.

The inducer triggers gene expression by preventing the *lac* repressor from binding the operator. *The inducer binds to the lac repressor and thereby greatly reduces the repressor's affinity for operator DNA.* An inducer molecule binds in the center of the large domain within each monomer. This binding leads to conformational changes that modify the relation between the two small DNA-binding domains (Figure 31.9). These domains can no longer easily contact DNA simultaneously, leading to a dramatic reduction in DNA-binding affinity.

Let us recapitulate the processes that regulate gene expression in the lactose operon (Figure 31.10). In the absence of inducer, the *lac* repressor is bound to DNA in a manner that blocks RNA polymerase from transcribing the *z*, *y*, and *a* genes. Thus, very little  $\beta$ -galactosidase, permease, or transacetylase are produced. The addition of lactose to the environment leads to the formation of allolactose. This inducer binds to the *lac* repressor, leading to conformational changes and the release of DNA by the *lac* repressor. With the operator site unoccupied, RNA polymerase can then transcribe the other *lac* genes and the bacterium will produce the proteins necessary for the efficient use of lactose.

The structure of the large domain of the *lac* repressor is similar to those of a large class of proteins that are present in *E. coli* and other bacteria. This family of homologous proteins binds ligands such as sugars and amino acids at their centers. Remarkably, domains of this family are utilized by eukaryotes in taste proteins and in neurotransmitter receptors, as will be discussed in Chapter 33.

## The operon is a common regulatory unit in prokaryotes

Many other gene-regulatory networks function in ways analogous to those of the *lac* operon. For example, genes taking part in purine and, to a lesser degree, pyrimidine biosynthesis are repressed by the

**FIGURE 31.10 Induction of the *lac* operon.** (A) In the absence of lactose, the *lac* repressor binds DNA and represses transcription from the *lac* operon. (B) Allolactose or another inducer binds to the *lac* repressor, leading to its dissociation from DNA and to the production of *lac* mRNA.

*pur* repressor. This dimeric protein is 31% identical in sequence with the *lac* repressor and has a similar three-dimensional structure. However, the behavior of the *pur* repressor is opposite that of the *lac* repressor: whereas the *lac* repressor is released from DNA by binding to a small molecule, the *pur* repressor binds DNA specifically, blocking transcription, only when bound to a small molecule. Such a small molecule is called a corepressor. For the *pur* repressor, the corepressor can be either guanine or hypoxanthine. The dimeric *pur* repressor binds to inverted-repeat DNA sites of the form 5'-ANGCAANCGNTTNCNT-3', in which the bases shown in bold-face type are particularly important. Examination of the *E. coli* genome sequence reveals the presence of more than 20 such sites, regulating 19 operons and including more than 25 genes (Figure 31.11).

Because the DNA-binding sites for these regulatory proteins are short, it is likely that they evolved independently and are not related by divergence from an ancestral regulatory site. Once a ligand-regulated DNA-binding protein is present in a cell, binding sites for the protein may arise by mutation adjacent to additional genes. Binding sites for the *pur* repressor have evolved in the regulatory regions of a wide range of genes taking part in nucleotide biosynthesis. All such genes can then be regulated in a concerted manner.

The organization of prokaryotic genes into operons is useful for the analysis of completed genome sequences. Sometimes a gene of unknown function is discovered to be part of an operon containing well-characterized genes. Such associations can provide powerful clues to the biochemical and physiological functions of the uncharacterized gene.

### Transcription can be stimulated by proteins that contact RNA polymerase

All the DNA-binding proteins discussed thus far function by inhibiting transcription until some environmental condition, such as the presence of lactose, is met. There are also DNA-binding proteins that stimulate transcription. One particularly well studied example is a protein in *E. coli* that stimulates the expression of catabolic enzymes.

*E. coli* grown on glucose, a preferred energy source, have very low levels of catabolic enzymes for metabolizing other sugars. Clearly, the synthesis of these enzymes when glucose is abundant would be wasteful. Glucose has an inhibitory effect on the genes encoding these enzymes, an effect called *catabolite repression*. It is due to the fact that glucose lowers the concentration of cyclic AMP in *E. coli*. When the cAMP concentration is high, it stimulates the concerted transcription of many catabolic enzymes by acting through a protein called the *catabolite activator protein* (CAP), which is also known as the cAMP receptor protein (CRP).

When bound to cAMP, CAP stimulates the transcription of lactose- and arabinose-catabolizing genes. CAP is a sequence-specific DNA-binding protein. Within the *lac* operon, CAP binds to an inverted repeat that is centered near position  $-61$  relative to the start site for transcription (Figure 31.12). This site is approximately 70 base pairs from the operator site. As expected from the symmetry of the binding site, CAP functions as a dimer of identical subunits.

The CAP-cAMP complex stimulates the initiation of transcription by approximately a factor of 50. Energetically favorable contacts between CAP and RNA polymerase increase the likelihood that transcription will be initiated at sites to which the CAP-cAMP complex is bound (Figure 31.13). Thus, in regard to the *lac* operon, gene expression is maximal when the

**FIGURE 31.11 Binding-site distributions.** The *E. coli* genome contains only a single region that closely matches the sequence of the *lac* operator (shown in blue). In contrast, 20 sites match the sequence of the *pur* operator (shown in red). Thus, the *pur* repressor regulates the expression of many more genes than does the *lac* repressor.

**FIGURE 31.12 Binding site for catabolite activator protein (CAP).** This protein binds as a dimer to an inverted repeat that is at the position  $-61$  relative to the start site of transcription. The CAP-binding site on DNA is adjacent to the position at which RNA polymerase binds.

**FIGURE 31.13** Structure of a dimer of CAP bound to DNA. The residues shown in yellow in each CAP monomer have been implicated in direct interactions with RNA polymerase. [Drawn from 1RUN.pdb.]

binding of allolactose relieves the inhibition by the *lac* repressor and the CAP–cAMP complex stimulates the binding of RNA polymerase.

The *E. coli* genome contains many CAP-binding sites in positions appropriate for interactions with RNA polymerase. Thus, an increase in the cAMP level inside an *E. coli* bacterium results in the formation of CAP–cAMP complexes that bind to many promoters and stimulate the transcription of genes encoding a variety of catabolic enzymes.

### 31.3 Regulatory Circuits Can Result in Switching Between Patterns of Gene Expression

The study of viruses that infect bacteria has led to significant advances in our understanding of the processes that control gene expression. Again, sequence-specific DNA-binding proteins play key roles in these processes. Investigations of bacteriophage  $\lambda$  have been particularly revealing. We examined the alternative infection modes of  $\lambda$  phage in Chapter 5. In the lytic pathway, most of the genes in the viral genome are transcribed, initiating the production of many virus particles and leading to the eventual lysis of the bacterial cell with the concomitant release of approximately 100 virus particles. In the lysogenic pathway, the viral genome is incorporated into the bacterial DNA where most of the viral genes remain unexpressed, allowing the viral genome to be carried along as the bacteria replicate. Two key proteins and a set of regulatory sequences in the viral genome are responsible for the switch that determines which of these two pathways is followed.

#### The $\lambda$ repressor regulates its own expression

The first protein that we shall consider is the  $\lambda$  repressor, sometimes known as the  $\lambda$  cI protein. This protein is key because it blocks, either directly or indirectly, the transcription of almost all genes encoded by the virus. The one exception is the gene that encodes the  $\lambda$  repressor itself. The  $\lambda$  repressor consists of an amino-terminal DNA-binding domain and a carboxyl-terminal domain that participates in protein oligomerization (Figure 31.14). This protein binds to a number of key sites in the  $\lambda$  phage genome. The sites of greatest interest for our present discussion are in the so-called right operator (Figure 31.15). This region includes three binding sites for the  $\lambda$  repressor dimer, as well as two promoters within a region of approximately 80 base pairs. One promoter drives the expression of the gene for the  $\lambda$  repressor itself, whereas the other drives the expression of a number of other viral genes.

**FIGURE 31.14** Structure of the  $\lambda$  repressor bound to DNA. The  $\lambda$  repressor binds to DNA as a dimer. The amino-terminal domain of one subunit is shown in red and the carboxyl-terminal domain is shown in blue. In the other subunit, both domains are shown in yellow. Notice how  $\alpha$  helices on the amino-terminal domains fit into the major groove of the DNA. [Drawn from 3DBN.pdb.]

**FIGURE 31.15 Sequence of the  $\lambda$  right operator.** The three operator sites ( $O_{R1}$ ,  $O_{R2}$ , and  $O_{R3}$ ) are shaded yellow with their centers indicated. The start sites for the  $\lambda$  repressor mRNA and the Cro mRNA are indicated, as are their  $-10$  and  $-35$  sequences.

The  $\lambda$  repressor does not have the same affinity for the three sites; it binds the site  $O_{R1}$  with the highest affinity. In addition, the binding to adjacent sites is cooperative so that, after a  $\lambda$  repressor dimer has bound at  $O_{R1}$ , the likelihood that a protein will bind to the adjacent site  $O_{R2}$  increases by approximately 25-fold. Thus, when  $\lambda$  repressor is present in the cell at moderate concentrations, the most likely configuration has  $\lambda$  repressor bound at  $O_{R1}$  and  $O_{R2}$ , but not at  $O_{R3}$ . In this configuration, the  $\lambda$  repressor dimer bound at  $O_{R1}$  blocks access to the promoter on the right side of the operator sites, repressing transcription of the adjacent gene, which encodes a protein termed Cro (controller of repressor and others), while the repressor dimer at  $O_{R2}$  can be in contact with RNA polymerase and stimulate transcription of the promoter that controls the transcription of the gene that encodes the  $\lambda$  repressor itself.

Thus, the  $\lambda$  repressor stimulates its own production. As the concentration of the  $\lambda$  repressor increases further, an additional repressor dimer can bind to the  $O_{R3}$  site, blocking the other promoter and repressing the production of additional repressor. Thus, the right operator serves to maintain the  $\lambda$  repressor in a narrow, stable concentration range (Figure 31.16). The  $\lambda$  repressor also blocks other promoters in the  $\lambda$  phage genome so that the repressor is the only phage protein produced, which corresponds to the lysogenic state.

### A circuit based on the $\lambda$ repressor and Cro forms a genetic switch

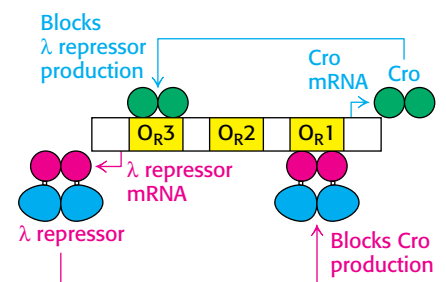

What stimulates the switch to the lytic pathway? Changes such as DNA damage initiate the cleavage of the  $\lambda$  repressor at a specific bond between the DNA-binding and oligomerization domains. This process is mediated by the *E. coli* RecA protein (Section 28.5). After this cleavage has taken place, the affinity of the  $\lambda$  repressor for DNA is reduced. After the  $\lambda$  repressor is no longer bound to the  $O_{R1}$  site, the Cro gene can be transcribed. Cro is a small protein that binds to the same sites as the  $\lambda$  repressor does, but with a different order of affinity for the three sites in the right operator. In particular, Cro has the highest affinity for  $O_{R3}$ . Cro bound in this site blocks the production of new repressor. The absence of repressor leads to the production of other phage genes, leading to the production of virus particles and the eventual lysis of the host cells. Thus, this genetic circuit acts as a switch with two stable states: (1) repressor high, Cro low, corresponding to the lysogenic state, and (2) Cro high, repressor low, corresponding to the lytic state (Figure 31.17). Regulatory circuits with different DNA-binding proteins controlling the expression of each other's genes constitute a common motif for controlling gene expression.

### Many prokaryotic cells release chemical signals that regulate gene expression in other cells

Prokaryotic cells have been traditionally viewed as solitary single cells. However, it is becoming increasingly clear that, in many circumstances, prokaryotic cells live in complex communities, interacting with other cells

**FIGURE 31.16 The  $\lambda$  repressor controls its own synthesis.** (A) When  $\lambda$  repressor levels are relatively low, the repressor binds to sites  $O_{R1}$  and  $O_{R2}$  and stimulates the transcription of the gene that encodes the  $\lambda$  repressor itself. (B) When  $\lambda$  repressor levels are higher, the repressor also binds to site  $O_{R3}$ , blocking access to its promoter and repressing transcription from this gene.

**FIGURE 31.17 The  $\lambda$  repressor and Cro form a genetic circuit.** The  $\lambda$  repressor blocks the production of Cro by binding most favorably to site  $O_{R1}$  whereas Cro blocks the production of the  $\lambda$  repressor by binding most favorably to site  $O_{R3}$ . This circuit forms a switch that determines whether the lysogenic or the lytic pathway is followed.

**Acyl-homoserine lactone (AHL)**

**FIGURE 31.18 Autoinducer structure.**

The structure of the acyl-homoserine lactone *N*-3-oxo-hexanoyl homoserine lactone, the autoinducer from *V. fischeri*. The autoinducers from other bacterial species can have different acyl groups (shown in red).

of their own and different species. *These social interactions change the patterns of gene expression within the cells.*

An important type of interaction is called *quorum sensing*. This phenomenon was discovered in the bacteria *Vibrio fischeri*, a species of bacterium that can live inside a specialized light organ in the bobtail squid. In this symbiotic relation, the bacteria produce luciferase and bioluminesce, providing protection for the squid (by preventing being backlit by moonlight) in exchange for a safer place to live and reproduce. When these bacteria are grown in culture at low density, they are not bioluminescent. However, when the cell density reaches a critical level, the gene for luciferase is expressed and the cells bioluminesce. A key observation was that, when *V. fischeri* cells were transferred to a sterile medium in which other *V. fischeri* cells had been grown to high density, the cells became bioluminescent even at low cell density. This experiment revealed that a chemical, subsequently shown to be *N*-3-oxo-hexanoyl homoserine lactone (hereafter AHL for acyl-homoserine lactone), had been released into the medium where it triggered the development of the bioluminescence (Figure 31.18). This compound and other compounds that play similar roles are termed *autoinducers*.

Cells of *V. fischeri* release the autoinducer into their environment and other *V. fischeri* cells take up the chemical. *V. fischeri* cells express a DNA-binding protein LuxR that serves as the receptor for the autoinducer. LuxR comprises two domains, one of which binds AHL and the other of which binds DNA through a helix-turn-helix motif (Figure 31.19). After the AHL concentration inside the cell has increased to an appropriate level, a substantial fraction of the LuxR molecules bind AHL. When bound to AHL, LuxR dimers bind to specific sites on DNA and increase the rate of transcription initiation at specific genes. The target genes include an operon that contains LuxA and LuxB, which together encode the luciferase enzyme, and LuxI, which produces an enzyme that catalyzes the formation of more AHL.

Because each cell produces only a small amount of the autoinducer, this regulatory system allows each *V. fischeri* cell to determine the density of the *V. fischeri* population in its environment—hence the term *quorum sensing* for this process. Studies of other prokaryotic cells are revealing an elaborate chemical language of different autoinducers (as well as autorepressors that repress specific genes). The “words” in this language include other acyl-

homoserine lactone molecules with different acyl chain lengths and functionalities, as well as other distinct classes of molecules.

**Biofilms are complex communities of prokaryotes**

Many species of prokaryotes can be found in specialized structures termed *biofilms* that can form on surfaces. Biofilms are of considerable medical importance because organisms within them are often quite resistant to the immune response of the host as well as to antibiotics. Quorum sensing appears to play a major role in the formation of biofilms, in that cells are able to sense other cells in their environments and to promote the formation of communities with particular compositions. Some genes controlled by quorum-sensing mechanisms promote the formation of specific molecules that serve as scaffolds for the biofilm. An intriguing recent discovery is that many of the organisms that are present in biofilms on or in our bodies (perhaps 95% or more) have not been

**FIGURE 31.19 Quorum-sensing gene regulator.** The structure of a homolog of LuxR (TraR from the bacterium *Agrobacterium tumefaciens*) is shown. Notice that the dimeric protein binds to DNA through an  $\alpha$ -helical domain, whereas the autoinducer binds to a separate domain.

grown in culture. Through DNA-sequencing methods, we are developing a better census of our microbiome and are working toward understanding the gene-regulatory mechanisms that support these complex communities.

### 31.4 Gene Expression Can Be Controlled at Posttranscriptional Levels

The modulation of the rate of transcription initiation is the most common mechanism of gene regulation. However, other stages of transcription also can be targets for regulation. In addition, the process of translation provides other points of intervention for regulating the level of a protein produced in a cell. In Chapter 29, we considered riboswitches that control transcription termination (Section 29.1). Other riboswitches control gene expression by other mechanisms such as the formation of structures that inhibit translation. Additional mechanisms for posttranscriptional gene regulation have been discovered, one of which will be described here.

#### Attenuation is a prokaryotic mechanism for regulating transcription through the modulation of nascent RNA secondary structure

A means for regulating transcription in bacteria was discovered by Charles Yanofsky and his colleagues as a result of their studies of the tryptophan operon. This operon encodes five enzymes that convert chorismate into tryptophan. Analysis of the 5' end of *trp* mRNA revealed the presence of a *leader sequence* of 162 nucleotides before the initiation codon of the first enzyme. The next striking observation was that bacteria produced a transcript consisting of only the first 130 nucleotides when the tryptophan level was high, but they produced a 7000-nucleotide *trp* mRNA, including the entire leader sequence, when tryptophan was scarce. Thus, when tryptophan is plentiful and the biosynthetic enzymes are not needed, transcription is abruptly broken off before any mRNA coding for the enzymes is produced. The site of termination is called the attenuator, and this mode of regulation is called *attenuation*.

Attenuation depends on features at the 5' end of the mRNA product (Figure 31.20). The first part of the leader sequence encodes a 14-amino-acid leader peptide. Following the open reading frame for the peptide is the

**FIGURE 31.20 Leader region of *trp* mRNA.** (A) The nucleotide sequence of the 5' end of *trp* mRNA includes a short open reading frame that encodes a peptide comprising 14 amino acids; the leader encodes two tryptophan residues and has an untranslated attenuator region that includes a region that can form a terminator structure (red and blue). (B and C) The attenuator region can adopt either of two distinct stem-loop structures.

**FIGURE 31.21 Attenuation.** (A) In the presence of adequate concentrations of tryptophan (and, hence, Trp-tRNA), translation proceeds rapidly and an RNA structure forms that terminates transcription. (B) At low concentrations of tryptophan, translation stalls while awaiting Trp-tRNA, giving time for an alternative RNA structure to form that prevents the formation of the terminator and transcription can proceed.

attenuator, a region of RNA that is capable of forming several alternative structures. Recall that transcription and translation are tightly coupled in bacteria. Thus, the translation of the *trp* mRNA begins soon after the ribosome-binding site has been synthesized.

How does the level of tryptophan alter transcription of the *trp* operon? An important clue was the finding that the 14-amino-acid leader peptide includes two adjacent tryptophan residues. A ribosome is able to translate the leader region of the mRNA product only in the presence of adequate concentrations of tryptophan. When enough tryptophan is present, a stem-loop structure forms in the attenuator region, which leads to the release of RNA polymerase from the DNA (Figure 31.21). However, when tryptophan is scarce, transcription is terminated less frequently. Little tryptophanyl-tRNA is present, and so the ribosome stalls at the tandem UGG codons encoding tryptophan. This delay leaves the adjacent region of the mRNA exposed as transcription continues. An alternative RNA structure that does not function as a terminator is formed, and transcription continues into and through the coding regions for the enzymes. Thus, attenuation provides an elegant means of sensing the supply of tryptophan required for protein synthesis.

Several other operons for the biosynthesis of amino acids in *E. coli* also are regulated by attenuator sites. The leader peptide of each contains an abundance of the amino acid residues of the type synthesized by the operon (Figure 31.22). For example, the leader peptide for the phenylalanine operon includes 7 phenylalanine residues among 15 residues. The threonine operon encodes enzymes required for the synthesis of both threonine and isoleucine; the leader peptide contains 8 threonine and 4 isoleucine residues in a 16-residue sequence. The leader peptide for the histidine operon includes

**FIGURE 31.22 Leader peptide sequences.** Amino acid sequences and the corresponding mRNA nucleotide sequences of the (A) threonine operon, (B) phenylalanine operon, and (C) histidine operon. In each case, an abundance of one amino acid in the leader peptide sequence leads to attenuation.

7 histidine residues in a row. In each case, low levels of the corresponding charged tRNA cause the ribosome to stall, trapping the nascent mRNA in a state that can form a structure that allows RNA polymerase to read through the attenuator site. Evolution has apparently converged on this strategy repeatedly as a mechanism for controlling amino acid biosynthesis.

The examples of prokaryotic gene regulation that we have been describing come from bacteria, as opposed to archaea. The transcriptional apparatus present in archaea shares many features with that found in eukaryotes. This commonality is frequently interpreted to suggest that eukaryotes evolved after a cell fusion event in which a bacterial cell was engulfed by an archaeal cell. Nonetheless, the key principles of gene regulation such as the occurrence of operons and the roles of DNA-binding proteins in directly blocking or stimulating RNA polymerase are the same in bacteria and archaea, perhaps because of similar genome sizes. As we shall see in the next chapter, eukaryotic cells with larger genomes and, often, many distinct cell types, utilize quite different strategies.

## SUMMARY

### 31.1 Many DNA-Binding Proteins Recognize Specific DNA Sequences

The regulation of gene expression depends on the interplay between specific sequences within the genome and proteins that bind specifically to these sites. Specific DNA-binding proteins recognize regulatory sites that usually lie adjacent to the genes whose transcription is regulated by these proteins. The proteins of the largest family contain a helix-turn-helix motif. The first helix of this motif inserts into the major groove of DNA and makes specific hydrogen-bonding and other contacts with the edges of the base pairs.

### 31.2 Prokaryotic DNA-Binding Proteins Bind Specifically to Regulatory Sites in Operons

In prokaryotes, many genes are clustered into operons, which are units of coordinated genetic expression. An operon consists of control sites (an operator and a promoter) and a set of structural genes. In addition, regulator genes encode proteins that interact with the operator and promoter sites to stimulate or inhibit transcription. The treatment of *E. coli* with lactose induces an increase in the production of  $\beta$ -galactosidase and two additional proteins that are encoded in the lactose operon. In the absence of lactose or a similar galactoside inducer, the *lac* repressor protein binds to an operator site on the DNA and blocks transcription. The binding of allolactose, a derivative of lactose, to the *lac* repressor induces a conformational change that leads to dissociation from DNA. RNA polymerase can then move through the operator to transcribe the *lac* operon.

Some proteins activate transcription by directly contacting RNA polymerase. For example, cyclic AMP stimulates the transcription of many catabolic operons by binding to the catabolite activator protein. The binding of the cAMP–CAP complex to a specific site in the promoter region of an inducible catabolic operon enhances the binding of RNA polymerase and the initiation of transcription.

### 31.3 Regulatory Circuits Can Result in Switching Between Patterns of Gene Expression

The study of bacterial viruses, particularly bacteriophage  $\lambda$ , has revealed key aspects of gene-regulatory networks. Bacteriophage  $\lambda$  can

develop by either a lytic or a lysogenic pathway. A key regulatory protein, the  $\lambda$  repressor, regulates its own expression, promoting transcription of the gene that encodes the repressor when repressor levels are low and blocking transcription of the gene when levels are high. This behavior depends on the  $\lambda$  right operator, which includes three sites to which  $\lambda$  repressor dimers can bind. Cooperative binding of the  $\lambda$  repressor to two of the sites stabilizes the state in which two  $\lambda$  repressor dimers are bound. The Cro protein binds to the same sites as does the  $\lambda$  repressor, but with reversed affinities. When Cro is present at sufficient concentrations, it blocks the transcription of the gene for the  $\lambda$  repressor while allowing the transcription of its own gene. Thus, these two proteins and the operator form a genetic switch that can exist in either of two states.

Some prokaryotic species participate in quorum sensing. This process includes the release of chemicals called autoinducers into the medium surrounding the cells. These autoinducers are often, but not always, acyl homoserine lactones. Autoinducers are taken up by surrounding cells. When the autoinducer concentration reaches an appropriate level, it is bound by receptor proteins that activate the expression of genes, including those that promote the synthesis of more autoinducer. These chemically mediated social interactions allow these prokaryotes to change their gene-expression patterns in response to the number of other cells in their environments. Biofilms are complex communities of prokaryotes that are promoted by quorum-sensing mechanisms.

### 31.4 Gene Expression Can Be Controlled at Posttranscriptional Levels

Gene expression can also be regulated at the level of translation. In prokaryotes, many operons important in amino acid biosynthesis are regulated by attenuation, a process that depends on the formation of alternative structures in mRNA, one of which favors the termination of transcription. Attenuation is mediated by the translation of a leader region of mRNA. A ribosome stalled by the absence of an aminoacyl-tRNA needed to translate the leader mRNA alters the structure of mRNA, allowing RNA polymerase to transcribe the operon beyond the attenuator site.

attenuation (p. 935)

## PROBLEMS

1. *Missing genes.* Predict the effects of deleting the following regions of DNA:

- The gene encoding *lac* repressor
- The *lac* operator
- The gene encoding CAP

2. *Minimal concentration.* Calculate the concentration of *lac* repressor, assuming that one molecule is present per cell. Assume that each *E. coli* cell has a volume of  $10^{-12}$  cm<sup>3</sup>. Would you expect the single molecule to be free or bound to DNA?

3. *Counting sites.* Calculate the expected number of times that a given 8-base-pair DNA site should be present in the *E. coli* genome. Assume that all four bases are equally probable. Repeat for a 10-base-pair site and a 12-base-pair site.

4. *The same but not the same.* The *lac* repressor and the *pur* repressor are homologous proteins with very similar three-dimensional structures, yet they have different effects on gene expression. Describe two important ways in which the gene-regulatory properties of these proteins differ.

5. *The opposite direction.* Some compounds called anti-inducers bind to repressors such as the *lac* repressor and inhibit the action of inducers; that is, transcription is repressed and higher concentrations of inducer are required to induce transcription. Propose a mechanism of action for anti-inducers.

6. *Inverted repeats.* Suppose that a nearly perfect 20-base-pair inverted repeat is observed in a DNA sequence. Provide two possible explanations.

7. *Broken operators.* Consider a hypothetical mutation in  $O_{R2}$  that blocks both  $\lambda$  repressor and Cro binding. How would this mutation affect the likelihood of bacteriophage  $\lambda$  entering the lytic phase?

8. *Promoters.* Compare the  $-10$  and  $-35$  sequences for the  $\lambda$  repressor and Cro genes in the right operator. How many differences are there between these sequences?

9. *Positive and negative feedback.* What is the effect of an increased Cro concentration on the expression of the gene for the  $\lambda$  repressor? Of an increased concentration of  $\lambda$  repressor on the expression of the Cro gene? Of an increased concentration of  $\lambda$  repressor on the expression of the  $\lambda$  repressor gene?

10. *Leaderless.* The mRNA for the  $\lambda$  repressor begins with 5'-AUG-3', which encodes the methionine residue that begins the protein. What is unusual about this beginning? Would it cause the mRNA to translate efficiently or not?

11. *Quorum count.* Suppose you have a series of compounds that you wish to test for the autoinducer activity in *Vibrio fischeri*. Propose a simple assay, assuming that you can grow *V. fischeri* cultures at low cell densities.

12. *Codon utilization.* There are four codons that encode threonine. Consider the leader sequence in Figure 31.22A. What codons are used and with what frequency?

### Mechanism Problem

13. *Follow the stereochemistry.* The hydrolysis of lactose is catalyzed by  $\beta$ -galactosidase. Does the overall reaction proceed with retention or inversion of configuration? Given

that each step likely proceeds with inversion of configuration, what does the overall change in stereochemistry suggest about the mechanism? A key residue in the reaction has been identified to be Glu 537. Propose an overall mechanism for the hydrolysis of lactose.

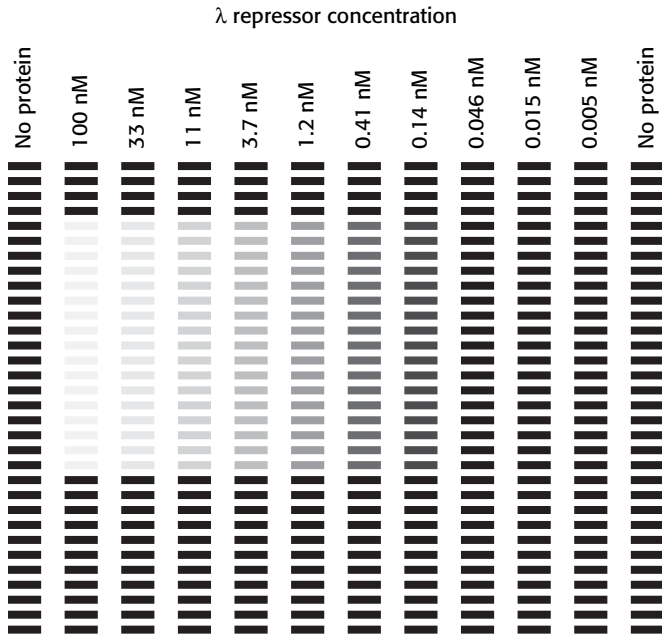

### Data Interpretation Problem

14. *Leaving tracks.* A powerful method for examining protein–DNA interactions is called DNA footprinting. In this method, a DNA fragment containing a potential binding site is radiolabeled on one end. The labeled DNA is then treated with a DNA-cleaving agent such as DNase I such that each DNA molecule within the population is cut only once. The same cleavage process is carried out in the presence of the DNA-binding protein. The bound protein protects some sites within the DNA from cleavage. The patterns of DNA fragments in the cleaved pool of DNA molecules are then examined by electrophoresis followed by autoradiography (a).

This method is applied to a DNA fragment containing a single binding site for the  $\lambda$  repressor in the presence of different concentrations of the  $\lambda$  repressor. The results are shown below (b):

Estimate the dissociation constant for the  $\lambda$  repressor–DNA complex and the standard free energy of binding.

# The Control of Gene Expression in Eukaryotes

Complex biological processes often require coordinated control of the expression of many genes. The maturation of a tadpole into a frog is largely controlled by thyroid hormone. This hormone regulates gene expression by binding to a protein, the thyroid-hormone receptor, as shown at the right. In response to the hormone's binding, this protein binds to specific DNA sites in the genome and modulates the expression of nearby genes. [(Left) Gary Meszaros/Getty Images.]

Many of the most important and intriguing features in modern biology and medicine, such as the pathways crucial for the development of multicellular organisms, the changes that distinguish normal cells and cancer cells, and the evolutionary changes leading to new species, entail networks of gene-regulatory pathways. Gene regulation in eukaryotes is significantly more complex than in prokaryotes in several ways. First, the genomes being regulated are significantly larger. The *E. coli* genome consists of a single, circular chromosome containing 4.6 megabases (Mb). This genome encodes approximately 2000 proteins. In comparison, one of the simplest eukaryotes, *Saccharomyces cerevisiae* (baker's yeast), contains 16 chromosomes ranging in size from 0.2 to 2.2 Mb (Figure 32.1). The yeast genome totals 12 Mb and encodes approximately 6000 proteins. The genome within a human cell contains 23 pairs of chromosomes ranging in size from 50 to 250 Mb. Approximately 21,000 genes are present within the 3000 Mb of human DNA.

Second, whereas prokaryotic genomic DNA is relatively accessible, eukaryotic DNA is packaged into chromatin, a complex between the DNA and a special set of proteins (Figure 32.2). Although the principles for the construction of chromatin are relatively simple, the chromatin structure for a complete genome is quite complex. Importantly, in a given eukaryotic cell, some genes and their associated regulatory regions are relatively accessible

## OUTLINE

- 32.1 Eukaryotic DNA Is Organized into Chromatin
- 32.2 Transcription Factors Bind DNA and Regulate Transcription Initiation
- 32.3 The Control of Gene Expression Can Require Chromatin Remodeling
- 32.4 Eukaryotic Gene Expression Can Be Controlled at Posttranscriptional Levels

### Megabase

A length of DNA consisting of  $10^6$  base pairs (if double stranded) or  $10^6$  bases (if single stranded).

1 Mb =  $10^3$  kb =  $10^6$  bases

**FIGURE 32.1** Yeast chromosomes.

Pulsed-field electrophoresis allows the separation of 16 yeast chromosomes. [From G. Chu, D. Vollrath, and R. W. Davis, *Science* 234:1582–1585, 1986.]

**FIGURE 32.2** Chromatin structure. An electron micrograph of chromatin showing its “beads on a string” character. The beads correspond to DNA complexes with specific proteins. [Don W. Fawcett/Science Source.]

for transcription and regulation, whereas other genes are tightly packaged and are thus rendered inactive. Eukaryotic gene regulation frequently requires the manipulation of chromatin structure.

A manifestation of this complexity is the presence of many different *cell types* in most eukaryotes. A liver cell, a pancreatic cell, and an embryonic stem cell contain the same DNA sequences, yet the subset of genes highly expressed in cells from the pancreas, which secretes digestive enzymes, differs markedly from the subset highly expressed in the liver, the site of lipid transport and energy transduction. Embryonic stem cells do not express any subset of genes at high levels; the most highly expressed genes are “house-keeping” genes involved in the cytoskeleton and processes such as translation (Table 32.1). The existence of stable cell types is due to differences in the *epigenome*, differences in chromatin structure, and covalent modifications of the DNA, not in the DNA sequence itself. Thus, different cell types share the same genome (DNA sequence) but differ in their epigenomes, the packaging and modification of this genome.

In addition, eukaryotic genes are not generally organized into operons. Instead, genes that encode proteins for steps within a given pathway are often spread widely across the genome. This characteristic requires that other mechanisms function to regulate genes in a coordinated way.

Despite these differences, some aspects of gene regulation in eukaryotes are quite similar to those in prokaryotes. In particular, activator and repressor proteins that recognize specific DNA sequences are central to many gene-regulatory processes. In this chapter, we will focus first on chromatin structure. We will then turn to transcription factors—DNA-binding proteins similar in many ways to the prokaryotic proteins that we encountered in the preceding chapter. Eukaryotic transcription factors can act directly by interacting with the transcriptional machinery or indirectly by influencing chromatin structure. Finally, we examine selected

**TABLE 32.1** Highly expressed protein-encoding genes of the pancreas, liver, and embryonic stem cells (as percentage of total mRNA pool)

Rank	Proteins expressed in pancreas	%	Proteins expressed in liver	%	Proteins expressed in stem cells	%
1	Procarboxypeptidase A1	7.6	Albumin	3.5	Glyceraldehyde-3-phosphate dehydrogenase	0.7
2	Pancreatic trypsinogen 2	5.5	Apolipoprotein A-I	2.8	Translation elongation factor 1 $\alpha$ 1	0.6
3	Chymotrypsinogen	4.4	Apolipoprotein C-I	2.5	Tubulin $\alpha$	0.5
4	Pancreatic trypsin 1	3.7	Apolipoprotein C-III	2.1	Translationally controlled tumor protein	0.5
5	Elastase IIIB	2.4	ATPase 6/8	1.5	Cyclophilin A	0.4
6	Protease E	1.9	Cytochrome oxidase 3	1.1	Cofilin	0.4
7	Pancreatic lipase	1.9	Cytochrome oxidase 2	1.1	Nucleophosmin	0.3
8	Procarboxypeptidase B	1.7	$\alpha_1$ -Antitrypsin	1.0	Connexin 43	0.3

posttranscriptional gene-regulatory mechanisms, including those based on microRNAs, an important class of gene-regulatory molecules discovered in recent years.

### 32.1 Eukaryotic DNA Is Organized into Chromatin

Eukaryotic DNA is tightly bound to a group of small basic proteins called *histones*. In fact, histones constitute half the mass of a eukaryotic chromosome. The entire complex of a cell's DNA and associated protein is called *chromatin*. Chromatin compacts and organizes eukaryotic DNA and its presence has dramatic consequences for gene regulation.

#### Nucleosomes are complexes of DNA and histones

Chromatin is made up of repeating units, each containing 200 bp of DNA and two copies each of four histone proteins H2A, H2B, H3, and H4. Histones have strikingly basic properties because a quarter of the residues in each histone are either arginine or lysine, positively charged amino acids that strongly interact with the negatively charged DNA. The protein complex is called the *histone octamer*. The repeating units of the histone octamer and the associated DNA are known as *nucleosomes*. Chromatin viewed with the electron microscope has the appearance of beads on a string (Figure 32.2); each bead has a diameter of approximately 100 Å. Partial digestion of chromatin with DNase yields the isolated beads. These particles consist of fragments of DNA about 200 bp in length bound to the histone octamer. More-extensive digestion yields a shorter DNA fragment of 145 bp bound to the octamer. The smaller complex formed by the histone octamer and the 145-bp DNA fragment is the *nucleosome core particle*. The DNA connecting core particles in undigested chromatin is called linker DNA. Histone H1 binds, in part, to the linker DNA.

#### DNA wraps around histone octamers to form nucleosomes

The overall structure of the nucleosome was revealed through electron microscopic and x-ray crystallographic studies pioneered by Aaron Klug and his colleagues. More recently, the three-dimensional structure of a reconstituted nucleosome core particle (Figure 32.3) was determined to

**FIGURE 32.3 Nucleosome core particle.** The structure consists of a core of eight histone proteins surrounded by DNA. (A) A view showing the DNA wrapping around the histone core. (B) A 90-degree rotation of the view in part (A). Notice that the DNA forms a left-handed superhelix as it wraps around the core. (C) A schematic view. [Drawn from 1AOI.pdb.]

**FIGURE 32.4 Homologous histones.** Histones H2A, H2B, H3, and H4 adopt a similar three-dimensional structure as a consequence of common ancestry. Some parts of the tails at the termini of the proteins are not shown. [Drawn from 1AO1.pdb.]

higher resolution by x-ray diffraction methods. The four types of histone that make up the protein core are homologous and similar in structure (Figure 32.4). The eight histones in the core are arranged into a  $(H3)_2(H4)_2$  tetramer and a pair of H2A–H2B dimers. The tetramer and dimers come together to form a left-handed superhelical ramp around which the DNA wraps. In addition, each histone has an amino-terminal tail that extends out from the core structure. These tails are flexible and contain a number of lysine and arginine residues. As we shall see, *covalent modifications of these tails play an essential role in regulating gene expression.*

The DNA forms a left-handed superhelix as it wraps around the outside of the histone octamer. The protein core forms contacts with the inner surface of the DNA superhelix at many points, particularly along the phosphodiester backbone and the minor groove. Nucleosomes will form on almost all DNA sites, although some sequences are preferred because the dinucleotide steps are properly spaced to favor bending around the histone core. A histone with a different structure from that of the others, called histone H1, seals off the nucleosome at the location at which the linker DNA enters and leaves. The amino acid sequences of histones, including their amino-terminal tails, are remarkably conserved from yeast to human beings.

The winding of DNA around the nucleosome core contributes to the packing of DNA by decreasing its linear extent. An extended 200-bp stretch of DNA would have a length of about 680 Å. Wrapping this DNA around the histone octamer reduces the length to approximately 100 Å along the long dimension of the nucleosome. Thus the DNA is compacted by a factor of 7. However, human chromosomes in metaphase, which are highly condensed, are compacted by a factor of  $10^4$ . Clearly, the nucleosome is just the first step in DNA compaction. What is the next step? The nucleosomes themselves are arranged in a helical array approximately 360 Å across, forming a series of stacked layers approximately 110 Å apart (Figure 32.5). The folding of these fibers of nucleosomes into loops further compacts DNA.

The wrapping of DNA around the histone octamer as a left-handed helix also stores negative supercoils; if the DNA in a nucleosome is straightened out, the DNA will be underwound. This underwinding is exactly what is needed to separate the two DNA strands during replication and transcription.

**FIGURE 32.5 Higher-order chromatin structure.** A proposed model for chromatin arranged in a helical array consisting of six nucleosomes per turn of helix. The DNA double helix (shown in red) is wound around each histone octamer (shown in blue). The actual structure in cells is likely more heterogeneous and dynamic than suggested by this model. [Information from J. T. Finch and A. Klug, *Proc. Natl. Acad. Sci. U. S. A.* 73:1897–1901, 1976.]

## 32.2 Transcription Factors Bind DNA and Regulate Transcription Initiation

DNA-binding *transcription factors* are key to gene regulation in eukaryotes, just as they are in prokaryotes. However, the roles of eukaryotic transcription factors are different in several ways. First, whereas the DNA-binding sites crucial for the control of gene expression in prokaryotes are usually quite close to promoters, those in eukaryotes can be farther away from promoters and can exert their action at a distance. Second, most prokaryotic genes are regulated by single transcription factors, and multiple genes in a pathway are expressed in a coordinated fashion because such genes are often transcribed as part of a polycistronic mRNA. In eukaryotes, the expression of each gene is typically controlled by multiple transcription factors, and the coordinated expression of different genes depends on having similar transcription-factor-binding sites in each gene in the set. Third, in prokaryotes, transcription factors usually interact directly with RNA polymerase. In eukaryotes, while some transcription factors interact directly with RNA polymerase, many others act more indirectly, interacting with other proteins associated with RNA polymerase or modifying chromatin structure. Let us now examine eukaryotic transcription factors in more detail.

Eukaryotic transcription factors usually consist of several domains. The *DNA-binding domain* binds to regulatory sequences that can either be adjacent to the promoter or at some distance from it. Most commonly, transcription factors include additional domains that help activate transcription. When a transcription factor is bound to the DNA, its *activation domain* promotes transcription by interacting with RNA polymerase II, by interacting with other associated proteins, or by modifying the local structure of chromatin.

### A range of DNA-binding structures are employed by eukaryotic DNA-binding proteins

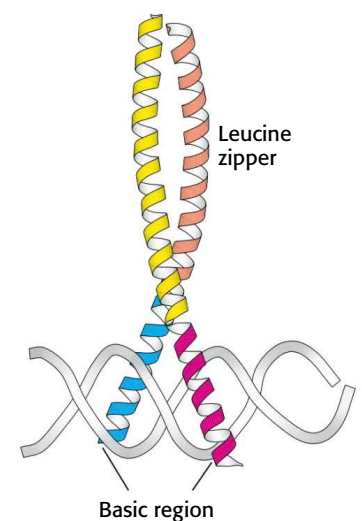

The structures of many eukaryotic DNA-binding proteins have been determined and a range of structural motifs have been observed, but we will focus on three that reveal the common features and the diversity of these motifs. The first class of eukaryotic DNA-binding unit that we will consider is the *homeodomain* (Figure 32.6). The structure of the homeodomain and its mode of recognition of DNA are very similar to those of the prokaryotic helix-turn-helix proteins. In eukaryotes, homeodomain proteins often form heterodimeric structures, sometimes with other homeodomain proteins, that recognize asymmetric DNA sequences.

The second class of eukaryotic DNA-binding unit comprises the *basic-leucine zipper* (bZip) proteins (Figure 32.7). This DNA-binding unit consists of a pair of long  $\alpha$  helices. The first part of each  $\alpha$  helix is a basic region that lies in the major groove of the DNA and makes contacts responsible for DNA-site recognition. The second part of each  $\alpha$  helix forms a coiled-coil structure with its partner. Because these units are often stabilized by appropriately spaced leucine residues, these structures are often referred to as *leucine zippers*.

The final class of eukaryotic DNA-binding units that we will consider here are the *Cys<sub>2</sub>His<sub>2</sub> zinc-finger domains* (Figure 32.8). A DNA-binding unit of this class comprises tandem sets of small domains, each of which binds a zinc ion through conserved sets of two cysteine and two histidine residues. These structures, often called *zinc-finger domains*, form a string that follows the major

**FIGURE 32.6 Homeodomain structure.** The structure of a heterodimer formed from two different DNA-binding domains, each based on a homeodomain. Notice that each homeodomain has a helix-turn-helix motif with one helix inserted into the major groove of DNA. [Drawn from 1AKH.pdb.]

**FIGURE 32.7 Basic-leucine zipper.** This heterodimer comprises two basic-leucine zipper proteins. Notice that the basic region lies in the major groove of DNA. The leucine-zipper part stabilizes the protein dimer. [Drawn from 1FOS.pdb.]

**FIGURE 32.8 Zinc-finger domains.** A DNA-binding domain comprising three Cys<sub>2</sub>His<sub>2</sub> zinc-finger domains (shown in yellow, blue, and red) is shown in a complex with DNA. Each zinc-finger domain is stabilized by a bound zinc ion (shown in green) through interactions with two cysteine residues and two histidine residues. Notice how the protein wraps around the DNA in the major groove. [Drawn from 1AAY.pdb.]

**FIGURE 32.9 Mediator.** Mediator, a large complex of protein subunits, acts as a bridge between transcription factors bearing activation domains and RNA polymerase II. These interactions help recruit and stabilize RNA polymerase II near specific genes that are then transcribed.

groove of DNA. An  $\alpha$  helix from each domain makes specific contact with the edges of base pairs within the groove. Some proteins contain arrays of 10 or more zinc-finger domains, potentially enabling them to contact long stretches of DNA. The human genome encodes several hundred proteins that contain zinc-finger domains of this class. We will encounter another class of zinc-based DNA-binding domain when we consider nuclear hormone receptors in Section 32.3.

### Activation domains interact with other proteins

The activation domains of transcription factors generally recruit other proteins that promote transcription. In some cases, these activation domains interact directly with RNA polymerase II or closely associated proteins. The activation domains act through

intermediary proteins that bridge between the transcription factors and the polymerase. An important target of activators is *mediator*, a complex of 25 to 30 subunits conserved from yeast to human beings, that acts as a bridge between transcription factors and promoter-bound RNA polymerase II (Figure 32.9).

Activation domains are less conserved than DNA-binding domains. In fact, very little sequence similarity has been found. For example, they may be acidic, hydrophobic, glutamine rich, or proline rich. However, they have certain features in common. First, they are often *redundant*; that is, a part of the activation domain can be deleted without loss of function. Second, they are *modular* and can activate transcription when paired with a variety of DNA-binding domains. Third, they can act *synergistically*: two activation domains acting together create a stronger effect than either acting separately.

We have been considering the case in which gene control increases the expression level of a gene. In many cases, the expression of a gene must be decreased by blocking transcription. The agents in such cases are *transcriptional repressors*. Like activators, transcriptional repressors act in many cases by altering chromatin structure.

### Multiple transcription factors interact with eukaryotic regulatory regions

The basal transcription complex described in Chapter 29 initiates transcription at a low frequency. Recall that several general transcription factors join with RNA polymerase II to form the basal transcription complex. Additional transcription factors must bind to other sites that can be near the promoter or quite distant for a gene to achieve a higher rate of mRNA synthesis. In contrast with the regulators of prokaryotic transcription, few eukaryotic transcription factors have any effect on their own. Instead, each factor recruits other proteins to build up large complexes that interact with the transcriptional machinery to activate transcription.

A major advantage of this mode of regulation is that a given regulatory protein can have different effects, depending on what other proteins are present in the same cell. This phenomenon, called *combinatorial control*, is crucial to multicellular organisms that have many different cell types. Even in unicellular eukaryotes such as yeast, combinatorial control allows the generation of distinct cell types.

### Enhancers can stimulate transcription in specific cell types

Transcription factors can often act even if their binding sites lie at a considerable distance from the promoter. These distant regulatory sites are

called *enhancers* (Chapter 29). Enhancers function by serving as binding sites for specific transcription factors. An enhancer is effective only in the specific cell types in which appropriate regulatory proteins are expressed. In many cases, these DNA-binding proteins influence transcription initiation by perturbing the local chromatin structure to expose a gene or its regulatory sites rather than by direct interactions with RNA polymerase. This mechanism accounts for the ability of enhancers to act at a distance.

The properties of enhancers are illustrated by studies of the enhancer controlling the muscle isoform of creatine kinase (Figure 32.10). The results of mutagenesis and other studies revealed the presence of an enhancer located between 1350 and 1050 base pairs upstream of the start site of the gene for this enzyme. Experimentally inserting this enhancer near a gene not normally expressed in muscle cells is sufficient to cause the gene to be expressed at high levels in muscle cells but not in other cells (Figure 32.11).

**FIGURE 32.11 An experimental demonstration of enhancer function.**

A promoter for muscle creatine kinase artificially drives the transcription of  $\beta$ -galactosidase in a zebrafish embryo. Only specific sets of muscle cells produce  $\beta$ -galactosidase, as visualized by the formation of the blue product on treatment of the embryo with X-Gal. [From F. Müller, D. W. Williamson, J. Kobilák, L. Gauvry, G. Goldspink, L. Orbán, and N. MacLean, *Mol. Reprod. Dev.* 47:404–412, 1997.]

### Induced pluripotent stem cells can be generated by introducing four transcription factors into differentiated cells

An important application illustrating the power of transcription factors is the development of *induced pluripotent stem (iPS) cells*. Pluripotent stem cells have the ability to differentiate into many different cell types on appropriate treatment. Previously isolated cells derived from embryos show a very high degree of pluripotency. Over time, researchers identified dozens of genes in embryonic stem cells that contributed to this pluripotency when expressed. In a remarkable experiment reported for mouse cells in 2006 and human cells in 2007, Shinya Yamanaka demonstrated that just four genes out of this entire set could induce pluripotency in already-differentiated skin cells. Yamanaka introduced genes encoding four transcription factors into skin cells called fibroblasts. The fibroblasts de-differentiated into cells that appeared to have characteristics very nearly identical with those of embryonic stem cells (Figure 32.12).

These iPS cells represent powerful research tools and, potentially, a new class of therapeutic agents. The proposed concept is that a sample of a patient's fibroblasts could be readily isolated and converted into iPS cells. These iPS cells could be treated to differentiate into a desired cell type that could then be transplanted into the patient. For example, such an approach might be used to restore a particular class of nerve cells that had been depleted by a neurodegenerative disease. Although the field of iPS cell research is still evolving, it holds great promise as a possible approach to treat any common and difficult-to-treat diseases.

**FIGURE 32.10 Enhancer binding sites.**

A schematic structure for the region 1 kb upstream of the start site for the muscle creatine kinase gene. One binding site of the form 5'-CAGCTG-3' is present near the TATA box. The enhancer region farther upstream contains two binding sites for the same protein and two additional binding sites for other proteins.

**FIGURE 32.12 Induced pluripotent stem cells.**

A micrograph of human induced pluripotent stem cells stained green for a transcription factor that is characteristic of pluripotent cells. [From K. Takahashi et al., *Cell* 131:861–872, 2007; with permission from Elsevier, courtesy of Shinya Yamanaka, Kyoto University.]

## 32.3 The Control of Gene Expression Can Require Chromatin Remodeling

Early observations suggested that chromatin structure plays a major role in controlling eukaryotic gene expression. DNA that is densely packaged into chromatin is less susceptible to cleavage by the nonspecific DNA-cleaving enzyme DNase I. Regions adjacent to genes that are being transcribed are more sensitive to cleavage by DNase I than are other sites in the genome, suggesting that the DNA in these regions is less compacted than it is elsewhere and more accessible to proteins. In addition, some sites, usually within 1 kb of the start site of an active gene, are exquisitely sensitive to DNase I and other nucleases. These *hypersensitive sites* correspond to regions that have few nucleosomes or contain nucleosomes in an altered conformation. *Hypersensitive sites are cell-type specific and developmentally regulated.* For example, globin genes in the precursors of erythroid cells from 20-hour-old chicken embryos are insensitive to DNase I. However, when hemoglobin synthesis begins at 35 hours, regions adjacent to these genes become highly susceptible to digestion. In tissues such as the brain that produce no hemoglobin, the globin genes remain resistant to DNase I throughout development and into adulthood. These studies suggest that a prerequisite for gene expression is a relaxing of the chromatin structure.

Recent experiments even more clearly revealed the role of chromatin structure in regulating access to DNA-binding sites. Genes required for galactose utilization in yeast are activated by a transcription factor called GAL4, which recognizes DNA-binding sites with two 5'-CGG-3' sequences on complementary strands separated by 11 base pairs (Figure 32.13). Approximately 4000 potential GAL4 binding sites of the form 5'-CGG(N)<sub>11</sub>CCG-3' are present in the yeast genome, but only 10 of them regulate genes necessary for galactose metabolism. How is GAL4 targeted to only a small fraction of the potential binding sites? This question is addressed through the use of a technique called *chromatin immunoprecipitation* (ChIP; Figure 32.14). GAL4 is first cross-linked to its DNA-binding sites in chromatin. The DNA is then fragmented into small pieces, and antibodies to GAL4 are used to isolate the chromatin fragments containing GAL4. The cross-linking is reversed, and the DNA is isolated and characterized. The results of these studies reveal that only approximately 10 of the 4000 potential GAL4 sites are occupied by GAL4 when the cells are growing on galactose; more than 99% of the sites appear to be blocked, presumably by the local chromatin structure. Thus, whereas in prokaryotes all sites appear to be equally accessible, chromatin structure

**FIGURE 32.13 GAL4 binding sites.**

The yeast transcription factor GAL4 binds to DNA sequences of the form 5'-CGG(N)<sub>11</sub>CCG-3'. Two zinc-based domains are present in the DNA-binding region of this protein. Notice that these domains contact the 5'-CGG-3' sequences, leaving the center of the site uncontacted. [Drawn from 1D66.pdb.]

**FIGURE 32.14 Chromatin immunoprecipitation.**

Cells or isolated nuclei are treated with formaldehyde to cross-link proteins to DNA. The cells are then lysed and the DNA is fragmented by sonication. DNA fragments bound to a particular protein are isolated through the use of an antibody specific for that protein. The cross-links are then reversed and the DNA fragments are characterized.

shields a large number of the potential binding sites in eukaryotic cells. GAL4 is thereby prevented from binding to sites that are unimportant in galactose metabolism. These lines of evidence and others reveal that chromatin structure is altered in active genes compared with inactive ones.

### The methylation of DNA can alter patterns of gene expression

The degree of methylation of DNA provides another mechanism, in addition to packaging with histones, for inhibiting gene expression inappropriate to a specific cell type. Carbon 5 of cytosine can be methylated by specific methyltransferases. About 70% of the 5'-CpG-3' sequences (where "p" represents the phosphate residue in the DNA backbone) in mammalian genomes are methylated. However, the distribution of these methylated cytosines varies, depending on the cell type. Consider the  $\beta$ -globin gene. In cells that are actively expressing hemoglobin, the region from approximately 1 kb upstream of the start site to approximately 100 bp downstream of the start site is less methylated than the corresponding region in cells that do not express this gene. The relative absence of 5-methylcytosines near the start site is referred to as *hypomethylation*. The methyl group of 5-methylcytosine protrudes into the major groove where it could easily interfere with the binding of proteins that stimulate transcription.

The distribution of CpG sequences in mammalian genomes is not uniform. Many CpG sequences have been converted into TpG through mutation by the deamination of 5-methylcytosine to thymine. However, sites near the 5' ends of genes have been maintained because of their role in gene expression. Thus, most genes are found in *CpG islands*, regions of the genome that contain approximately four times as many CpG sequences as does the remainder of the genome.

### Steroids and related hydrophobic molecules pass through membranes and bind to DNA-binding receptors

We next look at an example that illustrates how transcription factors can stimulate changes in chromatin structure that affect transcription. We will consider in some detail the system that detects and responds to estrogens. Synthesized and released by the ovaries, *estrogens*, such as estradiol, are cholesterol-derived steroid hormones (Section 26.4). They are required for the development of female secondary sex characteristics and, along with progesterone, participate in the ovarian cycle.

Because they are hydrophobic molecules, estrogens easily diffuse across cell membranes. When inside a cell, estrogens bind to highly specific, soluble receptor proteins. Estrogen receptors are members of a large family of proteins that act as receptors for a wide range of hydrophobic molecules, including other steroid hormones, thyroid hormones, and retinoids.

The human genome encodes approximately 50 members of this family, often referred to as *nuclear hormone receptors*. The genomes of other

**FIGURE 32.15 Structure of two nuclear hormone-receptor domains.** Nuclear hormone receptors contain two crucial conserved domains: (1) a DNA-binding domain toward the center of the sequence and (2) a ligand-binding domain toward the carboxyl terminus. The structure of a dimer of the DNA-binding domain bound to DNA is shown, as is one monomer of the normally dimeric ligand-binding domain. [Drawn from 1HCQ and 1LBD.pdb.]

multicellular eukaryotes encode similar numbers of nuclear hormone receptors, although they are absent in yeast.

All these receptors have a similar mode of action. On binding of the signal molecule (called, generically, a *ligand*), the ligand–receptor complex modifies the expression of specific genes by binding to control elements in the DNA. Estrogen receptors bind to specific DNA sites (referred to as *estrogen response elements* or EREs) that contain the consensus sequence 5′-AGGTCANNNTGACCT-3′. As expected from the symmetry of this sequence, an estrogen receptor binds to such sites as a dimer.

A comparison of the amino acid sequences of members of this family reveals two highly conserved domains: a DNA-binding domain and a ligand-binding domain (Figure 32.15). The DNA-binding domain lies toward the center of the molecule and consists of a set of zinc-based domains different from the Cys<sub>2</sub>His<sub>2</sub> zinc-finger proteins introduced in Section 32.2. These zinc-based domains bind to specific DNA sequences by virtue of an  $\alpha$  helix that lies in the major groove in the specific DNA complexes formed by estrogen receptors.

### Nuclear hormone receptors regulate transcription by recruiting coactivators to the transcription complex

The second highly conserved domain of the nuclear receptor proteins lies near the carboxyl terminus and is the ligand-binding site. This domain folds into a structure that consists almost entirely of  $\alpha$  helices, arranged in three layers. The ligand binds in a hydrophobic pocket that lies in the center of this array of helices (Figure 32.16). This domain changes conformation when it binds its ligand, estrogen. How does ligand binding lead to changes in gene expression? The simplest model would have the binding of ligand alter the DNA-binding properties of the receptor, analogously to the *lac* repressor in prokaryotes. However, experiments with purified nuclear hormone receptors revealed that ligand binding does *not* significantly alter DNA-binding affinity and specificity. Another mechanism is operative.

Investigators sought to determine whether specific proteins might bind to the nuclear hormone receptors only in the presence of ligand. Such searches led to the identification of several related proteins called *coactivators*, such as SRC-1 (steroid receptor coactivator-1), GRIP-1 (glucocorticoid receptor interacting protein-1), and NcoA-1 (*nuclear hormone receptor*

**FIGURE 32.16 Ligand binding to nuclear hormone receptor.** The ligand lies completely surrounded within a pocket in the ligand-binding domain. Notice that the last  $\alpha$  helix, helix 12 (shown in purple), folds into a groove on the side of the structure on ligand binding. [Drawn from 1LDB and 1ERE.pdb.]

*coactivator-1*). These coactivators are referred to as the p160 family because of their size. The binding of ligand to the receptor induces a conformational change that allows the recruitment of a coactivator (Figure 32.17). In many cases, these coactivators are enzymes that catalyze reactions that lead to the modification of chromatin structure.

### Steroid-hormone receptors are targets for drugs

Molecules such as estradiol that bind to a receptor and trigger signaling pathways are called *agonists*. Athletes sometimes take natural and synthetic agonists of the androgen receptor, a member of the family of nuclear hormone receptors, because their binding to the androgen receptor stimulates the expression of genes that enhance the development of lean muscle mass.

Referred to as *anabolic steroids*, such compounds used in excess are not without side effects. In men, excessive use leads to a decrease in the secretion of testosterone, to testicular atrophy, and sometimes to breast enlargement

**FIGURE 32.17 Coactivator recruitment.** The binding of ligand to a nuclear hormone receptor induces a conformational change in the ligand-binding domain. This change in conformation generates favorable sites for the binding of a coactivator.

**FIGURE 32.18 Estrogen receptor—tamoxifen complex.** Tamoxifen binds in the pocket normally occupied by estrogen. However, notice that part of the tamoxifen structure extends from this pocket, and so helix 12 cannot pack in its usual position. Instead, this helix blocks the coactivator-binding site. [Drawn from 3ERT.pdb.]

The determination of the structures of complexes between the estrogen receptor and these drugs revealed the basis for their antagonist effect (Figure 32.18). Tamoxifen binds to the same site as estradiol does. However, tamoxifen has a group that extends out of the normal ligand-binding pocket, as do other antagonists. These groups block the normal conformational changes induced by estrogen. Tamoxifen blocks the binding of coactivators and thus inhibits the activation of gene expression.

**FIGURE 32.19 Structure of histone acetyltransferase.** The amino-terminal tail of histone H3 extends into a pocket in which a lysine side chain can accept an acetyl group from acetyl Coenzyme A bound in an adjacent site. [Drawn from 1QSN.pdb.]

### Chromatin structure is modulated through covalent modifications of histone tails

We have seen that nuclear receptors respond to signal molecules by recruiting coactivators. Now we can ask, How do coactivators modulate transcriptional activity? *These proteins act to loosen the histone complex from the DNA, exposing additional DNA regions to the transcription machinery.*

Much of the effectiveness of coactivators appears to result from their ability to covalently modify the amino-terminal tails of histones as well as regions on other proteins. Some of the p160 coactivators and the proteins that they recruit catalyze the transfer of acetyl groups from acetyl CoA to specific lysine residues in these amino-terminal tails.

Enzymes that catalyze such reactions are called *histone acetyltransferases* (HATs). The histone tails are readily extended; so they can fit into the HAT active site and become acetylated (Figure 32.19).

What are the consequences of histone acetylation? Lysine bears a positively charged ammonium group at neutral pH. The addition of an acetyl group generates an uncharged amide group. This change dramatically reduces the affinity of the tail for DNA and modestly decreases the affinity

of the entire histone complex for DNA, loosening the histone complex from the DNA.

In addition, the acetylated lysine residues interact with a specific *acetyllysine-binding domain* that is present in many proteins that regulate eukaryotic transcription. This domain, termed a *bromodomain*, comprises approximately 110 amino acids that form a four-helix bundle containing a peptide-binding site at one end (Figure 32.20).

Bromodomain-containing proteins are components of two large complexes essential for transcription. One is a complex of more than 10 polypeptides that binds to the *TATA-box-binding protein*. Recall that the TATA-box-binding protein is an essential transcription factor for many genes (Section 29.2). Proteins that bind to the TATA-box-binding protein are called *TAFs* (for *TATA-box-binding protein associated factors*). In particular, TAF1 contains a pair of bromodomains near its carboxyl terminus. The two domains are oriented such that each can bind one of two acetyllysine residues at positions 5 and 12 in the histone H4 tail. Thus, *acetylation of the histone tails provides a mechanism for recruiting other components of the transcriptional machinery*.

Bromodomains are also present in some components of large complexes known as *chromatin-remodeling complexes* or *chromatin-remodeling engines*. These complexes, which also contain domains homologous to those of helicases, utilize the free energy of ATP hydrolysis to shift the positions of nucleosomes along the DNA and to induce other conformational changes in chromatin (Figure 32.21). Histone acetylation can lead to a reorganization of the chromatin structure, potentially exposing binding sites for other factors. Thus, *histone acetylation can activate transcription through a combination of three mechanisms: by reducing the affinity of the histones for DNA, by recruiting other components of the transcriptional machinery, and by initiating the remodeling of the chromatin structure*.

Nuclear hormone receptors also include regions that interact with components of the mediator complex. Thus, two mechanisms of gene regulation can work in concert. Modification of histones and chromatin remodeling can open up regions of chromatin into which the transcription complex can be recruited through protein–protein interactions.

### Histone deacetylases contribute to transcriptional repression

Just as in prokaryotes, some changes in a cell's environment lead to the repression of genes that had been active. The modification of histone tails

**FIGURE 32.20 Structure of a bromodomain.** This four-helix-bundle domain binds peptides containing acetyllysine. Notice that an acetylated peptide from histone H4 is bound in the structure. [Drawn from 1EGL.pdb.]

**FIGURE 32.21 Chromatin remodeling.** Eukaryotic gene regulation begins with an activated transcription factor bound to a specific site on DNA. One scheme for the initiation of transcription by RNA polymerase II requires five steps: (1) recruitment of a coactivator, (2) acetylation of lysine residues in the histone tails, (3) binding of a remodeling-engine complex to the acetylated lysine residues, (4) ATP-dependent remodeling of the chromatin structure to expose a binding site for RNA polymerase II or for other factors, and (5) recruitment of RNA polymerase II. Only two subunits are shown for each complex, although the actual complexes are much larger. Other schemes are possible.

**TABLE 32.2** Selected histone modifications

Modification	Associated with
H4 K8 acetylation	Activation
H3 K14 acetylation	Activation
H3 K27 monomethylation	Activation
H3 K27 trimethylation	Repression
H3 R17 methylation	Activation
H2B S14 phosphorylation	DNA repair
H2B K120 ubiquitination	Activation

again plays an important role. However, in repression, a key reaction appears to be the deacetylation of acetylated lysine, catalyzed by specific *histone deacetylase* enzymes.

In many ways, the acetylation and deacetylation of lysine residues in histone tails (and, likely, in other proteins) is analogous to the phosphorylation and dephosphorylation of serine, threonine, and tyrosine residues in other stages of signaling processes. Like the addition of phosphoryl groups, the addition of acetyl groups can induce conformational changes and generate novel binding sites. Without a means of removal of these groups, however, these signaling switches will become stuck in one position and lose their effectiveness. Like phosphatases, deacetylases help reset the switches.

Acetylation is not the only modification of histones and other proteins in gene-regulation processes. The methylation of specific lysine and arginine residues also can be important. Some of the more common modifications are shown in Table 32.2.

The elucidation of the roles of these modifications is a very active area of research at present. The relation between various histone modifications and their roles in controlling gene expression is sometimes referred to as “the histone code.” Although important generalizations have been discovered, this code clearly is subtle and complicated rather than being a set of hard and fast rules. Nonetheless, the development and application of methods that allow probing of histone modifications on a genome-wide scale in a range of cell types has provided large data sets that can be examined to test and refine models.

**FIGURE 32.22** Structure of ferritin.

(A) Twenty-four ferritin polypeptides form a nearly spherical shell. (B) A cutaway view reveals the core that stores iron as an iron oxide–hydroxide complex [Drawn from 1IES.pdb.]

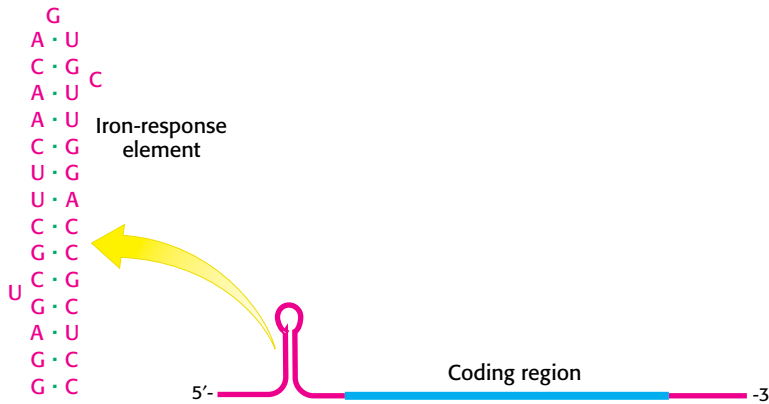

## 32.4 Eukaryotic Gene Expression Can Be Controlled at Posttranscriptional Levels

Just as in prokaryotes, gene expression in eukaryotes can be regulated subsequent to transcription. We shall consider two examples. The first is the regulation of genes taking part in iron metabolism through key features in RNA secondary structure, similar in many ways to prokaryotic posttranscriptional regulation (Section 31.4). The second entails an entirely new mechanism, first glimpsed with the discovery of RNA interference (p. 162). Certain small regulatory RNA molecules allow the regulation of gene expression through interaction with a range of mRNA molecules. Remarkably, this mechanism, discovered only recently, affects the expression of approximately 60% of all human genes.

### Genes associated with iron metabolism are translationally regulated in animals

RNA secondary structure plays a role in the regulation of iron metabolism in eukaryotes. Iron is an essential nutrient, required for the synthesis of hemoglobin, cytochromes, and many other proteins. However, excess iron can be quite harmful because, untamed by a suitable protein environment, iron can initiate a range of free-radical reactions that damage proteins, lipids, and nucleic acids. Animals have evolved sophisticated systems for the accumulation of iron in times of scarcity and for the safe storage of excess iron for later use. Key proteins include *transferrin*, a transport protein that carries iron in the serum, *transferrin receptor*, a membrane protein that binds iron-loaded transferrin and initiates its entry into cells, and *ferritin*, an impressively efficient iron-storage protein found primarily in the liver and kidneys. Twenty-four ferritin polypeptides form a nearly spherical shell that encloses as many as 2400 iron atoms, a ratio of one iron atom per amino acid (Figure 32.22).

Ferritin and transferrin-receptor expression levels are reciprocally related in their responses to changes in iron levels. When iron is scarce, the amount of

**FIGURE 32.23 Iron-response element.** Ferritin mRNA includes a stem-loop structure, termed an iron-response element (IRE), in its 5' untranslated region. The IRE binds a specific protein that blocks the translation of this mRNA under low iron conditions.

transferrin receptor increases and little or no new ferritin is synthesized. Interestingly, the extent of mRNA synthesis for these proteins does not change correspondingly. Instead, regulation takes place at the level of translation.

Consider ferritin first. Ferritin mRNA includes a stem-loop structure termed an *iron-response element* (IRE) in its 5' untranslated region (Figure 32.23). This stem-loop binds a 90-kDa protein, called an *IRE-binding protein* (IRP), that blocks the initiation of translation as the IRE binds on the 5' side of the coding region. When the iron level increases, the IRP binds iron as a 4Fe-4S cluster. The IRP bound to iron cannot bind RNA, because the binding sites for iron and RNA substantially overlap. Thus, in the presence of iron, ferritin mRNA is released from the IRP and translated to produce ferritin, which sequesters the excess iron.

An examination of the nucleotide sequence of transferrin-receptor mRNA reveals the presence of several IRE-like regions. However, these regions are located in the 3' untranslated region rather than in the 5' untranslated region (Figure 32.24). Under low-iron conditions, IRP binds to these IREs. However, given the location of these binding sites, the transferrin-receptor mRNA can still be translated. What happens when the iron level increases and the IRP no longer binds transferrin-receptor mRNA? Freed from the IRP, transferrin-receptor mRNA is rapidly degraded. Thus, an increase in the cellular iron level leads to the destruction of transferrin-receptor mRNA and, hence, a reduction in the production of transferrin-receptor protein.

**FIGURE 32.24 Transferrin-receptor mRNA.** This mRNA has a set of iron-response elements (IREs) in its 3' untranslated region. The binding of the IRE-binding protein to these elements stabilizes the mRNA but does not interfere with translation.

The purification of the IRP and the cloning of its cDNA were sources of truly remarkable insight into evolution. The IRP was found to be approximately 30% identical in amino acid sequence with the citric acid cycle enzyme aconitase from mitochondria. Further analysis revealed that the IRP is, in fact, an active aconitase enzyme; it is a cytoplasmic aconitase that had been known for a long time, but its function was not well understood (Figure 32.25). The iron-sulfur center at the active site of the IRP is rather unstable, and loss

**FIGURE 32.25 The IRP is an aconitase.** (A) Aconitase contains an unstable 4Fe-4S cluster at its center. (B) Under conditions of low iron, the 4Fe-4S cluster dissociates and appropriate RNA molecules can bind in its place. [Drawn from 1C96.pdb.]

**FIGURE 32.26 MicroRNA-Argonaute complex.** The miRNA (shown in red) is bound by the Argonaute protein. Notice that the miRNA serves as a guide that binds the RNA substrate (shown in gray) through the formation of a double helix. Two magnesium ions are shown in green. [Drawn from 3HK2.pdb.]

of the iron triggers significant changes in protein conformation. Thus, this protein can serve as an iron-sensing factor.

Other mRNAs, including those taking part in heme synthesis, have been found to contain IREs. Thus, genes encoding proteins required for iron metabolism acquired sequences that, when transcribed, provided binding sites for the iron-sensing protein. An environmental signal—the concentration of iron—controls the translation of proteins required for the metabolism of this metal. Thus, mutations in the untranslated region of mRNAs have been selected for beneficial regulation by iron levels.

### Small RNAs regulate the expression of many eukaryotic genes

Genetic studies of development in *C. elegans* revealed that a gene called *lin-4* encodes an RNA molecule 61 nucleotides long that can regulate the expression of certain other genes. The 61-nucleotide *lin-4* RNA does not encode a protein, but rather is cleaved into a 22-nucleotide RNA that possesses the regulatory activity. This discovery was the first view of a large class of regulatory RNA

molecules that are now called *microRNAs* or *miRNAs*. The key to the activity of microRNAs and their specificity for particular genes is their ability to form Watson-Crick base-pair-stabilized complexes with the mRNAs of those genes.

These miRNAs do not function on their own. Instead, the miRNAs bind to members of a class of proteins called the *Argonaute* family (Figure 32.26). These Argonaute-miRNA complexes can then bind mRNAs that have sequences that are substantially complementary to the miRNAs. Once bound, such an mRNA can be cleaved by the Argonaute-miRNA complex through the action of a magnesium-based active site. Thus, *the miRNAs serve as guide RNAs that determine the specificity of the Argonaute complex* (Figure 32.27). Cleavage of mRNA by the Argonaute-miRNA complex is similar to the mechanism of RNA interference (p. 162). The small RNA molecules participating in RNAi, however, come from a different source. In RNAi, double-stranded RNAs are cleaved into 21-nucleotide fragments, single-stranded components of which are bound by members of the Argonaute family to form an RNA-induced silencing complex (RISC) that cleaves complementary mRNAs. For miRNAs, the single-stranded RNAs are generated from larger genetically encoded precursors, as described in Chapter 29.

The occurrence of gene regulation by miRNAs was originally thought to be limited to a relatively small number of species. However, subsequent studies have revealed that this mode of gene regulation is nearly ubiquitous in eukaryotes. Indeed, more than 700 miRNAs encoded by the human genome have been identified. Each miRNA can regulate many different genes because many different target sequences are present in each mRNA. An estimated 60% of all human genes are regulated by one or more miRNAs. As one example, consider the human miRNA called miR-206. This miRNA down-regulates the expression of one isoform of the estrogen receptor. In addition, it appears to down-regulate the expression of several different coactivators that interact with the estrogen receptor. Thus, this

**FIGURE 32.27 MicroRNA action.** MicroRNAs bind to members of the Argonaute family where they target specific mRNA molecules for cleavage.

miRNA can mute the influence of estrogen by blocking the estrogen-initiated signaling pathway at several different steps.

The microRNA pathway has tremendous implications for the evolution of gene-regulatory pathways. Most of the target sites for miRNAs are present in the 3'-untranslated regions of mRNAs. These sequences are quite free to mutate because they do not encode proteins and are not required to fold into any specific structures. Thus, in the context of a set of expressed miRNAs, mutations in this region of any particular gene could, in principle, increase or decrease the affinity for one or more miRNAs and, hence, alter the regulation of the gene.

## SUMMARY

### 32.1 Eukaryotic DNA Is Organized into Chromatin

Eukaryotic DNA is tightly bound to basic proteins called histones; the combination is called chromatin. DNA wraps twice around an octamer of core histones to form a nucleosome. The four core histones are homologous and fold into similar structures. Each core histone has an amino-terminal tail rich in lysine and arginine residues. Nucleosomes are the first stage of compaction of eukaryotic DNA. Chromatin blocks access to many potential DNA-binding sites. Changes in chromatin structure play a major role in regulating gene expression.

### 32.2 Transcription Factors Bind DNA and Regulate Transcription Initiation

Most eukaryotic genes are not expressed unless they are activated by the binding of specific proteins, called transcription factors, to sites on the DNA. These specific DNA-binding proteins interact directly or indirectly with RNA polymerases or their associated proteins. Eukaryotic transcription factors are modular: they consist of separate DNA-binding and activation domains. Important classes of DNA-binding proteins include the homeodomains, the basic-leucine zipper proteins, and Cys<sub>2</sub>His<sub>2</sub> zinc-finger proteins. Each of these classes of proteins uses an  $\alpha$  helix to make specific contacts with DNA. Activation domains interact with RNA polymerases or their associated factors or with other protein complexes such as mediator. Enhancers are DNA elements that can modulate gene expression from more than 1000 bp away from the start site of transcription. Enhancers are often specific for certain cell types, depending on which DNA-binding proteins are present. The introduction of genes for a specific set of four transcription factors into fibroblasts can cause these cells to dedifferentiate into induced pluripotent stem cells.

### 32.3 The Control of Gene Expression Can Require Chromatin Remodeling

Chromatin structure is crucial to the control of gene expression; it is more open near the transcription start sites of actively transcribed genes. Steroids such as estrogens bind to eukaryotic transcription factors called nuclear hormone receptors. These proteins are capable of binding DNA whether or not ligands are bound. The binding of ligands induces a conformational change that allows the recruitment of additional proteins called coactivators. Among the most important functions of coactivators is to catalyze the addition of acetyl groups to lysine residues in the tails of histone proteins. Histone acetylation decreases the affinity of the histones for DNA, making additional genes accessible for transcription. In addition, acetylated histones are targets for proteins containing specific binding units called bromodomains. Bromodomains are components of

two classes of large complexes: (1) chromatin-remodeling engines and (2) factors associated with RNA polymerase II. These complexes open up sites on chromatin and initiate transcription.

### 32.4 Eukaryotic Gene Expression Can Be Controlled at Posttranscriptional Levels

Genes encoding proteins that transport and store iron are regulated at the translational level. Iron-response elements, structures that are present in certain mRNAs, are bound by an IRE-binding protein when this protein is not binding iron. Whether the expression of a gene is stimulated or inhibited in response to changes in the iron status of a cell depends on the location of the IRE within the mRNA. The IRE-binding protein is a cytoplasmic aconitase that loses its iron-sulfur center under low-iron conditions. MicroRNAs are specialized RNA molecules encoded as parts of larger RNA precursors. They bind to proteins of the Argonaute family; the bound miRNAs function as guides that help bind specific mRNA molecules that are then cleaved.

2. *Chromatin immunoprecipitation.* You have used the technique of chromatin immunoprecipitation to isolate DNA fragments containing a DNA-binding protein of interest. Suppose that you wish to know whether a particular known DNA fragment is present in the isolated mixture. How might you detect its presence?

3. *Around we go.* Assuming that 145 base pairs of DNA wrap around the histone octamer 1.75 times, estimate the radius of the histone octamer. Assume 3.4 Å per base pair and simplify the calculation by assuming that the wrapping is in two rather than three dimensions and neglecting the thickness of the DNA.

4. *Nitrogen substitution.* Growth of mammalian cells in the presence of 5-azacytidine results in the activation of some normally inactive genes. Propose an explanation.

5. *A new domain.* A protein domain that recognizes 5-methylcytosine in the context of double-stranded DNA has been characterized. What role might proteins containing such a domain play in regulating gene expression? Where on a double-stranded DNA molecule would you expect such a domain to bind?

6. *Hybrid receptor.* Through recombinant DNA methods, a modified steroid hormone receptor was prepared that consists of an estrogen receptor with its ligand-binding domain replaced by the ligand-binding domain from the progesterone receptor. Predict the expected responsiveness of gene expression for cells treated with estrogen or with progesterone.

7. *Different modifications.* What is the effect of acetylation of a lysine residue on the charge of a histone protein? Of lysine methylation?

8. *Transformer.* The following amino acid sequence of one of the four transcription factors is used to generate iPS cells:

HTCDYAGCGKTYTKSSHLKAHLRTHTGEKPYHCDWDGCGWKFARSEDELTRHYRKHTGHRPFQCQKCD  
RAFSRSDHLALHMKRHF

This transcription factor belongs to one of the three structural classes discussed in Section 32.2. Identify the class.

9. *Coverage.* What percentage of the DNA sites in yeast are accessible, assuming that the fraction of sites observed for GAL4 is typical? To how many base pairs of the 12-Mb yeast genome does this percentage correspond?

10. *Count the methyl groups.* Examination of the histone modifications of a gene reveals an abundance of histone H3 with lysine 27 modified with a single methyl group. Does this suggest that this gene is activated or repressed? How would your answer change if many lysine 27 residues were modified with three methyl groups each?

11. *Iron regulation.* What effect would you expect from the addition of an IRE to the 5' end of a gene that is not normally regulated by iron levels? To the 3' end?

12. *Predicting microRNA regulation.* Suppose that you have identified an miRNA that has the sequence 5'-GCCUAGCCUUAGCAUUGAUUGG-3'. Propose a strategy for identifying mRNA that might be regulated by this miRNA, given the sequences of all mRNAs encoded by the human genome.

### Mechanism Problem

13. *Acetyltransferases.* Propose a mechanism for the transfer of an acetyl group from acetyl CoA to the amino group of lysine.

### Data Interpretation Problem

14. *Limited restriction.* The restriction enzyme HpaII is a powerful tool for analyzing DNA methylation. This enzyme cleaves sites of the form 5'-CCGG-3' but will not cleave such sites if the DNA is methylated on any of the cytosine residues. Genomic DNA from different organisms is treated with HpaII and the results are analyzed by gel electrophoresis (see the adjoining patterns). Provide an explanation for the observed patterns.

## Sensory Systems

Color perception requires specific photoreceptors. The photoreceptor rhodopsin (right), which absorbs light in the process of vision, consists of the protein opsin and a bound vitamin A derivative, retinal. The amino acids (shown in red) that surround the retinal determine the color of light that is most efficiently absorbed. A person lacking a light-absorbing photoreceptor for the color green will see a bowl of fruits of many colors (left) as similar shades of yellow-green (middle). [From Africa Studio/Shutterstock (left), modified by Jeremy Berg using Coblis ([www.color-blindness.com/coblis-color-blindness-simulator/](http://www.color-blindness.com/coblis-color-blindness-simulator/)) (middle).]

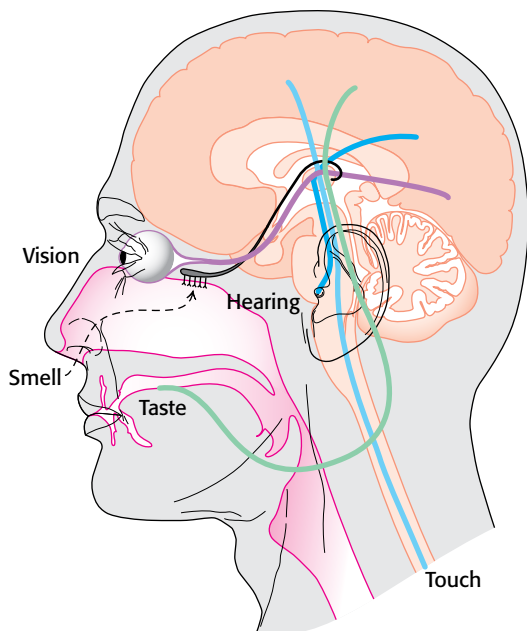

Our senses provide us with means for detecting a diverse set of external signals, often with incredible sensitivity and specificity. For example, when fully adapted to a darkened room, our eyes allow us to sense very low levels of light, down to a limit of less than 10 photons. With more light, we are able to distinguish millions of colors. Through our senses of smell and taste, we are able to detect thousands of chemicals in our environment and sort them into categories: pleasant or unpleasant? healthful or toxic? Finally, we can perceive mechanical stimuli in the air and around us through our senses of hearing and touch.

How do our sensory systems work? How are the initial stimuli detected? How are these initial biochemical events transformed into perceptions and experiences? We have already encountered systems that sense and respond to chemical signals—namely, receptors that bind to growth factors and hormones. Our knowledge of these receptors and their associated signal-transduction pathways provides us with concepts and tools for unraveling some of the workings of sensory systems. For example, 7TM receptors (seven-transmembrane receptors; Section 14.1) play key roles in olfaction, taste, and vision. Ion channels that are sensitive to mechanical stress are essential for hearing and touch.

In this chapter, we focus on the five major sensory systems found in human beings and other mammals: olfaction (the sense of smell—i.e., the detection of small molecules in the air), taste, or gustation (the detection of selected organic compounds and ions by the tongue), vision (the detection

## OUTLINE

of light), hearing (the detection of sound, or pressure waves in the air), and touch (the detection of changes in pressure, temperature, and other factors by the skin). Each of these primary sensory systems contains specialized sensory neurons that transmit nerve impulses to the central nervous system (Figure 33.1). In the central nervous system, these signals are processed and combined with other information to yield a perception that may trigger a change in behavior. By these means, our senses allow us to detect changes in our environments and to adjust our behavior appropriately.

### 33.1 A Wide Variety of Organic Compounds Are Detected by Olfaction

Human beings can detect and distinguish thousands of different compounds by smell, often with considerable sensitivity and specificity. Most odorants are small organic compounds with sufficient volatility that they can be carried as vapors into the nose. For example, a major component responsible for the odor of almonds is the simple aromatic compound benzaldehyde, whereas the sulfhydryl compound 3-methylbutane-1-thiol is a major component of the odor of skunks.

What properties of these molecules are responsible for their odors? First, *the shape of the molecule rather than its other physical properties is crucial*. We can most clearly see the importance of shape by comparing molecules such as those responsible for the odors of spearmint and caraway.

These compounds are identical in essentially all physical properties such as hydrophobicity because they are exact mirror images of one another. Thus, the odor produced by an odorant depends not on a physical property but on the compound's interaction with a specific binding surface, most likely a protein receptor. Second, some human beings (and other animals) suffer from *specific anosmias*; that is, they are incapable of smelling specific compounds even though their olfactory systems are otherwise normal. Such anosmias are often inherited. These observations suggest that mutations in individual receptor genes lead to the loss of the ability to detect a small subset of compounds.

#### Olfaction is mediated by an enormous family of seven-transmembrane-helix receptors

Odorants are detected in a specific region of the nose, called the *main olfactory epithelium*, that lies at the top of the nasal cavity (Figure 33.2). Approximately 1 million sensory neurons line the surface of this region. Cilia containing the odorant-binding protein receptors project from these neurons into the mucous lining of the nasal cavity.

**FIGURE 33.2 The main nasal epithelium.**

This region of the nose, which lies at the top of the nasal cavity, contains approximately 1 million sensory neurons. Nerve impulses generated by odorant molecules binding to receptors on the cilia travel from the sensory neurons to the olfactory bulb.

Biochemical studies in the late 1980s examined isolated cilia from rat olfactory epithelia that had been treated with odorants. Exposure to the odorants increased the cellular level of cyclic AMP, and this increase was observed only in the presence of GTP. On the basis of what was known about signal-transduction systems, *the participation of cAMP and GTP strongly suggested the involvement of a G protein and, hence, 7TM receptors*. Indeed, Randall Reed purified and cloned a G-protein  $\alpha$  subunit, termed  $G_{(olf)}$ , which is uniquely expressed in olfactory cilia. The involvement of 7TM receptors suggested a strategy for identifying the olfactory receptors themselves. Complementary DNAs were sought that (1) were expressed primarily in the sensory neurons lining the nasal epithelium, (2) encoded members of the 7TM-receptor family, and (3) were present as a large and diverse family to account for the range of odorants. Through the use of these criteria, cDNAs for odorant receptors from rats were identified in 1991 by Richard Axel and Linda Buck.

The *odorant receptor* (hereafter, OR) family is even larger than expected: *more than 1000 OR genes are present in the mouse and the rat, whereas the human genome encodes approximately 350 ORs*. In addition, the human genome includes approximately 500 OR pseudogenes containing mutations that prevent the generation of a full-length, proper odorant receptor. The OR family is thus one of the largest gene families in human beings. Further analysis of primate OR genes reveals that the fraction of pseudogenes is greater in species more closely related to human beings (Figure 33.3). Thus, we may have a glimpse at the evolutionary loss of acuity in the sense of smell as higher mammals presumably became less dependent on this sense for survival. For rodents that are highly dependent on their sense of smell, essentially all OR genes encode functional proteins.

The OR proteins are typically 20% identical in sequence with the  $\beta$ -adrenergic receptor (Section 14.1) and from 30% to 60% identical with one another. Several specific sequence features are present in most or all OR family members (Figure 33.4). The central region,

**FIGURE 33.3 Evolution of odorant receptors.** Odorant receptors appear to have lost function through conversion into pseudogenes in the course of primate evolution. The percentage of OR genes that appear to be functional for each species is given in parentheses.

**FIGURE 33.4 Conserved and variant regions in odorant receptors.** Odorant receptors are members of the 7TM-receptor family. The green cylinders represent the seven presumed transmembrane helices. Strongly conserved residues characteristic of this protein family are shown in blue, whereas highly variable residues are shown in red.

particularly transmembrane helices 4 and 5, is highly variable, suggesting that this region is the site of odorant binding. That site must be different in odorant receptors that bind distinct odorant molecules.

What is the relation between OR gene expression and the individual neuron? Interestingly, *each olfactory neuron expresses only a single OR gene*, among hundreds available. Apparently, the precise OR gene expressed is determined largely at random. After one OR gene is expressed and a functional OR protein is produced, the expression of all other OR genes is suppressed by a feedback mechanism that remains to be fully elucidated.

The binding of an odorant to an OR on the neuronal surface initiates a signal-transduction cascade that results in an action potential (Figure 33.5). The ligand-bound OR activates  $G_{(olf)}$ , the specific G protein mentioned earlier.  $G_{(olf)}$  is initially in its GDP-bound form. When activated, it releases GDP, binds GTP, and releases its associated  $\beta\gamma$  subunits. The  $\alpha$  subunit then activates a specific adenylate cyclase, increasing the intracellular concentration of cAMP. The rise in the intracellular concentration of cAMP activates a nonspecific cation channel that allows calcium and other cations into the cell. The flow of cations through the channel depolarizes the neuronal membrane and initiates an action potential. This action potential, combined with those from other olfactory neurons, leads to the perception of a specific odor.

**FIGURE 33.5 The olfactory signal-transduction cascade.** The binding of odorant to the olfactory receptor activates a signaling pathway similar to those initiated in response to the binding of some hormones to their receptors. The final result is the opening of cAMP-gated ion channels and the initiation of an action potential.

### Odorants are decoded by a combinatorial mechanism

An obvious challenge presented to an investigator by the large size of the OR family is to match each OR with the one or more odorant molecules to which it binds. Exciting progress has been made in this regard. Initially, an OR was matched with odorants by overexpressing a single, specific OR gene in rats. This OR responded to straight-chain aldehydes, most favorably to *n*-octanal and less strongly to *n*-heptanal and *n*-hexanal. More-dramatic progress was made by taking advantage of our knowledge of the OR signal-transduction pathway and the power of the polymerase chain reaction (PCR). A section of nasal epithelium from a mouse was loaded with the calcium-sensitive dye Fura-2 (Section 14.1). The tissue was then treated with different odorants, one at a time, at a specific concentration. If the

**FIGURE 33.6** Four series of odorants tested for olfactory-receptor activation.

odorant had bound to an OR and activated it, that neuron could be detected under a microscope by the change in fluorescence caused by the influx of calcium that takes place as part of the signal-transduction process. To determine which OR was responsible for the response, cDNA was generated from mRNA that had been isolated from single identified neurons. The cDNA was then subjected to PCR with the use of primers that are effective in amplifying most or all OR genes. The sequence of the PCR product from each neuron was then determined and analyzed.

Using this approach, investigators analyzed the responses of neurons to a series of compounds having varying chain lengths and terminal functional groups (Figure 33.6). The results of these experiments appear surprising at first glance (Figure 33.7). Importantly, there is not a simple 1:1 correspondence between odorants and receptors. *Almost every odorant activates a number of receptors* (usually to different extents) and *almost every receptor is activated by more than one odorant*. Note, however, that each odorant activates a unique combination of receptors. In principle, this combinatorial mechanism allows even a small array of receptors to distinguish a vast number of odorants.

How is the information about which receptors have been activated transmitted to the brain? Recall that each neuron expresses only one OR and that the pattern of expression appears to be largely random. A substantial clue to the connections between receptors and the brain has been provided by the creation of mice that express a gene for an easily detectable colored marker in conjunction with a specific OR gene. Olfactory neurons that express the OR–marker-protein combination were traced to their destination in the brain, a structure called the olfactory bulb (Figure 33.8). The processes from neurons that express the same OR gene were found to connect to the same location in the olfactory bulb. Moreover, this pattern of neuronal connection was found to be identical in all mice examined. Thus, *neurons that express specific ORs are linked to specific sites in the brain*. This property creates a spatial map of odorant-responsive neuronal activity within the olfactory bulb.

Can such a combinatorial mechanism truly distinguish many different odorants? An electronic “nose” that functions by the same principles

provides compelling evidence that it can (Figure 33.9). The receptors for the electronic nose are polymers that bind a range of small molecules. Each polymer binds every odorant, but to varying degrees. Importantly, the electrical properties of these polymers change on odorant binding. A set of 32 of these polymer sensors, wired together so that the pattern of responses can be evaluated, is capable of distinguishing individual compounds such as *n*-pentane and *n*-hexane as well as complex mixtures such as the odors of fresh and spoiled fruit.

### 33.2 Taste Is a Combination of Senses That Function by Different Mechanisms

The inability to taste food is a common complaint when nasal congestion reduces the sense of smell. Thus, smell greatly augments our sense of taste (also known as *gustation*), and taste is, in many ways, the sister sense to olfaction. Nevertheless, the two senses differ from each other in several important ways. First, we are able to sense several classes of compounds by taste that we are unable to detect by smell; salt and sugar have very little odor, yet they are primary stimuli of the gustatory system. Second, whereas we are able to discriminate thousands of odorants, discrimination by taste is much more modest. Five primary tastes are perceived: *bitter*, *sweet*, *sour*, *salty*, and *umami* (the taste of glutamate and aspartate from the Japanese word for “deliciousness”). These five tastes serve to classify compounds into potentially nutritive and beneficial (sweet, salty, umami) or potentially harmful or toxic (bitter, sour). Tastants (the molecules sensed by taste) are quite distinct for the different groups (Figure 33.10).

**FIGURE 33.10** Examples of tastant molecules. Tastants fall into five groups: sweet, salty, umami, bitter, and sour.

The simplest tastant, the hydrogen ion, is perceived as sour. Other simple ions, particularly sodium ion, are perceived as salty. The taste called umami is evoked by the amino acids glutamate and aspartate, the former often encountered as the flavor enhancer monosodium glutamate (MSG). In contrast, *tastants perceived as sweet and, particularly, bitter are extremely diverse*. Many bitter compounds are alkaloids or other plant products, many of which are toxic. However, they do not have any common structural elements or other common properties. Carbohydrates such as glucose and sucrose are perceived as sweet, as are other compounds including some simple peptide derivatives, such as aspartame, and even some proteins.

These differences in specificity among the five tastes are due to differences in their underlying biochemical mechanisms. The sense of taste is, in fact, a number of independent senses all utilizing the same organ, the tongue, for their expression.

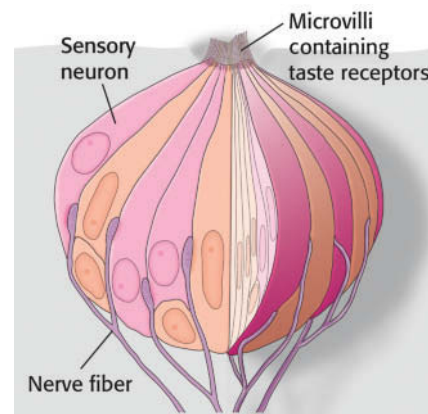

Tastants are detected by specialized structures called *taste buds*, which contain approximately 150 cells, including sensory neurons (Figure 33.11). Fingerlike projections called *microvilli*, which are rich in taste receptors, project from one end of each sensory neuron to the surface of the tongue. Nerve fibers at the opposite end of each neuron carry electrical impulses to the brain in response to stimulation by tastants. Structures called *taste papillae* contain numerous taste buds.

### Sequencing of the human genome led to the discovery of a large family of 7TM bitter receptors

Just as in olfaction, a number of clues pointed to the involvement of G proteins and, hence, 7TM receptors in the detection of bitter and sweet tastes. The evidence included the isolation of a specific G-protein  $\alpha$  subunit termed *gustducin*, which is expressed primarily in taste buds (Figure 33.12). How could the 7TM receptors be identified? The ability to detect some compounds depends on specific genetic loci in both human beings and mice. For instance, the ability to taste the bitter compound 6-*n*-propyl-2-thiouracil (PROP) was mapped to a region on human chromosome 5 by comparing DNA markers of persons who vary in sensitivity to this compound.

This observation suggested that this region might encode a 7TM receptor that responded to PROP. Approximately 450 kilobases in this region had been sequenced early in the human genome project. This sequence was searched by computer for potential 7TM-receptor genes, and, indeed, one was detected and named T2R1. Additional database searches detected approximately 30 sequences similar to T2R1 in the human genome. The encoded proteins are between 30 and 70% identical with T2R1 (Figure 33.13).

Are these proteins, in fact, bitter receptors? Several lines of evidence suggest that they are. First, their genes are expressed in taste-sensitive cells—in fact, in many of the same cells that express *gustducin*. Second, cells that express individual members of this family respond to specific bitter compounds. For example, cells that express a specific mouse receptor (mT2R5) responded when exposed specifically to cycloheximide. Third, mice that had been found unresponsive to cycloheximide were found to have point mutations in the gene encoding mT2R5. Finally, cycloheximide

**FIGURE 33.11 A taste bud.** Each taste bud contains sensory neurons that extend microvilli to the surface of the tongue, where they interact with tastants.

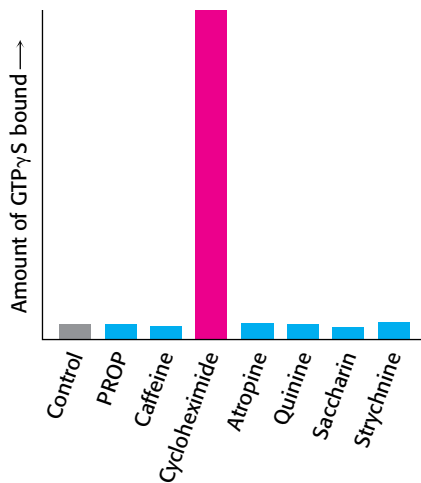

**FIGURE 33.12 Expression of gustducin in the tongue.** (A) A section of tongue stained with a fluorescent antibody reveals the position of the taste buds. (B) The same region stained with an antibody directed against gustducin reveals that this G protein is expressed in taste buds. [Courtesy of Dr. Charles S. Zuker.]

**FIGURE 33.13 Conserved and variant regions in bitter receptors.** The bitter receptors are members of the 7TM-receptor family. Strongly conserved residues characteristic of this protein family are shown in blue, and highly variable residues are shown in red.

Cycloheximide uniquely stimulates the binding of the GTP analog GTP-γS to gustducin in the presence of the mT2R protein. [Information from J. Chandrashekar et al., *Cell* 100:703–711, 2000.]

specifically stimulates the binding of GTP analogs to gustducin in the presence of the mT2R5 protein (Figure 33.14).

Importantly, each taste-receptor cell expresses many different members of the T2R family. This pattern of expression stands in sharp contrast to the pattern of one receptor type per cell that characterizes the olfactory system (Figure 33.15). The difference in expression patterns accounts for the much greater specificity of our perceptions of odors compared with tastes. *We are able to distinguish among subtly different odors because each odorant stimulates a unique pattern of neurons. In contrast, many tastants stimulate the same neurons.* Thus, we perceive only “bitter” without the ability to discriminate cycloheximide from quinine.

**FIGURE 33.15 Differing gene-expression and connection patterns in olfactory and bitter taste receptors.** In olfaction, each neuron expresses a single OR gene, and the neurons expressing the same OR converge to specific sites in the brain, enabling specific perception of different odorants. In gustation, each neuron expresses many bitter receptor genes, and so the identity of the tastant is lost in transmission.

**FIGURE 33.16 Evidence for a heterodimeric sweet receptor.**

The sensitivity to sweetness of mice with genes for T1R1 only, both T1R1 and T1R2, both T1R1 and T1R3, or both T1R2 and T1R3 was determined by observing the relative rates at which they licked solutions containing various amounts of sucrose. These studies revealed that both T1R2 and T1R3 were required for a full response to sucrose. [Data from G. Q. Zhao et al., *Cell* 115:255–266, 2003.]

### A heterodimeric 7TM receptor responds to sweet compounds

Most sweet compounds are carbohydrates, energy rich and easily digestible. Some noncarbohydrate compounds such as saccharin and aspartame also taste sweet. Members of a second family of 7TM receptors are expressed in taste-receptor cells sensitive to sweetness. The three members of this family, referred to as T1R1, T1R2, and T1R3, are distinguished by their large extracellular domains compared with those of the bitter receptors. Studies in knockout mice have revealed that T1R2 and T1R3 are expressed simultaneously in mice able to taste carbohydrates (Figure 33.16). Thus, T1R2 and T1R3 appear to form a specific heterodimeric receptor responsible for mediating the response to sugars. This heterodimeric receptor also responds to artificial sweeteners and to sweet-tasting proteins and therefore appears to be the receptor responsible for responses to all sweet tastants. Note that T1R2 and T1R3 do respond to sweet tastants individually but only at very high concentrations of tastant.

The requirement for an *oligomeric* 7TM receptor for a fully functional response is surprising, considering our previous understanding of 7TM receptors. This discovery has at least two possible explanations. First, the sweet receptor could be a member of a small subset of the 7TM-receptor family that functions well only as oligomers. Alternatively, many 7TM receptors may function as oligomers, but this notion is not clear, because these oligomers contain only one type of 7TM-receptor subunit. Further studies will be required to determine which of these explanations is correct.

### Umami, the taste of glutamate and aspartate, is mediated by a heterodimeric receptor related to the sweet receptor

The family of receptors responsible for detecting sweetness is also responsible for detecting amino acids. In human beings, only glutamate and aspartate elicit a taste response. Studies similar to those for the sweet receptor revealed that the umami receptor consists of T1R1 and T1R3. Thus, this receptor has one subunit (T1R3) in common with the sweet receptor but has an additional subunit (T1R1) that does not participate in the sweet response. This conclusion is supported by the observation that mice in which the gene for T1R1 is disrupted do not respond to aspartate but do respond normally to sweet tastants; mice having disrupted genes for both T1R1 and T1R3 respond poorly to both umami and sweet tastants.

### Salty tastes are detected primarily by the passage of sodium ions through channels

Salty tastants are not detected by 7TM receptors. Rather, they are detected directly by their passage through ion channels expressed on the surface of cells in the tongue. Evidence for the role of these ion channels comes from examining known properties of  $\text{Na}^+$  channels characterized in other biological contexts. One class of channels, characterized first for its role in salt reabsorption, is thought to be important in the detection of salty tastes because these channels are sensitive to the compound *amiloride*, which mutes the taste of salt and significantly lowers sensory-neuron activation in response to sodium.

An *amiloride-sensitive*  $\text{Na}^+$  channel comprises four subunits that may be either identical or distinct but in any case are homologous. An individual subunit ranges in length from 500 to 1000 amino acids and includes two presumed membrane-spanning helices as well as a large extracellular domain in between them (Figure 33.17). The extracellular region includes two (or, sometimes, three) distinct regions rich in cysteine residues (and, presumably, disulfide bonds). A region just ahead of the second membrane-spanning helix appears to form part of the pore in a manner analogous to that of the structurally characterized potassium channel. The members of the amiloride-sensitive  $\text{Na}^+$ -channel family are numerous and diverse in their biological roles. We shall encounter them again in the context of the sense of touch.

Sodium ions passing through these channels produce a significant transmembrane current. Amiloride blocks this current, accounting for its effect on taste. However, about 20% of the response to sodium remains even in the presence of amiloride, suggesting that other ion channels also contribute to salt detection.

### Sour tastes arise from the effects of hydrogen ions (acids) on channels

Like salty tastes, *sour tastes are detected by direct interactions with ion channels*, but the incoming ions are hydrogen ions (in high concentrations) rather than sodium ions. For example, in the absence of high concentrations of sodium,

**FIGURE 33.17 Schematic structure of the amiloride-sensitive sodium channel.** Only one of the four subunits that constitute the functional channel is illustrated. The amiloride-sensitive sodium channel belongs to a superfamily having common structural features, including two hydrophobic membrane-spanning regions, intracellular amino and carboxyl termini, and a large, extracellular region with conserved cysteine-rich domains.

hydrogen ion flow can induce substantial transmembrane currents through amiloride-sensitive  $\text{Na}^+$  channels. However, hydrogen ions are also sensed by mechanisms other than their direct passage through membranes. Binding by hydrogen ions blocks some potassium ion channels and activates other types of channels. Together, these mechanisms lead to changes in membrane polarization in sensory neurons that produce the sensation of sour taste. We shall consider an additional receptor related to taste, one responsible for the “hot” taste of spicy food, when we examine mechanisms of touch perception.

### 33.3 Photoreceptor Molecules in the Eye Detect Visible Light

Vision is based on the absorption of light by photoreceptor cells in the eye. These cells are sensitive to light in a narrow region of the electromagnetic spectrum, the region with wavelengths between 390 and 750 nm (Figure 33.18). Vertebrates have two kinds of photoreceptor cells, called *rods* and *cones* because of their distinctive shapes. Cones function in bright light and are responsible for color vision, whereas rods function in dim light but do not perceive color. A human retina contains about 3 million cones and 100 million rods. Remarkably, a rod cell can respond to a single photon, and the brain requires fewer than 10 such responses to register the sensation of a flash of light.

**FIGURE 33.18** The electromagnetic spectrum. Visible light has wavelengths between 390 and 750 nm.

#### Rhodopsin, a specialized 7TM receptor, absorbs visible light

Rods are slender, elongated structures; the outer segment is specialized for photoreception (Figure 33.19). It contains a stack of about 1000 discs, which are membrane-enclosed sacs densely packed with photoreceptor molecules. The photosensitive molecule is often called a *visual pigment* because it is highly colored owing to its ability to absorb light. The photoreceptor molecule in rods is *rhodopsin* (Section 14.1), which consists of the protein *opsin* linked to *11-cis-retinal*, a prosthetic group.

**FIGURE 33.19** The rod cell. (Left) Scanning electron micrograph of retinal rod cells. (Right) Schematic representation of a rod cell. [Photograph courtesy of Dr. Deric Bownds.]

Rhodopsin absorbs light very efficiently in the middle of the visible spectrum, its absorption being centered on 500 nm, which nicely matches the solar output (Figure 33.20). A rhodopsin molecule will absorb a high percentage of the photons of the correct wavelength that strike it, as indicated by the extinction coefficient of  $40,000 \text{ M}^{-1}\text{cm}^{-1}$  at 500 nm. The extinction coefficient for rhodopsin is more than an order of magnitude greater than that for tryptophan, the most efficient absorber in proteins that lack prosthetic groups.

Opsin, the protein component of rhodopsin, is a member of the 7TM-receptor family. Indeed, rhodopsin was the first member of this family to be purified, its gene was the first to be cloned and sequenced, and its three-dimensional structure was the first to be determined. The color of rhodopsin and its responsiveness to light depend on the presence of the light-absorbing group (*chromophore*) 11-*cis*-retinal. This compound is a powerful absorber of light because it is a polyene; its six alternating single and double bonds constitute a long, unsaturated electron network. Recall that alternating single and double bonds account for the chromophoric properties of chlorophyll (Section 19.2). The aldehyde group of 11-*cis*-retinal forms a Schiff base (Figure 33.21) with the  $\epsilon$ -amino group of lysine residue 296, which lies in the center of the seventh transmembrane helix. Free retinal absorbs maximally at 370 nm, and its unprotonated Schiff-base adduct absorbs at 380 nm, whereas the protonated Schiff base absorbs at 440 nm or longer wavelengths. Thus, *the 500-nm absorption maximum for rhodopsin strongly suggests that the Schiff base is protonated*; additional interactions with opsin shift the absorption maximum farther toward the red. The positive charge of the protonated Schiff base is compensated by the negative charge of glutamate 113 located in helix 2; the glutamate residue closely approaches the lysine-retinal linkage in the three-dimensional structure of rhodopsin.

**FIGURE 33.20 Rhodopsin absorption spectrum.** Almost all photons with wavelengths near 500 nm that strike a rhodopsin molecule are absorbed.

**FIGURE 33.21 Retinal-lysine linkage.** Retinal is linked to lysine 296 in opsin by a Schiff-base linkage. In the resting state of rhodopsin, this Schiff base is protonated.

### Light absorption induces a specific isomerization of bound 11-*cis*-retinal

How does the absorption of light by the retinal Schiff base generate a signal? George Wald and his coworkers discovered that *light absorption results in the isomerization of the 11-*cis*-retinal group of rhodopsin to its all-*trans* form* (Figure 33.22). This isomerization causes the Schiff-base nitrogen atom to move approximately  $5 \text{ \AA}$ , assuming that the cyclohexane ring of the retinal group remains fixed. In essence, *the light energy of a photon is converted into atomic motion*. The change in atomic positions, like the binding of a ligand to other 7TM receptors, sets in train a series of events that lead to the closing of ion channels and the generation of a nerve impulse.

The isomerization of the retinal Schiff base takes place within a few picoseconds of a photon being absorbed. The initial product, termed *bathorhodopsin*, contains a strained all-*trans*-retinal group. Within approximately

**FIGURE 33.22 Atomic motion in retinal.** The Schiff-base nitrogen atom moves 5 Å as a consequence of the light-induced isomerization of 11-*cis*-retinal to all-*trans*-retinal by rotation about the bond shown in red.

**FIGURE 33.23 Analogous 7TM receptors.** The conversion of rhodopsin into metarhodopsin II activates a signal-transduction pathway analogously to the activation induced by the binding of other 7TM receptors to appropriate ligands.

1 ms, this intermediate is converted through several additional intermediates into *metarhodopsin II*. In metarhodopsin II, the Schiff base is deprotonated and the opsin protein has undergone significant reorganization.

Metarhodopsin II (also referred to as  $R^*$ ) is analogous to the ligand-bound state of 7TM receptors such as the  $\beta_2$ -adrenergic receptor (Section 14.1) and the odorant and tastant receptors discussed previously (Figure 33.23). Like these receptors, this form of rhodopsin activates a heterotrimeric G protein that propagates the signal. The G protein associated with rhodopsin is called *transducin*. Metarhodopsin II triggers the exchange of GDP for GTP by the  $\alpha$  subunit of transducin (Figure 33.24). On the binding of GTP, the  $\beta\gamma$  subunits of transducin are released and the  $\alpha$  subunit switches on a *cGMP phosphodiesterase* by binding to an inhibitory subunit and removing it. The activated phosphodiesterase is a potent enzyme that rapidly hydrolyzes cGMP to GMP. The reduction in cGMP concentration causes *cGMP-gated ion channels* to close, leading to the hyperpolarization of the membrane and neuronal signaling. *At each step in this process, the initial signal—the absorption of a single photon—is amplified so that it leads to sufficient membrane hyperpolarization to result in signaling.*

### Light-induced lowering of the calcium level coordinates recovery

As we have seen, the visual system responds to changes in light and color within a few milliseconds, quickly enough that we are able to perceive continuous motion at nearly 1000 frames per second. To achieve a rapid response, the signal must also be terminated rapidly and the system must be returned to its initial state. First, activated rhodopsin must be blocked from continuing to activate transducin. *Rhodopsin kinase* catalyzes the phosphorylation of the carboxyl terminus of  $R^*$  at multiple serine and threonine residues. *Arrestin*, an inhibitory protein then binds phosphorylated  $R^*$  and prevents additional interaction with transducin.

**FIGURE 33.24 Visual signal transduction.** The light-induced activation of rhodopsin leads to the hydrolysis of cGMP, which in turn leads to ion-channel closing and the initiation of an action potential.

Second, the  $\alpha$  subunit of transducin must be returned to its inactive state to prevent further signaling. Like other G proteins, the  $\alpha$  subunit possesses built-in GTPase activity that hydrolyzes bound GTP to GDP. Hydrolysis takes place in less than a second when transducin is bound to the phosphodiesterase. The GDP form of transducin then leaves the phosphodiesterase and reassociates with the  $\beta\gamma$  subunits, and the phosphodiesterase returns to its inactive state. Third, the level of cGMP must be raised to reopen the cGMP-gated ion channels. *The action of guanylate cyclase accomplishes this third step by synthesizing cGMP from GTP.*

Calcium ion plays an essential role in controlling guanylate cyclase because it markedly inhibits the activity of the enzyme. In the dark,  $\text{Ca}^{2+}$  as well as  $\text{Na}^+$  enter the rod outer segment through the cGMP-gated channels. Calcium ion influx is balanced by its efflux through an exchanger, a transport system that uses the thermodynamically favorable flow of four  $\text{Na}^+$  ions into the cell and one  $\text{K}^+$  ion out of the cell to extrude one  $\text{Ca}^{2+}$  ion. After illumination, the entry of  $\text{Ca}^{2+}$  through the cGMP-gated channels stops, but its export through the exchanger continues. Thus, the cytoplasmic  $\text{Ca}^{2+}$  level drops from 500 nM to 50 nM after illumination. This drop markedly stimulates guanylate cyclase, rapidly restoring the concentration of cGMP to reopen the cGMP-gated channels.

By controlling the rate of cGMP synthesis,  $\text{Ca}^{2+}$  levels govern the speed with which the system is restored to its initial state.

### Color vision is mediated by three cone receptors that are homologs of rhodopsin

Cone cells, like rod cells, contain visual pigments. Like rhodopsin, these photoreceptor proteins are members of the 7TM-receptor family and use 11-*cis*-retinal as their chromophore. In human cone cells, there are three distinct photoreceptor proteins with absorption maxima at 426, 530, and ~560 nm (Figure 33.25). *These absorbances correspond to the blue, green, and yellow-green regions of the spectrum.* Recall that the absorption maximum for rhodopsin is 500 nm. The photoreceptor protein with its absorption maximum near 560 nm absorbs red light (with wavelength >620 nm) whereas the other two photoreceptors do not. For simplicity, we shall refer to the three proteins as the blue, green, and red photoreceptors.

The amino acid sequences of the cone photoreceptors have been compared with one another and with rhodopsin. The result is striking. Each of the cone photoreceptors is approximately 40% identical in sequence with rhodopsin. Similarly, the blue photoreceptor is 40% identical with each of the green and red photoreceptors. The green and red photoreceptors, however, are >95% identical with each other, differing in only 15 of 364 positions (Figure 33.26).

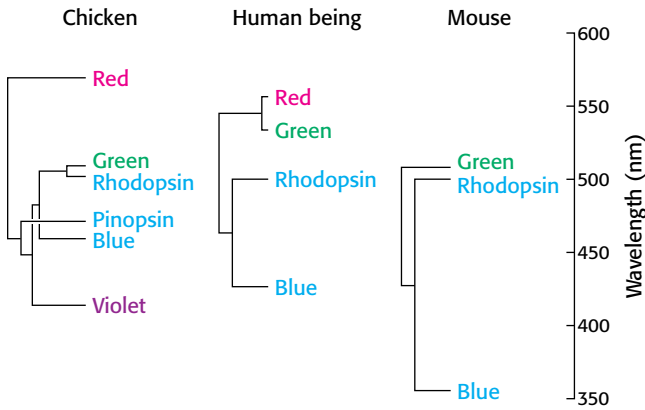

These observations are sources of insight into photoreceptor evolution. First, the green and red

**FIGURE 33.25** Cone-pigment absorption spectra. The absorption spectra of the cone visual pigment responsible for color vision.

**FIGURE 33.26** Comparison of the amino acid sequences of the green and red photoreceptors. Open circles correspond to identical residues, whereas colored circles mark residues that are different. The differences in the three black positions are responsible for most of the difference in their absorption spectra.

**FIGURE 33.27 Evolutionary relationships among visual pigments.** Visual pigments have evolved by gene duplication along different branches of the animal evolutionary tree. The branch lengths of the “trees” correspond to the percentage of amino acid divergence. [Information from J. Nathans, *Neuron* 24:299–312, 1999; by permission of Cell Press.]

photoreceptors are clearly products of a recent evolutionary event (Figure 33.27). The green and red pigments appear to have diverged in the primate lineage approximately 35 million years ago. Mammals, such as dogs and mice, that diverged from primates earlier have only two cone photoreceptors, blue and green. They are not sensitive to light as far toward the infrared region as we are, and they do not discriminate colors as well. In contrast, birds such as chickens have a total of six pigments: rhodopsin, four cone pigments, and a pineal visual pigment called *pinopsin*. Birds have highly acute color perception.

Second, the high level of similarity between the green and the red pigments has made the identification of the specific amino acid residues responsible for spectral tuning possible. Three residues (at positions 180, 277, and 285) are responsible for most of the difference between the green and the red pigments. In the green pigment, these residues are alanine, phenylalanine, and alanine, respectively; in the red pigment, they are serine, tyrosine, and threonine. A hydroxyl group has been added to each amino acid in the red pigment. The hydroxyl groups can interact with the photoexcited state of retinal and lower its energy, leading to a shift toward the lower-energy (red) region of the spectrum.

#### Homologous recombination

The exchange of DNA segments with substantial sequence similarity at equivalent positions between chromosomes.

#### Rearrangements in the genes for the green and red pigments lead to “color blindness”

The genes for the green and red pigments lie adjacent to each other on the human X chromosome. These genes are more than 98% identical in nucleotide sequence, including introns and untranslated regions as well as the protein-coding region. Regions with such high similarity are very susceptible to unequal homologous recombination.

**FIGURE 33.28 Recombination pathways leading to color blindness.** Rearrangements in the course of DNA replication may lead to (A) the loss of visual pigment genes or (B) the formation of hybrid pigment genes that encode photoreceptors with anomalous absorption spectra. Because the amino acids most important for determining absorption spectra are in the carboxyl-terminal half of each photoreceptor protein, the part of the gene that encodes this region most strongly affects the absorption characteristics of hybrid receptors. [Information from J. Nathans, *Neuron* 24:299–312, 1999; by permission of Cell Press.]

Recombination can take place either between or within transcribed regions of the gene (Figure 33.28). If recombination takes place between transcribed regions, the product chromosomes will differ in the number of pigment genes that they carry. One chromosome will lose a gene and thus may lack the gene for, say, the green pigment; the other chromosome will gain a gene. Consistent with this scenario, approximately 2% of human X chromosomes carry only a single color-pigment gene, approximately 20% carry two, 50% carry three, 20% carry four, and 5% carry five or more. A person lacking the gene for the green pigment will have trouble distinguishing red and green color, characteristic of the most common form of color blindness. Approximately 5% of males have this form of color blindness. Recombination can also take place within the

#### (A) Recombination between genes

#### (B) Recombination within genes

transcription units, resulting in genes that encode hybrids of the green and red photoreceptors. The absorption maximum of such a hybrid lies between that of the red and green pigments. A person with such hybrid genes who also lacks either a functional red- or green-pigment gene does not discriminate color well.

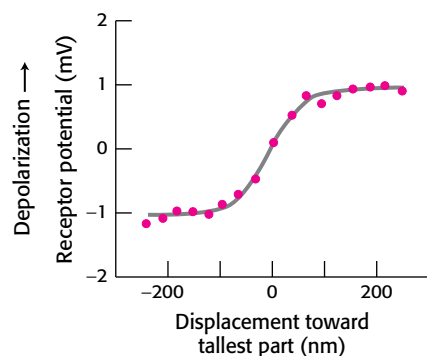

### 33.4 Hearing Depends on the Speedy Detection of Mechanical Stimuli

Hearing and touch are based on the detection of mechanical stimuli. Although the proteins of these senses have not been as well characterized as those of the senses already discussed, anatomical, physiological, and biophysical studies have elucidated the fundamental processes. *A major clue to the mechanism of hearing is its speed.* We hear frequencies ranging from 200 to 20,000 Hz (cycles per second), corresponding to times of 5 to 0.05 ms. Furthermore, our ability to locate sound sources, one of the most important functions of hearing, depends on the ability to detect the time delay between the arrival of a sound at one ear and its arrival at the other. Given the separation of our ears and the speed of sound, we must be able to accurately sense time differences of 0.7 ms. In fact, human beings can locate sound sources associated with temporal delays as short as 0.02 ms. This high time resolution implies that hearing must employ direct transduction mechanisms that do not depend on second messengers. Recall that, in vision, for which speed also is important, the signal-transduction processes take place in milliseconds.

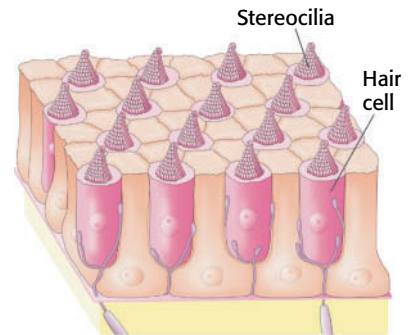

#### Hair cells use a connected bundle of stereocilia to detect tiny motions

Sound waves are detected inside the cochlea of the inner ear. The *cochlea* is a fluid-filled, membranous sac that is coiled like a snail shell. The primary detection is accomplished by specialized neurons inside the cochlea called *hair cells* (Figure 33.29). Each cochlea contains approximately 16,000 hair cells, and each hair cell contains a hexagonally shaped bundle of 20 to 300 hairlike projections called *stereocilia* (Figure 33.30). These stereocilia are graded in length across the bundle. Mechanical deflection of the hair bundle, as takes place when a sound wave arrives at the ear, creates a change in the membrane potential of the hair cell.

Micromanipulation experiments have directly probed the connection between mechanical stimulation and membrane potential. Displacement toward the direction of the tallest part of the hair bundle results in the depolarization of the hair cell, whereas displacement in the opposite direction results in its hyperpolarization (Figure 33.31). Motion perpendicular to the hair-length gradient does not produce any change in resting potential.

**FIGURE 33.31** Micromanipulation of a hair cell. Movement toward the tallest part of the bundle depolarizes the cell as measured by the microelectrode. Movement toward the shortest part hyperpolarizes the cell. Lateral movement has no effect. [After A. J. Hudspeth, *Nature* 341:397–404, 1989.]

**FIGURE 33.29** Hair cells, the sensory neurons crucial for hearing. These specialized neurons are capped with hairlike projections called stereocilia that are responsible for detecting very subtle vibrations. [Information from A. J. Hudspeth, *Nature* 341:397–404, 1989.]

**FIGURE 33.30** An electron micrograph of a hair bundle. [Courtesy of Dr. A. Jacobs and Dr. A. J. Hudspeth.]

**FIGURE 33.32 Electron micrograph of tip links.** The tip link between two hair fibers is marked by an arrow. [Courtesy of Dr. A. Jacobs and Dr. A. J. Hudspeth.]

**FIGURE 33.33 Model for hair-cell transduction.** When the hair bundle is tipped toward the tallest part, the tip link pulls on an ion channel and opens it. Movement in the opposite direction relaxes the tension in the tip link, increasing the probability that any open channels will close. [Information from A. J. Hudspeth, *Nature* 341:397–404, 1989.]

Remarkably, displacement of the hair bundle by as little as  $3 \text{ \AA}$  ( $0.3 \text{ nm}$ ) results in a measurable (and functionally important) change in membrane potential. This motion of  $0.001$  degree corresponds to a  $0.3$  inch movement of the top of the Empire State Building.

How does the motion of the hair bundle create a change in membrane potential? The rapid response, within microseconds, suggests that the movement of the hair bundle acts on ion channels directly. An important observation is that adjacent stereocilia are linked by individual filaments called *tip links* (Figure 33.32).

The presence of these tip links suggests a simple mechanical model for transduction by hair cells (Figure 33.33). The tip links are coupled to ion channels in the membranes of the stereocilia that are gated by mechanical stress. In the absence of a stimulus, approximately 15% of these channels are open. When the hair bundle is displaced toward its tallest part, the stereocilia slide across one another and the tension on the tip links increases, causing additional channels to open. The flow of ions through the newly opened channels depolarizes the membrane. Conversely, if the displacement is in the opposite direction, the tension on the tip links decreases, the open channels close, and the membrane hyperpolarizes. Thus, the mechanical motion of the hair bundle is directly converted into current flow across the hair-cell membrane.

### Mechanosensory channels have been identified in *Drosophila* and vertebrates

The search for ion channels that respond to mechanical impulses has been pursued in a variety of organisms. *Drosophila* have sensory bristles used for detecting small air currents. These bristles respond to mechanical displacement in ways similar to those of hair cells; displacement of a bristle in one direction leads to substantial transmembrane current. Strains of mutant fruit flies that show uncoordinated motion and clumsiness have been examined for their electrophysiological responses to displacement of the sensory bristles. In one set of strains, transmembrane currents were dramatically reduced. The mutated gene in these strains was found to encode a protein of 1619 amino acids, called NompC for *no mechanoreceptor potential*.

The carboxyl-terminal 469 amino acids of NompC resemble a class of ion-channel proteins called TRP (transient receptor potential) channels. This region includes six putative transmembrane helices with a pore-like region between the fifth and the sixth helices. The amino-terminal 1150 amino acids consist almost exclusively of 29 *ankyrin repeats* (Figure 33.34).

**FIGURE 33.34 Ankyrin repeat structure.** One ankyrin domain is shown in red in this series of four ankyrin repeats. Notice the hairpin loop followed by a helix-turn-helix motif in the red-colored ankyrin unit. Ankyrin domains interact with other proteins, primarily through their loops. [Drawn from 1AWC.pdb.]

Ankyrin repeats are structural motifs consisting of a hairpin loop followed by a helix-turn-helix. Importantly, in other proteins, regions with tandem arrays of these motifs mediate protein–protein interactions, suggesting that these arrays couple the motions of other proteins to the activity of the NompC channel.

A candidate for at least one component of the mechanosensory channel taking part in hearing has been identified. The protein, TRPA1, is a member of the TRP channel family. The sequence of TRPA1 also includes 17 ankyrin repeats. TRPA1 is expressed in hair cells, particularly near their tips. Further studies are under way to test and extend the exciting hypothesis that this protein is a component of the sought-after channel.

### 33.5 Touch Includes the Sensing of Pressure, Temperature, and Other Factors

Like taste, touch is a combination of sensory systems that are expressed in a common organ—in this case, the skin. The detection of pressure and the detection of temperature are two key components. Amiloride-sensitive  $\text{Na}^+$  channels, homologous to those of taste, appear to play a role. Other systems are responsible for detecting painful stimuli such as high temperature, acid, or certain specific chemicals. Although our understanding of this sensory system is not as advanced as that of the others, recent work has revealed a fascinating relation between pain and taste sensation, a relation well known to anyone who has eaten “spicy” food.

#### Studies of capsaicin reveal a receptor for sensing high temperatures and other painful stimuli

Our sense of touch is intimately connected with the sensation of pain. Specialized neurons, termed *nociceptors*, transmit signals from skin to pain-processing centers in the spinal cord and brain in response to the onset of tissue damage. What is the molecular basis for the sensation of pain? An intriguing clue came from the realization that *capsaicin*, the chemical responsible for the “hot” taste of spicy food, activates nociceptors.

Early research suggested that capsaicin would act by opening ion channels that are expressed in nociceptors. Thus, a cell that expresses the *capsaicin receptor* should take up calcium on treatment with the molecule. This insight led to the isolation of the capsaicin receptor with the use of cDNA from cells expressing this receptor. Such cells had been detected by their fluorescence when loaded with the calcium-sensitive compound Fura-2 and then treated with capsaicin or related molecules. Cells expressing the capsaicin receptor, which is called VR1 (for *vanilloid receptor 1*), respond to capsaicin below a concentration of  $1 \mu\text{M}$ . The deduced 838-residue sequence of VR1 revealed it to be a member of the TRP channel family (Figure 33.35). The amino-terminal region of VR1 includes three ankyrin repeats.

**FIGURE 33.35** The membrane topology deduced for VR1, the capsaicin receptor.

The proposed site of the membrane pore is indicated in red, and the three ankyrin (A) repeats are shown in orange. The active receptor comprises four of these subunits. [Information from M. J. Caterina et al., *Nature* 389:816–824, 1997.]

**FIGURE 33.36 Response of the capsaicin receptor to pH and temperature.** The ability of this receptor to respond to acid and to increased temperature helps detect potentially noxious situations. [Data from M. Tominaga et al., *Neuron* 21:531–543, 1998.]

Currents through VR1 are also induced by temperatures above 40°C and by exposure to dilute acid, with a midpoint for activation at pH 5.4 (Figure 33.36). Temperatures and acidity in these ranges are associated with infection and cell injury. The responses to capsaicin, temperature, and acidity are not independent. The response to heat is greater at lower pH, for example. Thus, VR1 acts to integrate several noxious stimuli. We feel these responses as pain and act to prevent the potentially destructive conditions that cause the unpleasant sensation. Studies of mice that do not express VR1 suggest that this is the case; such mice do not mind food containing high concentrations of capsaicin and are, indeed, less responsive than control mice to normally noxious heat. Plants such as chili peppers presumably gained the ability to synthesize capsaicin and other “hot” compounds to protect themselves from being consumed by mammals. Birds, which play the beneficial role of spreading pepper seeds into new territory, do not appear to respond to capsaicin.

Because of its ability to simulate VR1, capsaicin is used in pain management for arthritis, neuralgia, and other neuropathies. How can a compound that induces pain assist in its alleviation? Chronic exposure to capsaicin overstimulates pain-transmitting neurons, leading to their desensitization.

## SUMMARY

Smell, taste, vision, hearing, and touch are based on signal-transduction pathways activated by signals from the environment. These sensory systems function similarly to the signal-transduction pathways for many hormones. These intercellular signaling pathways appear to have been appropriated and modified to process environmental information.

### 33.1 A Wide Variety of Organic Compounds Are Detected by Olfaction

The sense of smell, or olfaction, is remarkable in its specificity; it can, for example, discern stereoisomers of small organic compounds as distinct aromas. The 7TM receptors that detect these odorants operate in conjunction with  $G_{(olf)}$ , a G protein that activates a cAMP cascade resulting in the opening of an ion channel and the generation of a nerve impulse. An outstanding feature of the olfactory system is its ability to detect a vast array of odorants. Each olfactory neuron expresses only one type of receptor and connects to a particular region of the olfactory

bulb. Odors are decoded by a combinatorial mechanism: each odorant activates a number of receptors, each to a different extent, and most receptors are activated by more than one odorant.

### 33.2 Taste Is a Combination of Senses That Function by Different Mechanisms

We can detect only five tastes: bitter, sweet, salt, sour, and umami. The transduction pathways that detect taste are, however, diverse. Bitter, sweet, and umami tastants are experienced through 7TM receptors acting through a special G protein called gustducin. Salty and sour tastants act directly through membrane channels. Salty tastants are detected by passage through  $\text{Na}^+$  channels, whereas sour taste results from the effects of hydrogen ions on a number of types of channels. The end point is the same in all cases—membrane polarization that results in the transmission of a nerve impulse.

### 33.3 Photoreceptor Molecules in the Eye Detect Visible Light

Vision is perhaps the best understood of the senses. Two classes of photoreceptor cells exist: cones, which respond to bright lights and colors, and rods, which respond only to dim light. The photoreceptor in rods is rhodopsin, a 7TM receptor that is a complex of the protein opsin and the chromophore 11-*cis*-retinal. The absorption of light by 11-*cis*-retinal changes its structure into that of all-*trans*-retinal, setting in motion a signal-transduction pathway that leads to the breakdown of cGMP, to membrane hyperpolarization, and to a subsequent nerve impulse. Color vision is mediated by three distinct 7TM photoreceptors that employ 11-*cis*-retinal as a chromophore and absorb light in the blue, green, and red parts of the spectrum.

### 33.4 Hearing Depends on the Speedy Detection of Mechanical Stimuli

The immediate receptors for hearing are found in the hair cells of the cochleae, which contain bundles of stereocilia. When the stereocilia move in response to sound waves, cation channels will open or close, depending on the direction of movement. The mechanical motion of the cilia is converted into current flow and then into a nerve impulse.

### 33.5 Touch Includes the Sensing of Pressure, Temperature, and Other Factors

Touch, detected by the skin, senses pressure, temperature, and pain. Specialized nerve cells called nociceptors transmit signals that are interpreted in the brain as pain. A receptor responsible for the perception of pain has been isolated on the basis of its ability to bind capsaicin, the molecule responsible for the hot taste of spicy food. The capsaicin receptor, also called VR1, functions as a cation channel that initiates a nerve impulse.

## PROBLEMS

1. *Olfaction in worms.* Unlike the olfactory neurons in the mammalian systems discussed herein, olfactory neurons in the nematode *C. elegans* express multiple olfactory receptors. In particular, one neuron (called AWA) expresses receptors for compounds to which the nematode is attracted, whereas a different neuron (called AWB) expresses receptors for compounds that the nematode avoids. Suppose that a transgenic nematode is generated such that one of the receptors for an attractant is expressed in AWB rather than AWA. What behavior would you expect in the presence of the corresponding attractant?

2. *Odorant matching.* A mixture of two of the compounds illustrated in Figure 33.6 is applied to a section of olfactory epithelium. Only receptors 3, 5, 9, 12, and 13 are activated, according to Figure 33.7. Identify the likely compounds in the mixture.

3. *Timing.* Compare the aspects of taste (bitter, sweet, salty, sour) in regard to their potential for rapid time resolution.

4. *Two ears.* Our ability to determine the direction from which a sound is coming is partly based on the difference in time at which our two ears detect the sound. Given the speed of sound ( $350 \text{ m s}^{-1}$ ) and the separation between our ears (0.15 m), what difference is expected in the times at which a sound arrives at our two ears? How does this difference compare with the time resolution of the human hearing system? Would a sensory system that utilized 7TM receptors and G proteins be capable of adequate time resolution?

5. *It's better to be bitter.* Some nontoxic plants taste very bitter to us. Suggest one or more explanations.

6. *Of mice and men.* In human beings, the umami taste is triggered only by glutamate and aspartate. In contrast, mice respond to many more amino acids. Design an experiment to test which of the subunits (T1R1 or T1R3) determines the specificity of this response. Assume that all desired mouse strains can be readily produced.

7. *It's not easy being green.* Would you expect light with wavelength 530 nm to be absorbed only by the "green" photoreceptor?

8. *Color discrimination.* Some women who have had male children who display color blindness have been demonstrated

to distinguish between colors that are not readily distinguished by other people. Propose an explanation.

9. *Combinatorial power.* How many different odorants could a person distinguish if each odorant is bound by a single type of receptor and each receptor binds only a single odorant? How many if each odorant binds to two different odorant receptors? Three odorant receptors?

10. *Light action.* Describe the effect of light absorption on 11-*cis*-retinal bound within rhodopsin.

11. *Mirror, mirror.* Compounds A and B typically evoke different odors, with compound A described as smelling like tropical fruit and compound B smelling oniony.

Explain how two such similar compounds can smell so different.

12. *Channeling.* Provide an example of an ion channel in vision, taste, and hearing.

## Chapter Integration Problem

13. *Energy and information.* The transmission of sensory information requires the input of free energy. For each sensory system (olfaction, gustation, vision, hearing, and touch), identify mechanisms for the input of free energy that allow the transmission of sensory information.

## Mechanism Problem

14. *Schiff-base formation.* Propose a mechanism for the reaction between opsin and 11-*cis*-retinal.

# The Immune System

Just as medieval fortresses, such as the Dover Castle, used walls and fortifications to defend their territory, the immune system constantly battles against foreign invaders such as viruses, bacteria, and parasites to defend the organism. Antibody molecules provide a key element in the immune system's defensive arsenal. For example, specific antibodies can bind to molecules on the surfaces of viruses and prevent the viruses from infecting cells. Above right, an antibody binds to one subunit on hemagglutinin from the surface of influenza virus. [Skyscan Photolibrary/Alamy.]

We are constantly exposed to an incredible diversity of bacteria, viruses, and parasites, many of which would flourish in our cells or extracellular fluids were it not for our immune system. How does the immune system protect us? The human body has two lines of defense: an *innate immune system* that responds rapidly to features present in many pathogens, and an *adaptive immune system* that responds to specific features present only in a given pathogen. *Both the innate and the adaptive immune systems first identify features on disease-causing organisms and then work to eliminate or neutralize those organisms.* While a thorough description of the immune system is certainly beyond the scope of this book, this chapter will focus on how biochemical concepts such as protein structure, receptor-ligand interactions, and signal transduction are applied to the identification of pathogens.

The immune system must meet two tremendous challenges in the identification of pathogens: (1) to produce a system of receptors diverse enough to recognize a wide array of potential pathogens and (2) to distinguish invaders and their disease-causing products from the organism's own products (i.e., self- versus nonself-recognition). To meet these challenges, the innate immune system evolved the ability to recognize structural elements,

## OUTLINE

- 34.1 Antibodies Possess Distinct Antigen-Binding and Effector Units
- 34.2 Antibodies Bind Specific Molecules Through Hypervariable Loops
- 34.3 Diversity Is Generated by Gene Rearrangements
- 34.4 Major-Histocompatibility-Complex Proteins Present Peptide Antigens on Cell Surfaces for Recognition by T-Cell Receptors
- 34.5 The Immune System Contributes to the Prevention and the Development of Human Diseases

such as specific glycolipids or forms of nucleic acid, that are well conserved in pathogens but absent in the host organism. The repertoire of such elements is limited, however, and so some pathogens have strategies to escape detection. The adaptive immune system has the remarkable ability to produce more than  $10^8$  distinct proteins, called antibodies, that can recognize different foreign molecules, and more than  $10^{12}$  receptors on immune cells, called T-cell receptors (TCRs), each of which presents a different surface with the potential to specifically bind a structure from a foreign organism. In producing this vast range of defensive molecules, however, the adaptive immune system has the potential to create antibodies and T-cells that recognize and attack cells or molecules normally present in our bodies—a situation that can result in autoimmune diseases.

This chapter will examine these challenges, focusing first on the structures of proteins that recognize foreign organisms and then on the mechanisms for protecting us from a specific pathogen once it has been recognized. The chapter will closely examine the modular construction of the proteins of the immune system—identifying structural motifs and considering how spectacular diversity can arise from modular construction.

### Innate immunity is an evolutionarily ancient defense system

Innate immunity is an evolutionarily ancient defense system found, at least in some form, in all multicellular plants and animals. The innate immune system represents the first line of defense against foreign pathogens, relying on common features of invading organisms to identify and eliminate these threats. Components of the innate immune system include the epithelial lining that surrounds host cells and the specialized cells, called *phagocytes*, that can ingest and destroy pathogens without the aid of the adaptive immune system.

The innate immune system also includes a family of receptors that can recognize specific features present in most pathogens and yet not respond to materials normally present in the host. The best-understood of these receptors are the *Toll-like receptors* (TLRs). The name “toll-like” is derived from a receptor known as Toll encoded in the *Drosophila* genome; Toll was first identified in a screen for genes important for *Drosophila* development and was subsequently shown to play a key role in the innate immune system. The TLRs have a common structure (Figure 34.1). Each receptor consists of a large extracellular domain built primarily from repeated amino acid sequences termed leucine-rich repeats (LRRs). Each LRR typically contains 20–30 residues, including 6 that are usually leucine. The human TLRs have from 18 to 27 LRR repeats that are capped by a cysteine-rich domain and followed by a sequence forming a single transmembrane helix and an intracellular signaling domain. This signaling domain is not a protein kinase but acts as a docking site for other proteins. Most TLRs are expressed in the cell membrane for the detection of extracellular pathogens such as fungi and bacteria. Other TLRs are located in the membranes of internal compartments for the detection of intracellular pathogens such as viruses and some bacteria.

Each TLR targets a specific molecular characteristic, often called a *pathogen-associated molecular pattern* (PAMP), found primarily on invading organisms (Table 34.1). Typically, a PAMP is a critical component of the pathogen’s function: mutations in these targets cannot easily block recognition by the TLR without compromising the activity of the pathogen. One particularly important PAMP is lipopolysaccharide (LPS), also referred to as *endotoxin*, a specific class of glycolipid found in the cell walls of Gram-negative bacteria such as *E. coli*. LPS is recognized by TLR4. The response

**FIGURE 34.1 Toll-like receptor.** Each receptor is made up of a set of 18 or more leucine-rich repeat sequences, followed by a cysteine-rich domain, a single transmembrane helix, and an intracellular domain that functions in signal transduction.

**TABLE 34.1** Pathogen-associated molecular patterns (PAMPs) recognized by human TLRs

Receptor	PAMP	Source of PAMP
TLR1 (with TLR2)	Triacyl lipoprotein	Bacteria
TLR2	Lipoprotein	Bacteria, viruses, parasites
TLR3	Double-stranded RNA (dsRNA)	Viruses
TLR4	Lipopolysaccharide (LPS)	Bacteria, viruses
TLR5	Flagellin	Bacteria
TLR6 (with TLR2)	Diacyl lipoprotein	Bacteria, viruses
TLR7	Single-stranded RNA (ssRNA)	Viruses, bacteria
TLR8	Single-stranded RNA (ssRNA)	Viruses, bacteria
TLR9	CpG-DNA motifs	Viruses, bacteria, protozoa
TLR10	Unknown	Unknown

Data from: O. Takeuchi and S. Akira, *Cell* 140:805–820, 2010.

of the innate immune system to LPS can be easily demonstrated. Injection of less than 1 mg of LPS into a human being produces a fever and other signs of inflammation even though no living organisms are introduced.

How do TLRs recognize PAMPs? The extracellular domain from human TLR3 has a remarkable structure that is representative of many other TLRs (Figure 34.2). Each LRR contributes a single  $\beta$  strand to a large parallel  $\beta$  sheet that lines the inside of a concave, hooklike structure. In most cases, the PAMP is recognized by the surface formed between two receptors. The PAMP for TLR3, double-stranded RNA, fits in the groove between two monomers, colored blue and yellow in Figure 34.3. Ligand-induced dimerization of the receptor enables the initiation of a signaling cascade within the cell. We encountered similar examples of signal transduction across a membrane through receptor dimerization in Chapter 14.

Because the TLRs and other components of the innate immune system are always expressed, they provide the host organism with a rapid response to resist attack by pathogens. However, a number of pathogens have evolved the ability to escape detection by the innate immune system. For protection against such pathogens, the host relies on the adaptive immune system, which is able to target specific pathogens, even those that it has never encountered in the course of evolution.

**FIGURE 34.2** Extracellular domain of the Toll-like receptor. (A) The structure of the leucine-rich repeat (LRR) domain from human TLR3. Notice that the LRR units come together to form a central parallel  $\beta$  sheet that curls to form a concave structure. (B) The structure of a single LRR showing the positions of the residues that are generally approximately conserved. Notice that the leucine residues come together to form a hydrophobic core with the single  $\beta$  strand on one side. [Drawn from 1ZIW.pdb].

**FIGURE 34.3 Recognition of a PAMP by a Toll-like receptor.** The structure of TLR3 bound to its PAMP, a fragment of double-stranded RNA, as seen from the side (top) and from above (bottom). Notice that the PAMP induces receptor dimerization by binding the surfaces on the side of each of the extracellular domains. [Drawn from 3CIY.pdb].

## The adaptive immune system responds by using the principles of evolution

The adaptive immune system comprises two parallel but interrelated systems: humoral and cellular immune responses. In the *humoral immune response*, soluble proteins called *antibodies* (*immunoglobulins*) function as recognition elements that bind to foreign molecules and serve as markers signaling foreign invasion. Antibodies are secreted by *plasma cells*, which are derived from *B lymphocytes* (*B cells*) (Figure 34.4). A foreign macromolecule that binds selectively to an antibody is called an *antigen*. In a physiological context, if the binding of the foreign molecule stimulates an immune response, that molecule is called an *immunogen*. The specific affinity of an antibody is not for the entire macromolecular antigen but for a particular site on the antigen called the *epitope* or *antigenic determinant*. Each B cell produces just one type of antibody that can recognize a single epitope.

In the *cellular immune response*, cells called *cytotoxic T lymphocytes* (also commonly called *killer T cells*) destroy cells that have been invaded by a pathogen. Because intracellular pathogens do not leave markings on the exteriors of infected cells, vertebrates have evolved a mechanism to mark the exterior of cells with a sample of the interior contents, both self and foreign. Some of the internal proteins are broken into peptides, which are then bound to a complex of integral membrane proteins encoded by the *major histocompatibility complex* (MHC). T cells continually scan the bound peptides to find and kill cells that display foreign motifs on their surfaces. Another class of T cells called *helper T lymphocytes* (*helper T cells*) contributes to both the humoral and the cellular

immune responses by stimulating the differentiation and proliferation of appropriate B cells and cytotoxic T cells. The cellular immune response is mediated by specific receptors that are expressed on the surfaces of the T cells.

The remarkable ability of the immune system to adapt to an essentially limitless set of potential pathogens requires a powerful system for transforming the immune cells and molecules in response to the presence of pathogens. *This adaptive system operates through the principles of evolution, including reproduction with variation followed by selection of the most well suited members of a population.*

If the human genome contains, by the latest estimates, only 21,000 genes, how can the immune system generate more than  $10^8$  different antibody proteins and  $10^{12}$  T-cell receptors? The answer is found in a novel mechanism for generating a highly diverse set of genes from a limited set of genetic building blocks. Linking different sets of DNA regions in a combinatorial manner produces many distinct protein-encoding genes that are not present in the genome. A rigorous selection process then leaves for proliferation only cells that synthesize proteins determined to be useful in the immune response. The subsequent reproduction of these cells without additional recombination enriches the cell population with members expressing particular protein species.

Critical to the development of the immune response is the selection process, which determines which immune cells will reproduce. The process comprises several stages. In the early stages of immune cell development, cells expressing molecules that bind tightly to self-molecules are destroyed or silenced, whereas cells expressing molecules that do not bind strongly to self-molecules and that have the potential for binding strongly to foreign molecules are preserved. The appearance of an immunogenic invader at a later time will stimulate the reproduction of cells expressing antibodies or T-cell receptors that bind specifically to elements of that pathogen—in evolutionary terms, such cells are positively selected. Thus, the immune response is based on the selection of cells expressing molecules that are specifically effective against a particular invader; the response evolves from a population with wide-ranging specificities to a more-focused collection of cells and molecules that are well suited to defend the host when confronted with that particular challenge.

Not only are antibodies and T-cell receptors a result of genetic diversity and recombination, but antibodies have highly diverse structures as well. Antibodies require many different structural solutions for binding many different antigens, each of which has a different form. T-cell receptors, in contrast, are not structurally diverse, because they have coevolved with the MHC. The docking mode of a T-cell receptor to the peptide bound to MHC is similar for all structures. As a consequence of this coevolution, every T-cell receptor has an inherent reactivity with every MHC. The coevolution ensures that all T-cell receptors can scan all peptide–MHC complexes on all tissues. The genetic diversity of the  $10^{12}$  different T-cell receptors is concentrated in a highly diverse set of residues in the center of the MHC groove. This localized diversity allows the T-cell receptor to recognize the many different foreign peptides bound to the MHC. T-cell receptors must survey many different MHC–peptide complexes with rapid turnover. Therefore, the binding affinities between T-cell receptors and the MHC are weaker than those between antibody and antigen.

---

### 34.1 Antibodies Possess Distinct Antigen-Binding and Effector Units

Antibodies are central molecular players in the immune response. In Chapter 3, we discussed the application of antibodies as tools to study proteins; let us now consider the native structures and functions of these remarkable molecules. In 1959, Rodney Porter showed that *immunoglobulin G* (IgG), the major antibody in serum, can be cleaved into three 50-kDa fragments by the limited proteolytic action of papain. Two of these fragments bind antigen. They are called  $F_{ab}$  ( $F$  stands for *fragment*,  $ab$  for *antigen binding*). The other fragment, called  $F_c$  because it crystallizes readily, does not bind antigen, but it has other important biological activities, including the mediation of responses termed *effector functions*. These functions include the initiation of the *complement cascade*, a process that leads to the lysis of target cells. Although such effector functions are crucial to the functioning of the immune system, they will not be considered further here.

How do these fragments relate to the three-dimensional structure of whole IgG molecules? Immunoglobulin G consists of two kinds of polypeptide chains, a 25-kDa *light* (L) *chain* and a 50-kDa *heavy* (H) *chain*

**FIGURE 34.5 Immunoglobulin G structure.** (A) The three-dimensional structure of an IgG molecule showing the light chains in yellow and the heavy chains in blue. (B) A schematic view of an IgG molecule indicating the positions of the interchain disulfide bonds. Abbreviations: N, amino terminus; C, carboxyl terminus. [Drawn from 1IGT.pdb.]

(Figure 34.5). The subunit composition is  $L_2H_2$ . Each L chain is linked to an H chain by a disulfide bond, and the H chains are linked to each other by at least one disulfide bond. Examination of the amino acid sequences and three-dimensional structures of IgG molecules reveals that each L chain comprises two homologous domains, termed *immunoglobulin domains*, to be described in detail in Section 34.2. Each H chain has four immunoglobulin domains. Overall, the molecule adopts a conformation that resembles the letter Y. The stem of this Y, corresponding to the  $F_c$  fragment obtained by cleavage with papain, consists of the two carboxyl-terminal immunoglobulin domains of each H chain. The two arms of the Y, corresponding to the two  $F_{ab}$  fragments, are formed by the two amino-terminal domains of each H chain and the two domains of each L chain. The linkers between the stem and the two arms consist of extended polypeptide regions within the H chains and are quite flexible.

Papain cleaves the H chains on the carboxyl-terminal side of the disulfide bond that links each L and H chain (Figure 34.6). Thus, each  $F_{ab}$  consists of an entire L chain and the amino-terminal half of an H chain, whereas  $F_c$  consists of the carboxyl-terminal halves of both H chains. Each  $F_{ab}$  contains a single antigen-binding site. Because an intact IgG contains two  $F_{ab}$  components and therefore has two binding sites, it can cross-link multiple antigens (Figure 34.7). Furthermore, the  $F_c$  and the two  $F_{ab}$  units of the intact IgG are joined by flexible polypeptide regions that allow

**FIGURE 34.6 Immunoglobulin G cleavage.** Treatment of intact IgG molecules with the protease papain results in the formation of three large fragments: two  $F_{ab}$  fragments that retain antigen-binding capability and one  $F_c$  fragment that does not.

**FIGURE 34.7 Antigen cross-linking.** Because IgG molecules include two antigen-binding sites, antibodies can cross-link multivalent antigens such as viral surfaces.

**TABLE 34.2** Properties of immunoglobulin classes

Class	Serum concentration (mg ml <sup>-1</sup> )	Mass (kDa)	Light chains	Heavy chains	Chain structure
IgG	12	150	κ or λ	γ	κ <sub>2</sub> γ <sub>2</sub> or λ <sub>2</sub> γ <sub>2</sub>
IgA	3	180–500	κ or λ	α	(κ <sub>2</sub> α <sub>2</sub> ) <sub>n</sub> or (λ <sub>2</sub> α <sub>2</sub> ) <sub>n</sub>
IgM	1	950	κ or λ	μ	(κ <sub>2</sub> μ <sub>2</sub> ) <sub>5</sub> or (λ <sub>2</sub> μ <sub>2</sub> ) <sub>5</sub>
IgD	0.1	175	κ or λ	δ	κ <sub>2</sub> δ <sub>2</sub> or λ <sub>2</sub> δ <sub>2</sub>
IgE	0.001	200	κ or λ	ε	κ <sub>2</sub> ε <sub>2</sub> or λ <sub>2</sub> ε <sub>2</sub>

Note: *n* = 1, 2, or 3. IgM and oligomers of IgA also contain J chains that connect immunoglobulin molecules. IgA in secretions has an additional component.

facile variation in the angle between the F<sub>ab</sub> units through a wide range (Figure 34.8). This kind of mobility, called *segmental flexibility*, can enhance the formation of an antibody–antigen complex by enabling both recognition sites on an antibody to bind an antigen that possesses multiple binding sites, such as a viral coat composed of repeating identical monomers. The sites at the tips of the F<sub>ab</sub> units simply move to match the distance between specific determinants on the antigen.

Immunoglobulin G is the antibody present in highest concentration in the serum, but other classes of immunoglobulin also are present (Table 34.2). Each class includes an L chain (either κ or λ) and a distinct H chain (Figure 34.9). The heavy chains in IgG are called γ chains, whereas those in immunoglobulins A, M, D, and E are called α, μ, δ, and ε, respectively. *Immunoglobulin M* (IgM) is the first class of antibody to appear in the serum after exposure to an antigen. The presence of 10 antigen recognition sites enables IgM to bind especially tightly to antigens containing multiple identical epitopes. The strength of an interaction comprising multiple independent binding interactions between partners is termed *avidity* rather than *affinity*, which denotes the binding strength of a single binding site.

*Immunoglobulin A* (IgA) is the major class of antibody in external secretions, such as saliva, tears, bronchial mucus, and intestinal mucus. Thus, IgA serves as a first line of defense against bacterial and viral antigens. The role of *immunoglobulin D* (IgD) has long been a mystery, but recent studies suggest IgD plays a role in the activation of basophils, white blood cells that have antiparasitic functions. *Immunoglobulin E* (IgE) is important in conferring

**FIGURE 34.9** Classes of immunoglobulin.

Each of five classes of immunoglobulin has the same light chain (shown in yellow) combined with a different heavy chain (γ, α, μ, δ, or ε). Disulfide bonds are indicated by green lines. The IgA dimer and the IgM pentamer have a small polypeptide chain in addition to the light and heavy chains.

**FIGURE 34.8** Segmental flexibility. The linkages between the F<sub>ab</sub> and the F<sub>c</sub> regions of an IgG molecule are flexible, allowing the two antigen-binding sites to adopt a range of orientations with respect to each other. This flexibility allows effective interactions with a multivalent antigen without requiring that the epitopes on the target be a precise distance apart.

protection against parasites, but IgE also participates in allergic reactions. IgE–antigen complexes form cross-links with receptors on the surfaces of mast cells to trigger a cascade that leads to the release of granules containing pharmacologically active molecules. Histamine, one of the agents released, induces smooth-muscle contraction and stimulates the secretion of mucus.

## 34.2 Antibodies Bind Specific Molecules Through Hypervariable Loops

A comparison of the amino acid sequences of different IgG antibodies from human beings or mice shows that the carboxyl-terminal half of the L chains and the carboxyl-terminal three-quarters of the H chains are very similar in all of the antibodies. Importantly, the amino-terminal domain of each chain is more variable, including three stretches of approximately 7 to 12 amino acids within each chain that are hypervariable, as shown for the H chain in Figure 34.10. The amino-terminal immunoglobulin domain of each chain is thus referred to as the *variable region*, whereas the remaining immunoglobulin domains are much more similar in all antibodies and are referred to as *constant regions* (Figure 34.11).

**FIGURE 34.10 Immunoglobulin sequence diversity.** A plot of sequence variability as a function of position along the sequence of the amino-terminal immunoglobulin domain of the H chain of human IgG molecules. Three regions (in red) show remarkably high levels of variability. These hypervariable regions correspond to three loops in the immunoglobulin domain structure. [Data from R. A. Goldsby, T. J. Kindt, and B. A. Osborne, *Kuby Immunology*, 4th ed. (W. H. Freeman and Company, 2000), p. 91.]

### The immunoglobulin fold consists of a beta-sandwich framework with hypervariable loops

An IgG molecule consists of a total of 12 immunoglobulin domains. These domains have many sequence features in common and adopt a common structure, the *immunoglobulin fold* (Figure 34.12). Remarkably, this same structural domain is found in many other proteins that play key roles in both immune and nonimmune functions.

The immunoglobulin fold consists of a pair of  $\beta$  sheets, each built of antiparallel  $\beta$  strands, that surround a central hydrophobic core. A single disulfide bond bridges the two sheets. Two aspects of this structure are particularly important for its function. First, three loops present at one end of the structure form a potential binding surface. These loops contain the hypervariable sequences present in antibodies and in T-cell receptors. Variation of the

amino acid sequences of these loops provides the major mechanism for the generation of the vastly diverse set of antibodies and T-cell receptors expressed by the immune system. These loops are referred to as *hypervariable loops* or *complementarity-determining regions* (CDRs). Second, the amino terminus and the carboxyl terminus are at opposite ends of the structure, which allows structural domains to be strung together to form chains, as in the L and H chains of antibodies. Such chains are present in several other key molecules in the immune system.

**FIGURE 34.11 Variable and constant regions.** Each L and H chain includes one immunoglobulin domain at its amino terminus that is quite variable from one antibody to another. These domains are referred to as  $V_L$  and  $V_H$ . The remaining domains are more constant from one antibody to another and are referred to as constant domains ( $C_L1$ ,  $C_H1$ ,  $C_H2$ , and  $C_H3$ ).

The immunoglobulin fold is one of the most prevalent domains encoded by the human genome: more than 750 genes encode proteins with at least one immunoglobulin fold recognizable at the level of amino acid sequence. Such domains are also common in other multicellular animals such as flies and nematodes. However, from inspection of amino acid sequence alone, immunoglobulin-fold domains do not appear to be present in yeast or plants, although these organisms possess other structurally similar domains, including the key photosynthetic electron-transport protein

plastocyanin in plants (Section 19.3). Thus, the immunoglobulin-fold family appears to have expanded greatly along evolutionary branches leading to animals—particularly, vertebrates.

### X-ray analyses have revealed how antibodies bind antigens

For each class of antibody, the variable domains at the amino-terminal ends of the L and H chains (designated  $V_L$  and  $V_H$ ) come together to form a binding surface. The positions of the CDRs are striking. These hypervariable sequences, present in three loops of each domain, come together so that all six loops form a single surface at the end of each arm (Figure 34.13). Because virtually any  $V_L$  can pair with any  $V_H$ , a very large number of different binding sites can be constructed by their combinatorial association.

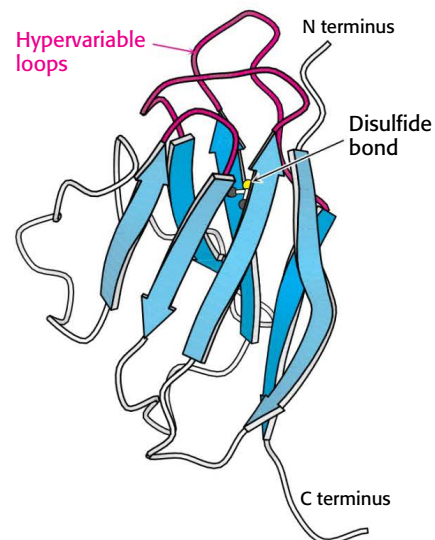

The results of x-ray crystallographic studies of several hundred large and small antigens bound to  $F_{ab}$  molecules have been sources of much insight into the structural basis of antibody specificity. The binding of antigens to antibodies is governed by the same principles that govern the binding of substrates to enzymes. The interaction between complementary shapes results in numerous contacts between amino acids at the binding surfaces of both molecules. Many hydrogen bonds, electrostatic interactions, and van der Waals interactions, reinforced by hydrophobic interactions, combine to give specific and strong binding.

A few aspects of antibody binding merit specific attention, inasmuch as they relate directly to the structure of immunoglobulins. The binding site on the antibody incorporates some or all of the CDRs in the variable domains of the antibody. Small molecules are likely to make contact with fewer CDRs, with perhaps 15 residues of the antibody participating in the binding interaction. Macromolecules often make more extensive contact, sometimes interacting with all six CDRs and 20 or more residues of the antibody. Small molecules often bind in a cleft of the antigen-binding region. Macromolecules, such as globular proteins, tend to interact across larger, fairly flat apposed surfaces bearing complementary protrusions and depressions.

A well-studied case of small-molecule binding is seen in an example of phosphorylcholine bound to  $F_{ab}$ . Crystallographic analysis revealed phosphorylcholine bound to a cavity lined by residues from five CDRs—two from the L chain and three from the H chain (Figure 34.14). The positively charged trimethylammonium group of phosphorylcholine is buried inside the wedge-shaped cavity, where it interacts electrostatically with two negatively charged residues, a glutamate and an aspartate. The negatively charged phosphoryl group of phosphorylcholine binds to the positively charged guanidinium group of an arginine residue at the mouth of the crevice and is hydrogen bonded to the side chain of a nearby tyrosine residue.

**FIGURE 34.14 Binding of a small antigen.** The structure of a complex between an  $F_{ab}$  fragment of an antibody (blue and yellow) and its target—in this case, phosphorylcholine. Notice that residues from the antibody interact with phosphorylcholine through hydrogen bonding and electrostatic interactions. [Drawn from 2MCP.pdb.]

**FIGURE 34.12 Immunoglobulin fold.** An immunoglobulin domain consists of a pair of  $\beta$  sheets linked by a disulfide bond and hydrophobic interactions. Notice that three hypervariable loops lie at one end of the structure. [Drawn from 1DQJ.pdb.]

**FIGURE 34.13 Variable domains.** A side view of the variable domains of the L chain (yellow) and the H chain (blue); the complementarity-determining regions (CDRs) are shown in red. Notice that the six CDRs come together to form a binding surface. The specificity of the surface is determined by the sequences and structures of the CDRs. [Drawn from 1DQJ.pdb.]

**FIGURE 34.15 Antibodies against lysozyme.** The structures of three complexes (i, ii, iii) between  $F_{ab}$  fragments (blue and yellow) and hen egg-white lysozyme (red) shown with lysozyme in the same orientation in each case. Notice that the three antibodies recognize completely different epitopes on the lysozyme molecule. [Drawn from 3HFL, 1DQJ, and 1FDL.pdb.]

Numerous van der Waals interactions, such as those made by a tryptophan side chain, also stabilize this complex.

Residues from five CDRs participate in the binding of phosphorylcholine to human  $F_{ab}$ . This binding does not significantly change the structure of the antibody, yet induced fit plays a role in the formation of many antibody–antigen complexes. A malleable binding site can accommodate many more kinds of ligands than can a rigid one. Thus, induced fit increases the repertoire of antibody specificities.

### Large antigens bind antibodies with numerous interactions

How do large antigens interact with antibodies? A large collection of antibodies against hen egg-white lysozyme has been structurally characterized in great detail (Figure 34.15). Each different antibody binds to a distinct surface of lysozyme. Let us examine the interactions in one of these complexes (complex ii in Figure 34.15) in detail. This antibody binds two polypeptide segments of lysozyme that are widely separated in the primary structure (Figure 34.16).

All six CDRs of the antibody make contact with this epitope. The region of contact is quite extensive (about  $30 \times 20 \text{ \AA}$ ). The apposed surfaces are rather flat. The only exception is the side chain of glutamine 121 of lysozyme, which penetrates deeply into the antibody's binding site, where it forms a hydrogen bond with a main-chain carbonyl oxygen atom and is surrounded by three aromatic side chains. The formation of 12 hydrogen bonds and numerous van der Waals interactions contributes to the high affinity ( $K_d = 20 \text{ nM}$ ) of this antibody–antigen interaction. Examination of the  $F_{ab}$  molecule without bound protein reveals that the structures of the  $V_L$  and  $V_H$  domains change little on binding, although they slide  $1 \text{ \AA}$  apart to allow more intimate contact with lysozyme.

**FIGURE 34.16 Antibody–protein interactions.** Notice that a single residue of lysozyme, glutamine 121, penetrates more deeply into the antibody binding site. [Drawn from 1FDL.pdb.]

### 34.3 Diversity Is Generated by Gene Rearrangements

A mammal such as a mouse or a human being can synthesize large amounts of specific antibody against virtually any foreign determinant within a matter of days after exposure. We have seen that antibody specificity is determined by the amino acid sequences of the variable regions of both light and heavy chains, which brings us to the key question: How are different variable-region sequences generated?

The discovery of distinct variable and constant regions in the L and H chains raised the possibility that the genes that encode immunoglobulins have an unusual architecture that facilitates the generation of a diverse set of polypeptide products. In 1965, William Dreyer and Claude Bennett proposed that multiple *V* (*variable*) genes are separate from a single *C* (*constant*) gene in embryonic (germ-line) DNA. According to their model, one of these *V* genes becomes joined to the *C* gene in the course of differentiation of the antibody-producing cell. A critical test of this novel hypothesis had to await the isolation of pure immunoglobulin mRNA and the development of techniques for analyzing mammalian genomes. Twenty years later, Susumu Tonegawa found that *V* and *C* genes are indeed far apart in embryonic DNA but are closely associated in the DNA of antibody-producing cells. Thus, immunoglobulin genes are rearranged in the differentiation of lymphocytes.

#### J (joining) genes and D (diversity) genes increase antibody diversity

Sequencing studies carried out by Susumu Tonegawa, Philip Leder, and Leroy Hood revealed that *V* genes in embryonic cells do not encode the entire variable region of L and H chains. Consider, for example, the region that encodes the  $\kappa$  light-chain family. A tandem array of 40 segments, each of which encodes approximately the first 97 residues of the variable domain of the L chain, is present on human chromosome 2 (Figure 34.17).

However, the variable region of the L chain contains 110 residues. Where is the DNA that encodes the last 13 residues of the variable domain? For L chains in undifferentiated cells, this stretch of DNA is located in an unexpected place: near the *C* gene. It is called the *J* gene because it joins the *V* and *C* gene segments in a differentiated cell. In fact, a tandem array of five *J* gene segments is located near the *C* gene in embryonic cells. In the differentiation of an antibody-producing cell, a *V* gene segment is joined to a *J* gene segment to form a complete gene for the variable region (Figure 34.18). RNA splicing (Section 29.3) generates an mRNA molecule for the complete

**FIGURE 34.17** The  $\kappa$  light-chain locus.

This part of human chromosome 2 includes an array of 40 segments that encode the variable (*V*) region (approximately residues 1–97) of the light chain, an array of 5 segments that encode the joining (*J*) region (residues 98–110), and a single region that encodes the constant (*C*) region.

**FIGURE 34.18** VJ recombination. A single *V* gene (in this case,  $V_2$ ) is linked to a *J* gene (here,  $J_4$ ) to form an intact VJ region. The intervening DNA is released in a circular form. Because the *V* and *J* regions are selected at random and the joint between them is not always in exactly the same place, many VJ combinations can be generated by this process.

**FIGURE 34.19 Light-chain expression.** The light-chain protein is expressed by the transcription of the rearranged gene to produce a pre-RNA molecule with the VJ and C regions separated. RNA splicing removes the intervening sequences to produce an mRNA molecule with the VJ and C regions linked. Translation of the mRNA and processing of the initial protein product produce the light chain.

L chain by linking the coding regions for the rearranged VJ unit with that for the C unit (Figure 34.19).

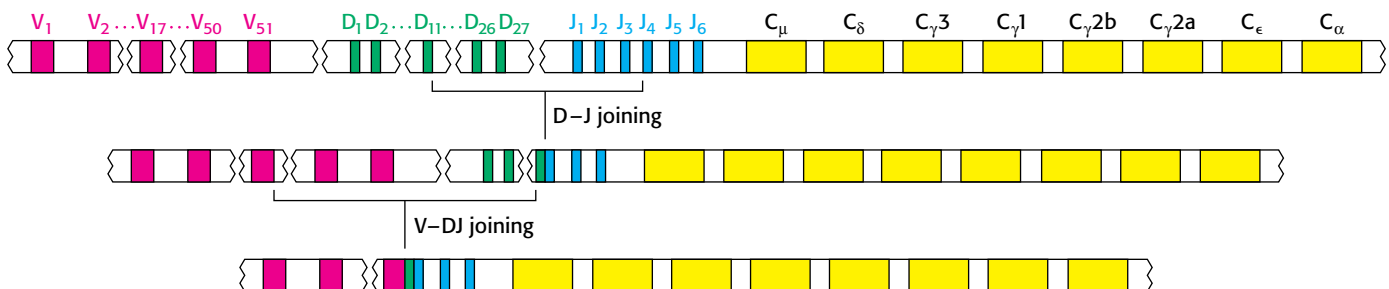

J gene segments are important contributors to antibody diversity because they encode part of the last hypervariable segment (CDR3). In forming a continuous variable-region gene, any of the 40 V gene segments can become linked to any of 5 J gene segments. Thus, somatic recombination of these gene segments amplifies the diversity already present in the germ line. The linkage between V and J is not precisely controlled. Recombination between these genes can take place at one of several bases near the codon for residue 95, generating additional diversity. A similar array of V and J gene segments encoding the  $\lambda$  light chain is present on human chromosome 22. This region includes 30  $V\lambda$  gene segments and four  $J\lambda$  gene segments. In addition, this region includes four distinct C genes, in contrast with the single C gene in the  $\kappa$  locus.

In humans, the genes encoding the heavy chain are present on chromosome 14. Remarkably, the variable domain of heavy chains is assembled from *three* rather than two segments. In addition to  $V_H$  gene segments that encode residues 1 through 94 and  $J_H$  gene segments that encode residues 98 through 113, this chromosomal region includes a distinct set of segments that encode residues 95 through 97 (Figure 34.20). These gene segments are called D (for *diversity*). Some 27 D gene segments lie between 51  $V_H$  and 6  $J_H$  gene segments. The recombination process first joins a D gene segment to a  $J_H$  gene segment; a  $V_H$  gene segment is then joined to  $DJ_H$ . A greater variety of antigen-binding patches and clefts can be formed by the H chain than by the L chain because the H chain is encoded by three rather than two gene segments. Moreover, CDR3 of the H chain is diversified by the action of terminal deoxyribonucleotidyl transferase, a special DNA polymerase that requires no template. This enzyme inserts extra nucleotides between  $V_H$  and D. The  $V(D)J$  recombination of both the L and the H chains is executed by specific enzymes present in immune cells. These proteins, called *RAG-1* and *RAG-2*, recognize specific DNA sequences called *recombination signal sequences* (RSSs) adjacent to the V, D, and J gene segments and facilitate the cleavage and religation of the DNA segments.

### More than $10^8$ antibodies can be formed by combinatorial association and somatic mutation

Let us recapitulate the sources of antibody diversity. The germ line contains a rather large repertoire of variable-region genes. For  $\kappa$  light chains, there are about 40 V-segment genes and 5 J-segment genes. Hence, a total of  $40 \times 5 = 200$  kinds of complete  $V_\kappa$  genes can be formed by the combinations of V and J. A similar analysis suggests that at least 120 different  $\lambda$  light chains can be generated. A larger number of heavy-chain genes can be formed because of the role of the D segments. For 51 V, 27 D, and 6 J gene segments, the number of complete  $V_H$  genes that can be formed is 8262. The association of 320 kinds of L chains with 8262 kinds of H chains would yield  $2.6 \times 10^6$

**FIGURE 34.20 V(D)J recombination.** The heavy-chain locus includes an array of 51 V segments, 27 D segments, and 6 J segments. Gene rearrangement begins with D–J joining, followed by further rearrangement to link the V segment to the DJ segment.

different antibodies. Variability in the exact points of segment joining and other mechanisms increases this value by at least two orders of magnitude.

Even more diversity is introduced into antibody chains by *somatic mutation*—that is, by the introduction of mutations into the recombined genes. In fact, a 1000-fold increase in binding affinity is seen in the course of a typical humoral immune response, arising from somatic mutation, a process called *affinity maturation*. The generation of an expanded repertoire leads to the selection of antibodies that more precisely fit the antigen. Thus, nature draws on each of three sources of diversity—a germ-line repertoire, somatic recombination, and somatic mutation—to form the rich variety of antibodies that protect an organism from foreign incursions.

### The oligomerization of antibodies expressed on the surfaces of immature B cells triggers antibody secretion

The processes heretofore described generate a highly diverse set of antibody molecules—a key first step in the generation of an immune response. The next stage is the selection of a particular set of antibodies directed against a specific invader. How is this selection accomplished? Each immature B cell, produced in the bone marrow, expresses a specific monomeric form of IgM attached to its surface (Figure 34.21). Each cell expresses approximately  $10^5$  IgM molecules, but *all of these molecules are identical in amino acid sequence and, hence, in antigen-binding specificity*. Thus, the selection of a particular immature B cell for growth will lead to the amplification of an antibody with a unique specificity. The selection process begins with the binding of an antigen to the membrane-bound antibody.

Associated with each membrane-linked IgM molecule are two molecules of a heterodimeric membrane protein called Ig- $\alpha$ -Ig- $\beta$  (Figure 34.21). Examination of the amino acid sequences of Ig- $\alpha$  and Ig- $\beta$  is highly instructive. The amino terminus of each protein lies outside the cell and corresponds to a single immunoglobulin fold, and the carboxyl terminus, which lies inside the cell, includes a sequence of 18 amino acids called an *immunoreceptor tyrosine-based activation motif* (ITAM; Figure 34.21). As its name suggests, each ITAM includes key tyrosine residues, which are subject to phosphorylation by particular protein kinases present in immune-system cells.

A fundamental observation linking the binding of antigen to membrane-bound antibody with the subsequent initiation of an immune response is that *oligomerization, or clustering, of the antibody molecules is required* (Figure 34.22). The requirement for oligomerization is reminiscent of the dimerization of receptors triggered by epidermal growth factor and insulin encountered in Section 14.3; indeed, the associated signaling mechanisms appear to be quite similar. The oligomerization of the membrane-bound antibodies results in the phosphorylation of the tyrosine residues within the ITAMs by protein tyrosine kinases including Lyn, a homolog of Src (Section 14.5). The phosphorylated ITAMs serve as docking sites for a protein kinase termed spleen tyrosine kinase (Syk), which has two SH2 domains that interact with the pair of phosphorylated tyrosine residues in each ITAM. Docked Syk adopts an active conformation, which then phosphorylates other signal-transduction proteins, including an inhibitory subunit of the transcription factor NF- $\kappa$ B and

**FIGURE 34.21 B-cell receptor.** This complex consists of a membrane-bound IgM molecule noncovalently bound to two Ig- $\alpha$ -Ig- $\beta$  heterodimers. The intracellular domains of each of the Ig- $\alpha$  and Ig- $\beta$  chains include an immunoreceptor tyrosine-based activation motif (ITAM).

**FIGURE 34.22 B-cell activation.** The binding of a multivalent antigen such as a bacterial or viral surface links membrane-bound IgM molecules. This oligomerization triggers the phosphorylation of tyrosine residues in the ITAM sequences by protein tyrosine kinases such as Lyn. After phosphorylation, the ITAMs serve as docking sites for Syk, a protein kinase that phosphorylates a number of targets, including transcription factors.

an isoform of phospholipase C. The signaling processes continue downstream to activate gene expression, leading to the stimulation of cell growth and initiating further B-cell differentiation.

Drugs that modulate the immune system have served as sources of insight into immune-system signaling pathways. For example, *cyclosporin*, a powerful suppressor of the immune system, inhibits *calcineurin*, a phosphatase which normally activates a transcription factor called NF-AT by dephosphorylating it.

**Cyclosporin A**

The potent inhibition of the immune system, or *immunosuppression*, induced by cyclosporin reveals how crucial the activity of NF-AT is to the development of an immune response. Without such drugs, organ transplantation would be extremely difficult because transplanted tissue expresses a wide range of foreign antigens, causing the host immune system to reject the new tissue.

The role of oligomerization in the B-cell signaling pathway is illuminated when we consider the nature of many antigens presented by pathogens. The surfaces of many viruses, bacteria, and parasites are characterized by arrays of identical membrane proteins or membrane-linked carbohydrates. Thus, most pathogens present multiple binding surfaces that will naturally cause membrane-associated antibodies to oligomerize as they bind adjacent epitopes. In addition, the mechanism accounts for the observation that most small molecules do not induce an immune response; however, coupling multiple copies of a small molecule to a large oligomeric protein such as keyhole limpet hemocyanin (KLH), which has a molecular mass of 1 million daltons or more, promotes antibody oligomerization and, hence, the production of antibodies against the small-molecule epitope. The large protein is called the *carrier* of the attached chemical group, which is called a *haptenic determinant*. The small foreign molecule by itself is called a *hapten*. Antibodies elicited by attached haptens will bind unattached haptens as well.

### Different classes of antibodies are formed by the hopping of $V_H$ genes

The development of an effective antibody-based immune response depends on the secretion into the blood of antibodies that have appropriate effector functions. At the beginning of this response, an alternative mRNA-splicing pathway is activated so that the production of membrane-linked IgM is

**FIGURE 34.23 Class switching.** Further rearrangement of the heavy-chain locus results in the generation of genes for antibody classes other than IgM. In the case shown, rearrangement places the VDJ region next to the C $\gamma$ 1 region, resulting in the production of IgG1. Note that no further rearrangement of the VDJ region takes place, and so the specificity of the antibody is not affected.

supplanted by the synthesis of secreted IgM. As noted in Section 34.1, secreted IgM is pentameric and has a high avidity for antigens containing multiple identical epitopes. Later, the antibody-producing cell makes either IgG, IgA, IgD, or IgE of the same specificity as that of the initially secreted IgM. In this switch, the light chain and the variable region of the heavy chain are unchanged. Only the constant region of the heavy chain changes. This step in the differentiation of an antibody-producing cell is called *class switching* (Figure 34.23). In undifferentiated cells, the genes for the constant region of each class of heavy chain, called C $\mu$ , C $\delta$ , C $\gamma$ , C $\epsilon$ , and C $\alpha$ , are next to one another. There are eight in all, including four genes for the constant regions of  $\gamma$  chains. A complete transcript for the heavy chain of an IgM antibody is formed by the translocation of a V<sub>H</sub> gene segment to a DJ<sub>H</sub> gene segment within the genomic DNA (Figure 34.20), followed by RNA splicing of the V<sub>H</sub>DJ<sub>H</sub> segment to the C $\mu$  segment, analogous to what is shown in Figure 34.19.

How are other heavy chains formed? Class switching is mediated by a gene-rearrangement process that moves a VDJ gene from a site near one C gene to a site near another C gene. Importantly, *the antigen-binding specificity is conserved in class switching because the entire V<sub>H</sub>DJ<sub>H</sub> gene is translocated in an intact form.* For example, the antigen-combining specificity of IgA produced by a particular cell is the same as that of IgM synthesized at an earlier stage of its development. The biological significance of C<sub>H</sub> switching is that a whole recognition domain (the variable domain) is shifted from the early constant region (C $\mu$ ) to one of several other constant regions that mediate different effector functions.

### 34.4 Major-Histocompatibility-Complex Proteins Present Peptide Antigens on Cell Surfaces for Recognition by T-Cell Receptors

Soluble antibodies are highly effective against extracellular pathogens, but they confer little protection against microorganisms that are predominantly intracellular, such as some viruses and mycobacteria (which cause tuberculosis and leprosy). These pathogens are shielded from antibodies by the host-cell membrane (Figure 34.24). A different and more subtle strategy, *cell-mediated immunity*, evolved to cope with intracellular pathogens. *T cells* continually scan the surfaces of all cells and kill those that exhibit foreign markings. The task is not simple; intracellular microorganisms are not so obliging as to intentionally leave tell-tale traces on the surface of their host. Quite the contrary, successful pathogens are masters of the art of camouflage. Vertebrates have evolved an ingenious mechanism—cut and display—to reveal the presence of stealthy intruders. Nearly all vertebrate cells exhibit on their surfaces a sample of peptides derived from the digestion of proteins in their cytoplasm. These peptides are

**FIGURE 34.24 Intracellular pathogen.** An electron micrograph showing mycobacteria (arrows) inside an infected macrophage. [Courtesy of Dr. Stanley Falkow.]

**FIGURE 34.25 Presentation of peptides from cytoplasmic proteins.** Class I MHC proteins on the surfaces of most cells display peptides that are derived from cytoplasmic proteins by proteolysis.

displayed by integral membrane proteins that are encoded by the *major histocompatibility complex* (MHC). Specifically, peptides derived from cytoplasmic proteins are bound to and displayed by *class I MHC proteins*. The dendritic cells of the innate immune system that subject pathogens to phagocytosis migrate to lymphatic tissue, where they use an MHC-like mechanism to present foreign peptides or lipid components to T cells—thus linking the innate and adaptive immune responses to pathogens.

How are these peptides generated and delivered to the plasma membrane? The process starts in the cytoplasm with the degradation of proteins—self-proteins as well as those of pathogens (Figure 34.25). Digestion is carried out by proteasomes (Section 23.2). The resulting peptide fragments are transported from the cytoplasm into the lumen of the endoplasmic reticulum by the *TAP protein* (for transporter associated with antigen processing), a member of the ABC transporter family of ATP-driven pumps (Section 13.2). In the ER, peptides combine with nascent class I MHC proteins; these complexes are then targeted to the plasma membrane.

MHC proteins embedded in the plasma membrane tenaciously grip their bound peptides so that they can be touched and scrutinized by T-cell receptors on the surface of a killer cell. Foreign peptides bound to class I MHC proteins signal that a cell is infected and mark it for destruction by cytotoxic T cells. An assembly consisting of the foreign peptide—MHC complex, the T-cell receptor, and numerous accessory proteins—triggers a cascade that induces apoptosis in the infected cell. Strictly speaking, infected cells are not killed but, instead, are triggered to commit suicide to benefit the host.

**FIGURE 34.26 Class I MHC protein.** A protein of this class consists of two chains. Notice that the  $\alpha$  chain begins with two domains ( $\alpha_1$ ,  $\alpha_2$ ) that include  $\alpha$  helices and continues with an immunoglobulin domain ( $\alpha_3$ ), a transmembrane domain, and a cytoplasmic tail. The second chain,  $\beta_2$ -microglobulin, adopts an immunoglobulin fold. [Drawn from 1HHK.pdb.]

### Peptides presented by MHC proteins occupy a deep groove flanked by alpha helices

The three-dimensional structure of a large extracellular fragment of a human MHC class I protein, *human leukocyte antigen A2* (HLA-A2), was solved in 1987 by Don Wiley and Pamela Bjorkman. Class I MHC proteins consist of a 44-kDa  $\alpha$  chain noncovalently bound to a 12-kDa polypeptide called  $\beta_2$ -microglobulin. The  $\alpha$  chain has three extracellular domains ( $\alpha_1$ ,  $\alpha_2$ , and  $\alpha_3$ ), a transmembrane segment, and a tail that extends into the cytoplasm (Figure 34.26). The  $\beta_2$ -microglobulin and the  $\alpha_3$  domains have immunoglobulin folds, although the pairing of the two domains differs

**FIGURE 34.27 Class I MHC peptide-binding site.** The  $\alpha_1$  and  $\alpha_2$  domains come together to form a groove in which peptides are displayed. Notice that the peptide is surrounded on three sides by a  $\beta$  sheet and two  $\alpha$  helices, but it is accessible from the top of the structure. [Drawn from 1HHK.pdb.]

from that in antibodies. The  $\alpha_1$  and  $\alpha_2$  domains exhibit a novel and remarkable architecture. They associate intimately to form a deep groove that serves as the peptide-binding site (Figure 34.27). The floor of the groove, which is about 25 Å long and 10 Å wide, is formed by eight  $\beta$  strands, four from each domain. A long helix contributed by the  $\alpha_1$  domain forms one side, and a helix contributed by the  $\alpha_2$  domain forms the other side. *This groove is the binding site for the presentation of peptides.*

The groove can be filled by a peptide from 8 to 10 residues long in an extended conformation. As we shall see (p. 1002), MHC proteins are remarkably diverse in the human population; each person expresses as many as six distinct class I MHC proteins, and many different forms are present in different people. The first structure determined, HLA-A2, binds peptides that almost always have leucine in the second position and valine in the last position (Figure 34.28). Side chains from the MHC molecule interact with the amino and carboxyl termini and with the side chains in these two key positions. These two residues are often referred to as the *anchor residues*. The other residues are highly variable. Thus, many millions of different peptides can be presented by this particular class I MHC protein; the

**FIGURE 34.28 Anchor residues.** (A) The amino acid sequences of three peptides that bind to the class I MHC protein HLA-A2 are shown. Each of these peptides has leucine in the second position and valine in the carboxyl-terminal position. (B) Comparison of the structures of these peptides reveals that the amino and carboxyl termini, as well as the side chains of the leucine and valine residues, are in essentially the same positions in each peptide, whereas the remainder of the structures are quite different.

**FIGURE 34.29 T-cell receptor.** This protein consists of an  $\alpha$  chain and a  $\beta$  chain, linked by a disulfide bond. Notice that each chain consists of two immunoglobulin domains on the cell surface, a membrane-spanning domain, and a short cytoplasmic tail. [Drawn from 1BD2.pdb.]

**FIGURE 34.30 T-cell receptor–class I MHC complex.** The T-cell receptor binds to a class I MHC protein containing a bound peptide (red). Notice that the T-cell receptor contacts both the MHC protein and the peptide. [Drawn from 1BD2.pdb.]

identities of only two of the nine residues are crucial for binding. Each class of MHC molecules requires a unique set of anchor residues. Thus, a tremendous range of peptides can be presented by these molecules. Note that *one face of the bound peptide is exposed to solution, where it can be examined by other molecules, particularly T-cell receptors.* An additional remarkable feature of MHC–peptide complexes is their kinetic stability; once bound, a peptide is not released, even after a period of days.

### T-cell receptors are antibody-like proteins containing variable and constant regions

We are now ready to consider the receptor that recognizes peptides displayed by MHC proteins on target cells. The *T-cell receptor* consists of a 43-kDa  $\alpha$  chain joined by a disulfide bond to a 43-kDa  $\beta$  chain (Figure 34.29). Each chain spans the plasma membrane and has a short carboxyl-terminal region on the cytoplasmic side. A small proportion of T cells express a receptor consisting of  $\gamma$  and  $\delta$  chains in place of  $\alpha$  and  $\beta$ . The  $\alpha$  and  $\beta$  chains of the T-cell receptor, like immunoglobulin L and H chains, consist of *variable* and *constant* regions. Indeed, *these domains of the T-cell receptor are homologous to the V and C domains of immunoglobulins.* Furthermore, hypervariable sequences present in the V regions of the  $\alpha$  and  $\beta$  chains of the T-cell receptor form the binding site for the epitope.

The genetic architecture of these proteins is similar to that of immunoglobulins, though the antibody genetic diversity is distributed over all the CDR loops, whereas T-cell-receptor genetic diversity is concentrated in the CDR3 loop that interacts with the peptide bound to the MHC. The variable region of the T-cell receptor  $\alpha$  chain is encoded by about 50 V gene segments and 70 J gene segments. The T-cell receptor  $\beta$  chain is encoded by two D gene segments in addition to 57 V gene segments and 13 J gene segments. Again, the diversity of gene segments and the use of slightly imprecise modes of joining them increase the number of distinct proteins formed. *At least  $10^{12}$  different specificities could arise from combinations of this repertoire of genes.* Thus, T-cell receptors, like immunoglobulins, can recognize a very large number of different epitopes. All the receptors on a particular T cell have the same specificity.

How do T cells recognize their targets? The variable regions of the  $\alpha$  and  $\beta$  chains of the T-cell receptor form a binding site that recognizes a combined epitope–foreign peptide bound to an MHC protein (Figure 34.30). Neither the foreign peptide alone nor the MHC protein alone forms a complex with the T-cell receptor. Thus, fragments of an intracellular pathogen are presented in a context that allows their detection, leading to the initiation of an appropriate response.

### CD8 on cytotoxic T cells acts in concert with T-cell receptors

The T-cell receptor does not act alone in recognizing and mediating the fate of target cells. Cytotoxic T cells also express a protein termed *CD8* on their surfaces that is crucial for the recognition of the class I MHC–peptide complex. The abbreviation CD stands for *cluster of differentiation*, referring to a cell-surface marker that is used to identify a lineage or stage of differentiation. Antibodies specific for particular CD proteins have been invaluable in following the development of leukocytes and in discovering new interactions between specific cell types.

Each chain in the CD8 dimer contains a domain that resembles an immunoglobulin variable domain (Figure 34.31). CD8 interacts primarily with the constant  $\alpha_3$  domain of class I MHC proteins. This interaction further stabilizes the interactions between the T cell and its target.

**FIGURE 34.31 The coreceptor CD8.**

This dimeric protein extends from the surface of a cytotoxic T cell and binds to class I MHC molecules that are expressed on the surface of the cell that is bound to the T cell. The dashed lines represent extended polypeptide chains that link the immunoglobulin domains of CD8 to the membrane. Notice that the coreceptor interacts primarily with the constant  $\alpha_3$  domain of the class I MHC domain. [Drawn from 1AKJ.pdb.]

The cytoplasmic tail of CD8 contains a docking site for Lck, a cytoplasmic tyrosine kinase akin to Src. The T-cell receptor itself is associated with six polypeptides that form the CD3 complex (Figure 34.32). The  $\gamma$ ,  $\delta$ , and  $\epsilon$  chains of CD3 are homologous to Ig- $\alpha$  and Ig- $\beta$  associated with the B-cell receptor (Figure 34.21); each chain consists of an extracellular immunoglobulin domain and an intracellular ITAM region. These chains associate into CD3- $\gamma\epsilon$  and CD3- $\delta\epsilon$  heterodimers. An additional component, the CD3- $\zeta$  chain, has only a small extracellular domain and a larger intracellular domain containing three ITAM sequences.

On the basis of these components, a model for T-cell activation can be envisaged that is closely parallel to the pathway for B-cell activation (Section 34.3; Figure 34.33). The binding of the T-cell receptor to the class I MHC–peptide complex and the concomitant binding of CD8 from the T cell to the MHC molecule link the kinase Lck to the ITAM substrates of the components of the CD3 complex. The phosphorylation of the tyrosine residues in the ITAM sequences generates docking sites for a protein kinase called ZAP-70 (for 70-kDa zeta-associated protein) that is homologous to Syk in B cells. Docked by its two SH2 domains, ZAP-70 phosphorylates

**FIGURE 34.32 T-cell receptor complex.**

The T-cell receptor is associated with six CD3 molecules: a CD3- $\gamma$ -CD3- $\epsilon$  heterodimer, a CD3- $\delta$ -CD3- $\epsilon$  heterodimer, and two chains of CD3- $\zeta$ . Single ITAM sequences are present in the cytoplasmic domains of CD3- $\gamma$ , CD3- $\delta$ , and CD3- $\epsilon$ , whereas three such sequences are found in each CD3- $\zeta$  chain.

**FIGURE 34.33 T-cell activation.**

The interaction between the T-cell receptor and a class I MHC–peptide complex results in the binding of CD8 to the MHC protein, the recruitment of the protein tyrosine kinase Lck, and the phosphorylation of tyrosine residues in the ITAM sequences of the CD3 chains. After phosphorylation, the ITAM regions serve as docking sites for the protein kinase ZAP-70, which phosphorylates protein targets to transmit the signal.

downstream targets in the signaling cascade. Additional molecules, including a membrane-bound protein phosphatase called CD45 and a cell-surface protein called CD28, play ancillary roles in this process.

T-cell activation has two important consequences. First, the activation of cytotoxic T cells results in the secretion of several proteins, including *perforin* and *granzymes*. Perforin is a 70-kDa protein that destabilizes the plasma membrane of the target cell, enabling the entry of *granzymes* into the cytoplasm of the target cell. Granzymes are serine proteases (Section 9.1) that initiate the pathway of apoptosis, leading to the death of the target cell and the fragmentation of its DNA, including any viral DNA that may be present. Second, after it has stimulated its target cell to commit suicide, the activated T cell disengages and is stimulated to reproduce. Thus, additional T cells that express the same T-cell receptor are generated to continue the battle against the invader after these T cells have been identified as a suitable weapon.

### Helper T cells stimulate cells that display foreign peptides bound to class II MHC proteins

Not all T cells are cytotoxic. *Helper T cells* stimulate the proliferation of specific B lymphocytes and cytotoxic T cells and thereby serve as partners in determining the immune responses that are produced. The importance of helper T cells is graphically revealed by the devastation wrought by AIDS, a condition that destroys these cells. Helper T cells, like cytotoxic T cells, detect foreign peptides that are presented on cell surfaces by MHC proteins. However, the source of the peptides, the MHC proteins that bind them, and the transport pathway are different.

Helper T cells recognize peptides bound to MHC molecules referred to as class II. Their helping action is focused on B cells, macrophages, and dendritic cells. *Class II MHC proteins are expressed only by these antigen-presenting cells*, unlike class I MHC proteins, which are expressed on nearly all cells. The peptides presented by class II MHC proteins do not come from the cytoplasm. Rather, *they arise from the degradation of proteins that have been internalized by endocytosis*. Consider, for example, a virus particle that is captured by membrane-bound immunoglobulins on the surface of a B cell (Figure 34.34). This complex is delivered to an endosome, a membrane-enclosed acidic compartment, where it is digested. The resulting peptides become associated with class II MHC proteins, which move to the cell surface. Peptides from the cytoplasm cannot reach class II proteins, whereas peptides from endosomal compartments cannot reach class I proteins. This segregation of displayed peptides is biologically critical. The association of a foreign peptide with a class II MHC protein signals that a cell has *encountered* a pathogen and serves as a call for *help*. In contrast, association with a class I MHC protein signals that a cell has *succumbed* to a pathogen and is a call for *destruction*.

**FIGURE 34.34 Presentation of peptides from internalized proteins.** Antigen-presenting cells bind and internalize foreign proteins and display peptides that are formed from the digestion of these proteins in class II MHC proteins.

### Helper T cells rely on the T-cell receptor and CD4 to recognize foreign peptides on antigen-presenting cells

The overall structure of a class II MHC molecule is remarkably similar to that of a class I molecule. Class II molecules consist of a 33-kDa  $\alpha$  chain and a noncovalently bound 30-kDa  $\beta$  chain (Figure 34.35). Each contains two extracellular domains, a transmembrane segment, and a short cytoplasmic tail. The peptide-binding site is formed by the  $\alpha_1$  and  $\beta_1$  domains, each of

**FIGURE 34.35 Class II MHC protein.** A class II MHC protein consists of homologous  $\alpha$  and  $\beta$  chains, each of which has an amino-terminal domain that constitutes half of the peptide-binding structure, as well as a carboxyl-terminal immunoglobulin domain. Notice the trough-like peptide-binding site, which is similar to that in class I MHC proteins except that it is open at both ends, allowing class II MHC proteins to bind longer peptides than those bound by class I. [Drawn from 1DLH.pdb.]

which contributes a long helix and part of a  $\beta$  sheet. Thus, the same structural elements are present in class I and class II MHC molecules, but they are combined into polypeptide chains in different ways. The peptide-binding site of a class II molecule is open at both ends, and so this groove can accommodate longer peptides than can be bound by class I molecules; typically, peptides between 13 and 18 residues long are bound. The peptide-binding specificity of each class II molecule depends on binding pockets that recognize particular amino acids, also known as anchor residues, in specific positions along the sequence.

Helper T cells express T-cell receptors that are produced from the same genes as those on cytotoxic T cells. These T-cell receptors interact with class II MHC molecules in a manner that is analogous to T-cell-receptor interaction with class I MHC molecules. Nonetheless, helper T cells and cytotoxic T cells are distinguished by other proteins that they express on their surfaces. In particular, helper T cells express a protein called *CD4* instead of expressing *CD8*. *CD4* consists of four immunoglobulin domains that extend from the T-cell surface, as well as a small cytoplasmic region (Figure 34.36). The amino-terminal immunoglobulin domains of *CD4* interact with the base on the class II MHC molecule. Thus, helper T cells bind cells expressing class II MHC specifically because of the interactions with *CD4* (Figure 34.37).

**FIGURE 34.36 Coreceptor CD4.** This protein comprises four tandem immunoglobulin domains that extend from the surface of a helper T cell. [Drawn from 1WIO.pdb.]

**FIGURE 34.37 Variations on a theme.** (A) Cytotoxic T cells recognize foreign peptides presented in class I MHC proteins with the aid of the coreceptor *CD8*. (B) Helper T cells recognize peptides presented in class II MHC proteins by specialized antigen-presenting cells with the aid of the coreceptor *CD4*.

**FIGURE 34.38 Helper-T-cell action.** The engagement of the T-cell receptor in helper T cells results in the secretion of cytokines. These cytokines bind to cytokine receptors expressed on the surface of the antigen-presenting cell, stimulating cell growth, differentiation, and, in regard to a B cell, antibody secretion.

When a helper T cell binds to an antigen-presenting cell expressing an appropriate class II MHC–peptide complex, signaling pathways analogous to those in cytotoxic T cells are initiated by the action of the kinase Lck on ITAMs in the CD3 molecules associated with the T-cell receptor. However, rather than triggering events leading to the death of the attached cell, *these signaling pathways result in the secretion of cytokines from the helper cell.* Cytokines are a family of molecules that include, among others, interleukin-2 and interferon- $\gamma$ . Cytokines bind to specific receptors on the antigen-presenting cell and stimulate its growth and differentiation (Figure 34.38). For example, these cytokines stimulate the differentiation of B cells into *plasma cells*, which specialize in the production of large amounts of antibody. Thus, the internalization and presentation of parts of a foreign pathogen help to generate a local environment in which cells taking part in the defense against this pathogen can flourish through the action of helper T cells.

### MHC proteins are highly diverse

MHC class I and II proteins, the presenters of peptides to T cells, were discovered because of their role in *transplantation rejection*. A tissue transplanted from one person to another or from one mouse to another is usually rejected by the immune system. In contrast, tissues transplanted from one identical twin to another or between mice of an inbred strain are accepted. Genetic analyses revealed that rejection occurs when tissues are transplanted between individual organisms having different genes in the major histocompatibility complex, a cluster of more than 75 genes playing key roles in immunity. The 3500-kb span of the MHC is nearly the length of the entire *E. coli* chromosome. The MHC encodes class I proteins (presenters to cytotoxic T cells) and class II proteins (presenters to helper T cells), as well as class III proteins (components of the complement cascade) and many other proteins that play key roles in immunity.

Human beings express six different class I genes (three from each parent) and six different class II genes. The three loci for class I genes are called HLA-A, -B, and -C; those for class II genes are called HLA-DP, -DQ, and -DR. These loci are *highly polymorphic*: many alleles of each are present in

the population. For example, more than 50 each of HLA-A, -B, and -C alleles are known; the numbers discovered increase each year. Hence, the likelihood that two unrelated persons have identical class I and II proteins is very small ( $<10^{-4}$ ), accounting for transplantation rejection unless the genotypes of donor and acceptor are closely matched in advance.

Differences between class I proteins are located mainly in the  $\alpha_1$  and  $\alpha_2$  domains, which form the peptide-binding site (Figure 34.39). The  $\alpha_3$  domain, which interacts with a constant  $\beta_2$ -microglobulin, is largely conserved. Similarly, the differences between class II proteins cluster near the peptide-binding groove. Why are MHC proteins so highly variable? *Their diversity makes the presentation of a very wide range of peptides to T cells possible. A particular class I or class II molecule may not be able to bind any of the peptide fragments of a viral protein. The likelihood of a fit is markedly increased by having several kinds (usually six) of each class of presenters in each individual organism. If all members of a species had identical class I or class II molecules, the population would be much more vulnerable to devastation by a pathogen that had mutated and thereby evaded presentation. The evolution of the diverse human MHC repertoire has been driven by the selection for individual members of the species who resist infections to which other members of the population may be susceptible.*

**FIGURE 34.39 Polymorphism in class I MHC proteins.** Notice that the positions of sites with a high degree of polymorphism in the human population are displayed as red spheres on the structure of the amino-terminal part of a class I MHC protein. [Drawn from 1HHK.pdb.]

### Human immunodeficiency viruses subvert the immune system by destroying helper T cells

In 1981, the first cases of a new disease now called *acquired immune deficiency syndrome* (AIDS) were recognized. The victims died of rare infections because their immune systems were crippled. The cause was identified 2 years later by Luc Montagnier and coworkers. AIDS is produced by *human immunodeficiency virus* (HIV), of which two major classes are known: HIV-1 and the much less common HIV-2. Like other *retroviruses*, HIV contains a single-stranded RNA genome that is replicated through a double-stranded DNA intermediate. This viral DNA becomes integrated into the genome of the host cell. In fact, viral genes are transcribed only when they are integrated into the host DNA.

The HIV virion is enveloped by a lipid-bilayer membrane containing two glycoproteins: gp41 spans the membrane and is associated with gp120, which is located on the external face (Figure 34.40). The core of the virus contains two copies of the RNA genome and associated transfer RNAs, as well as several molecules of reverse transcriptase. They are surrounded by many copies of two proteins called p17 and p24. *The host cell for HIV is the helper T cell.* The gp120 molecules on the membrane of HIV bind to CD4 molecules on the surface of the helper T cell (Figure 34.41). This interaction allows the associated viral gp41 to insert its amino-terminal head into the host-cell membrane. The viral membrane and the helper-T-cell membrane fuse, and the viral core is released directly into the cytoplasm. Infection by

**FIGURE 34.40 Human immunodeficiency virus.** A schematic representation of HIV reveals its proteins and nucleic acid components. [Information from G. B. Karlsson Hedestam et al., *Nat. Rev. Microbiol.* 6:143–155, 2008, Fig. 2a.]

**FIGURE 34.41 HIV receptor.** A complex between a modified form of the envelope glycoprotein gp120 from HIV and a peptide corresponding to the two amino-terminal domains from the helper-T-cell protein CD4 reveals how viral infection of helper T cells is initiated. [Drawn from 1GC1.pdb.]

HIV leads to the destruction of helper T cells because the permeability of the host plasma membrane is markedly increased by the insertion of viral glycoproteins and the budding of virus particles. The influx of ions and water disrupts the ionic balance, causing osmotic lysis.

### 34.5 The Immune System Contributes to the Prevention and the Development of Human Diseases

The primary function of the immune system is to protect the host from invasion by foreign organisms. But how does the immune system prevent itself from mounting attacks against its host? In other words, how does the immune system distinguish between self and nonself? Clearly, proteins from the organism itself do not bear some special tag identifying them. Instead, selection processes early in the developmental pathways for immune cells kill or suppress those immune cells that react strongly with self-antigens. The evolutionary paradigm still applies; immune cells that recognize self-antigens are generated, but selective mechanisms eliminate such cells in the course of development.

#### T cells are subjected to positive and negative selection in the thymus

T cells derive their name from the location of their production—the thymus, a small organ situated just above the heart. Examination of the developmental pathways leading to the production of mature cytotoxic and helper T cells reveals the selection mechanisms that are crucial for distinguishing self from nonself. These selection criteria are quite stringent; approximately 98% of the thymocytes, the precursors of T cells, die before the completion of the maturation process.

Thymocytes produced in the bone marrow do not express the T-cell receptor complex, CD4, or CD8. On relocation to the thymus and rearrangement of the T-cell-receptor genes, the immature thymocyte expresses all of these molecules. These cells are first subjected to *positive selection* (Figure 34.42). Cells for which the T-cell receptor can bind with reasonable affinity to either class I or class II MHC molecules survive this selection; those for which the T-cell receptor does not participate in such an interaction undergo apoptosis and die. *The role of the positive selection step is to prevent the production of T cells that will not bind to any MHC complex present, regardless of the peptide bound.*

The cell population that survives positive selection is subjected to a second step, *negative selection*. Here, T cells that bind with high affinity to MHC complexes bound to self-peptides expressed on the surfaces of

**FIGURE 34.42 T cell selection.**

A population of thymocytes is subjected first to positive selection to remove cells that express T-cell receptors that will not bind to MHC proteins expressed by the individual organism. The surviving cells are then subjected to negative selection to remove cells that bind strongly to MHC complexes bound to self-peptides.

**FIGURE 34.43 Consequences of autoimmunity.** Photomicrographs of an islet of Langerhans (A) in the pancreas of a normal mouse and (B) in the pancreas of a mouse with an immune response against pancreatic  $\beta$  cells, which results in a disease resembling insulin-dependent diabetes mellitus in human beings. Notice that the relatively pale cellular area in the center of part A is populated with the dark nuclei of inflammatory cells in part B. [From M. A. Atkinson and N. K. Maclaren. What causes diabetes? *Scientific American*, 1990. Courtesy Mark Atkinson.]

antigen-presenting cells in the thymus undergo apoptosis or are otherwise suppressed. Those that do not bind too avidly to any such MHC complex complete development and become mature cytotoxic T cells (which express only CD8) or helper T cells (which express only CD4). The negative selection step leads to *self-tolerance*; cells that bind an MHC–self-peptide complex are removed from the T-cell population. Similar mechanisms apply to developing B cells: maturing B cells that express antibodies that interact strongly with self-antigens are suppressed.

### Autoimmune diseases result from the generation of immune responses against self-antigens

Although thymic selection is remarkably efficient in suppressing the immune response to self-antigens, failures do occur. Such failures result in *autoimmune diseases*. These diseases include common illnesses such as insulin-dependent diabetes mellitus, multiple sclerosis, and rheumatoid arthritis. In these illnesses, immune responses against self-antigens result in damage to selective tissues that express the antigen (Figure 34.43).

In many cases, the cause of the generation of self-reactive antibodies or T cells is unclear. However, in other cases, infectious organisms such as bacteria or viruses may play a role. Infection leads to the generation of antibodies and T cells that react with many different epitopes from the infectious organism. If one of these antigens closely resembles a self-antigen, an autoimmune response can result. For example, *Streptococcus* infections sometimes lead to rheumatic fever owing to the production of antibodies to streptococcal antigens that cross-react with exposed epitopes in heart muscle.

### The immune system plays a role in cancer prevention

The development of immune responses against proteins encoded by our own genomes can be beneficial in some circumstances. Cancer cells have undergone significant changes that often result in the production of proteins that are not normally expressed. For example, the mutation of genes can generate proteins that do not correspond in amino acid sequence to any normal protein. Such proteins may be recognized as foreign, and an immune response will be generated specifically against the cancer cell. Alternatively, cancer cells often produce proteins that are expressed during

embryonic development but are not expressed or are expressed at very low levels after birth. For example, a membrane glycoprotein called *carcinoembryonic antigen* (CEA) appears in the gastrointestinal cells of developing fetuses but is not normally expressed at significant levels after birth. More than 50% of patients with colorectal cancer have elevated serum levels of CEA. Immune cells recognizing epitopes from such proteins will not be subjected to negative selection and, hence, will be present in the adult immune repertoire. These cells may play a cancer surveillance role, killing cells that overexpress antigens such as CEA and preventing genetically damaged cells from developing into tumors.

### Vaccines are a powerful means to prevent and eradicate disease

The discovery and utilization of *vaccines*, biological preparations that stimulate immunity to a particular pathogen or disease, represents a significant milestone in modern medical history. The pioneering work of Edward Jenner and Louis Pasteur in the eighteenth and nineteenth centuries revealed that inoculation with inactivated forms of a pathogen could protect against subsequent infection with the active pathogen. Treatment of a person with a vaccine, or *immunization*, leads to the development of *immunological memory*, the ability of the immune system to respond more rapidly and effectively to pathogens that have been encountered previously. At the cellular level, memory arises because positively selected B cells and T cells that have a high affinity for their target persist within the organism as *memory B cells* and *memory T cells*.

In order for a vaccine to be effective, it must generate a sustained protective response appropriate for the targeted pathogen. For example, pathogens such as *Clostridium tetani*, the causative agent of tetanus, cause disease by the release of destructive proteins called *toxins*. Hence, an effective tetanus vaccine should generate a strong B-cell-mediated response. In contrast, a vaccine designed to prevent disease caused by an intracellular pathogen should generate a strong T-cell-mediated response. The active component of a vaccine that is responsible for stimulating this immune response can take many forms:

*Killed or inactivated vaccines* contain pathogens that have been rendered harmless by treatment with chemicals or high heat.

*Live attenuated vaccines* contain live pathogens that have accumulated mutations so that they are no longer virulent to human cells. These vaccines are most commonly generated by repeated infection of the pathogen in cultured cells until its virulence is lost.

*Subunit vaccines* contain a purified protein component of the pathogen. Such proteins can be either isolated from infected material (such as blood from chronically infected patients) or generated by recombinant methods.

*Toxoid vaccines* are used against pathogens that employ an extracellular toxin to cause disease. These vaccines contain a form of the toxin that has been inactivated by treatment with chemicals or high heat.

The effectiveness of immunization efforts has made the global eradication of certain diseases possible. In 1966, 20 million cases of smallpox were reported worldwide. Just 14 years later, after coordinated vaccination efforts in regions of endemic disease, the World Health Assembly declared that smallpox had been eradicated. Nevertheless, despite the success of vaccines in the prevention of many devastating diseases, several pathogens have posed a significant challenge to vaccine development. For example, the

development of an effective HIV vaccine has been complicated by the antigenic diversity of HIV strains. Because its mechanism for replication is prone to error, a population of HIV presents an ever-changing array of coat proteins. Indeed, the mutation rate of HIV is more than 65 times higher than that of influenza virus. Nevertheless, the identification of protective antibodies in individuals resistant to HIV and advancements in vaccine design suggest that the development of an effective HIV vaccine remains a real possibility.

## SUMMARY

Two lines of defense against pathogens are the innate immune system and the adaptive immune system. The innate immune system targets features common to many different pathogens but misses those pathogens lacking these features. The adaptive immune system is both more specific and wide-reaching. To respond effectively to a vast array of pathogens, this type of immune system must be tremendously flexible. The adaptive immune system follows the principles of evolution: an enormously diverse set of potentially useful proteins is generated; these proteins are then subjected to intense selection so that only cells that express useful proteins flourish and continue development, until an effective immune response to a specific invader is generated.

### 34.1 Antibodies Possess Distinct Antigen-Binding and Effector Units

The major immunoglobulin in the serum is immunoglobulin G. An IgG protein is a heterotetramer with two heavy chains and two light chains. Treatment of IgG molecules with proteases such as papain produces three fragments: two  $F_{ab}$  fragments that retain antigen-binding activity and an  $F_c$  fragment that retains the ability to activate effector functions such as the initiation of the complement cascade. The  $F_{ab}$  fragments include the L chain and the amino-terminal half of the H chain; the  $F_c$  domain is a dimer consisting of the carboxyl-terminal halves of two H chains. Five different classes of antibody—IgG, IgM, IgA, IgD, and IgE—differ in their heavy chains and, hence, in their effector functions.

### 34.2 Antibodies Bind Specific Molecules Through Hypervariable Loops

One particular protein fold is found in many of the key proteins of the immune system. The immunoglobulin fold consists of a pair of  $\beta$  sheets that pack against each other, linked by a single disulfide bond. Loops projecting from one end of the structure form a binding surface that can be varied by changing the amino acid sequences within the loops. Domains with immunoglobulin folds are linked to form antibodies and other classes of proteins in the immune system, including T-cell receptors. Two chains come together to form the binding surface of an antibody. Three loops from each domain, the complementarity-determining regions, form an essentially continuous surface that can vary tremendously in shape, charge, and other characteristics to allow particular antibodies to bind to molecules ranging from small molecules to large protein surfaces.

### 34.3 Diversity Is Generated by Gene Rearrangements

The tremendous diversity of the amino acid sequences of antibodies is generated by segmental rearrangements of genes. For antibody  $\kappa$  light chains, 1 of 40 variable regions is linked to 1 of 5 joining regions. The combined VJ unit is then linked to the constant region. Thousands of different genes can be generated in this manner. Similar arrays are

rearranged to form the genes for the heavy chains, but an additional region called the diversity region lies between the V and the J regions. The combination of L and H chains, each obtained through such rearranged genes, can produce more than  $10^8$  distinct antibodies. Different classes of antibodies are also generated by gene rearrangements that lead to class switching. Oligomerization of membrane-bound antibody molecules initiates a signal-transduction cascade inside B cells. Key steps in this signaling process include the phosphorylation of specific tyrosine residues in sequences termed immunoreceptor tyrosine-based activation motifs, present in proteins that associate with the membrane-bound antibodies.

#### 34.4 Major-Histocompatibility-Complex Proteins Present Peptide Antigens on Cell Surfaces for Recognition by T-Cell Receptors

Intracellular pathogens such as viruses and mycobacteria cannot be easily detected. Intracellular proteins are constantly being cut into small peptides by proteasomes and displayed in class I major-histocompatibility-complex proteins on cell surfaces. Such peptides lie in a groove defined by two helices in the class I MHC proteins. The combination of MHC protein and peptide can be bound by an appropriate T-cell receptor. T-cell receptors resemble the antigen-binding domains of antibodies in structure, and diversity in T-cell-receptor sequence is generated by V(D)J gene rearrangements. The T-cell receptor recognizes features of both the peptide and the MHC molecule that presents it.

Cytotoxic T cells initiate apoptosis in cells to which they bind through interactions between T-cell receptors and class I MHC-peptide complexes aided by interactions with the coreceptor molecule CD8. Helper T cells recognize peptides presented in class II MHC proteins, a distinct type of MHC protein expressed only on antigen-presenting cells, such as B cells and macrophages. Helper T cells express the coreceptor CD4 rather than CD8. CD4 interacts with class II MHC proteins present on antigen-presenting cells. Signaling pathways, analogous to those in B cells, are initiated by interactions between MHC-peptide complexes and T-cell receptors and the CD8 and CD4 coreceptors. Human immunodeficiency virus damages the immune system by infecting and killing cells that express CD4, such as helper T cells.

#### 34.5 The Immune System Contributes to the Prevention and the Development of Human Diseases

In principle, the immune system is capable of generating antibodies and T-cell receptors that bind to self-molecules—that is, molecules that are normally present in a healthy and uninfected individual organism. Selection mechanisms prevent such self-directed molecules from being expressed at high levels. The selection process includes both positive selection, to enrich the population of cells that express molecules that have the potential to bind foreign antigens in an appropriate context, and negative selection, which eliminates cells that express molecules with too high an affinity for self-antigens. Autoimmune diseases such as insulin-dependent diabetes mellitus can result from the amplification of a response against a self-antigen. Vaccines stimulate immunological memory so as to prevent, and even eradicate, disease.

## PROBLEMS

- First things first.* Distinguish between the innate and adaptive immune systems.
- Antibody diversity.* What are the mechanisms used by B cells to generate antibody diversity?
- Hang in there.* Explain the difference between *affinity* and *avidity*. For which immunoglobulin class might avidity be particularly important in antigen recognition?
- Innate abilities.* A strain of mice has been identified that does not respond to LPS. This lack of response is due to a single amino acid change in the intracellular domain of mouse TLR4. Propose an explanation for the lack of response.
- TLR ligands.* The PAMP recognized by TLR3 is double-stranded RNA (dsRNA). Against which pathogens would TLR3 be an effective immune receptor?
- Energetics and kinetics.* Suppose that the dissociation constant of an  $F_{ab}$ -hapten complex is  $3 \times 10^{-7}$  M at 25°C.
  - What is the standard free energy of binding?
  - Immunologists often speak of affinity ( $K_a$ ), the reciprocal of the dissociation constant, in comparing antibodies. What is the affinity of this  $F_{ab}$ ?
  - The rate constant for the release of hapten from the complex is  $120 \text{ s}^{-1}$ . What is the rate constant for association? What does the magnitude of this value imply about the extent of structural change in the antibody on binding hapten?
- A brilliant emitter.* Certain naphthalene derivatives, such as the dansyl group, exhibit a weak yellow fluorescence when they are in a highly polar environment (such as water) and an intense blue fluorescence when they are in a markedly nonpolar environment (such as hexane). The binding of  $\epsilon$ -dansyl-lysine to specific antibody is accompanied by a marked increase in its fluorescence intensity and a shift in color from yellow to blue. What does this finding reveal about the hapten-antibody complex?
- Miniantibody.* The  $F_{ab}$  fragment of an antibody molecule has essentially the same affinity for a monovalent hapten as does intact IgG.
  - What is the smallest unit of an antibody that can retain the specificity and binding affinity of the whole protein?
  - Design a compact single-chain protein that is likely to specifically bind antigen with high affinity.
- Turning on B cells.* B lymphocytes, the precursors of plasma cells, are triggered to proliferate by the binding of multivalent antigens to receptors on their surfaces. The cell-surface receptors are transmembrane immunoglobulins. Univalent antigens, in contrast, do not activate B cells.
  - What do these findings reveal about the mechanism of B-cell activation?
  - How might antibodies be used to activate B cells?
- An ingenious cloning strategy.* In the cloning of the gene for the  $\alpha$  chain of the T-cell receptor, T-cell cDNAs were

hybridized with B-cell mRNAs. What was the purpose of this hybridization step? Can the principle be applied generally?

11. *Pathogen susceptibility.* Patients carrying specific mutations in the gene encoding the TLR4 protein are susceptible to infections from Gram-negative bacteria. Why are these patients vulnerable to this particular type of pathogen?

12. *Matchmaker, matchmaker.* Why is it important to match HLA alleles between donor and recipient in organ transplantation?

13. *Instruction.* Before the mechanism for generating antibody diversity had been established, a mechanism based on protein folding around an antigen was proposed, primarily by Linus Pauling. In this model, antibodies that had different specificities had the same amino acid sequence but were folded in different ways. Propose a test of this model.

14. *Dealing with nonsense.* Cells, including immune cells, degrade mRNA molecules in which no long open reading frame is present. The process is called nonsense-mediated RNA decay. Suggest a role for this process in immune cells.

15. *Down, but not out.* To understand the genes responsible for growth and infectivity in a disease-causing bacterial strain, you perform chemical mutagenesis on a culture of these bacteria. In the course of your investigation into the properties of the resulting mutants, you identify a set of mutant bacteria that is still viable but their virulence is significantly impaired. How might these mutants be useful for vaccine development?

16. *Presentation.* The amino acid sequence of a small protein is

MSRLASKNLI RSDHAGLLQATYS AVSS-  
IKNTMSFGAWSNAALNDSRDA

Predict the most likely peptide to be presented by the class I MHC molecule HLA-A2.

### Mechanism Problem

17. *Catalytic antibody.* Antibody is generated against a transition state for the hydrolysis of the following ester.

Some of these antibodies catalyze the hydrolysis of the ester. What amino acid residue might you expect to find in the binding site on the antibody?

### Chapter Integration Problem

18. *Signaling.* Protein tyrosine phosphatases, such as the molecule CD45 expressed in both B cells and T cells, play important roles in activating such protein tyrosine kinases as Fyn and Lck, which are quite similar to Src. Suggest a mechanism for the activation of such protein kinases by the removal of a phosphoryl group from a phosphotyrosine residue.

### Data Interpretation Problem

19. *Affinity maturation.* A mouse is immunized with an oligomeric human protein. Shortly after immunization, a cell line that expresses a single type of antibody molecule (antibody A) is derived. The ability of antibody A to bind the human protein is assayed, with the results shown in the graph below.

After repeated immunizations with the same protein, another cell line is derived that expresses a different antibody (antibody B). The results of analyzing the binding of antibody B to the protein also are shown. From these data, estimate

(a) the dissociation constant ( $K_d$ ) for the complex between the protein and antibody A.

(b) the dissociation constant for the complex between the protein and antibody B.

Comparison of the amino acid sequences of antibody A and antibody B reveals them to be identical except for a single amino acid. What does this finding suggest about the mechanism by which the gene encoding antibody B was generated?

## Molecular Motors

The impressive muscles of the horse, like the muscles of all animals, are powered by the molecular-motor protein myosin. A part of myosin moves dramatically (as shown above) in response to ATP binding, hydrolysis, and product release, propelling myosin along an actin filament. This molecular movement is translated into movement of the entire animal, vividly depicted in da Vinci's rearing horse. [(Left) The Royal Collection © 2014 Her Majesty Queen Elizabeth II/Bridgeman Images.]

Organisms, from human beings to bacteria, move to adapt to changes in their environments, navigating toward food and away from danger. Cells themselves are not static but are bustling assemblies of moving proteins, nucleic acids, and organelles. This motion is enabled by two elements: molecular-motor proteins and complex networks of filamentous proteins termed the *cytoskeleton* (Figure 35.1). The dynamic networks that determine the shape and mobility of cells are among the most active areas of investigation in modern cell biology. Remarkably, the fundamental biochemical mechanisms that produce contractions in our muscles are the same as those that propel organelles along the cytoskeleton. In fact, many of the proteins that play key roles in converting chemical energy into kinetic energy are members of the same protein family, the P-loop NTPases, the hugely important group of proteins that we first examined in Chapter 9. These molecular motors are homologous to proteins that we have encountered in other contexts, including the G proteins in protein synthesis, signaling, and other processes. Once again, we see the economy of evolution in adapting existing proteins to perform new functions.

Molecular motors operate by small increments, converting changes in protein conformation into directed motion. Orderly motion across distances requires a track that steers the motion of the motor assembly. Indeed, we have

## OUTLINE

- 35.1** Most Molecular-Motor Proteins Are Members of the P-Loop NTPase Superfamily
- 35.2** Myosins Move Along Actin Filaments
- 35.3** Kinesin and Dynein Move Along Microtubules
- 35.4** A Rotary Motor Drives Bacterial Motion

**FIGURE 35.1 Motion within cells.** This high-voltage electron micrograph shows the mitotic apparatus in a metaphase mammalian cell. The large cylindrical objects are chromosomes, and the threadlike structures stretched across the center are microtubules, key components of the skeleton. Microtubules serve as tracks for the molecular motors that move chromosomes. Many processes, including chromosome segregation in mitosis, depend on the action of molecular-motor proteins. [Courtesy of Dr. J. R. McIntosh.]

already encountered a class of molecular motors that utilize mechanisms that we will examine here—namely, the helicases that move along DNA during DNA replication (Section 28.1). The proteins on which we will focus in this chapter move along actin and microtubules—protein filaments composed of repeating subunits. The motor proteins cycle between forms having high or low affinity for the filament tracks in response to ATP binding and hydrolysis, enabling a bind, pull, and release mechanism that generates motion.

We will also consider a completely different strategy for generating motion, one used by bacteria such as *E. coli*. A set of flagella act as propellers, rotated by a motor in the bacterial cell membrane. This rotary motor is driven by a proton gradient across the membrane, rather than by ATP hydrolysis. The mechanism for coupling the proton gradient to rotatory motion is analogous to that used by the  $F_0$  subunit of ATP synthase. Thus, both of the major modes for storing biochemical energy—namely, ATP and ion gradients—have been harnessed by evolution to drive organized molecular motion.

---

### 35.1 Most Molecular-Motor Proteins Are Members of the P-Loop NTPase Superfamily

Eukaryotic cells contain three major families of motor proteins: myosins, kinesins, and dyneins. Members of each of these classes move along components of the cytoskeleton, but, at first glance, these protein families appear to be quite different from one another. *Myosin*, first characterized on the basis of its role in muscle, moves along filaments of the protein actin. Each molecule of muscle myosin consists of two copies each of a *heavy chain* with a molecular mass of 220 kDa, an *essential light chain*, and a *regulatory light chain*. The human genome encodes more than 40 distinct myosins; some function in muscle contraction, and others participate in a variety of other processes. *Kinesins*, which have roles in protein, mRNA, and vesicle transport as well as construction of the mitotic spindle and chromosome segregation, are generally dimers of two polypeptides. The human genome encodes more than 40 kinesins. *Dyneins* power the motion of cilia and flagella, and a general cytoplasmic dynein contributes to a variety of motions in all cells, including vesicle transport and various transport events in mitosis. Dyneins are enormous, with heavy chains of molecular mass greater than 500 kDa. The human genome encodes approximately 10 dyneins.

Initially, comparison of the amino acid sequences of myosins, kinesins, and dyneins did not reveal significant relationships between these protein families but, after their three-dimensional structures were determined, members of the myosin and kinesin families were found to have remarkable similarities. In particular, both myosin and kinesin contain P-loop NTPase cores homologous to those found in G proteins. Sequence analysis of the dynein heavy chain reveals it to be a member of the AAA subfamily of P-loop NTPases that we encountered in the context of the 19S proteasome (Section 23.2). Dynein has six sequences encoding such P-loop NTPase domains arrayed along its length, although only four actually appear to bind nucleotides. Thus, we expect similarities in the mechanisms of action, and we can draw on our knowledge of P-loop NTPases in general as we analyze the mechanisms of action of these motor proteins.

#### **Molecular motors are generally oligomeric proteins with an ATPase core and an extended structure**

Let us first consider the structure of myosin, which we examined briefly in Chapter 9. The results of electron microscopic studies of skeletal-muscle

**FIGURE 35.2 Myosin dissection.** Treatment of muscle myosin with proteases forms stable fragments, including subfragments S1 and S2 and light meromyosin. Each S1 fragment includes a head (shown in yellow or purple) from the heavy chain and one copy of each light chain (shown in blue and orange).

myosin show it to be a two-headed structure linked to a long stalk (Figure 9.42). The treatment of myosin with trypsin and papain results in the formation of four fragments: two S1 fragments; heavy meromyosin (HMM) which consists of the S1 fragments and an additional region termed S2; and a fragment called light meromyosin (LMM; Figure 35.2). Each *S1 fragment* corresponds to one of the heads of the intact structure and includes 850 amino-terminal amino acids from one of the two heavy chains as well as one copy of each of the light chains. Examination of the structure of an S1 fragment at high resolution reveals the presence of the P-loop NTPase-domain core that is the site of ATP binding and hydrolysis (Figure 35.3). We examined the structure and mechanism of action of this motor domain in Chapter 9.

**FIGURE 35.3 Myosin structure at high resolution.** The structure of the S1 fragment from muscle myosin reveals the presence of a P-loop NTPase domain (shaded in purple). Notice that an  $\alpha$  helix extending from this domain is the binding site for the two light chains. [Drawn from 1DFL.pdb.]

Extending away from this structure is a long  $\alpha$  helix from the heavy chain. This helix is the binding site for the two light chains. The light chains are members of the EF-hand family, similar to calmodulin (Figure 14.17), although most of the EF hands in light chains do not bind metal ions (Figure 35.4). Like calmodulin, these proteins wrap around an  $\alpha$  helix, serving to thicken and

**FIGURE 35.4 Myosin light chains.** The structures of the essential and regulatory light chains of muscle myosin are compared with the structure of calmodulin. Notice the similarities in the structures that allow each of these homologous proteins to bind an  $\alpha$  helix (not shown) by wrapping around it. [Drawn from 1DFL.pdb and 1CM1.pdb.]

**FIGURE 35.5 Myosin two-stranded coiled coil.** The two  $\alpha$  helices form left-handed supercoiled structures that spiral around each other. Such structures are stabilized by hydrophobic residues at the contact points between the two helices. [Drawn from 2TMA.pdb.]

stiffen it. The remaining fragments of myosin—S2 and light meromyosin—are largely  $\alpha$  helical, forming two-stranded coiled coils created by the remaining lengths of the two heavy chains wrapping around each other (Figure 35.5). These structures, together extending approximately 1700 Å, link the myosin heads to other structures. In muscle myosin, several LMM domains come together to form higher-order bundles.

*Conventional kinesin* (kinesin 1), the first kinesin discovered, has several structural features in common with myosin. The dimeric protein has two heads connected by an extended structure (Figure 35.6). The size of the head domain is approximately one-third that of myosin. Determination of the three-dimensional structure of a kinesin fragment revealed that the head domain also is built around a P-loop NTPase core (Figure 35.7). The myosin domain is so much larger than that of kinesin because of two large insertions in the myosin domain that bind to actin filaments. For conventional kinesin, a region of approximately 500 amino acids extends from the head domain. Like the corresponding region in myosin, the extended part of kinesin forms an  $\alpha$ -helical coiled coil. Conventional kinesin also has light chains, but, unlike those of myosin, these light chains bind near the carboxyl terminus of the heavy chain and are thought to link the motor to intracellular cargo.

**FIGURE 35.6 Structure of kinesin.** The elongated structure has the head domains at one end and the cargo-binding domains at the other, linked by a long coiled-coil region.

**FIGURE 35.7 Structure of head domain of kinesin at high resolution.** Notice that the head domain of kinesin has the structure of a P-loop NTPase core (indicated by purple shading). [Drawn from 1l6l.pdb.]

Dynein has a significantly different structure than myosin or kinesin. As noted earlier, the dynein heavy chain includes six regions that are homologous to the AAA subfamily of ATPase domains. A model for the structure of the motor domain of dynein was generated based on the structures of other AAA ATPases. This model has been confirmed and extended by more recent structure determinations of dynein itself (Figure 35.8). The head domain is appended to a region of approximately 1300 amino acids that forms an extended structure that links dynein units together to form oligomers and interacts with other proteins.

Although the structures of these three classes of molecular motors have significant differences, some common features emerge. Almost all structures are dimeric with two head domains, have regions of extended but quite rigid structures, and have regions for interacting with other proteins. As we shall see, these structures are suitable for actions that resemble climbing a rope, hand over hand. The regions for interacting with other proteins represent the grasping hands, the extended structures represent the arms that act as levers to promote larger-scale motion, and the head domains are the engines that provide the necessary mechanical energy.

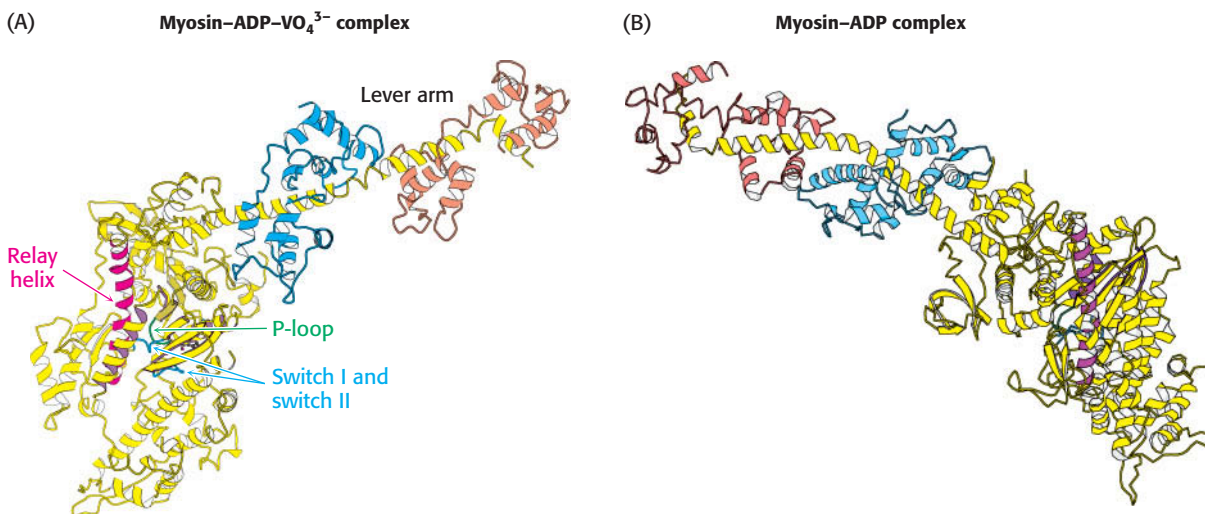

### ATP binding and hydrolysis induce changes in the conformation and binding affinity of motor proteins

In Chapter 9, we examined the conformational changes that take place in the myosin ATPase domain from the slime mold *Dictyostelium*. The structures

**FIGURE 35.8 Dynein structure.** (A) The overall structure of dynein. (B) A model of the motor domain of dynein. Notice the six P-loop NTPase domains, some of which bind to and hydrolyze ATP. [Drawn from 1HN5.pdb.]

of myosin ATP domains from other sources have been elucidated in a variety of forms as well. The S1 fragment of myosin from scallop muscle provides a striking example of the changes observed (Figure 35.9). The structure of this S1 fragment has been determined in a number of forms including that without bound nucleotide and that bound to a complex formed of ADP and vanadate ( $\text{VO}_4^{3-}$ ), which, as mentioned in Chapter 9, is an analog of the ATP-hydrolysis transition state. The long helix that binds the light chains (hereafter referred to as the *lever arm*) protrudes outward from the head domain. Comparison of the structures reveals that the lever arm has rotated by nearly 90 degrees in the  $\text{ADP-VO}_4^{3-}$  complex compared with its position in the nucleotide-free form. How does the species in the nucleotide-binding site cause this dramatic transition? Two regions around the nucleotide-binding site (termed *switch I* and *switch II*) tightly conform to the shape of the  $\gamma$ -phosphoryl group of the ATP analog and adopt a looser

**FIGURE 35.9 Lever-arm motion.** Two forms of the S1 fragment of scallop-muscle myosin. Notice the dramatic conformational changes when the identity of the bound nucleotide changes from the  $\text{ADP-VO}_4^{3-}$  complex (A) to the nucleotide-free form (B) or vice versa, including a nearly 90-degree reorientation of the lever arm. [Drawn from 1DFL.pdb and 1SR6.pdb.]

**FIGURE 35.10 Relay helix.** A superposition of key elements in two forms of scallop myosin reveals the structural changes that are transmitted by the relay helix from the switch I and switch II loops to the base of the lever arm. Notice that the switch I and switch II loops interact with  $\text{VO}_4^{3-}$  in the position that would be occupied by the  $\gamma$ -phosphoryl group of ATP. The structure of the myosin-ADP- $\text{VO}_4^{3-}$  complex is shown in lighter colors. [Drawn from 1DFL.pdb and 1SR6.pdb.]

conformation when the  $\gamma$ -phosphoryl group is absent (Figure 35.10). This conformational change allows a long  $\alpha$  helix (termed the *relay helix*) to adjust its position. The carboxyl-terminal end of the relay helix interacts with structures at the base of the lever arm, and so a change in the position of the relay helix leads to a reorientation of the lever arm.

Analogous conformational changes take place in kinesin. The kinesins also have a relay helix that can adopt different configurations when kinesin binds different nucleotides. Kinesin lacks an  $\alpha$ -helical lever arm, however. Instead, a relatively short segment termed the *neck linker* changes conformation in response to nucleotide binding (Figure 35.11). The neck linker binds to the head domain of kinesin when ATP is bound but is released when the nucleotide-binding site is vacant or occupied by ADP.

## 35.2 Myosins Move Along Actin Filaments

Myosins, kinesins, and dyneins move by cycling between states with different affinities for the long, polymeric macromolecules that serve as tracks along which they move. For myosin, the molecular track is a polymeric form of *actin*, a 42-kDa protein that is among the most abundant in cells, typically accounting for as much as 10% of the protein in eukaryotic cells. We begin with a general discussion of the polymeric structure of actin and its assembly. We then examine the interactions between myosin and actin, including both structure and the dynamic interactions between these two proteins. Finally, we turn to the structure of muscle and the roles of myosin and actin in muscle contraction.

**FIGURE 35.11 Neck linker.** A comparison of the structures of a kinesin bound to ADP and bound to an ATP analog. Notice that the neck linker (orange), which connects the head domain to the remainder of the kinesin molecule, is bound to the head domain in the presence of the ATP analog but is free in the presence of ADP only. [Drawn from 116l.pdb and 115S.pdb.]

### Actin is a polar, self-assembling, dynamic polymer

The structure of the actin monomer has been determined to atomic resolution by x-ray crystallography and has been used to interpret the structure of actin filaments, already somewhat understood through electron microscopy studies at lower resolution. Each actin monomer comprises four domains

**FIGURE 35.12 Actin structure.** (Left) Schematic view of actin monomers (one in blue) of an actin filament. (Right) The domains in the four-domain structure of an actin monomer are identified by different shades of blue. Notice the nucleotide-binding site at the center of the structure. [Drawn from 1J6Z.pdb.]

(Figure 35.12). These domains come together to surround a bound nucleotide, either ATP or ADP. The ATP form can be converted into the ADP form by hydrolysis.

Actin monomers (often called *G-actin* for globular) come together to form actin filaments (often called *F-actin*; see Figure 35.12). F-actin has a helical structure; each monomer is related to the preceding one by a translation of 27.5 Å and a rotation of 166 degrees around the helical axis. Because the rotation is nearly 180 degrees, F-actin resembles a two-stranded cable. Note that each actin monomer is oriented in the same direction along the F-actin filament, and so the structure is polar, with discernibly different ends. One end is called the barbed (plus) end, and the other is called the pointed (minus) end. The names “barbed” and “pointed” refer to the appearance of an actin filament when myosin S1 fragments are bound to it.

How are actin filaments formed? Like many biological structures, actin filaments self-assemble; that is, under appropriate conditions, actin monomers will come together to form well-structured, polar filaments. The aggregation of the first two or three monomers to form a filament is highly unfavorable. Thus, specialized protein complexes, including one called Arp2/3, serve as nuclei for actin assembly in cells. Once such a filament nucleus exists, the addition of subunits is more favorable. Let us consider the polymerization reaction in more detail. We designate an actin filament with  $n$  subunits  $A_n$ . This filament can bind an additional actin monomer,  $A$ , to form  $A_{n+1}$ .

$$K_d = \frac{[A_n][A]}{[A_{n+1}]}$$

The dissociation constant,  $K_d$ , for this reaction, defines the monomer concentrations at which the polymerization reaction will take place, because the concentration of polymers of length  $n + 1$  will be essentially equal to that for polymers of length  $n$ . Thus,

$$[A_n] \sim [A_{n+1}] \quad \text{and} \quad K_d = \frac{[A_n][A]}{[A_{n+1}]} \sim [A]$$

In other words, the polymerization reaction will proceed until the monomer concentration is reduced to the value of  $K_d$ . If the monomer concentration is below the value of  $K_d$ , the polymerization reaction will not proceed at all; indeed, existing filaments will depolymerize until the monomer concentration reaches the value of  $K_d$ . Because of these phenomena,  $K_d$  is referred to as the *critical concentration* for the polymer. Recall that actin contains a nucleotide-binding site that can contain either ATP or ADP. The critical concentration for the actin–ATP complex is approximately 20-fold lower than that for the actin–ADP complex; actin–ATP polymerizes more readily than does actin–ADP.

Actin filaments inside cells are highly dynamic structures that are continually gaining and losing monomers. Nucleation by complexes such as Arp2/3 can initiate the polymerization of actin–ATP. In contrast, the hydrolysis of bound ATP to ADP favors actin depolymerization. This reaction acts as a timer to make actin filaments kinetically unstable as ATP hydrolyzes over time, making the filaments more unstable. Proteins that bind actin monomers or promote the severing of actin filaments also play roles. Polymerization reactions can exert force, pushing or pulling on cell membranes. *Regulated actin polymerization is central to the changes in cell shape associated with cell motility in amoebae as well as in human cells such as macrophages.*

### Myosin head domains bind to actin filaments

It has not been possible to determine the *in vivo* structure of a complex between actin and myosin at sufficiently high resolution to discern molecular details. However, treatment of actin filaments with myosin S1 fragments in the absence of ATP results in a complex referred to as *decorated actin* for which the structure has been determined by cryoelectron microscopy to a resolution of 13 Å. Although a structure at this resolution alone would not be adequate to observe molecular details, superimposition of the high-resolution structures of actin monomers and the myosin S1 fragment on the structure of decorated actin can be a source of insight into the details of its structure (Figure 35.13). The myosin head domain is in a conformation close to that observed for the nucleotide-free form. This structure also reveals the interaction surfaces between myosin and actin. The modeling suggests that the myosin head-domain conformation changes somewhat to increase its interaction with the actin filament. These conformational changes result in a slight opening of the nucleotide-binding site in myosin. This observation has implications for the mechanism by which myosin moves along actin filaments.

### Motions of single motor proteins can be directly observed

Now that we understand the conformational changes behind myosin's action, we can explore how myosin “walks” along its actin track. Studies of *single myosin molecules* moving relative to actin filaments have been sources of deep insight into the mechanisms underlying muscle contraction and

**FIGURE 35.13** The structure of myosin bound to actin.

(A) The gray surface represents the structure observed by cryoelectron microscopy, with the green space-filling model representing one actin subunit. The ribbon diagram shows the structure of the S1 fragment of myosin docked into the cryoelectron microscopic structure. *Notice* that some of the myosin structure lies outside the gray surface. (B) The structure after the myosin S1 fragment has been allowed to adjust to more closely match the structure observed by cryoelectron microscopy. *Notice* that the myosin structure now more closely matches the gray surface. **FIGURE 35.14 Watching a single motor protein in action.** (A) An actin filament (blue) is placed above a heavy meromyosin (HMM) fragment (yellow) that projects from a bead on a glass slide. A bead attached to each end of the actin filament is held in an optical trap produced by a focused, intense infrared laser beam (orange). The position of these beads can be measured with nanometer precision. (B) Recording of the displacement of an actin filament due to a myosin derivative attached to a bead, influenced by the addition of ATP. Note the fairly uniform step sizes that are observed. [(A) Information from J. T. Finer, R. M. Simmons, and J. A. Spudich, *Nature* 368:113–119, 1994. (B) Data from R. S. Rock, M. Rief, A. D. Metra, and J. A. Spudich, *Methods* 22:378–381, 2000.]

other complex processes. A powerful tool for these studies, called an *optical trap*, relies on highly focused laser beams (Figure 35.14). Small beads can be caught in these traps and held in place in solution.

The position of the beads can be monitored with nanometer precision. James Spudich and his coworkers designed an experimental arrangement consisting of an actin filament that had a bead attached to each end. Each bead could be caught in an optical trap (one at each end of the filament) and the actin filament could be pulled taut over a microscope slide containing other beads that had been coated with fragments of myosin such as the heavy meromyosin fragment (Figure 35.14). On the addition of ATP, transient displacements of the actin filament were observed along its long axis. The size of the displacement steps was fairly uniform with an average size of 11 nm (110 Å).

The results of these studies, performed in the presence of varying concentrations of ATP, are interpreted as showing that individual myosin heads bind the actin filament and undergo a conformational change (the *power stroke*) that pulls the actin filament, leading to the displacement of the beads. After a period of time, the myosin head releases the actin, which then snaps back into place.

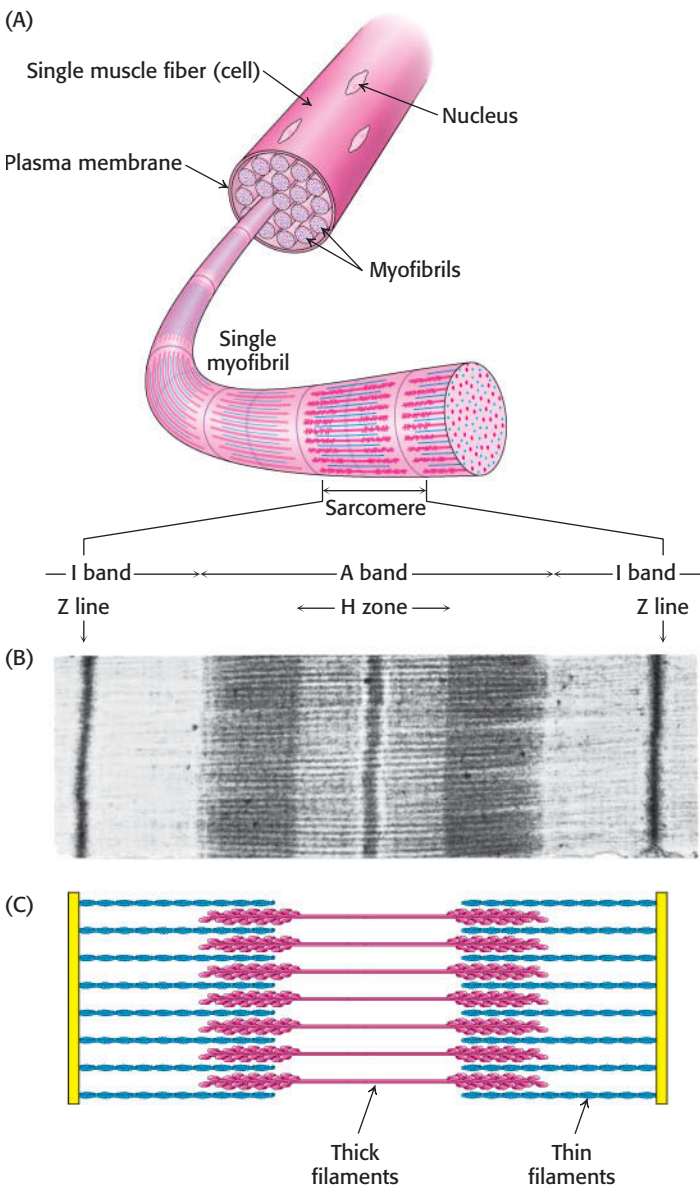

### Phosphate release triggers the myosin power stroke

How does ATP hydrolysis drive the power stroke? A key observation is that the addition of ATP to a complex of myosin and actin results in the dissociation of the complex. Thus, ATP binding and hydrolysis cannot be directly responsible for the power stroke. We can combine this fact with the structural observations described earlier to construct a mechanism for the motion of myosin along actin (Figure 35.15). Let us begin with nucleotide-free myosin bound to actin. The binding of ATP to actin results in the dissociation of myosin from actin. With ATP bound and free of actin, the myosin domain can undergo the conformational change associated with the formation of the transition state for ATP hydrolysis. This conformational change results in the reorientation of the lever arm. In this form, the myosin head can dock onto the actin filament; phosphate is released with concomitant motion of the lever arm. *This conformational change represents the power stroke and moves the body of the myosin molecule relative to the actin filament by approximately 110 Å.* The release of ADP completes the cycle.

### Muscle is a complex of myosin and actin

The mechanism of moving a single myosin molecule relative to an actin filament explains how muscles contract. Vertebrate muscle that is under voluntary control, such as the biceps and triceps in your upper arm, has a banded (striated) appearance when examined under a light microscope. It consists of multinucleated cells that are bounded by an electrically excitable plasma

**FIGURE 35.15 Myosin motion along actin.** A myosin head (yellow) in the apo form is bound to an actin filament (blue). The binding of ATP (1) results in the release of myosin from actin. The reversible hydrolysis of ATP bound to myosin (2) can result in the reorientation of the lever arm. With ATP hydrolyzed but still bound to actin, myosin can bind actin (3). The release of  $P_i$  (4) results in the reorientation of the lever arm and the concomitant motion of actin relative to myosin. The release of ADP (5) completes the cycle.

membrane. A muscle cell contains many parallel *myofibrils*, each about  $1\ \mu\text{m}$  in diameter. The functional unit, called a *sarcomere*, typically repeats every  $2.3\ \mu\text{m}$  ( $23,000\ \text{\AA}$ ) along the fibril axis in relaxed muscle (Figure 35.16). A dark *A band* and a light *I band* alternate regularly. The central region of the *A band*, termed the *H zone*, is less dense than the rest of the band. The *I band* is bisected by a very dense, narrow *Z line*.

The underlying molecular plan of a sarcomere is revealed by cross sections of a myofibril. These cross sections show the presence of two kinds of interacting protein filaments. The *thick filaments* have diameters of about  $15\ \text{nm}$  ( $150\ \text{\AA}$ ) and consist primarily of myosin. The *thin filaments* have diameters of approximately  $8\ \text{nm}$  ( $80\ \text{\AA}$ ) and consist of actin as well as *tropomyosin* and the *troponin complex*. Muscle contraction is achieved through the sliding of the thin filaments along the length of the thick filaments, driven by the hydrolysis of ATP (Figure 35.17).

To form the thick filaments, myosin molecules self-assemble into thick bipolar structures, with the myosin heads protruding at both ends of a bare region in the center (Figure 35.18A). Approximately 500 head domains line the surface of each thick filament. Each head-rich region associates with two actin filaments, one on each side of the myosin molecules (Figure 35.18B). The interaction of individual myosin heads with actin units creates the sliding force that gives rise to muscle contraction.

**FIGURE 35.16 Sarcomere.** (A) Structure of muscle cell and myofibril containing sarcomeres. (B) Electron micrograph of a longitudinal section of a skeletal-muscle myofibril showing a single sarcomere. (C) Schematic representation of the sarcomere corresponding to the regions in the micrograph. [(B) Courtesy of Dr. Hugh Huxley.]

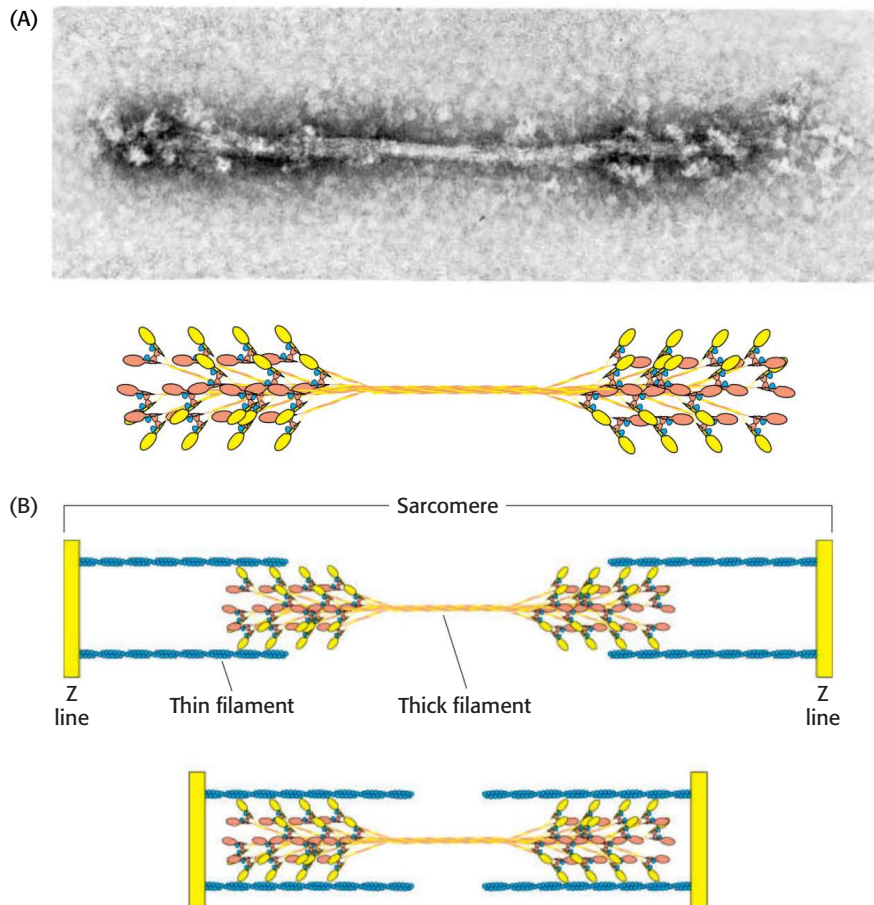

Tropomyosin and the troponin complex regulate this sliding in response to nerve impulses. Under resting conditions, tropomyosin blocks the intimate interaction between myosin and actin. A nerve impulse leads to an increase in calcium ion concentration within the muscle cell. A component of the troponin complex senses the increase in  $\text{Ca}^{2+}$  and, in response, relieves the inhibition of myosin–actin interactions by tropomyosin.

How does the myosin reaction cycle apply to muscle contraction? Recall that hundreds of head domains project from the ends of each thick filament. The head domains are paired in myosin dimers, but the two heads within each dimer act independently. Actin filaments associate with each head-rich region, with the barbed ends of actin toward the Z line. In the presence of normal levels of ATP, most of the myosin heads are detached from actin. Each head can independently hydrolyze ATP, bind to actin, release  $\text{P}_i$ , and undergo its power stroke. Because few other heads are attached, the actin filament is relatively free to slide. Each head cycles approximately five times per second with a movement of  $110 \text{ \AA}$  per cycle. However, when hundreds of heads are interacting with the same actin filament, the overall rate of movement of myosin relative to the actin filament may reach  $80,000 \text{ \AA}$  per second, allowing a sarcomere to contract from its fully relaxed to its fully contracted form rapidly. Having many myosin heads briefly and independently attaching and moving an actin filament allows for much greater speed than could be achieved by a single motor protein.

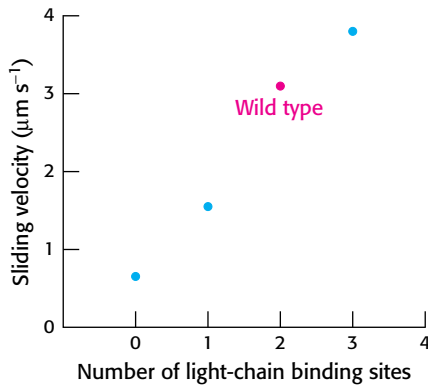

**FIGURE 35.17 Sliding-filament model.**

Muscle contraction depends on the motion of thin filaments (blue) relative to thick filaments (red). [Information from H. E. Huxley. The mechanism of muscular contraction. Copyright © 1965 by Scientific American, Inc. All rights reserved.]

**FIGURE 35.18 Thick filament.** (A) An electron micrograph of a reconstituted thick filament reveals the presence of myosin head domains at each end and a relatively narrow central region. A schematic view below shows how myosin molecules come together to form the thick filament. (B) A diagram showing the interaction of thick and thin filaments in skeletal-muscle contraction. **FIGURE 35.19 Myosin lever-arm length.** Examination of the rates of actin movement supported by a set of myosin mutants with different numbers of light-chain binding sites revealed a linear relation; the greater the number of light-chain binding sites (and, hence, the longer the lever arm), the faster the sliding velocity. [Data from T. Q. P. Uyeda, P. D. Abramson, and J. A. Spudich, *Proc. Natl. Acad. Sci. U. S. A.* 93:4459–4464, 1996.]

### The length of the lever arm determines motor velocity

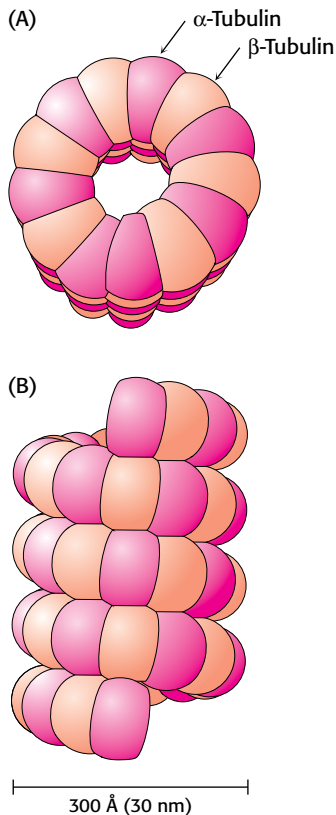

A key feature of myosin motors is the role of the lever arm as an amplifier. The lever arm amplifies small structural changes at the nucleotide-binding site to achieve the 110-Å movement along the actin filament that takes place in each ATP hydrolysis cycle. A strong prediction of the mechanism proposed for the movement of myosin along actin is that the length traveled per cycle should depend on the length of this lever arm. Thus, the length of the lever arm should influence the overall rate at which actin moves relative to a collection of myosin heads.

This prediction was tested with the use of mutated forms of myosin with lever arms of different lengths. The lever arm in muscle myosin includes binding sites for two light chains (Section 35.1). Thus, investigators shortened the lever arm by deleting the sequences that correspond to one or both of these binding sites. They then examined the rates at which actin filaments were transported along collections of these mutated myosins (Figure 35.19). As predicted, the rate decreased as the lever arm was shortened. A mutated form of myosin with an unusually long lever arm was generated by inserting 23 amino acids corresponding to the binding site for an additional regulatory light chain. Remarkably, this form was found to support actin movement that was *faster than that of the wild-type protein*. These results strongly support the proposed role of the lever arm in contributing to myosin motor activity.

## 35.3 Kinesin and Dynein Move Along Microtubules

In addition to actin, the cytoskeleton includes other components, notably intermediate filaments and microtubules. Microtubules serve as tracks for two classes of motor proteins—namely, kinesins and dyneins. Kinesins moving along microtubules usually carry cargo such as organelles and vesicles from the center of a cell to its periphery. Dyneins are important in sliding microtubules relative to one another during the beating of cilia and flagella on the surfaces of some eukaryotic cells. Additionally, dynein carries cargo from the cell periphery to the cell center.

 Some members of the kinesin family are crucial to the transport of organelles and other cargo to nerve endings at the peripheries of neurons. It is not surprising, then, that mutations in these kinesins can lead to nervous system disorders. For example, mutations in a kinesin called KIF1 $\beta$  can lead to the most common peripheral neuropathy (weakness and pain in the hands and feet), Charcot-Marie-Tooth disease, which affects 1 in 2500 people. A glutamine-to-leucine mutation in the P-loop of the motor domain of this kinesin has been found in some affected persons. Knockout mice with a disruption of the orthologous gene have been generated. Mice heterozygous for the disruption show symptoms similar to those observed in human beings; homozygotes die shortly after birth. Mutations in other kinesin genes have been linked to human spastic paraplegia. In these disorders, defects in kinesin-linked transport may impair nerve function directly, and the decrease in the activity of specific neurons may lead to other degenerative processes.

**FIGURE 35.20 Microtubule structure.** Schematic views of the helical structure of a microtubule.  $\alpha$ -Tubulin is shown in dark red and  $\beta$ -tubulin in light red. (A) Top view. (B) Side view.

### Microtubules are hollow cylindrical polymers

*Microtubules* are a major component of the cytoskeleton. They are built from two kinds of homologous 50-kDa subunits,  $\alpha$ - and  $\beta$ -tubulin, which assemble in a helical array of alternating tubulin types to form the wall of a hollow cylinder (Figure 35.20). Alternatively, a microtubule can be regarded as 13 protofilaments that run parallel to its long axis. The outer diameter of

a microtubule is 30 nm, much larger than that of actin (8 nm). Like actin, microtubules are polar structures. The minus end of a microtubule is anchored near the center of a cell, whereas the plus end extends toward the cell surface.

Microtubules are also key components of cilia and flagella present on some eukaryotic cells. For example, sperm propel themselves through the motion of flagella containing microtubules. The microtubules present in these structures adopt a common architecture (Figure 35.21). A bundle of microtubules called an *axoneme* is surrounded by a membrane contiguous with the plasma membrane. The axoneme is composed of a peripheral group of nine microtubule pairs surrounding two singlet microtubules. This recurring motif is often called a *9 + 2 array*. Dynein drives the motion of one member of each outer pair relative to the other, causing the overall structure to bend.

Microtubules are important in determining the shapes of cells and in separating daughter chromosomes in mitosis. They are highly dynamic structures that grow through the addition of  $\alpha$ - and  $\beta$ -tubulin to the ends of existing structures. Like actin, *tubulins* bind and hydrolyze nucleoside triphosphates, although, for tubulin, the nucleotide is GTP rather than ATP. The critical concentration for the polymerization of the GTP forms of tubulin is lower than that for the GDP forms. Thus, a newly formed microtubule consists primarily of GTP-tubulins. Through time, the GTP is hydrolyzed to GDP. The GDP-tubulin subunits in the interior length of a microtubule remain stably polymerized, whereas GDP subunits exposed at an end have a strong tendency to dissociate. Marc Kirschner and Tim Mitchison found that some microtubules in a population lengthen while others simultaneously shorten. This property, called *dynamic instability*, arises from random fluctuations in the number of GTP- or GDP-tubulin subunits at the plus end of the polymer. The dynamic character of microtubules is crucial for processes such as mitosis, which require the assembly and disassembly of elaborate microtubule-based structures such as spindle fibers.

The structure of a tubulin dimer was determined at high resolution by electron crystallographic methods (Figure 35.22). As expected from their 40% sequence identity,  $\alpha$ - and  $\beta$ -tubulin have very similar three-dimensional structures. Further analysis revealed that the tubulins are members of the P-loop NTPase family and contain a nucleotide-binding site adjacent to the P-loop. Tubulins are present only in eukaryotes, although a prokaryotic homolog has been found. Sequence analysis identified a prokaryotic protein called FtsZ (for filamentous temperature-sensitive mutant Z) that is quite similar to the tubulins. The homology was confirmed when the structure was determined by x-ray crystallography. Interestingly, this protein participates in bacterial cell division, forming ring-shaped structures at the constriction that arises when a cell divides. These observations suggest that tubulins may have evolved from an ancient cell-division protein.

The continual lengthening and shortening of microtubules is essential to their role in cell division. *Taxol*, a compound isolated from the bark of the Pacific yew tree, was discovered through its ability to interfere with cell proliferation.

**FIGURE 35.21 Microtubule arrangement.** Electron micrograph of a cross section of a flagellar axoneme shows nine microtubule doublets surrounding two singlets. [Courtesy of Dr. Joel Rosenbaum.]

**FIGURE 35.22 Tubulin.** Microtubules can be viewed as an assembly of  $\alpha$ -tubulin- $\beta$ -tubulin dimers. The structures of  $\alpha$ -tubulin and  $\beta$ -tubulin are quite similar. Notice that each includes a P-loop NTPase domain (shown in purple) and a bound guanine nucleotide. [Drawn from 1JFF.pdb.]

Taxol binds to microtubules and stabilizes the polymerized form. Taxol and its derivatives have been developed as anticancer agents because they preferentially affect rapidly dividing cells, such as those in tumors.

### Kinesin motion is highly processive

Kinesins are motor proteins that move along microtubules. We have seen that muscle myosin moves along actin filaments by a process in which actin is released in each cycle; a myosin head group acting independently dissociates from actin after every power stroke. In contrast, when a kinesin molecule moves along a microtubule, the two head groups of the kinesin molecule operate in tandem: one binds, and then the next one does. A kinesin molecule may take many steps before both head groups are dissociated at the same time. In other words, the motion of kinesin is highly processive. Single-molecule measurements allow processive motion to be observed (Figure 35.23). A single kinesin molecule will typically take 100 or more steps toward the plus end of a microtubule in a period of seconds before the molecule becomes detached from the microtubule. These measurements also revealed that the average step size is approximately 80 Å, a value that corresponds to the distance between consecutive  $\alpha$ - or  $\beta$ -tubulin subunits along each protofilament.

An additional fact is crucial to the development of a mechanism for kinesin motion—namely, that the addition of ATP strongly *increases* the affinity of kinesin for microtubules. This behavior stands in contrast with the behavior of myosin; ATP binding to myosin promotes its *dissociation* from actin. Do these differences imply that kinesin and myosin operate by completely different mechanisms? Indeed not. Kinesin-generated movement

**FIGURE 35.23 Monitoring movements mediated by kinesin.** (A) The movement of beads or vesicles, carried by individual kinesin dimers along a microtubule, can be directly observed. (B) A trace shows the displacement of a bead carried by a kinesin molecule. Multiple steps are taken in the 6-s interval. The average step size is about 8 nm (80 Å). [(B) Data from K. Svoboda et al., *Nature* 365:721–727, 1993.]

**FIGURE 35.24 Kinesin moving along a microtubule.** (1) One head of a two-headed kinesin molecule, initially with both heads in the ADP form, binds to a microtubule. (2) The release of ADP and the binding of ATP results in a conformational change that locks the head to the microtubule and pulls the neck linker (orange) to the head domain, throwing the second domain toward the plus end of the microtubule. (3) ATP undergoes hydrolysis while the second head interacts with the microtubule. (4) The exchange of ATP for ADP in the second head pulls the first head off the microtubule, releasing  $P_i$  and moving the first domain along the microtubule. (5) The cycle repeats, moving the kinesin dimer farther down the microtubule.

appears to proceed by a mechanism that is quite similar to that used by myosin (Figure 35.24). Let us begin with a two-headed kinesin molecule in its ADP form, dissociated from a microtubule. Recall that the neck linker binds the head domain when ATP is bound and is released when ADP is bound. The initial interaction of one of the head domains with a tubulin dimer on a microtubule stimulates the release of ADP from this head domain and the subsequent binding of ATP. The binding of ATP triggers a conformational change in the head domain that leads to two important events. First, the affinity of the head domain for the microtubule increases, essentially locking this head domain in place. Second, the neck linker binds to the head domain. This change, transmitted through the coiled-coil domain that connects the two kinesin monomers, repositions the other head domain. In its new position, the second head domain is close to a second tubulin dimer, 80 Å along the microtubule in the direction of the plus end. Meanwhile, the intrinsic ATPase activity of the first head domain hydrolyzes the ATP to ADP and  $P_i$ . When the second head domain binds to the microtubule, the first head releases ADP and binds ATP. Again, ATP binding favors a conformational change that pulls the first domain forward. This process can continue for many cycles until, by chance, both head domains are in the ADP form simultaneously and kinesin dissociates from the microtubule. Because of the relative rates of the component reactions, a simultaneous dissociation takes place approximately every 100 cycles. Thus, kinesin “walks” hand over hand along the microtubule for approximately 100 steps before both “hands” simultaneously let go. Although recent studies have led to a structural model for the dynein power stroke, the mechanism by which it works is unknown and an interesting research frontier.

Kinesin hydrolyzes ATP at a rate of approximately 80 molecules per second. Thus, given the step size of 80 Å per molecule of ATP, kinesin moves along a microtubule at a speed of 6400 Å per second. This rate is considerably lower than the maximum rate for myosin, which moves relative to actin at

80,000 Å per second. Recall, however, that myosin movement depends on the independent action of hundreds of different head domains working along the same actin filament, whereas the movement of kinesin is driven by the processive action of kinesin head groups working in pairs. Muscle myosin evolved to maximize the speed of the motion, whereas kinesin functions to achieve steady, but slower, transport in one direction along a filament.

### 35.4 A Rotary Motor Drives Bacterial Motion

In 1 s, a motile bacterium can move approximately 25  $\mu\text{m}$ , or about 10 body lengths. A human being sprinting at a proportional rate would complete the 100-meter dash in slightly more than 5 s. The motors that power this impressive motion are strikingly different from the eukaryotic motors that we have seen so far. In the bacterial motor, an element spins around a central axis rather than moving along a polymeric track. The direction of rotation can change rapidly, a feature that is central to chemotaxis, the process by which bacteria swim preferentially toward an increasing concentration of certain useful compounds and away from potentially harmful ones. One type of flagellar motor, powered by a  $\text{Na}^+$  gradient, turns at a rate of 200,000 revolutions per minute.

**FIGURE 35.25 Bacterial flagella.** Electron micrograph of *Salmonella typhimurium* shows flagella directed backwards, where they can form a bundle under appropriate circumstances. [Science Source.]

#### Bacteria swim by rotating their flagella

Bacteria such as *Escherichia coli* and *Salmonella typhimurium* swim by rotating flagella that lie on their surfaces (Figure 35.25). When the flagella rotate in a counterclockwise direction (viewed from outside a bacterium), the separate flagella form a bundle that very efficiently propels the bacterium through solution.

Bacterial flagella are polymers approximately 15 nm in diameter and as much as 15  $\mu\text{m}$  in length, composed of 53-kDa subunits of a protein called *flagellin* (Figure 35.26). These subunits associate into a helical structure that has 5.5 subunits per turn, giving the appearance of 11 protofilaments. Each flagellum has a hollow core. Remarkably, flagella form not by growing at the base adjacent to the cell body but, instead, by the addition of new subunits that pass through the hollow core and add to the free end. Each flagellum is intrinsically twisted in a left-handed sense. At its base, each flagellum has a rotary motor.

**FIGURE 35.26 Structure of flagellin.** A bacterial flagellum is a helical polymer of the protein flagellin. Notice that each subunit corresponds to a bent structure with a relatively flat surface facing the hollow core of the flagellum. [Drawn from 1IO1.pdb.]

#### Proton flow drives bacterial flagellar rotation

Early experiments by Julius Adler demonstrated that ATP is *not* required for flagellar motion. What powers these rotary motors? The necessary free energy is derived from the proton gradient that exists across the plasma

membrane. The flagellar motor is quite complex, containing as many as 40 distinct proteins (Figure 35.27). Five components particularly crucial to motor function have been identified through genetic studies. MotA is a membrane protein that appears to have four transmembrane helices as well as a cytoplasmic domain. MotB is another membrane protein with a single trans-membrane helix and a large periplasmic domain. Approximately 11 *MotA–MotB* pairs form a ring around the base of the flagellum. The proteins *FliG*, *FliM*, and *FliN* are part of a disc-like structure called the MS (membrane and supramembrane) ring, with approximately 30 *FliG* subunits coming together to form the ring. The three-dimensional structure of the carboxyl-terminal half of *FliG* reveals a wedge-shaped domain with a set of charged amino acids, conserved among many species, lying along the thick edge of the wedge (Figure 35.28).

The *MotA–MotB* pair and *FliG* combine to create a proton channel that drives the rotation of the flagellum. How can proton flow across a membrane drive mechanical rotation? We have seen such a process earlier in regard to ATP synthase (Section 18.4). Recall that the key to driving the rotation of the  $\gamma$  subunit of ATP synthase is the  $a$  subunit of the  $F_0$  fragment. This subunit appears to have two half-channels; protons can move across the membrane only by moving into the half-channel from the side of the membrane with the higher local proton concentration, binding to a disc-like structure formed by the  $c$  subunits, riding on this structure as it rotates to the opening of the other half-channel, and exiting to the side with the lower local proton concentration. Could a similar mechanism apply to flagellar rotation? Indeed, such a mechanism was first proposed by Howard Berg to explain flagellar rotation before the rotary mechanism of ATP synthase was elucidated. Each *MotA–MotB* pair is conjectured to form a structure that has two half-channels; *FliG* serves as the rotating proton carrier, perhaps with the participation of some of the charged residues identified in crystallographic studies (Figure 35.29). In this scenario, a proton from the periplasmic space passes into the outer half-channel and is transferred to an *FliG* subunit. The MS ring rotates, rotating the flagellum with it and allowing the proton to pass into the inner half-channel and into the cell. Ongoing structural and mutagenesis studies are testing and refining this hypothesis.

**FIGURE 35.28 Flagellar motor components.** Approximately 30 subunits of *FliG* assemble to form part of the MS ring. The ring is surrounded by approximately 11 structures consisting of *MotA* and *MotB*. Notice that the carboxyl-terminal domain of *FliG* includes a ridge lined with charged residues that may participate in proton transport. [Drawn from 1QC7.pdb.]

**FIGURE 35.27 Flagellar motor.** A schematic view of the flagellar motor, a complex structure containing as many as 40 distinct types of protein. The approximate positions of the proteins *MotA* and *MotB* (red), *FliG* (orange), *FliN* (yellow), and *FliM* (green) are shown.

**FIGURE 35.29 Proton-transport-coupled rotation of the flagellum.** (A) MotA–MotB may form a structure having two half-channels. (B) One model for the mechanism of coupling rotation to a proton gradient requires protons to be taken up into the outer half-channel and transferred to the MS ring. The MS ring rotates in a counterclockwise direction, and the protons are released into the inner half-channel. The flagellum is linked to the MS ring and so the flagellum rotates as well.

### Bacterial chemotaxis depends on reversal of the direction of flagellar rotation

Many species of bacteria respond to changes in their environments by adjusting their swimming behavior. Examination of the paths taken is highly revealing (Figure 35.30). The bacteria swim in one direction for some length of time (typically about a second), tumble briefly, and then set off in a new direction. The tumbling is caused by a brief reversal in the direction of the flagellar motor. When the flagella rotate counterclockwise, the helical filaments form a coherent bundle favored by the intrinsic shape of each filament, and the bacterium swims smoothly. When the rotation reverses, the bundle flies apart because the screw sense of the helical flagella does not match the direction of rotation. Each flagellum then pulls in a different direction and the cell tumbles.

In the presence of a gradient of certain substances such as glucose, bacteria swim preferentially toward the direction of the higher concentration of the substance. Such compounds are referred to as *chemoattractants*. Bacteria also swim preferentially away from potentially harmful compounds such as phenol, a *chemorepellant*. The process of moving in specific directions in response to environmental cues is called *chemotaxis*. In the presence of a gradient of a chemoattractant, bacteria swim for longer periods of time without tumbling when moving toward higher concentrations of the chemoattractant. In contrast, they tumble more frequently when moving toward lower concentrations of the chemoattractant. This behavior is reversed for chemorepellants. The result of these actions is a *biased random walk* that facilitates net motion toward conditions more favorable to the bacterium.

Chemotaxis depends on a signaling pathway that terminates at the flagellar motor. The signaling pathway begins with the binding of molecules to receptors in the plasma membrane (Figure 35.31). In their *unoccupied* forms, these receptors initiate a pathway leading eventually to the phosphorylation of a specific aspartate residue on a soluble protein called *CheY*. In its phosphorylated form, *CheY* binds to the base on the flagellar motor. When bound to phosphorylated *CheY*, the flagellar motor rotates in a clockwise rather than a counterclockwise direction, causing tumbling.

The binding of a chemoattractant to a surface receptor blocks the signaling pathway leading to *CheY* phosphorylation. Phosphorylated *CheY* spontaneously hydrolyzes and releases its phosphoryl group in a process accelerated by another protein, *CheZ*. The concentration of phosphorylated *CheY* drops, and the flagella are less likely to rotate in a clockwise direction. Under these conditions, bacteria swim smoothly without tumbling. Thus, the reversible rotary flagellar motor and a phosphorylation-based signaling pathway work together to generate an effective means for responding to environmental conditions.

**FIGURE 35.30 Charting a course.** This projection of the track of an *E. coli* bacterium was obtained with a microscope that automatically follows bacterial motion in three dimensions. The points show the locations of the bacterium at 80-ms intervals. [Information from H. C. Berg, *Nature* 254:389–392, 1975.]

**FIGURE 35.31 Chemotaxis signaling pathway.** Receptors in the plasma membrane initiate a signaling pathway leading to the phosphorylation of the CheY protein. Phosphorylated CheY binds to the flagellar motor and favors clockwise rotation. When an attractant binds to the receptor, this pathway is blocked, and counterclockwise flagellar rotation and, hence, smooth swimming result. When a repellent binds, the pathway is stimulated, leading to an increased concentration of phosphorylated CheY and, hence, more-frequent clockwise rotation and tumbling.

Bacteria sense spatial gradients of chemoattractants by measurements separated in time. A bacterium sets off in a random direction and, if the concentration of the chemoattractant has increased after the bacterium has been swimming for a period of time, the likelihood of tumbling decreases and the bacterium continues in roughly the same direction. If the concentration has decreased, the tumbling frequency increases and the bacterium tests other random directions. The success of this mechanism once again reveals the power of evolutionary problem solving: many possible solutions are tried at random, and those that are beneficial are selected and exploited.

## SUMMARY

### 35.1 Most Molecular-Motor Proteins Are Members of the P-Loop NTPase Superfamily

Eukaryotic cells contain three families of molecular-motor proteins: myosins, kinesins, and dyneins. These proteins move along tracks defined by the actin and microtubule cytoskeletons of eukaryotic cells, contributing to cell and organismal movement and to the intracellular transport of proteins, vesicles, and organelles. Despite considerable differences in size and a lack of similarity detectable at the level of amino acid sequence, these proteins are homologous, containing core structures of the P-loop NTPase family. The ability of these core structures to change conformations in response to nucleoside triphosphate binding and hydrolysis is key to molecular-motor function. Motor proteins consist of motor domains attached to extended structures that serve to amplify the conformational changes in the core domains and to link the core domains to one another or to other structures.

### 35.2 Myosins Move Along Actin Filaments

The motile structure of muscle consists of a complex of myosin and actin, along with accessory proteins. Actin, a highly abundant 42-kDa protein, polymerizes to form long filaments. Each actin monomer can bind either ATP or ADP. A myosin motor domain moves along actin filaments in a cyclic manner, beginning with myosin free of bound

nucleotides bound to actin: (1) ATP binds to myosin and the myosin is released from actin; (2) a reversible conformational change associated with the hydrolysis of ATP while still bound to myosin leads to a large motion of a lever arm that extends from the motor domain; (3) myosin with bound ADP and  $P_i$  binds to actin; (4)  $P_i$  is released from myosin, resulting in resetting the position of the lever arm and moving actin relative to myosin; and (5) the release of ADP returns the motor domain to its initial state. The length of the lever arm determines the size of the step taken along actin in each cycle. The ability to monitor single molecular-motor proteins has provided key tests for hypotheses concerning motor function. Muscle contraction entails the rapid sliding of thin filaments, composed of actin, relative to thick filaments, composed of myosin. The thick filaments consist of multiple myosin molecules bound together. Each myosin molecule has two heads that can bind to actin and move it relative to myosin, driven by the hydrolysis of ATP by myosin. Muscle contraction is regulated by tropomyosin and the troponin complex. These proteins prevent actin and myosin from productively interacting until an increase in calcium concentration associated with a nerve impulse results in calcium-induced changes in troponin and tropomyosin.

### 35.3 Kinesin and Dynein Move Along Microtubules

Kinesin and dynein move along microtubules rather than actin. Microtubules are polymeric structures composed of  $\alpha$ - and  $\beta$ -tubulin, two very similar guanine-nucleotide-binding proteins. Each microtubule comprises 13 protofilaments with alternating  $\alpha$ - and  $\beta$ -tubulin subunits. Kinesins move along microtubules by a mechanism quite similar to that used by myosin to move along actin but with several important differences. First, ATP binding to kinesin favors motor-domain binding rather than dissociation. Second, the power stroke is triggered by the binding of ATP rather than the release of  $P_i$ . Finally, kinesin motion is processive. The two heads of a kinesin dimer work together, taking turns binding and releasing the microtubule, and many steps are taken along a microtubule before both heads dissociate. Most kinesins move toward the plus end of microtubules.

### 35.4 A Rotary Motor Drives Bacterial Motion

Many motile bacteria use rotating flagella to propel themselves. When rotating counterclockwise, multiple flagella on the surface of a bacterium come together to form a bundle that effectively propels the bacterium through solution. A proton gradient across the plasma membrane, rather than ATP hydrolysis, powers the flagellar motor. The mechanism for coupling transmembrane proton transport to macromolecular rotation appears to be similar to that used by ATP synthase. When rotating clockwise, the flagella fly apart and the bacterium tumbles. Bacteria swim preferentially toward chemoattractants in a process called chemotaxis. When bacteria are swimming in the direction of an increasing concentration of a chemoattractant, clockwise flagellar motion predominates and tumbling is suppressed, leading to a biased random walk in the direction of increasing chemoattractant concentration.

## PROBLEMS

1. *Diverse motors.* Skeletal muscle, eukaryotic cilia, and bacterial flagella use different strategies for the conversion of free energy into coherent motion. Compare and contrast these motility systems with respect to (a) the free-energy source and (b) the number of essential components and their identity.

2. *You call that slow?* At maximum speed, a kinesin molecule moves at a rate of 6400 Å per second. Given the dimensions of the motor region of a kinesin dimer of approximately 80 Å, calculate its speed in “body lengths” per second. To what speed does this body-length speed correspond for an automobile 10 feet long?

3. *Heavy lifting.* A single myosin motor domain can generate a force of approximately 4 piconewtons (4 pN). How many times its “body weight” can a myosin motor domain lift? Note that 1 newton = 0.22 pounds (100 g). Assume a molecular mass of 100 kDa for the motor domain.

4. *Compare and contrast.* Describe two similarities and two differences between actin filaments and microtubules.

5. *Lighten up.* What is the primary role of the light chains in myosin? In kinesin?

6. *Rigor mortis.* Propose an explanation for the fact that the body stiffens after death.

7. *Now you see it, now you don't.* Under certain stable concentration conditions, actin monomers in their ATP form will polymerize to form filaments that disperse again into free actin monomers over time. Explain.

8. *Helicases as motors.* Helicases can use single-stranded DNA as tracks. Consider a helicase that moves one base in the 3' → 5' direction in each cycle. Assuming that the helicase can hydrolyze ATP at a rate of 50 molecules per second in the presence of a single-stranded DNA template, calculate the velocity of the helicase in micrometers per second. How does this velocity compare with that of kinesin?

9. *New moves.* When bacteria such as *E. coli* are starved to a sufficient extent, they become nonmotile. However, when such bacteria are placed in an acidic solution, they resume swimming. Explain.

10. *Going straight.* Suppose you measure the mean distance that an *E. coli* bacterium moves along a straight path before it tumbles over a period of time. Would you expect this distance to change in the presence of a gradient of a chemoattractant? Would it be longer or shorter?

11. *Hauling a load.* Consider the action of a single kinesin molecule in moving a vesicle along a microtubule track. The force required to drag a spherical particle of radius  $a$  at a velocity  $v$  in a medium having a viscosity  $\eta$  is

$$F = 6\pi\eta av$$

Suppose that a 2- $\mu\text{m}$ -diameter bead is carried at a velocity of 0.6  $\mu\text{m s}^{-1}$  in an aqueous medium ( $\eta = 0.01$  poise = 0.01  $\text{g cm}^{-1} \text{s}^{-1}$ ).

(a) What is the magnitude of the force exerted by the kinesin molecule? Express the value in dynes (1 dyne = 1  $\text{g cm s}^{-2}$ ).

(b) How much work is performed in 1 s? Express the value in ergs (1 erg = 1 dyne cm).

(c) A kinesin motor hydrolyzes approximately 80 molecules of ATP per second. What is the energy associated with the hydrolysis of this much ATP in ergs? Compare this value with the actual work performed.

12. *Unusual strides.* A publication describes a kinesin molecule that is claimed to move along microtubules with a step size of 6 nm. You are skeptical. Why?

13. *The sound of one hand clapping.* KIF1A is a motor protein that moves toward the plus end of microtubules as a monomer. KIF1A has only a single motor domain. What additional structural elements would you expect to find in the KIF1A structure?

14. *Building blocks.* Actin filaments, microtubules, and bacterial flagella are all built from small subunits. Describe three advantages of assembling long filamentous structures from subunits rather than from single, long proteins.

### Mechanism Problem

15. *Backward rotation.* On the basis of the proposed structure in Figure 35.29 for the bacterial flagellar motor, suggest

a pathway for transmembrane proton flow when the flagellar motor is rotating clockwise rather than counterclockwise.

### Chapter Integration Problem

16. *Smooth muscle.* Smooth muscle, in contrast with skeletal muscle, is not regulated by a tropomyosin–troponin mechanism. Instead, vertebrate smooth-muscle contraction is controlled by the degree of phosphorylation of its light chains. Phosphorylation induces contraction, and dephosphorylation leads to relaxation. Like that of skeletal muscle, smooth-muscle contraction is triggered by an increase in the cytoplasmic calcium ion level. Propose a mechanism for this action of calcium ion on the basis of your knowledge of other signal-transduction processes.

### Data Interpretation Problem

17. *Myosin V.* An abundant myosin-family member, myosin V is isolated from brain tissue. This myosin has a number of unusual properties. First, on the basis of its amino acid sequence, each heavy chain has six tandem binding sites for calmodulin-like light chains. Second, it forms dimers but not higher-order oligomers. Finally, unlike almost all other myosin-family members, myosin V is highly processive.

The rate of ATP hydrolysis by myosin has been examined as a function of ATP concentration, as shown in graph A.

(a) Estimate the values of  $k_{\text{cat}}$  and  $K_M$  for ATP.

With the use of optical-trap measurements, the motion of single myosin V dimers could be followed, as shown in graph B.

[Based on M. Rief et al., *Proc. Natl. Acad. Sci. U. S. A.* 97:9482–9486, 2000.]

(b) Estimate the step size for myosin V.

The rate of ADP release from myosin V is found to be approximately 13 molecules per second.

(c) Combine the observations about the amino acid sequence of myosin, the observed step size, and the kinetics results to propose a mechanism for the processive motion of myosin V.

## Drug Development

Many drugs are based on natural products. Aspirin (above) is a molecule related to a compound isolated from willow bark (near left). Extracts of willow bark had long been known to have medicinal properties. The active compound was isolated, modified, and, beginning in 1899, packaged for consumers (far left). [(Far left) AP Images/Bayer. (Near left) H. Mark Weidman Photography/Alamy.]

The development of drugs is among the most important interfaces between biochemistry and medicine. Throughout the previous chapters in this book, we have encountered a number of types of proteins—enzymes, receptors, and transporters—that serve as targets for a majority of the drugs in clinical use (Figure 36.1). In most cases, drugs act by binding to these proteins and inhibiting or otherwise modulating their activities. Thus, knowledge of these molecules and the pathways in which they participate is crucial to drug development. An effective drug is much more than a potent modulator of its target, however. Drugs must be readily administered to patients, preferably as small tablets taken orally, and must survive within the body long enough to reach their targets. Furthermore, to prevent unwanted physiological effects, drugs must not modulate the properties of biomolecules other than the intended targets. These requirements tremendously limit the number of compounds that have the potential to be clinically useful drugs.

Drugs have been discovered by two fundamentally distinct approaches (Figure 36.2). The first approach identifies a substance that has a desirable physiological consequence when administered to a human being, to an appropriate animal, or to cells. Such substances can be discovered by serendipity, by the fractionation of plants or other materials known to have

## OUTLINE

- 36.1 The Development of Drugs Presents Huge Challenges
- 36.2 Drug Candidates Can Be Discovered by Serendipity, Screening, or Design
- 36.3 Analyses of Genomes Hold Great Promise for Drug Discovery
- 36.4 The Clinical Development of Drugs Proceeds Through Several Phases

**FIGURE 36.1 The targets of drugs in current use.** In this pie chart, currently-used drugs that modulate human proteins are sorted by target type: enzymes in green, receptors in blue, transporters in red, and other targets in gray. [Data from M. Rask-Andersen et al., *Nat. Rev. Drug Discov.* 10:579–590, 2011]

medicinal properties, or by screening natural products or other “libraries” of compounds. In this approach, a biological effect is known before the molecular target is identified. The mode of action of the substance is only later identified after substantial additional work. The second approach begins with a known molecular target. Compounds are sought, either by screening or by designing molecules with desired properties, that bind to the target molecule and modulate its properties. After such compounds are available, scientists can explore their effects on appropriate cells or organisms. Many unexpected results may be encountered in this process as the complexity of biological systems reveals itself.

In this chapter, we explore the science of pharmacology. We examine a number of case histories that illustrate drug development—including many of its concepts, methods, and challenges. We then see how the concepts and tools from genomics are influencing approaches to drug discovery. The chapter ends with a summary of the clinical trial phases required for drug development.

#### Pharmacology

The science that deals with the discovery, chemistry, composition, identification, biological and physiological effects, uses, and manufacture of drugs.

(A)

(B)

**FIGURE 36.2 Two paths to drug discovery.** (A) A compound is discovered to have a desirable physiological effect. The molecular target can be identified in a separate step as needed. (B) A molecular target is selected first. Drug candidates that bind to the target are identified and then examined for their physiological effects.

## 36.1 The Development of Drugs Presents Huge Challenges

Many compounds have significant effects when taken into the body, but only a very small fraction of them have the potential to be useful drugs. A foreign compound, not adapted to its role in the cell through long evolution, must have a range of special properties to function effectively without

causing serious harm. Let us consider some of the challenges faced by drug developers.

### Drug candidates must be potent and selective modulators of their targets

Most drugs bind to specific proteins, usually receptors or enzymes, within the body. To be effective, a drug should bind a sufficient number of its target proteins when taken at a reasonable dose. One factor in determining drug effectiveness is the strength of the interaction between the drug and its target. A molecule that binds to some target protein is often referred to as a *ligand*. A ligand-binding curve is shown in Figure 36.3. Ligand molecules occupy progressively more target binding sites as ligand concentration increases until essentially all of the available sites are occupied. The tendency of a ligand to bind to its target is measured by the *dissociation constant*,  $K_d$ , defined by the expression

$$K_d = [R][L]/[RL]$$

where  $[R]$  is the concentration of the free receptor,  $[L]$  is the concentration of the free ligand, and  $[RL]$  is the concentration of the receptor–ligand complex. The dissociation constant is a measure of the strength of the interaction between the drug candidate and the target; the lower the value, the stronger the interaction. The concentration of free ligand at which one-half of the binding sites are occupied equals the dissociation constant, as long as the concentration of binding sites is substantially less than the dissociation constant.

In many cases, biological assays using living cells or tissues (rather than direct enzyme or binding assays) are employed to examine the potency of drug candidates. For example, the fraction of bacteria killed by a drug might indicate the potency of a potential antibiotic. In these cases, values such as  $EC_{50}$  are used.  $EC_{50}$  is the concentration of the drug candidate required to elicit 50% of the maximal biological response (Figure 36.4). Similarly,  $EC_{90}$  is the concentration required to achieve 90% of the maximal response. In the example of an antibiotic,  $EC_{90}$  would be the concentration required to kill 90% of bacteria exposed to the drug. For drug candidates that are inhibitors, the corresponding terms  $IC_{50}$  and  $IC_{90}$  are often used to describe the concentrations of the inhibitor required to reduce a response by 50% or 90%, relative to its value in the absence of inhibitor, respectively.

Values such as the  $IC_{50}$  and  $EC_{50}$  are measures of the *potency* of a drug candidate in modulating the activity of the desired biological target. To prevent unwanted effects, often called *side effects*, ideal drug candidates should also be *selective*. That is, they should not bind biomolecules other than the target to any significant extent. Developing such a drug can be quite challenging, particularly if the drug target is a member of a large family of evolutionarily related proteins. The degree of selectivity can be described in terms of the ratio of the  $K_d$  values for the binding of the drug candidate to any other molecules to the  $K_d$  value for the binding of the drug candidate to the desired target.

Under physiological conditions, achieving sufficient binding of a target site by a drug can be quite challenging. Most drug targets also bind ligands normally present in tissues; often, the drug and these ligands will compete for binding sites on the target. We encountered this scenario when we considered competitive inhibitors in Chapter 8. Suppose that the drug target is an enzyme and the drug candidate is competitive with respect to the enzyme's natural substrate. The concentration of the drug candidate necessary to inhibit the enzyme will depend on the physiological concentration of the normal substrate (Figure 36.5). Biochemists Yung-Chi Cheng and William Prusoff

**FIGURE 36.3 Ligand binding.** The titration of a receptor,  $R$ , with a ligand,  $L$ , results in the formation of the complex  $RL$ . In uncomplicated cases, the binding reaction follows a simple saturation curve. Half of the receptors are bound to ligand when the ligand concentration equals the dissociation constant,  $K_d$ , for the  $RL$  complex.

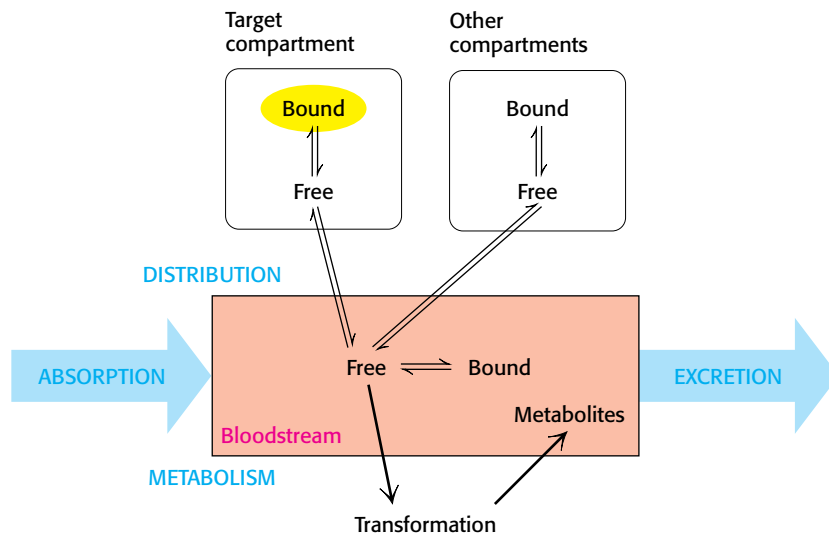

**FIGURE 36.4 Effective concentrations.** The concentration of a ligand required to elicit a biological response can be quantified in terms of  $EC_{50}$ , the concentration required to give 50% of the maximum response, and  $EC_{90}$ , the concentration required to give 90% of the maximum response.

**FIGURE 36.5 Inhibitors compete with substrates for enzyme active sites.**

The measured  $IC_{50}$  of a competitive inhibitor to its target enzyme depends on the concentration of substrate present.

**FIGURE 36.6** Absorption, distribution, metabolism, and excretion (ADME). The concentration of a compound at its target site (yellow) is affected by the extents and rates of absorption, distribution, metabolism, and excretion.

described the relation between the  $IC_{50}$  of an enzyme inhibitor and its *inhibition constant*  $K_i$  (analogous to the dissociation constant,  $K_d$ , of a ligand):

$$IC_{50} = K_i (1 + [S]/K_M)$$

This relation, referred to as the *Cheng–Prusoff equation*, demonstrates that the  $IC_{50}$  of a competitive inhibitor will depend on the concentration and the Michaelis constant ( $K_M$ ) for the substrate  $S$ . The higher the concentration of the natural substrate, the higher the concentration of drug needed to inhibit the enzyme.

### Drugs must have suitable properties to reach their targets

Thus far, we have focused on the ability of molecules to act on specific target molecules. However, an effective drug must also have other characteristics. It must be easily administered and must reach its target at sufficient concentration to be effective. After a drug molecule has entered the body, it is acted upon by several processes—absorption, distribution, metabolism, and excretion—that will determine the effective concentration of this molecule over time (Figure 36.6). A drug's response to these processes is referred to as its *ADME* (pronounced “add-me”) properties.

**Administration and absorption.** Ideally, a drug can be taken orally as a small tablet. An orally administered active compound must be able to survive the acidic conditions in the gut and then be absorbed through the intestinal epithelium. Thus, the compound must be able to pass through cell membranes at a significant rate. Larger molecules such as proteins cannot be administered orally, because they often cannot survive the acidic conditions in the stomach and, if they do, are not readily absorbed. Even many small molecules are not absorbed well; they may be too polar and not pass through cell membranes easily, for example. The ability to be absorbed is often quantified in terms of the *oral bioavailability*. This quantity is defined as the ratio of the peak concentration of a compound given orally to the peak concentration of the same dose injected directly into the bloodstream. Bioavailability can vary considerably from species to species, and so results from animal studies may be difficult to apply to human beings. Despite this variability, some useful generalizations have been made. One powerful set consists of *Lipinski's rules*.

Lipinski's rules tell us that poor absorption is likely when

1. the molecular weight is greater than 500.
2. the number of hydrogen-bond donors is greater than 5.

- the number of hydrogen-bond acceptors is greater than 10.
- the partition coefficient [measured as  $\log(P)$ ] is greater than 5.

The partition coefficient is a way to measure the tendency of a molecule to dissolve in membranes, which correlates with its ability to dissolve in organic solvents. It is determined by allowing a compound to equilibrate between water and an organic phase, *n*-octanol. The  $\log(P)$  value is defined as  $\log_{10}$  of the ratio of the concentration of a compound in *n*-octanol to the concentration of the compound in water. For example, if the concentration of the compound in the *n*-octanol phase is 100 times that in the aqueous phase, then  $\log(P)$  is 2. Although the ability of a drug to partition in organic solvents is ideal, because it implies that the compound can penetrate membranes, a  $\log(P)$  value that is too high suggests that the molecule may be poorly soluble in an aqueous environment.

Morphine, for example, satisfies all of Lipinski's rules and has moderate bioavailability (Figure 36.7). A drug that violates one or more of these rules may still have satisfactory bioavailability. Nonetheless, these rules serve as guiding principles for evaluating new drug candidates.

**Morphine (C<sub>17</sub>H<sub>19</sub>O<sub>3</sub>N)**

Molecular weight = 285

$\log(P)$  = 1.27

**FIGURE 36.7 Lipinski's rules applied to morphine.** Morphine satisfies all of Lipinski's rules and has an oral bioavailability in human beings of 33%.

**Distribution.** Compounds taken up by intestinal epithelial cells can pass into the bloodstream. However, hydrophobic compounds and many others do not freely dissolve in the bloodstream. These compounds bind to proteins, such as albumin (Figure 36.8), that are abundant in the blood serum and by this means are carried throughout the circulatory system.

When a compound has reached the bloodstream, it is distributed to different fluids and tissues, which are often referred to as *compartments*. Some compounds are highly concentrated in their target compartments, either by binding to the target molecules themselves or by other mechanisms. Other compounds are distributed more widely (Figure 36.9). An effective drug will reach the target compartment in sufficient quantity; the concentration of the compound in the target compartment is reduced whenever the compound is distributed into other compartments.

Some target compartments are particularly hard to reach. Many compounds are excluded from the central nervous system by the *blood-brain barrier*, the tight junctions between endothelial cells that line blood vessels within the brain and spinal cord.

**Metabolism.** A final challenge to a potential drug molecule is to evade the body's defenses against foreign compounds. Many such compounds (called *xenobiotic compounds*) are released from the body in the urine or stool, often after having been metabolized to aid in excretion. This *drug metabolism* poses a considerable threat to drug effectiveness because the concentration of the desired compound decreases as it is metabolized. Thus, a rapidly metabolized compound must be administered more frequently or at higher doses.

Two of the most common pathways in xenobiotic metabolism are *oxidation* and *conjugation*. Oxidation reactions can aid excretion in at least two ways: by increasing water solubility, and thus ease of transport, and by introducing functional groups that participate in subsequent metabolic steps. These reactions are often promoted by cytochrome P450 enzymes in the liver (Section 26.4). The human genome encodes more than 50 different P450 isozymes, many of which participate in xenobiotic metabolism.

**FIGURE 36.8 Structure of the drug carrier human serum albumin.** Seven hydrophobic molecules (in red) are shown bound to the molecule. [Drawn from 1BKE.pdb.]

**FIGURE 36.9 Distribution of the drug fluconazole.** After having been taken in, compounds distribute themselves to various organs within the body. The distribution of the antifungal agent fluconazole has been monitored through the use of positron emission tomography (PET) scanning. These images were taken of a healthy human volunteer 90 minutes after injection of a dose of  $5 \text{ mg kg}^{-1}$  of fluconazole containing trace amounts of fluconazole labeled with the positron-emitting isotope  $^{18}\text{F}$ . [Reprinted by permission from Macmillan Publishers Ltd: Nature Reviews Drug Discovery, Rudin, M., and Weissleder, R., "Molecular imaging in drug discovery and development," 2: 2, p. 123–131, Copyright 2003.]

A typical reaction catalyzed by a P450 isozyme is the hydroxylation of ibuprofen (Figure 36.10).

**FIGURE 36.10 P450 conversion of ibuprofen.** Cytochrome P450 isozymes, primarily in the liver, catalyze xenobiotic metabolic reactions such as hydroxylation. The reaction introduces an oxygen atom derived from molecular oxygen.

Conjugation is the addition of particular groups to the xenobiotic compound. Common groups added are glutathione (Section 20.5), glucuronic acid, and sulfate (Figure 36.11). These additions often increase water solubility and provide labels that can be recognized to target excretion. Examples of conjugation include the addition of glutathione to the anticancer drug cyclophosphamide, the addition of glucuronidate to the analgesic morphine, and the addition of a sulfate group to the hair-growth stimulator minoxidil.

Interestingly, the sulfation of minoxidil produces a compound that is more active in stimulating hair growth than is the unmodified compound. Thus, the metabolic products of a drug, though usually less active than the drug, can sometimes be more active.

**FIGURE 36.11 Conjugation reactions.**

Compounds that have appropriate groups are often modified by conjugation reactions. Such reactions include the addition of glutathione (top), glucuronic acid (middle), or sulfate (bottom). The conjugated product is shown boxed.

Note that an oxidation reaction often precedes conjugation because the oxidation reaction can generate modifications, such as the hydroxyl group, to which groups such as glucuronic acid can be attached. The oxidation reactions of xenobiotic compounds are often referred to as *phase I transformations*, and the conjugation reactions are referred to as *phase II transformations*. These reactions take place primarily in the liver. Because blood flows from the intestine directly to the liver through the portal vein, xenobiotic metabolism often alters drug compounds before they ever reach full circulation. This *first-pass metabolism* can substantially limit the availability of compounds taken orally.

**Excretion.** After compounds have entered the bloodstream, they can be removed from circulation and excreted from the body by two primary pathways. First, they can be absorbed through the kidneys and excreted in the urine. In this process, the blood passes through *glomeruli*, networks of fine capillaries in the kidney that act as filters. Compounds with molecular weights less than approximately 60,000 pass through the glomeruli. Many of the water molecules, glucose molecules, nucleotides, and other low-molecular-weight compounds that pass through the glomeruli are reabsorbed into the bloodstream, either by transporters that have broad specificities or by the passive transfer of hydrophobic molecules through membranes. Drugs and metabolites that pass through the first filtration step and are not reabsorbed are excreted.

Second, compounds can be actively transported into bile, a process that takes place in the liver. After concentration in the gall bladder, bile flows into the intestine. In the intestine, the drugs and metabolites can be excreted through the stool, reabsorbed into the bloodstream, or further degraded by

**FIGURE 36.12 Enterohepatic cycling.** Some drugs can move from the blood circulation to the liver, into the bile, into the intestine, to the liver, and back into circulation. This cycling decreases the rate of drug excretion.

**FIGURE 36.13 Half-life of drug excretion.** In the case shown, the concentration of a drug in the bloodstream decreases to one-half of its value in a period of time,  $t_{1/2}$ , referred to as its half-life.

digestive enzymes. Sometimes, compounds are recycled from the bloodstream into the intestine and back into the bloodstream, a process referred to as *enterohepatic cycling* (Figure 36.12). This process can significantly decrease the rate of excretion of some compounds because they escape from an excretory pathway and reenter the circulation.

The kinetics of compound excretion is often complex. In some cases, a fixed percentage of the remaining compound is excreted over a given period of time (Figure 36.13). This pattern of excretion results in exponential loss of the compound from the bloodstream that can be characterized by a half-life ( $t_{1/2}$ ). The half-life is the fixed period of time required to eliminate 50% of the remaining compound. It is a measure of how long an effective concentration of the compound remains in the system after administration. As such, the half-life is a major factor in determining how often a drug must be taken. A drug with a long half-life might need to be taken only once per day, whereas a drug with a short half-life might need to be taken three or four times per day.

### Toxicity can limit drug effectiveness

An effective drug must not be so toxic that it seriously harms the person who takes it. A drug may be toxic for any of several reasons. First, it may modulate the target molecule itself *too* effectively. For example, the presence of too much of the anticoagulant drug coumadin can result in dangerous, uncontrolled bleeding and death. Second, the compound may modulate the properties of proteins that are distinct from, but related to, the target molecule itself. Compounds that are directed to one member of a family of enzymes or receptors often bind to other family members. For example, an antiviral drug directed against viral proteases may be toxic if it also inhibits proteases normally present in the body such as those that regulate blood pressure.

A compound may also be toxic if it modulates the activity of a protein unrelated to its intended target. For example, many compounds block ion channels such as the potassium channel hERG (Section 13.4), causing potentially life-threatening disturbances of cardiac rhythm. To prevent cardiac side effects, many compounds are screened for their ability to block such channels.

Finally, even if a compound is not itself toxic, its metabolic by-products may be. Phase I metabolic processes can generate damaging reactive groups in products. An important example is liver toxicity observed with large doses of the common pain reliever acetaminophen (Figure 36.14). A particular cytochrome

**FIGURE 36.14 Acetaminophen toxicity.** A minor metabolic product of acetaminophen is *N*-acetyl-*p*-benzoquinone imine. This metabolite is conjugated to glutathione. Large doses of acetaminophen can deplete liver glutathione stores.

P450 isozyme oxidizes acetaminophen to *N*-acetyl-*p*-benzoquinone imine. The resulting compound is conjugated to glutathione. With large doses, however, the liver concentration of glutathione drops dramatically, and the liver is no longer able to protect itself from this reactive compound and others. Initial symptoms of excessive acetaminophen include nausea and vomiting. Within 24 to 48 hours, symptoms of liver failure may appear. Acetaminophen poisoning accounts for about 35% of cases of severe liver failure in the United States. A liver transplant is often the only effective treatment.

The toxicity of a drug candidate can be described in terms of the *therapeutic index*. This measure of toxicity is determined through animal tests, usually with mice or rats. The therapeutic index is defined as the ratio of the dose of a compound that is required to kill one-half of the animals (referred to as the LD<sub>50</sub> for “lethal dose”) to a comparable measure of the effective dose, usually the EC<sub>50</sub>. Thus, if the therapeutic index is 1000, then lethality is significant only when 1000 times the effective dose is administered. Analogous indices can provide measures of toxicity less severe than lethality.

Many compounds have favorable properties *in vitro*, yet fail when administered to a living organism because of difficulties with ADME and toxicity. Expensive and time-consuming animal studies are required to verify that a drug candidate is not toxic, yet differences between animal species in their response can confound decisions about moving forward with a compound toward human studies. One hope is that, with more understanding of the biochemistry of these processes, scientists can develop computer-based models to replace or augment animal tests. Such models would need to accurately predict the fate of a compound inside a living organism from its molecular structure or other properties that are easily measured in the laboratory without the use of animals.

## 36.2 Drug Candidates Can Be Discovered by Serendipity, Screening, or Design

Traditionally, many drugs were discovered by serendipity, or chance observation. More recently, drugs have been discovered by screening collections of natural products or other compounds for molecules that have desired medicinal properties. Alternatively, scientists have designed specific drug candidates by using their knowledge about a preselected molecular target. We will examine several examples of each of these pathways to reveal common principles.

### Serendipitous observations can drive drug development

Perhaps the most well-known observation in the history of drug development is Alexander Fleming’s chance observation in 1928 that colonies of the bacterium *Staphylococcus aureus* died when they were adjacent to colonies of the mold *Penicillium notatum*. Spores of the mold had landed accidentally on plates growing the bacteria. Fleming soon realized that the mold produced a substance that could kill disease-causing bacteria. This discovery led to a fundamentally new approach to the treatment of bacterial infections. Howard Florey and Ernest Chain developed a powdered form of the substance, termed penicillin, that became a widely used antibiotic in the 1940s. When the structure of penicillin was elucidated in 1945, it was found to contain a four-membered β-lactam ring. This unusual feature is key to the antibacterial function of penicillin, as noted earlier (Section 8.5).

Three steps were crucial to fully capitalize on Fleming’s discovery. First, an industrial process was developed for the production of penicillin from *Penicillium* mold on a large scale. Second, penicillin and its derivatives were chemically

**FIGURE 36.15 Mechanism of cell-wall biosynthesis disrupted by penicillin.**

A transpeptidase enzyme catalyzes the formation of cross-links between peptidoglycan groups. In the case shown, the transpeptidase catalyzes the linkage of D-alanine at the end of one peptide chain to the amino acid diaminopimelic acid (DAP) on another peptide chain. The diaminopimelic acid linkage (bottom left) is found in Gram-negative bacteria such as *E. coli*. Linkages of glycine-rich peptides are found in Gram-positive bacteria. Penicillin inhibits the action of the transpeptidase; so bacteria exposed to the drug have weak cell walls that are susceptible to lysis.

synthesized. The availability of synthetic penicillin derivatives opened the way for scientists to explore the relations between structure and function. Many such penicillin derivatives have found widespread use in medicine. Finally, in 1965, Jack Strominger and James Park independently determined that penicillin exerts its antibiotic activity by blocking a critical transpeptidase reaction in bacterial cell-wall biosynthesis (Figure 36.15), as introduced in Section 8.5.

Many other drugs have been discovered by serendipitous observations. Chlorpromazine (Thorazine), a drug used to treat psychosis, was discovered in the course of investigations directed toward the treatment of shock in surgical patients. In 1952, French surgeon Henri Laborit noticed that, after taking the compound, his patients were remarkably calm. This observation suggested that chlorpromazine could benefit psychiatric patients, and, indeed, the drug has been used for many years to treat patients with schizophrenia and bipolar disorder. The drug does have significant side effects, and its use has been largely superseded by more recently developed drugs.

Chlorpromazine acts by binding to receptors for the neurotransmitter dopamine and blocking them. Dopamine D2 receptors are the targets of many other psychoactive drugs. In the search for drugs with more-limited side effects, studies have been performed to correlate drug effects with biochemical parameters such as dissociation constants and binding and release rate constants.

A more recent example of a drug discovered by chance observation is sildenafil (Viagra). This compound was developed as an inhibitor of phosphodiesterase 5 (PDE5), an enzyme that catalyzes the hydrolysis of cGMP to GMP (Figure 36.16). The compound was intended as a treatment for hypertension and angina because cGMP plays a central role in the relaxation of

**FIGURE 36.16 Sildenafil, a mimic of cGMP.** Sildenafil was designed to resemble cGMP, the substrate of phosphodiesterase 5 (PDE5).

smooth-muscle cells in blood vessels (Figure 36.17). The inhibition of PDE5 was expected to increase the concentration of cGMP by blocking the pathway for its degradation. In the course of early clinical trials in Wales, some men reported unusual penile erections. Whether this chance observation by a few men was due to the compound or to other effects was unclear. However, the observation made some biochemical sense because smooth-muscle relaxation due to increased cGMP levels had been discovered to play a role in penile erection. Subsequent clinical trials directed toward the evaluation of sildenafil for erectile dysfunction were successful. This account testifies to the importance of collecting comprehensive information from clinical-trial participants. In this case, incidental observations led to a new treatment for erectile dysfunction and a multibillion-dollar-per-year drug market.

### Natural products are a valuable source of drugs and drug leads

No drug is as widely used as aspirin. Observers at least as far back as Hippocrates (~400 B.C.) have noted the use of extracts from the bark and leaves of the willow tree for pain relief. In 1829, a mixture called *salicin* was isolated from willow bark. Subsequent analysis identified salicylic acid as the active component of this mixture. Salicylic acid was formerly used to treat pain, but this compound often irritated the stomach. Several investigators attempted to find a means to neutralize salicylic acid. Felix Hoffmann, a chemist working at the German company Bayer, developed a less-irritating derivative by treating salicylic acid with a base and acetyl chloride. This derivative, acetylsalicylic acid, was named *aspirin* from “a” for acetyl chloride, “spir” for *Spiraea ulmaria* (meadowsweet, a flowering plant that also contains salicylic acid), and “in” (a common ending for drugs). Each year, approximately 35,000 tons of aspirin are taken worldwide, nearly the weight of the *Titanic*.

As discussed in Chapter 12, the acetyl group in aspirin is transferred to the side chain of a serine residue that lies along the path to the active site of the cyclooxygenase component of prostaglandin  $H_2$  synthase (Figure 12.24). In this position, the acetyl group blocks access to the active site. Thus, even though aspirin binds in the same pocket on the enzyme as salicylic acid, the acetyl group of aspirin dramatically increases its effectiveness as a drug. This account illustrates the value of screening extracts from plants and other materials that are believed to have medicinal properties for active compounds. The large number of herbal and folk medicines are a treasure trove of new drug leads.

Let us consider another example, which has also had a significant impact on the clinical management of individuals with cardiovascular disease. More than 100 years ago, a fatty, yellowish material was discovered on the arterial walls of patients who had died of vascular disease. The presence of the material was termed *atheroma* from the Greek word for porridge. This material proved to be cholesterol. The Framingham heart study, initiated in 1948, documented

**FIGURE 36.17 Muscle-relaxation pathway.** Increases in nitric oxide levels stimulate guanylate cyclase, which produces cGMP. The increased cGMP concentration promotes smooth-muscle relaxation. PDE5 hydrolyzes cGMP, which lowers the cGMP concentration. The inhibition of PDE5 by sildenafil maintains elevated levels of cGMP.

a correlation between high blood-cholesterol levels and high mortality rates from heart disease. This observation led to the notion that blocking cholesterol synthesis might lower blood-cholesterol levels and, in turn, lower the risk of heart disease. Initial attempts at blocking cholesterol synthesis focused on steps near the end of the pathway. However, these efforts were abandoned because the accumulation of the insoluble substrate for the inhibited enzyme led to the development of cataracts and other side effects. Investigators eventually identified a more-favorable target—namely, the enzyme HMG-CoA reductase (Section 26.2). This enzyme acts on a substrate, HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A), that does not accumulate, because it is water-soluble and can be utilized by other pathways.

A promising natural product, compactin, was discovered in a screen of compounds from a fermentation broth from *Penicillium citrinum* in a search for antibacterial agents. In some, but not all, animal studies, compactin was found to inhibit HMG-CoA reductase and to lower serum cholesterol levels. In 1982, a new HMG-CoA reductase inhibitor was discovered in a fermentation broth from *Aspergillus cereus*. This compound, now called lovastatin, was found to be structurally very similar to compactin, bearing one additional methyl group.

In clinical trials, lovastatin significantly reduced serum cholesterol levels with few side effects. Most side effects could be prevented by treatment with mevalonate (the product of HMG-CoA reductase), indicating that the side effects were likely due to the highly effective blocking of HMG-CoA reductase. One notable side effect is muscle pain or weakness (termed *myopathy*), although its cause remains to be fully established. After many studies, the Food and Drug Administration (FDA) approved lovastatin for treating high serum cholesterol levels.

A structurally related HMG-CoA reductase inhibitor was later shown to cause a statistically significant decrease in deaths due to coronary heart disease. This result validated the benefits of lowering serum cholesterol levels. Further mechanistic analysis revealed that the HMG-CoA reductase inhibitor acts not only by lowering the rate of cholesterol biosynthesis, but also by inducing the expression of the low-density-lipoprotein (LDL) receptor (Section 26.3). Cells with such receptors remove LDL particles from the bloodstream, and so these particles cannot contribute to atheroma.

### Screening libraries of synthetic compounds expands the opportunity for identification of drug leads

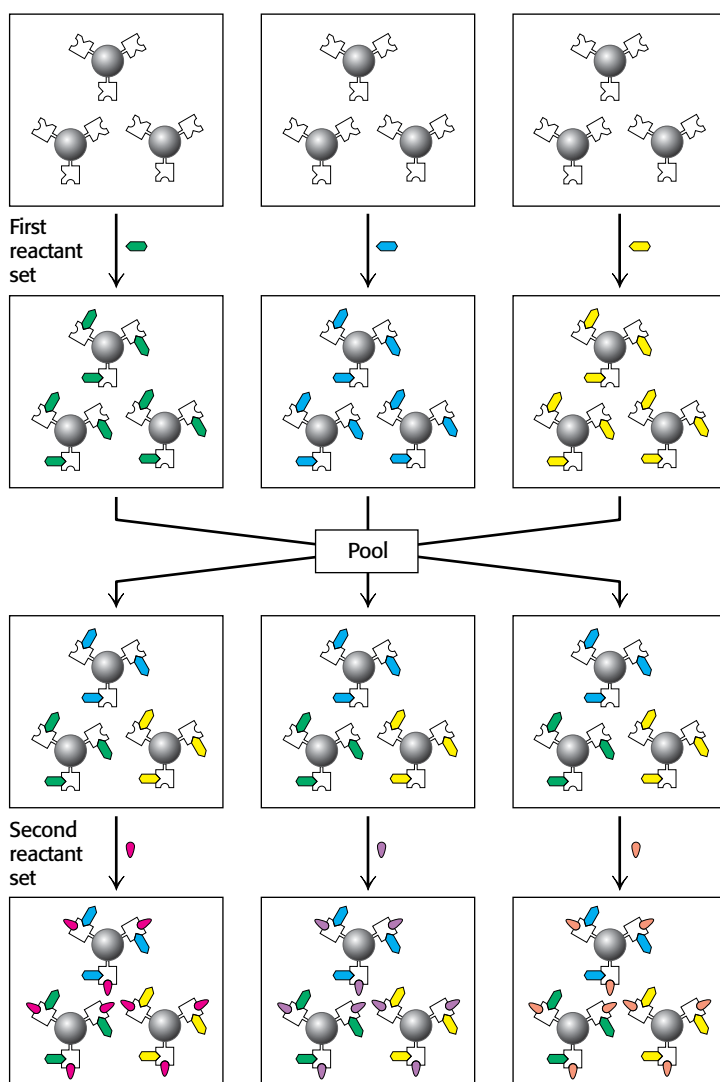

Lovastatin and its relatives are either natural products or readily derived from natural products. After the discovery of these compounds, totally synthetic molecules were developed that are more-potent inhibitors of HMG-CoA reductase (Figure 36.18). These compounds were found to be effective

**FIGURE 36.18 Synthetic statins.** Atorvastatin (Lipitor) and rosuvastatin (Crestor) are completely synthetic drugs that inhibit HMG-CoA reductase.

at lower dose levels, reducing side effects. The original HMG-CoA reductase inhibitors or their precursors were found by screening libraries of natural products. More recently, drug developers have tried screening large libraries of both natural products and purely synthetic compounds prepared in the course of many drug-development programs. Under favorable circumstances, hundreds of thousands or even millions of compounds can be tested in this process, termed *high-throughput screening*. Compounds in these libraries can be synthesized one at a time for testing. An alternative approach is to synthesize a large number of structurally related compounds that differ from one another at only one or a few positions all at once. This approach is often termed *combinatorial chemistry*. Here, compounds are synthesized with the use of the same chemical reactions but a variable set of reactants. Suppose that a molecular scaffold is constructed with two reactive sites and that 20 reactants can be used in the first site and 40 reactants can be used in the second site. A total of  $20 \times 40 = 800$  possible compounds can be produced.

A key method in combinatorial chemistry is *split-pool synthesis* (Figure 36.19). The method depends on solid-phase synthetic methods, first developed for the synthesis of peptides (Section 3.5). Compounds are synthesized on small beads. Beads containing an appropriate starting *scaffold* are produced and divided (split) into  $n$  sets, with  $n$  corresponding to the number of building blocks to be used at one site. Reactions adding the reactants at the

**FIGURE 36.19** Split-pool synthesis.

Reactions are performed on beads. Each of the reactions with the first set of reactants is performed on a separate set of beads. The beads are then pooled, mixed, and split into sets. The second set of reactants is then added. Many different compounds will be produced, but all of the compounds on a single bead will be identical.

**FIGURE 36.20 Screening a library of synthesized carbohydrates.** A small combinatorial library of carbohydrates synthesized on the surface of 130- $\mu\text{m}$  beads is screened for carbohydrates that are bound tightly by a lectin from peanuts. Beads that have such carbohydrates are darkly stained through the action of an enzyme linked to the lectin. [From Figure 3 in Liang et al., "Polyvalent binding to carbohydrates immobilized on an insoluble resin," *Proceedings of the National Academy of Sciences, USA*, vol. 94, pp. 10554–10559, September 1997. Copyright 2004 National Academy of Sciences, USA.]

first site are run, and the beads are isolated by filtration. The  $n$  sets of beads are then combined (pooled), mixed, and split again into  $m$  sets, with  $m$  corresponding to the number of reactants to be used at the second site. Reactions adding these  $m$  reactants are run, and the beads are again isolated. The important result is that each bead contains only one compound, even though the entire library of beads contains many. Furthermore, although only  $n + m$  reactions were run,  $n \times m$  compounds are produced. With the preceding values for  $n$  and  $m$ ,  $20 + 40 = 60$  reactions produce  $20 \times 40 = 800$  compounds. In some cases, assays can be performed directly with the compounds still attached to the bead to find compounds with desired properties (Figure 36.20). Alternatively, each bead can be isolated and the compound can be cleaved from the bead to produce free compounds for analysis. After an interesting compound has been identified, analytical methods of various types must be used to identify which of the  $n \times m$  compounds is present.

Note that the "universe" of druglike compounds is vast. More than an estimated  $10^{40}$  compounds are possible with molecular weights less than 750. Thus, even with "large" libraries of millions of compounds, only a tiny fraction of the chemical possibilities are present for study.

### Drugs can be designed on the basis of three-dimensional structural information about their targets

Many drugs bind to their targets in a manner reminiscent of Emil Fischer's lock and key (Figure 8.8). Therefore, we should be able to design a key, given enough knowledge about the shape and chemical composition of the lock. In the idealized case, we would like to design a small molecule that is complementary in shape and electronic structure to a target protein so that it binds effectively to the targeted site. Despite our ability to determine three-dimensional structures rapidly, the achievement of this goal remains in the future. Designing stable compounds *from scratch* that have the correct shape and other properties to fit precisely into a binding site is difficult because predicting the structure that will best fit into a binding site is difficult. Prediction of binding affinity requires a detailed understanding of the interactions between a compound and its binding partner *and* of the interactions between the compound and the solvent when the compound is free in solution.

Nonetheless, *structure-based drug design* has proved to be a powerful tool in drug development. Among its most prominent successes has been the development of drugs that inhibit the protease from the human immunodeficiency virus (HIV; Section 34.4). Consider the development of the protease inhibitor indinavir (Crixivan; Figure 9.19). Two sets of promising inhibitors that had high potency but poor solubility and bioavailability were discovered. X-ray crystallographic analysis and molecular-modeling findings suggested that a hybrid of these two inhibitor sets might have both high potency and improved bioavailability (Figure 36.21). The synthesized hybrid compound did show improvements but required further optimization. The structural data suggested one point where modifications could be tolerated. A series of compounds were prepared and tested for their ability to inhibit the protease (Figure 36.22). These data are a demonstration of a *structure-activity relationship (SAR)*; they provide an opportunity to correlate structure with function and guide design of further molecules.

The most-active compound showed poor bioavailability, but one of the other compounds (highlighted in yellow in Figure 36.22) showed good bioavailability and acceptable activity. The maximum serum concentration available through oral administration was significantly higher than the levels required to suppress

**FIGURE 36.21 Initial design of an HIV protease inhibitor.** This compound was designed by combining part of one compound with good inhibition activity but poor solubility (shown in red) with part of another compound with better solubility (shown in blue).

**FIGURE 36.22 Compound optimization.**

Four compounds are evaluated for characteristics including the IC<sub>50</sub>, log(*P*), and *c*<sub>max</sub> (the maximal concentration of compound present) measured in the serum of dogs. The compound shown at the bottom (highlighted in yellow) has the weakest inhibitory power (measured by IC<sub>50</sub>) but by far the best bioavailability (measured by *c*<sub>max</sub>). This compound was selected for further development, leading to the drug indinavir (Crixivan).

replication of the virus. This drug, as well as other protease inhibitors developed at about the same time, has been used in combination with other drugs to treat AIDS with much more encouraging results than had been obtained previously (Figure 36.23).

Aspirin targets the cyclooxygenase site in prostaglandin H<sub>2</sub> synthase, as discussed earlier. Animal studies suggested that mammals contain not one but two distinct cyclooxygenase enzymes, both of which are targeted by aspirin. The more recently discovered enzyme, cyclooxygenase 2 (COX2), is expressed primarily as part of the inflammatory response, whereas cyclooxygenase 1 (COX1) is expressed more generally. These observations suggested that a cyclooxygenase inhibitor that was specific for COX2 might be able to reduce inflammation in conditions such as arthritis without producing the gastric and other side effects associated with aspirin.

The amino acid sequences of COX1 and COX2 were deduced from cDNA cloning studies. These sequences are more than 60% identical, clearly indicating that the enzymes have the same overall structure. Nevertheless, there are some differences in the residues around the aspirin-binding site. X-ray crystallography revealed that an extension of the binding pocket was present in COX2, but absent in COX1. This structural difference suggested

**FIGURE 36.23 The effect of anti-HIV drug development.**

Death rates from HIV infection (AIDS) reveal the tremendous effect of HIV protease inhibitors and their use in combination with inhibitors of HIV reverse transcriptase. The death rates in this graph are from the leading causes of death among persons 24 to 44 years old in the United States. [Data from Centers for Disease Control.]

**FIGURE 36.24 COX2-specific inhibitors.** These compounds have protuberances (shown in red) that fit into a pocket in the COX2 isozyme but sterically clash with the COX1 isozyme.

a strategy for constructing COX2-specific inhibitors—namely, to synthesize compounds that had a protuberance that would fit into the pocket in the COX2 enzyme. Such compounds were designed and synthesized and then further refined to produce effective drugs familiar as Celebrex and Vioxx (Figure 36.24). Vioxx was subsequently withdrawn from the market because some people experienced adverse effects. Some of these effects may be due to the inhibition of COX2, the intended target. Thus, although the development of these drugs is a triumph for structure-based drug design, these outcomes highlight the fact that the inhibition of important enzymes can lead to complex physiological responses.

### 36.3 Analyses of Genomes Hold Great Promise for Drug Discovery

The completion of the sequencing of the human and other genomes is a potentially powerful driving force for the development of new drugs. Genomic sequencing and analysis projects have vastly increased our knowledge of the proteins encoded by the human genome. This new source of knowledge may greatly accelerate early stages of the drug-development process or even allow drugs to be tailored to the individual patient.

#### Potential targets can be identified in the human proteome

The human genome encodes approximately 21,000 proteins, not counting the variation produced by alternative mRNA splicing and posttranslational modifications. Many of these proteins are potential drug targets, in particular those that are enzymes or receptors and have significant biological effects when activated or inhibited. Several large protein families are particularly rich sources of targets. For example, the human genome includes genes for more than 500 protein kinases that can be recognized by comparing the deduced amino acid sequences. Many of these kinases are known to play a role in the progression of a variety of diseases. For example, Bcr-Abl kinase, a dysregulated kinase formed from a specific chromosomal defect, is known to contribute to certain leukemias and is the target of the drug imatinib mesylate (Gleevec; Section 14.5). Some of the other protein kinases undoubtedly play central roles in particular cancers as well. Similarly, the human genome encodes approximately 800 7TM receptors (Section 14.1), of which approximately 350 are odorant receptors. Many of the remaining 7TM receptors are known or potential drug targets. For example, the beta-blockers, which are widely used to treat hypertension, target the  $\beta_1$ -adrenergic receptor, and the

antiulcer medication ranitidine (Zantac) targets the histamine  $H_2$  receptor (a 7TM receptor that participates in the control of gastric acid secretion).

Novel proteins that are not part of large families already supplying drug targets can be more readily identified through the use of genomic information. There are a number of ways to identify proteins that could serve as targets of drug-development programs. One way is to look for changes in expression patterns, protein localization, or posttranslational modifications in cells from disease-afflicted organisms. Another is to perform studies of tissues or cell types in which particular genes are expressed. Such analyses of the human genome should increase the number of actively pursued drug targets.

#### Animal models can be developed to test the validity of potential drug targets

The genomes of a number of model organisms have now been sequenced. The most important of these genomes for drug development is that of the mouse. Remarkably, the mouse and human genomes are approximately 85% identical in sequence, and more than 98% of all human genes have recognizable mouse counterparts. Mouse studies provide drug developers with a powerful tool—the ability to disrupt (“knock out”) specific genes in the mouse (Section 5.4). If disruption of a gene has a desirable effect, then the product of this gene may represent a promising drug target. The utility of this approach has been demonstrated retrospectively. For example, disruption of the gene for the  $\alpha$  subunit of the  $H^+ - K^+$  ATPase, the key protein for secreting acid into the stomach, produces mice with a gastric pH of 6.9. Under similar conditions, their wild-type counterparts produce a gastric pH of 3.2. This protein is the target of the drugs omeprazole (Prilosec) and lansoprazole (Prevacid and Takepron), used for treating gastroesophageal reflux disease.

Several large-scale efforts are underway to generate hundreds or thousands of mouse strains, each having a different gene disrupted. The phenotypes of these mice are a good indication of whether the protein encoded by a disrupted gene is a promising drug target. This approach allows drug developers to evaluate potential targets without any preconceived notions regarding physiological function.

**FIGURE 36.25 Emerging drug target.**

The structure of a protease from the coronavirus that causes SARS (severe acute respiratory syndrome) is shown bound to an inhibitor. This structure was determined less than a year after the identification of the virus. [Drawn from 1P9S.pdb.]

### Potential targets can be identified in the genomes of pathogens

Human proteins are not the only important drug targets. Drugs such as penicillin and HIV protease inhibitors act by targeting proteins within a pathogen. The genomes of hundreds of pathogens have now been sequenced, and these genome sequences can be mined for potential targets.

New antibiotics are needed to combat bacteria that are resistant to many existing antibiotics. One approach seeks proteins essential for cell survival that are conserved in a wide range of bacteria. Drugs that inactivate such proteins are expected to be broad-spectrum antibiotics, useful for treating infections from any of a range

of different bacteria. One such protein is peptide deformylase, the enzyme that removes formyl groups present at the amino termini of bacterial proteins immediately after translation (Figure 30.19).

Alternatively, a drug may be needed against a specific pathogen. An example of such a pathogen is the strain of coronavirus responsible for severe acute respiratory syndrome (SARS). Within one month of the recognition of this emerging disease, investigators had isolated the virus that causes the syndrome, and, within weeks, completely sequenced its 29,751-base genome. This sequence revealed the presence of a gene encoding a viral protease, known to be essential for viral replication from studies of other members of the coronavirus family to which the SARS virus belongs. This structure has opened the possibility for specific antiviral treatments for this, and related, viruses (Figure 36.25).

### Genetic differences influence individual responses to drugs

Many drugs are not effective in everyone, often because of genetic differences among individuals. Nonresponding persons may have slight differences in either a drug's target molecule or the proteins taking part in drug transport and metabolism. The goal of the emerging fields of pharmacogenetics and pharmacogenomics is to design drugs that either act more consistently from person to person or are tailored to individual persons with particular genotypes.

Drugs such as metoprolol that target the  $\beta_1$ -adrenergic receptor are popular treatments for hypertension. These drugs are often referred to as "beta-blockers."

**FIGURE 36.26 Phenotype–genotype correlation.**

Average changes in diastolic blood pressure on treatment with metoprolol. Persons with two copies of the most common allele ( $S_{49}R_{389}$ ) showed significant decreases in blood pressure. Those with one variant allele (*GR* or *SG*) showed more modest decreases, and those with two variant alleles (*GR/SG*) showed no decrease. [Data from J. A. Johnson et al., *Clin. Pharmacol. Ther.* 74:44–52, 2003.]

However, some individuals do not respond well to beta-blockers. Two variants of the gene coding for the  $\beta_1$ -adrenergic receptor are common in the U.S. population. The most common allele has serine in position 49 and arginine in position 389. In some persons, however, glycine replaces one or the other of these residues. In clinical studies, participants with two copies of the most common allele responded well to metoprolol: their daytime diastolic blood pressure was reduced by  $14.7 \pm 2.9$  mm Hg on average. In contrast, participants with one variant allele showed a smaller reduction in blood pressure, and the drug had no significant effect on participants with two variant alleles (Figure 36.26). These observations suggest the potential utility of genotyping

individual patients at these positions. One could then predict whether treatment with metoprolol or other beta-blockers is likely to be effective.

Given the importance of ADME and toxicity properties in determining drug efficacy, it is not surprising that variations in proteins participating in drug transport and metabolism can alter a drug's effectiveness. An important example is the use of thiopurine drugs such as 6-thioguanine, 6-mercaptopurine, and azathioprine to treat diseases including leukemia, immune disorders, and inflammatory bowel disease.

A minority of patients who are treated with these drugs show signs of toxicity at doses that are well tolerated by most patients. These differences between patients are due to rare variations in the gene encoding the xenobiotic-metabolizing enzyme thiopurine methyltransferase, which adds a methyl group to sulfur atoms.

The variant enzyme is less stable. Patients with these variant enzymes can build up toxic levels of the drugs if appropriate care is not taken. Thus, genetic variability in an enzyme participating in drug metabolism plays a large role in determining the variation in the tolerance of different persons to particular drug levels. Many other drug-metabolism enzymes and drug-transport proteins have been implicated in controlling individual reactions to specific drugs. The identification of the genetic factors will allow a deeper understanding of why some drugs work well in some individuals but poorly in others. In the future, doctors may examine a patient's genes to help plan drug-therapy programs.

### 36.4 The Clinical Development of Drugs Proceeds Through Several Phases

In the United States, the FDA requires demonstration that drug candidates be effective and safe before they may be used in human beings on a large scale. This requirement is particularly true for drug candidates that are to be taken by people who are relatively healthy. More side effects are acceptable for drug candidates intended to treat significantly ill patients such as those with serious forms of cancer, where there are clear, unfavorable consequences for not having an effective treatment.

**FIGURE 36.27 Clinical-trial phases.**

Clinical trials proceed in phases examining safety and efficacy in increasingly large groups.

### Clinical trials are time consuming and expensive

Clinical trials test the effectiveness and potential side effects of a candidate drug before it is approved by the FDA for general use. These trials proceed in at least three phases

(Figure 36.27). In Phase I, a small number (typically from 10 to 100) of usually healthy volunteers take the drug for an initial study of safety. These volunteers are given a range of doses and are monitored for signs of toxicity. The efficacy of the drug candidate is not specifically evaluated.

In Phase II, the efficacy of the drug candidate is tested in a small number of persons who might benefit from the drug. Further data regarding the drug's safety are obtained. Such trials are often controlled and double-blinded. In a controlled study, subjects are divided randomly into two groups. Subjects in the treatment group are given the treatment under investigation. Subjects in the control group are given either a *placebo*—that is, a treatment such as sugar pills known to not have intrinsic value—or the best standard treatment available, if withholding treatment altogether would be unethical. In a double-blinded study, neither the subjects nor the researchers know which subjects are in the treatment group and which are in the control group. A double-blinded study prevents bias in the course of the trial. When the trial has been completed, the assignments of the subjects into treatment and control groups are unsealed and the results for the two groups are compared. A variety of doses are often investigated in Phase II trials to determine which doses appear to be free of serious side effects and which doses appear to be effective.

The power of the *placebo effect*—that is, the tendency to perceive improvement in a subject who believes that he or she is receiving a potentially beneficial treatment—should not be underestimated. In a study of arthroscopic surgical treatment for knee pain, for example, subjects who were led to believe that they had received surgery through the use of videotapes and other means showed the same level of improvement, on average, as subjects who actually received the procedure.

In Phase III, similar studies are performed on a larger and more diverse population. This phase is intended to more firmly establish the efficacy of the drug candidate and to detect side effects that may develop in a small percentage of the subjects who receive treatment. Thousands of subjects may participate in a typical Phase III study.

Clinical trials can be extremely costly. Hundreds or thousands of patients must be recruited and monitored for the duration of the trial. Many physicians, nurses, clinical pharmacologists, statisticians, and others participate in the design and execution of the trial. Costs can run from tens of millions to hundreds of millions of dollars. Extensive records must be kept, including documentation of any adverse reactions. These data are compiled and submitted to the FDA. The full cost of developing a drug is currently estimated to be more than \$800 million.

Even after a drug has been approved and is in use, difficulties can arise. Clinical trials run after a drug has entered the market, referred to as Phase IV studies, are designed to identify low-frequency side effects that may only emerge after widespread or long-term use. As mentioned earlier, rofecoxib (Vioxx), for example, was withdrawn from the market after significant cardiac side effects were detected in Phase IV clinical trials. Such events highlight the necessity for users of any drug to balance beneficial effects against potential risks.

## The evolution of drug resistance can limit the utility of drugs for infectious agents and cancer

Many drugs are used for long periods of time without any loss of effectiveness. However, in some cases, particularly for the treatment of cancer or infectious diseases, drug treatments that were initially effective become less so. In other words, the disease becomes resistant to the drug therapy. Why does this resistance develop? Infectious diseases and cancer have a common feature—namely, that an affected person contains many cells (or viruses) that can mutate and reproduce. These conditions are necessary for evolution to take place. Thus, an individual microorganism or cancer cell may, by chance, have a genetic variation that makes it more suitable for growth and reproduction in the presence of the drug. These microorganisms or cells are more fit than others in their population, and they will tend to take over the population. As the selective pressure due to the drug is continually applied, the population of microorganisms or cancer cells will tend to become more and more resistant to the presence of the drug. Note that resistance can develop by a number of mechanisms.

The HIV protease inhibitors discussed earlier provide an important example of the evolution of drug resistance. Retroviruses are very well suited to this sort of evolution because reverse transcriptase carries out replication without a proofreading mechanism. In a genome of approximately 9750 bases, each possible single point mutation is estimated to appear in a virus particle more than 1000 times per day in each infected person. Many multiple mutations also occur. Most of these mutations either have no effect or are detrimental to the virus. However, a few of the mutant virus particles encode proteases that are less susceptible to inhibition by the drug. In the presence of an HIV protease inhibitor, these virus particles will tend to replicate more effectively than does the population at large. With the passage of time, the less-susceptible viruses will come to dominate the population and the virus population will become resistant to the drug.

Pathogens may become resistant to antibiotics by completely different mechanisms. Some pathogens contain enzymes that inactivate or degrade specific antibiotics. For example, many bacteria are resistant to  $\beta$ -lactams such as penicillin because they contain  $\beta$ -lactamase enzymes. These enzymes hydrolyze the  $\beta$ -lactam ring and render the drugs inactive.

Many of these enzymes are encoded in plasmids, small circular pieces of DNA often carried by bacteria. Many plasmids are readily transferred from one bacterial cell to another, transmitting the capability for antibiotic resistance. Plasmid transfer thus contributes to the spread of antibiotic resistance, a major health-care challenge. On the other hand, plasmids have been harnessed for use in recombinant DNA methods (Section 5.2).

Drug resistance commonly emerges in the course of cancer treatment. Cancer cells are characterized by their ability to grow rapidly without the constraints that apply to normal cells. Many drugs used for cancer chemotherapy inhibit processes that are necessary for this rapid cell growth.

However, individual cancer cells may accumulate genetic changes that mitigate the effects of such drugs. These altered cancer cells will tend to grow more rapidly than others and will become dominant within the cancer-cell population. This ability of cancer cells to mutate quickly has been a challenge to one of the major breakthroughs in cancer treatment: the development of inhibitors for proteins specific to cancer cells present in certain leukemias (Section 14.5). For example, tumors become undetectable in patients treated with imatinib mesylate, which is directed against the Bcr-Abl protein kinase. Unfortunately, the tumors of many of the patients treated with imatinib mesylate recur after a period of years. In many of these cases, mutations have altered the Bcr-Abl protein so that it is no longer inhibited by the concentrations of imatinib mesylate used in therapy.

Cancer patients often take multiple drugs concurrently in the course of chemotherapy and, in many cases, cancer cells become simultaneously resistant to many or all of them. This multiple-drug resistance can be due to the proliferation of cancer cells that overexpress a number of ABC transporter proteins that pump drugs out of the cell (Section 13.2). Thus, cancer cells can evolve drug resistance by over expressing normal human proteins or by modifying proteins responsible for the cancer phenotype.

## SUMMARY

### 36.1 The Development of Drugs Presents Huge Challenges

Most drugs act by binding to enzymes or receptors and modulating their activities. To be effective, drugs must bind to these targets with high affinity and specificity. However, compounds with the desired affinity and specificity do not necessarily make suitable drugs. Most compounds are poorly absorbed or rapidly excreted from the body or they are modified by metabolic pathways that target foreign compounds. Consequently, when taken orally, these compounds do not reach their targets at appropriate concentrations for a sufficient period of time. A drug's properties related to its absorption, distribution, metabolism, and excretion are called ADME properties. Oral bioavailability is a measure of a drug's ability to be absorbed; it is the ratio of the peak concentration of a compound given orally to the peak concentration of the same dose directly injected. The structure of a compound can affect its bioavailability in complicated ways, but generalizations called Lipinski's rules provide useful guidelines. Drug-metabolism pathways include oxidation by cytochrome P450 enzymes (phase I metabolism) and conjugation to glutathione, glucuronic acid, and sulfate (phase II metabolism). A compound may also not be a useful drug because it is toxic, either because it modulates the target molecule too effectively or because it also binds to proteins other than the target. The liver and kidneys play central roles in drug metabolism and excretion.

### 36.2 Drug Candidates Can Be Discovered by Serendipity, Screening, or Design

Many drugs have been discovered by serendipity—that is, by chance observation. The antibiotic penicillin is produced by a mold that accidentally contaminated a culture dish, killing nearby bacteria. Drugs such as chlorpromazine and sildenafil were discovered to have beneficial, but unexpected, effects on human physiology. The cholesterol-lowering statin drugs were developed after large collections of compounds were screened for potentially interesting activities. Combinatorial chemistry methods have been developed to generate large collections of chemically related yet diverse compounds for screening. In some cases, the three-dimensional structure of a drug target is available and can be used to aid

the design of potent and specific inhibitors. Examples of drugs designed in this manner are the HIV protease inhibitor indinavir and cyclooxygenase 2 inhibitors such as celecoxib.

### 36.3 Analyses of Genomes Hold Great Promise for Drug Discovery

The human genome encodes approximately 21,000 proteins, and many more if derivatives due to alternative mRNA splicing and post-translational modification are included. The genome sequences can be examined for potential drug targets. Large families of proteins known to participate in key physiological processes such as the protein kinases and 7TM receptors have each yielded several targets for which drugs have been developed. The genomes of model organisms also are useful for drug-development studies. Strains of mice with particular genes disrupted have been useful in validating certain drug targets. The genomes of bacteria, viruses, and parasites encode many potential drug targets that can be exploited owing to their important functions and their differences from human proteins, minimizing the potential for side effects. Genetic differences between individuals can be examined and correlated with differences in responses to drugs, potentially aiding both clinical treatments and drug development.

### 36.4 The Clinical Development of Drugs Proceeds Through Several Phases

Before compounds can be given to human beings as drugs, they must be extensively tested for safety and efficacy. Clinical trials are performed in stages: first testing safety, then safety and efficacy in a small population, and finally safety and efficacy in a larger population to detect rarer adverse effects. Largely due to the expenses associated with clinical trials, the cost of developing a new drug has been estimated to be more than \$800 million. Even when a drug has been approved for use, complications can arise. With regard to infectious diseases and cancer, patients often develop resistance to a drug after it has been administered for a period of time because variants of the disease agent that are less susceptible to the drug arise and replicate, even when the drug is present.

## KEY TERMS

ligand (p. 1035)	xenobiotic compounds (p. 1037)	atheroma (p. 1043)
dissociation constant ( $K_d$ ) (p. 1035)	drug metabolism (p. 1037)	myopathy (p. 1044)
side effect (p. 1035)	oxidation (p. 1037)	high-throughput screening (p. 1045)
inhibition constant ( $K_i$ ) (p. 1036)	conjugation (p. 1037)	combinatorial chemistry (p. 1045)
Cheng–Prusoff equation (p. 1036)	phase I transformation (p. 1039)	split-pool synthesis (p. 1045)
ADME (p. 1036)	phase II transformation (p. 1039)	structure-based drug design (p. 1046)
oral bioavailability (p. 1036)	first-pass metabolism (p. 1039)	structure–activity relationship (SAR) (p. 1046)

## PROBLEMS

1. *Routes to discovery.* For each of the following drugs, indicate whether the physiological effects of the drug were known before or after the target was identified.

- |                         |                            |
|-------------------------|----------------------------|
| (a) Penicillin          | (d) Atorvastatin (Lipitor) |
| (b) Sildenafil (Viagra) | (e) Aspirin                |
| (c) Rofecoxib (Vioxx)   | (f) Indinavir (Crixivan)   |

2. *Lipinski's rules.* Which of the following compounds satisfy all of Lipinski's rules? [Log(*P*) values are given in parentheses.]

- |                       |
|-----------------------|
| (a) Atenolol (0.23)   |
| (b) Sildenafil (3.18) |
| (c) Indinavir (2.78)  |

3. *Calculating log tables.* Considerable effort has been expended to develop computer programs that can estimate  $\log(P)$  values entirely on the basis of chemical structure. Why would such programs be useful?

4. *An ounce of prevention.* Legislation has been proposed that would require that *N*-acetylcysteine be added to acetaminophen tablets. Speculate about the role of this additive.

5. *Clinical-trial design.* Distinguish between Phase I and Phase II clinical trials in regard to number of persons enrolled, the state of health of the subjects, and the goals of the study.

6. *Drug interactions.* As noted in this chapter, coumadin can be a very dangerous drug because too much can cause uncontrolled bleeding. Persons taking coumadin must be careful about taking other drugs, particularly those that bind to albumin. Propose a mechanism for this drug–drug interaction.

7. *A bad combination.* Explain why drugs that inhibit P450 enzymes may be particularly dangerous when used in combination with other medications.

8. *Mechanistically speaking.* Name one advantage of a non-competitive inhibitor as a potential drug compared with a competitive inhibitor.

9. *A helping hand.* You have developed a drug that is capable of inhibiting the ABC transporter MDR. Suggest a possible application for this drug in cancer chemotherapy.

10. *Find the target.* Trypanosomes are unicellular parasites that cause sleeping sickness. During one stage of their life cycle, these organisms live in the bloodstream and derive all of their energy from glycolysis, which takes place in a specialized organelle called a glycosome inside the parasite. Propose potential targets for treating sleeping sickness. What are some potential difficulties with your approach?

11. *Knowledge is power.* How might genomic information be helpful for the effective use of imatinib mesylate (Gleevec) in cancer chemotherapy?

12. *Multiple targets, same goal.* Sildenafil induces its physiological effects by increasing the intracellular concentrations of cGMP, leading to muscle relaxation. On the basis of the scheme shown in Figure 36.17, identify another approach for increasing cGMP levels with a small molecule.

### Mechanism Problem

13. *Variations on a theme.* The metabolism of amphetamine by cytochrome P450 enzymes results in the conversion shown here. Propose a mechanism and indicate any additional products.

### Data Interpretation Problem

14. *HIV protease inhibitor design.* Compound A is one of a series that were designed to be potent inhibitors of HIV protease.

**Compound A**

Compound A was tested by using two assays: (1) direct inhibition of HIV protease *in vitro* and (2) inhibition of viral RNA production in HIV-infected cells, a measure of viral replication. The results of these assays are shown below. The HIV protease activity is measured with a substrate peptide present at a concentration equal to its  $K_M$  value.

Compound A (nM)	HIV protease activity (arbitrary units)
0	11.2
0.2	9.9
0.4	7.4
0.6	5.6
0.8	4.8
1	4.0
2	2.2
10	0.9
100	0.2

Compound A (nM)	Viral RNA production (arbitrary units)
0	760
1.0	740
2.0	380
3.0	280
4.0	180
5.0	100
10	30
50	20

Estimate the values for the  $K_I$  of compound A in the protease-activity assay and for its  $IC_{50}$  in the viral-RNA-production assay.

Treating rats with the relatively high oral dose of 20 mg  $kg^{-1}$  results in a maximum concentration of compound A of 0.4  $\mu M$ . On the basis of this value, do you expect compound A to be effective in preventing HIV replication when taken orally?

# ANSWERS TO PROBLEMS

## Chapter 1

- The hydrogen-bond donors are the NH and NH<sub>2</sub> groups. The hydrogen-bond acceptors are the carbonyl oxygen atoms and those ring nitrogen atoms that are not bonded to hydrogen or to deoxyribose.
- Interchange the positions of the single and double bonds in the six-membered ring.
- (a) Ionic interactions; (b) van der Waals interactions.
- Processes *a* and *b*.
- $\Delta S_{\text{system}} = -661 \text{ J mol}^{-1} \text{ K}^{-1} (-158 \text{ kcal mol}^{-1} \text{ K}^{-1})$   
 $\Delta S_{\text{surroundings}} = +842 \text{ J mol}^{-1} \text{ K}^{-1} (+201 \text{ cal mol}^{-1} \text{ K}^{-1})$
- (a) 1.0; (b) 13.0; (c) 1.3; (d) 12.7
- 2.88
- 1.96
- 55.5 M
- 11.83
- 447; 0.00050
- 0.00066 M
- 6.0
- 5.53
- 6.48
- 7.8
- 100
- (a) 1.6; (b) 0.51; (c) 0.16.

- 0.1 M sodium acetate solution: 6.34; 6.03; 5.70; 4.75.  
0.01 M sodium acetate solution: 5.90; 4.75; 3.38; 1.40.
- 90 mM acetic acid; 160 mM sodium acetate, 0.18 moles acetic acid; 0.32 moles sodium acetate; 10.81 g acetic acid; 26.25 g sodium acetate.
- 0.50 moles of acetic acid; 0.32 moles of NaOH; 30.03 g of acetic acid; 12.80 g of NaOH.
- 250 mM; yes; no, it will also contain 90 mM NaCl.
- 8.63 g Na<sub>2</sub>HPO<sub>4</sub>; 4.71 g NaH<sub>2</sub>PO<sub>4</sub>
- 7.0; this buffer will not be very useful, because the pH value is far from the pK<sub>a</sub> value.
- +1.45 kJ mol<sup>-1</sup> (+0.35 kcal mol<sup>-1</sup>); +57.9 kJ mol<sup>-1</sup> (+13.8 kcal mol<sup>-1</sup>)
- There will be approximately 15 million differences.
- (20!)/(10!\*10!) = 184,756
- 7.9%

## Chapter 2

- (A) Proline, Pro, P; (B) tyrosine, Tyr, Y; (C) leucine, Leu, L; (D) lysine, Lys, K.
- (a) C, B, A; (b) D; (c) D, B; (d) B, D; (e) B.
- (a) 6; (b) 2; (c) 3; (d) 1; (e) 4; (f) 5.
- (a) Ala; (b) Tyr; (c) Ser; (d) His.
- Ser, Glu, Tyr, Thr
- (a) Alanine-glycine-serine; (b) Alanine; (c and d):

7. At pH 5.5, the net charge is +1:

- At pH 7.5, the net charge is 0:

8. There are 20 choices for each of the 50 amino acids: 20<sup>50</sup>, or 1 × 10<sup>65</sup>.
- 9.

- The (nitrogen- $\alpha$  carbon-carbonyl carbon) repeating unit.
- Side chain is the functional group attached to the  $\alpha$ -carbon atom of an amino acid.
- Amino acid composition refers simply to the amino acids that make up the protein. The order is not specified. Amino acid sequence is the same as the primary structure—the sequence of amino acids from the amino terminal to the carboxyl terminal of the protein. Different proteins may have the same amino acid composition, but amino acid sequence identifies a unique protein.
- (a) Each strand is 35 kDa and hence has about 318 residues (the mean residue mass is 110 daltons). Because the rise per residue in an  $\alpha$  helix is 1.5 Å, the length is 477 Å. More precisely, for an  $\alpha$ -helical coiled coil, the rise per residue is 1.46 Å; so the length is 464 Å. (b) Eighteen residues in each strand (40 minus 4 divided by 2) are in a  $\beta$ -sheet conformation. Because the rise per residue is 3.5 Å, the length is 63 Å.
- The methyl group attached to the  $\beta$ -carbon atom of isoleucine sterically interferes with  $\alpha$ -helix formation. In leucine, this methyl group is attached to the  $\gamma$ -carbon atom, which is farther from the main chain and hence does not interfere.

15. Proline and glycine. The cyclic side chain of proline linking the nitrogen and  $\alpha$ -carbon atoms limits  $\phi$  to a very narrow range (around  $-60$  degrees). The lack of steric hindrance exhibited by the side chain hydrogen atom of glycine enables this amino acid to access a much greater area of the Ramachandran plot.

16. The first mutation destroys activity because valine occupies more space than alanine does, and so the protein must take a different shape, assuming that this residue lies in the closely packed interior. The second mutation restores activity because of a compensatory reduction of volume; glycine is smaller than isoleucine.

17. Loops invariably are on the surface of proteins, exposed to the environment. Because many proteins exist in aqueous environments, the exposed loops will be hydrophilic to interact with water.

18. The native conformation of insulin is not the thermodynamically most stable form, because it contains two separate chains linked by disulfide bonds. Insulin is formed from proinsulin, a single-chain precursor, that is cleaved to form insulin, a 51-residue molecule, after the disulfide bonds have formed.

19. A segment of the main chain of the protease could hydrogen bond to the main chain of the substrate to form an extended parallel or antiparallel pair of  $\beta$  strands.

20. Glycine has the smallest side chain of any amino acid. Its size is often critical in allowing polypeptide chains to make tight turns or to approach one another closely.

21. Glutamate, aspartate, and the terminal carboxylate can form salt bridges with the guanidinium group of arginine. In addition, this group can be a hydrogen-bond donor to the side chains of glutamine, asparagine, serine, threonine, aspartate, tyrosine, and glutamate and to the main-chain carbonyl group. Histidine can form hydrogen bonds with arginine at pH 7.

22. Disulfide bonds in hair are broken by adding a thiol-containing reagent and applying gentle heat. The hair is curled, and an oxidizing agent is added to re-form disulfide bonds to stabilize the desired shape.

23. Some proteins that span biological membranes are “the exceptions that prove the rule” because they have the reverse distribution of hydrophobic and hydrophilic amino acids. For example, consider *porins*, proteins found in the outer membranes of many bacteria. Membranes are built largely of hydrophobic chains. Thus, porins are covered on the outside largely with hydrophobic residues that interact with the neighboring hydrophobic chains. In contrast, the center of the protein contains many charged and polar amino acids that surround a water-filled channel running through the middle of the protein. Thus, because porins function in hydrophobic environments, they are “inside out” relative to proteins that function in aqueous solution.

24. The amino acids would be hydrophobic in nature. An  $\alpha$  helix is especially suited to crossing a membrane because all of the amide hydrogen atoms and carbonyl oxygen atoms of the peptide backbone take part in intrachain hydrogen bonds, thus stabilizing these polar atoms in a hydrophobic environment.

25. This example demonstrates that the  $pK_a$  values are affected by the environment. A given amino acid can have a variety of  $pK_a$  values, depending on the chemical environment inside the protein.

26. Recall that hemoglobin exists as a tetramer while myoglobin is a monomer. Consequently, the hydrophobic residues on the surface of hemoglobin subunits are probably involved in van der Waals interactions with similar regions on the other subunits, and will be shielded from the aqueous environment by this interaction.

27. A possible explanation is that the severity of the symptoms corresponds to the degree of structural disruption. Hence, substitution

of alanine for glycine might result in mild symptoms, but substitution of the much larger tryptophan may result in little or no collagen triple-helix formation.

28. The energy barrier that must be crossed to go from the polymerized state to the hydrolyzed state is large even though the reaction is thermodynamically favorable.

29. Using the Henderson–Hasselbach equation, we find the ratio of alanine-COOH to alanine-COO<sup>-</sup> at pH 7 to be  $10^{-4}$ . The ratio of alanine-NH<sub>2</sub> to alanine-NH<sub>3</sub><sup>+</sup>, determined in the same fashion, is  $10^{-1}$ . Thus, the ratio of neutral alanine to the zwitterionic species is  $10^{-4} \times 10^{-1} = 10^{-5}$ .

30. The assignment of absolute configuration requires the assignment of priorities to the four groups connected to a tetrahedral carbon atom. For all amino acids except cysteine, the priorities are: (1) amino group; (2) carbonyl group; (3) side chain; (4) hydrogen. For cysteine, because of the sulfur atom in its side chain, the side chain has a greater priority than does the carbonyl group, leading to the assignment of an *R* rather than *S* configuration.

31. ELVISISLIVINGINLASVEGAS

32. No, Pro–X would have the characteristics of any other peptide bond. The steric hindrance in X–Pro arises because the R group of Pro is bonded to the amino group. Hence, in X–Pro, the proline R group is near the R group of X, which would not be the case in Pro–X.

33. A, c; B, e; C, d; D, a; E, b.

34. The reason is that the wrong disulfides formed pairs in urea. There are 105 different ways of pairing eight cysteine molecules to form four disulfides; only one of these combinations is enzymatically active. The 104 wrong pairings have been picturesquely termed “scrambled” ribonuclease.

### Chapter 3

1. (a) Phenyl isothiocyanate; (b) urea;  $\beta$ -mercaptoethanol to reduce disulfides; (c) chymotrypsin; (d) CNBr; (e) trypsin.

2. For each cell within an organism, the genome is a fixed property. However, the proteome is dynamic, reflecting different environmental conditions and external stimuli. Two different cell types will likely express different subsets of proteins encoded within the genome.

3. The *S*-aminoethylcysteine side chain resembles that of lysine. The only difference is a sulfur atom in place of a methylene group.

4. A  $1 \text{ mg ml}^{-1}$  solution of myoglobin (17.8 kDa; Table 3.2) corresponds to  $5.62 \times 10^{-5} \text{ M}$ . The absorbance of a 1-cm path length is 0.84, which corresponds to an  $I_0/I$  ratio of 6.96. Hence 14.4% of the incident light is transmitted.

5. The sample was diluted 1000-fold. The concentration after dialysis is thus 0.001 M, or 1 mM. You could reduce the salt concentration by dialyzing your sample, now 1 mM, in more buffer free of  $(\text{NH}_4)_2\text{SO}_4$ .

6. If the salt concentration becomes too high, the salt ions interact with the water molecules. Eventually, there will not be enough water molecules to interact with the protein, and the protein will precipitate. If there is lack of salt in a protein solution, the proteins may interact with one another—the positive charges on one protein with the negative charges on another or several others. Such an aggregate becomes too large to be solubilized by water alone. If salt is added, the salt neutralizes the charges on the proteins, preventing protein–protein interactions.

7. Tropomyosin is rod shaped, whereas hemoglobin is approximately spherical.

8. The frictional coefficient,  $f$ , and the mass,  $m$ , determine  $s$ . Specifically,  $f$  is proportional to  $r$  (see equation 2 on p. 71). Hence,  $f$  is proportional to  $m^{1/3}$ , and so  $s$  is proportional to  $m^{2/3}$  (see the

equation on p. 76). An 80-kDa spherical protein undergoes sedimentation 1.59 times as rapidly as a 40-kDa spherical protein.

9. The long hydrophobic tail on the SDS molecule (see p. 72) disrupts the hydrophobic interactions in the interior of the protein. The protein unfolds, with the hydrophobic R groups now interacting with SDS rather than with one another.

10. 50 kDa

11. The protein may be modified. For instance, asparagine residues in the protein may be modified with carbohydrate units (Section 2.6).

12. A fluorescence-labeled derivative of a bacterial degradation product (e.g., a formylmethionyl peptide) would bind to cells containing the receptor of interest.

13. (a) Trypsin cleaves after arginine (R) and lysine (K), generating AVGW<sup>R</sup>, VK, and S. Because they differ in size, these products could be separated by molecular exclusion chromatography. (b) Chymotrypsin, which cleaves after large aliphatic or aromatic R groups, generates two peptides of equal size (AVGW) and (RVKS). Separation based on size would not be effective. The peptide RVKS has two positive charges (R and K), whereas the other peptide is neutral. Therefore, the two products could be separated by ion-exchange chromatography.

14. Antibody molecules bound to a solid support can be used for affinity purification of proteins for which a ligand molecule is not known or unavailable.

15. If the product of the enzyme-catalyzed reaction is highly antigenic, it may be possible to obtain antibodies to this particular molecule. These antibodies can be used to detect the presence of product by ELISA, providing an assay format suitable for the purification of this enzyme.

16. An inhibitor of the enzyme being purified might have been present and subsequently removed by a purification step. This removal would lead to an apparent increase in the total amount of enzyme present.

17. Many proteins have similar masses but different sequences and different patterns when digested with trypsin. The set of masses of tryptic peptides forms a detailed “fingerprint” of a protein that is very unlikely to appear at random in other proteins regardless of size. (A conceivable analogy is: “Just as similarly sized fingers will give different individual fingerprints, so also similarly sized proteins will give different digestion patterns with trypsin.”)

18. Isoleucine and leucine are isomers and, hence, have identical masses. Peptide sequencing by mass spectrometry as described in this chapter is incapable of distinguishing these residues. Further analytical techniques are required to differentiate these residues.

19. See the table at the bottom of the page.

20. (a) Ion exchange chromatography will remove Proteins A and D, which have substantially lower isoelectric point; then gel filtration chromatography will remove Protein C, which has a lower molecular weight. (b) If Protein B carries a His tag, a single affinity chromatography step with an immobilized nickel(II) column may be sufficient to isolate the desired protein from the others.

21. Protein crystal formation requires the ordered arrangement of identically positioned molecules. Proteins with flexible linkers can introduce disorder into this arrangement and prevent the formation of suitable crystals. A ligand or binding partner may induce an ordered conformation to this linker and could be included in the solution to facilitate crystal growth. Alternatively, the individual domains separated by the linker may be expressed by recombinant methods and their crystal structures solved separately.

22. Treatment with urea will disrupt noncovalent bonds. Thus the original 60-kDa protein must be made of two 30-kDa subunits. When these subunits are treated with urea and  $\beta$ -mercaptoethanol, a single 15-kDa species results, suggesting that disulfide bonds link the 30-kDa subunits.

23. (a) Electrostatic repulsion between positively charged  $\epsilon$ -amino groups hinders  $\alpha$ -helix formation at pH 7. At pH 10, the side chains become deprotonated, allowing  $\alpha$ -helix formation.

(b) Poly-L-glutamate is a random coil at pH 7 and becomes  $\alpha$  helical below pH 4.5 because the  $\gamma$ -carboxylate groups become protonated.

24. The difference between the predicted and the observed masses for this fragment equals 28.0, exactly the mass shift that would be expected in a formylated peptide. This peptide is likely formylated at its amino terminus, and corresponds to the most N-terminal fragment of the protein.

25. Light was used to direct the synthesis of these peptides. Each amino acid added to the solid support contained a photolabile protecting group instead of a *t*-Boc protecting group at its  $\alpha$ -amino group. Illumination of selected regions of the solid support led to the release of the protecting group, which exposed the amino groups in these sites to make them reactive. The pattern of masks used in these illuminations and the sequence of reactants define the ultimate products and their locations.

26. Mass spectrometry is highly sensitive and capable of detecting the mass difference between a protein and its deuterated counterpart. Fragmentation techniques can be used to identify the amino acids that retained the isotope label. Alternatively, NMR spectroscopy can be used to detect the isotopically labeled atoms because the deuterium and the proton have very different nuclear-spin properties.

27. First amino acid: A

Last amino acid: R (not cleaved by carboxypeptidase).

Sequence of N-terminal tryptic peptide: AVR (tryptic peptide ends in K)

Sequence of N-terminal chymotryptic peptide: AVRY (chymotryptic peptide ends in Y)

Sequence: AVRYSR

28. First amino acid: S

Last amino acid: L

Cyanogen bromide cleavage: M is 10th position

C-terminal residues are: (2S,L,W)

Amino-terminal residues: (G,K,S,Y), tryptic peptide, ends in K

Amino-terminal sequence: SYGK

Chymotryptic peptide order: (S,Y), (G,K,L), (F,I,S), (M,T),

(S,W), (S,L)

Sequence: SYGKLSIFTMSWSL

Purification procedure	Total protein (mg)	Total activity (units)	Specific activity (units mg <sup>-1</sup> )	Purification level	Yield (%)
Crude extract	20,000	4,000,000	200	1	100
(NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub> precipitation	5,000	3,000,000	600	3	75
DEAE-cellulose chromatography	1,500	1,000,000	667	3.3	25
Gel-filtration chromatography	500	750,000	1,500	7.5	19
Affinity chromatography	45	675,000	15,000	75	17

## ANSWERS TO PROBLEMS

29. If the protein did not contain any disulfide bonds, then the electrophoretic mobility of the trypsin fragments would be the same before and after performic acid treatment: all the fragments would lie along the diagonal of the paper. If one disulfide bond were present, the disulfide-linked trypsin fragments would run as a single peak in the first direction, then would run as two separate peaks after performic acid treatment. The result would be two peaks appearing off the diagonal:

These fragments could then be isolated from the chromatography paper and analyzed by mass spectrometry to determine their amino acid composition and thus identify the cysteines participating in the disulfide bond.

## Chapter 4

1. A nucleoside is a base attached to a ribose or deoxyribose sugar. A nucleotide is a nucleoside with one or more phosphoryl groups attached to the ribose or deoxyribose.
2. Hydrogen-bond pairing between the base A and the base T as well as hydrogen-bond pairing between the base G and the base C in DNA.
3. T is always equal to A, and so these two nucleotides constitute 40% of the bases. G is always equal to C, and so the remaining 60% must be 30% G and 30% C.
4. Nothing, because the base-pair rules do not apply to single-stranded nucleic acids.
5. (a) TTGATC; (b) GTTCGA; (c) ACGCGT; (d) ATGGTA.
6. (a)  $[T] + [C] = 0.46$ . (b)  $[T] = 0.30$ ,  $[C] = 0.24$ , and  $[A] + [G] = 0.46$ .
7. Stable hydrogen bonding occurs only between GC and AT pairs. Moreover, two purines are too large to fit inside the double helix, and two pyrimidines are too small to form base pairs with each other.
8. The thermal energy causes the chains to wiggle about, which disrupts the hydrogen bonds between base pairs and the stacking forces between bases and thereby causes the strands to separate.
9. The probability that any sequence will appear is  $1/4^n$ , where 4 is the number of nucleotides and  $n$  is the length of the sequence. The probability of any 15-base sequence appearing is  $1/4^{15}$ , or  $1/1,073,741,824$ . Thus, a 15-nucleotide sequence would be likely to appear approximately three times ( $3 \text{ billion} \times \text{probability of appearance}$ ). The probability of a 16-base sequence appearing is  $1/4^{16}$ , which is equal to  $1/4,294,967,296$ . Such a sequence will be unlikely to appear more than once.
10. One end of a nucleic acid polymer ends with a free 5'-hydroxyl group (or a phosphoryl group esterified to the hydroxyl group), and the other end has a free 3'-hydroxyl group. Thus, the ends are different. Two strands of DNA can form a double helix only if the strands are running in different directions—that is, have opposite polarity.
11. Although the individual bonds are weak, the population of thousands to millions of such bonds provides much stability. There is strength in numbers.
12. There would be too much charge repulsion from the negative charges on the phosphoryl groups. These charges must be countered by the addition of cations.
13. The three forms are the A-DNA, the B-DNA and the Z-DNA, with B-DNA being the most common. There are many differences (Table 4.2). Some key differences are: A-DNA and B-DNA are right-handed, whereas Z-DNA is left-handed. A-DNA forms in less-hydrated conditions than does B-DNA. The A form is shorter and wider than the B form.
14.  $5.88 \times 10^3$  base pairs.
15. The diameter of DNA is  $20 \text{ \AA}$  and  $1 \text{ \AA} = 0.1 \text{ nm}$ , so the diameter is  $2 \text{ nm}$ . Because  $1 \text{ }\mu\text{m} = 10^3 \text{ nm}$ , the length is  $2 \times 10^4 \text{ nm}$ . Thus, the axial ratio is  $1 \times 10^4$ .
16. A template is the sequence of DNA or RNA that directs the synthesis of a complementary sequence. A primer is the initial segment of a polymer that is to be extended during elongation.
17. In conservative replication, after 1.0 generation, half of the molecules would be  $^{15}\text{N}-^{15}\text{N}$ , the other half  $^{14}\text{N}-^{14}\text{N}$ . After 2.0 generations, one-quarter of the molecules would be  $^{15}\text{N}-^{15}\text{N}$ , the other three-quarters  $^{14}\text{N}-^{14}\text{N}$ . Hybrid  $^{14}\text{N}-^{15}\text{N}$  molecules would not be observed in conservative replication.
18. The nucleotides used for DNA synthesis have the triphosphate attached to the 5'-hydroxyl group with free 3'-hydroxyl groups. Such nucleotides can be utilized only for 5'-to-3' DNA synthesis.
19. (a) Tritiated thymine or tritiated thymidine. (b) dATP, dGTP, dCTP, and TTP labeled with  $^{32}\text{P}$  in the innermost ( $\alpha$ ) phosphorus atom.
20. Molecules in parts *a* and *b* would not lead to DNA synthesis, because they lack a 3'-OH group (a primer). The molecule in part *d* has a free 3'-OH group at one end of each strand but no template strand beyond. Only the molecule in part *c* would lead to DNA synthesis.
21. A retrovirus is a virus that has RNA as its genetic material. However, for the information to be expressed, it must first be converted into DNA, a reaction catalyzed by the enzyme reverse transcriptase. Thus, at least initially, information flow is opposite that of a normal cell:  $\text{RNA} \rightarrow \text{DNA}$  rather than  $\text{DNA} \rightarrow \text{RNA}$ .
22. A thymidylate oligonucleotide should be used as the primer. The poly(A) template specifies the incorporation of T; hence, radioactive thymidine triphosphate (labeled in the  $\alpha$  phosphoryl group) should be used in the assay.
23. The ribonuclease serves to degrade the RNA strand, a necessary step in forming duplex DNA from the RNA-DNA hybrid.
24. Treat one aliquot of the sample with ribonuclease and another with deoxyribonuclease. Test these nuclease-treated samples for infectivity.
25. Deamination changes the original G · C base pair into a G · U pair. After one round of replication, one daughter duplex will contain a G · C pair and the other duplex will contain an A · U pair. After two rounds of replication, there will be two G · C pairs, one A · U pair, and one A · T pair.
26. (a)  $4^8 = 65,536$ . In computer terminology, there are 64K 8-mers of DNA.  
(b) A bit specifies two bases (say, A and C) and a second bit specifies the other two (G and T). Hence, two bits are needed to specify a single nucleotide (base pair) in DNA. For example, 00, 01, 10, and 11 could encode A, C, G, and T. An 8-mer stores 16 bits ( $2^{16} = 65,536$ ), the *E. coli* genome ( $4.6 \times 10^6 \text{ bp}$ ) stores  $9.2 \times 10^6$  bits, and the human genome ( $3.0 \times 10^9 \text{ bases}$ ) stores  $6.0 \times 10^9$  bits of genetic information.  
(c) A standard CD can hold about 700 megabytes, which is equal to  $5.6 \times 10^9$  bits. A large number of 8-mer sequences could be

stored on such a CD. The DNA sequence of *E. coli* could be written on a single CD with room to spare for a lot of music. One CD would not be quite enough to record the entire human genome.

27. (a) Deoxyribonucleoside triphosphates versus ribonucleoside triphosphates.

(b)  $5' \rightarrow 3'$  for both.

(c) Semiconserved for DNA polymerase I; conserved for RNA polymerase.

(d) DNA polymerase I needs a primer, whereas RNA polymerase does not.

28. The template strand has a sequence complementary to that of the RNA transcript. The coding strand has the same sequence as that of the RNA transcript except for thymine (T) in place of uracil (U).

29. Messenger RNA encodes the information that, on translation, yields a protein. Ribosomal RNA is the catalytic component of ribosomes, the molecular complexes that synthesize proteins.

Transfer RNA is an adaptor molecule, capable of binding a specific amino acid and recognizing a corresponding codon. Transfer RNAs with attached amino acids are substrates for the ribosome.

30. Three nucleotides encode an amino acid; the code is nonoverlapping; the code has no punctuation; the code exhibits directionality; the code is degenerate.

31. (a)  $5' \text{-UAACGGUACGAU-3'}$

(b) Leu-Pro-Ser-Asp-Trp-Met

(c) Poly(Leu-Leu-Thr-Tyr)

32. The  $2'$ -OH group in RNA acts as an intramolecular nucleophile. In the alkaline hydrolysis of RNA, it forms a  $2'$ - $3'$  cyclic intermediate.

33.

34. Gene expression is the process of expressing the information of a gene in its functional molecular form. For many genes, the functional information is a protein molecule. Thus, gene expression includes transcription and translation.

35. A nucleotide sequence whose bases represent the most-common, but not necessarily the only, members of the sequence.

A consensus sequence can be thought of as the average of many similar sequences.

36. Cordycepin terminates RNA synthesis. An RNA chain containing cordycepin lacks a  $3'$ -OH group.

37. Only single-stranded RNA can serve as a template for protein synthesis.

38. Degeneracy of the code refers to the fact that most amino acids are encoded by more than one codon.

39. If only 20 of the 64 possible codons encoded amino acids, then a mutation that changed a codon would likely result in a nonsense codon, leading to termination of protein synthesis. With degeneracy, a nucleotide change might yield a synonym or a codon for an amino acid with similar chemical properties.

40. (a) 2, 4, 8; (b) 1, 6, 10; (c) 3, 5, 7, 9.

41. (a) 3; (b) 6; (c) 2; (d) 5; (e) 7; (f) 1; (g) 4.

42. Incubation with RNA polymerase and only UTP, ATP, and CTP led to the synthesis of only poly(UAC). Only poly(GUA) was formed when GTP was used in place of CTP.

43. A peptide terminating with Lys (UGA is a stop codon), another containing -Asn-Glu-, and a third containing -Met-Arg-.

44. Phe-Cys-His-Val-Ala-Ala

45. Exon shuffling is a molecular process that can lead to the generation of new proteins by the rearrangement of exons within genes. Because many exons encode functional protein domains, exon shuffling is a rapid and efficient means of generating new genes.

46. Alternate splicing allows one gene to code for several different but related proteins.

47. It shows that the genetic code and the biochemical means of interpreting the code are common to even very distantly related life forms. It also testifies to the unity of life: that all life arose from a common ancestor.

48. (a) A codon for lysine cannot be changed to one for aspartate by the mutation of a single nucleotide. (b) Arg, Asn, Gln, Glu, Ile, Met, or Thr.

49. The genetic code is degenerate. Of the 20 amino acids, 18 are specified by more than one codon. Hence, many nucleotide changes (especially in the third base of a codon) do not alter the nature of the encoded amino acid. Mutations leading to an altered amino acid are usually more deleterious than those that do not and hence are subject to more stringent selection.

50. GC base pairs have three hydrogen bonds compared with two for AT base pairs. Thus, the higher content of GC means more hydrogen bonds and greater helix stability.

51.  $C_0t$  value essentially corresponds to the complexity of the DNA sequence—in other words, how long it will take for a sequence of DNA to find its complementary strand to form a double helix. The

more complex the DNA, the slower it reassociates to make the double-stranded form.

52. Increasing salt increases the melting temperature. Because the DNA backbone is negatively charged, there is a tendency for charge repulsion to destabilize the helix and cause it to melt. The addition of salt neutralizes the charge repulsion, thereby stabilizing

the double helix. The results show that within the parameters of the experiment, more salt results in more stabilization, which is reflected as a higher melting temperature.

### Chapter 5

1. *Taq* polymerase is the DNA polymerase from the thermophilic bacterium that lives in hot springs. Consequently, it is heat stable and can withstand the high temperatures required for PCR without denaturing.
2. Ovalbumin cDNA should be used. *E. coli* lacks the machinery to splice the primary transcript arising from genomic DNA.
3. Consistent with its planar, aromatic structure, ethidium bromide is a DNA intercalator: it aligns itself between the paired bases in a DNA duplex.
4. The presence of the *AluI* sequence would, on average, be  $(1/4)^4$ , or 1/256, because the likelihood of any base being at any position is one-fourth and there are four positions. By the same reasoning, the presence of the *NotI* sequence would be  $(1/4)^8$ , or 1/65,536. Thus, the average product of digestion by *AluI* would be 250 base pairs (0.25 kb) in length, whereas that by *NotI* would be 66,000 base pairs (66 kb) in length.
5. No, because most human genes are much longer than 4 kb. A fragment would contain only a small part of a complete gene.
6. Southern blotting of an *MstII* digest would distinguish between the normal and the mutant genes. The loss of a restriction site would lead to the replacement of two fragments on the Southern blot by a single longer fragment. Such a finding would not prove that GTG replaced GAG; other sequence changes at the restriction site could yield the same result.
7. Although the two enzymes cleave the same recognition site, they each break different bonds within the 6-bp sequence. Cleavage by *KpnI* yields an overhang on the 3' strand, whereas cleavage by *Acc65I* produces an overhang on the 5' strand. These sticky ends do not overlap.

8. A simple strategy for generating many mutants is to synthesize a degenerate set of cassettes by using a mixture of activated nucleotides in particular rounds of oligonucleotide synthesis. Suppose that the 30-bp coding region begins with GTT, which encodes valine. If a mixture of all four nucleotides is used in the first and second rounds of synthesis, the resulting oligonucleotides will begin with the sequence XYT (where X and Y denote A, C, G, or T). These 16 different versions of the cassette will encode proteins containing either Phe, Leu, Ile, Val, Ser, Pro, Thr, Ala, Tyr, His, Asn, Asp, Cys, Arg, or Gly at the first position. Likewise, degenerate cassettes can be made in which two or more codons are simultaneously varied.
9. Because PCR can amplify as little as one molecule of DNA, statements claiming the isolation of ancient DNA need to be

greeted with some skepticism. The DNA would need to be sequenced. Is it similar to human, bacterial, or fungal DNA? If so, contamination is the likely source of the amplified DNA. Is it similar to that of birds or crocodiles? This sequence similarity would strengthen the case that it is dinosaur DNA because these species are evolutionarily close to dinosaurs.

10. PCR amplification is greatly hindered by the presence of G–C-rich regions within the template. Owing to their high melting temperatures, these templates do not denature easily, preventing the initiation of an amplification cycle. In addition, rigid secondary structures prevent the progress of DNA polymerase along the template strand during elongation.
11. At high temperatures of hybridization, only very close matches between primer and target would be stable because all (or most) of the bases would need to find partners to stabilize the primer–target helix. As the temperature is lowered, more mismatches would be tolerated; so the amplification is likely to yield genes with less sequence similarity. In regard to the yeast gene, synthesize primers corresponding to the ends of the gene, and then use these primers and human DNA as the target. If nothing is amplified at 54°C, the human gene differs from the yeast gene, but a counterpart may still be present. Repeat the experiment at a lower temperature of hybridization.
12. Digest genomic DNA with a restriction enzyme, and select the fragment that contains the known sequence. Circularize this fragment. Then carry out PCR with the use of a pair of primers that serve as templates for the synthesis of DNA away from the known sequence.
13. The encoded protein contains four repeats of a specific sequence.
14. Use chemical synthesis or the polymerase chain reaction to prepare hybridization probes that are complementary to both ends of the known (previously isolated) DNA fragment. Challenge clones representing the library of DNA fragments with both of the hybridization probes. Select clones that hybridize to one of the probes but not the other; such clones are likely to represent DNA fragments that contain one end of the known fragment along with the adjacent region of the particular chromosome.
15. The codon(s) for each amino acid can be used to determine the number of possible nucleotide sequences that encode each peptide sequence (Table 4.5):

Ala–Met–Ser–Leu–Pro–Trp:  
 $4 \times 1 \times 6 \times 6 \times 4 \times 1 = 576$  total sequences

Gly–Trp–Asp–Met–His–Lys:  
 $4 \times 1 \times 2 \times 1 \times 2 \times 2 = 32$  total sequences

Cys–Val–Trp–Asn–Lys–Ile:  
 $2 \times 4 \times 1 \times 2 \times 2 \times 3 = 96$  total sequences

Arg–Ser–Met–Leu–Gln–Asn:  
 $6 \times 6 \times 1 \times 6 \times 2 \times 2 = 864$  total sequences

The set of DNA sequences encoding the peptide Gly–Trp–Asp–Met–His–Lys would be most ideal for probe design because it encompasses only 32 total oligonucleotides.

16. Within a single species, individual dogs show enormous variation in body size and substantial diversity in other physical characteristics. Therefore, genomic analysis of individual dogs would provide valuable clues concerning the genes responsible for the diversity within the species.
17. On the basis of the comparative genome map shown in Figure 5.28, the region of greatest overlap with human chromosome 20 can be found on mouse chromosome 2.
18.  $T_m$  is the melting temperature of a double-stranded nucleic acid. If the melting temperatures of the primers are too different,

Mutagenesis of the initial selected RNA molecules allows for the iterative improvement of these sequences for the desired property.  
 15. 107 or 108 identities (depending on which annotated human sequence is chosen).

### Chapter 7

- The whale swims long distances between breaths. A high concentration of myoglobin in the whale muscle maintains a ready supply of oxygen for the muscle between breathing episodes.
- (a)  $2.96 \times 10^{-11}$  g  
(b)  $2.74 \times 10^8$  molecules  
(c) No. There would be  $3.17 \times 10^8$  hemoglobin molecules in a red cell if they were packed in a cubic crystalline array. Hence, the actual packing density is about 84% of the maximum possible.
- 2.65 g (or  $4.75 \times 10^{-2}$  mol) of Fe
- (a) In human beings,  $1.44 \times 10^{-2}$  g ( $4.49 \times 10^{-4}$  mol) of  $O_2$  per kilogram of muscle. In sperm whale, 0.144 g ( $4.49 \times 10^{-3}$  mol) of  $O_2$  per kilogram.  
(b) 128
- The  $pK_a$  is (a) lowered; (b) raised; and (c) raised.
- Deoxy Hb A contains a complementary site, and so it can add on to a fiber of deoxy Hb S. The fiber cannot then grow further, because the terminal deoxy Hb A molecule lacks a sticky patch.
- 62.7% oxygen-carrying capacity
- Myoglobin does not exhibit a Bohr effect. The interactions responsible for mediating the Bohr effect in hemoglobin are dependent upon a tetrameric structure. Myoglobin is a monomer.
- A higher concentration of BPG would shift the oxygen-binding curve to the right, causing an increase in  $P_{50}$ . The larger value of  $P_{50}$  would promote dissociation of oxygen in the tissues and would thereby increase the percentage of oxygen delivered to the tissues.
- (a) The transfusion would increase the number of red blood cells, which increases the oxygen-carrying capacity of the blood, allowing more sustained effort.  
(b) BPG stabilizes the T-state of hemoglobin, which results in a more efficient release of oxygen. If BPG is depleted, the oxygen will not be released even though the red blood cells are carrying more oxygen.
- Oxygen binding appears to cause the copper ions and their associated histidine ligands to move closer to one another, thereby also moving the helices to which the histidines are attached (in similar fashion to the conformational change in hemoglobin).
- The modified hemoglobin should not show cooperativity. Although the imidazole in solution will bind to the heme iron (in place of histidine) and will facilitate oxygen binding, the imidazole lacks the crucial connection to the particular  $\alpha$  helix that must move so as to transmit the change in conformation.
- Inositol pentaphosphate (part c) is highly anionic, much like 2,3-bisphosphoglycerate.
- 

15. Release of acid will lower the pH. A lower pH promotes oxygen dissociation in the tissues. However, the enhanced release of

oxygen in the tissues will increase the concentration of deoxy-Hb, thereby increasing the likelihood that the cells will sickle.  
 16. (a)  $Y = 0.5$  when  $pO_2 = 10$  torr. The plot of  $Y$  versus  $pO_2$  appears to indicate little or no cooperativity.

(b) The Hill plot shows slight cooperativity with  $n = 1.3$  in the central region.

(c) Deoxy dimers of lamprey hemoglobin could have lower affinity for oxygen than do the monomers. If the binding of the first oxygen atom to a dimer causes dissociation of the dimer to give two monomers, then the process would be cooperative. In this mechanism, oxygen binding to each monomer would be easier than binding the first oxygen atom to a deoxy dimer.

17. (a) 2; (b) 4; (c) 2; (d) 1.

18. The electrostatic interactions between BPG and hemoglobin would be weakened by competition with water molecules. The T state would not be stabilized.

19. Fetal hemoglobin contains two  $\alpha$  chains and two  $\gamma$  chains. The increase in levels of the  $\gamma$  chain provides an alternative to the mutated  $\beta$  chain in sickle-cell anemia patients. Hence, by increasing fetal hemoglobin expression, hydroxyurea reduces the potential for the formation of insoluble hemoglobin aggregates.

### Chapter 8

- Rate enhancement and substrate specificity.
- A cofactor.
- Coenzymes and metals.

4. Vitamins are converted into coenzymes.  
 5. Enzymes facilitate the formation of the transition state.  
 6. The intricate three-dimensional structure of proteins allows the construction of active sites that will recognize only specific substrates.  
 7. The energy required to reach the transition state (the activation energy) is returned when the transition state proceeds to product.  
 8. (a)  $K = \frac{[P]}{[S]} = \frac{k_F}{k_R} = \frac{10^{-4}}{10^{-6}} = 100$ . Using equation 5 in the text,  $\Delta G^{\circ'} = -11.42 \text{ kJ mol}^{-1}$  ( $-2.73 \text{ kcal mol}^{-1}$ )  
 (b)  $k_F = 10^{-2} \text{ s}^{-1}$  and  $k_R = 10^{-4} \text{ s}^{-1}$ . The equilibrium constant and  $\Delta G^{\circ'}$  values are the same for both the uncatalyzed and catalyzed reactions.  
 9. Protein hydrolysis has a large activation energy. Protein synthesis must require energy to proceed.  
 10. The enzymes help protect the fluid that surrounds eyes from bacterial infection.  
 11. Binding energy is the free energy released when two molecules bind together, such as when an enzyme and a substrate interact.  
 12. Binding energy is maximized when an enzyme interacts with the transition state, thereby facilitating the formation of the transition state and enhancing the rate of the reaction.  
 13. There would be no catalytic activity. If the enzyme–substrate complex is more stable than the enzyme–transition-state complex, the transition state would not form and catalysis would not take place.  
 14. Transition states are very unstable. Consequently, molecules that resemble transition states are themselves likely to be unstable and, hence, difficult to synthesize.  
 15. (a) 0; (b) +28.53; (c) -22.84; (d) -11.42; (e) +5.69.  
 16. (a)  $\Delta G^{\circ'} = -RT \ln K'_{\text{eq}}$

$$+1.8 = -(1.98 \times 10^{-3} \text{ kcal}^{-1} \text{ K}^{-1} \text{ mol}^{-1})(298 \text{ K}) (\ln[G1P]/[G6P])$$

$$-3.05 = \ln[G1P]/[G6P]$$

$$+3.05 = \ln[G6P]/[G1P]$$

$$K'_{\text{eq}} = 21 \text{ or } K'_{\text{eq}} = 4.8 \times 10^{-2}$$

Because  $[G6P]/[G1P] = 21$ , there is 1 molecule of G1P for every 21 molecules of G6P. Because we started with 0.1 M, the  $[G1P]$  is  $1/22(0.1 \text{ M}) = 0.0045 \text{ M}$  and  $[G6P]$  must be  $21/22(0.1 \text{ M})$  or 0.096 M. Consequently, the reaction does not proceed as written to a significant extent.

(b) Supply G6P at a high rate and remove G1P at a high rate by other reactions. In other words, make sure that the  $[G6P]/[G1P]$  is kept large.

17.  $K'_{\text{eq}} = 19$ ,  $\Delta G^{\circ'} = -7.3 \text{ kJ mol}^{-1}$  ( $-1.77 \text{ kcal mol}^{-1}$ )

18. The three-dimensional structure of an enzyme is stabilized by interactions with the substrate, reaction intermediates, and products. This stabilization minimizes thermal denaturation.

19. At substrate concentrations near the  $K_M$ , the enzyme displays significant catalysis yet is sensitive to changes in substrate concentration.

20. No,  $K_M$  is not equal to the dissociation constant, because the numerator also contains  $k_2$ , the rate constant for the conversion of the enzyme–substrate complex into enzyme and product. If, however,  $k_2$  is much smaller than  $k_{-1}$ ,  $K_M \approx K_d$ .

21. When  $[S] = 10 K_M$ ,  $V_0 = 0.91 V_{\text{max}}$ . When  $[S] = 20 K_M$ ,  $V_0 = 95 V_{\text{max}}$ .

So any Michaelis–Menten curves showing that the enzyme actually attains  $V_{\text{max}}$  are pernicious lies.

22. (a) 31.1  $\mu\text{mol}$ ; (b) 0.05  $\mu\text{mol}$ ; (c) 622  $\text{s}^{-1}$ , a midrange value for enzymes (Table 8.5).

23. (a) Yes,  $K_M = 5.2 \times 10^{-6} \text{ M}$ ; (b)  $V_{\text{max}} = 6.8 \times 10^{-10} \text{ mol minute}^{-1}$ ; (c) 337  $\text{s}^{-1}$ .

24. Penicillinase, like glycopeptide transpeptidase, forms an acyl-enzyme intermediate with its substrate but transfers the intermediate to water rather than to the terminal glycine residue of the pentaglycine bridge.

25. (a)  $V_{\text{max}}$  is 9.5  $\mu\text{mol minute}^{-1}$ .  $K_M$  is  $1.1 \times 10^{-5} \text{ M}$ , the same as without inhibitor.

(b) Noncompetitive.

(c)  $2.5 \times 10^{-5} \text{ M}$

(d)  $f_{\text{ES}} = 0.73$ , in the presence or absence of this noncompetitive inhibitor.

26. (a)  $V_0 = V_{\text{max}} - (V_0/[S]) K_M$

(b) Slope =  $-K_M$ , y-intercept =  $V_{\text{max}}$ , x-intercept =  $V_{\text{max}}/K_M$

(c) An Eadie–Hofstee plot.

27. Sequential reactions are characterized by the formation of a ternary complex consisting of the enzyme and both substrates. Double-displacement reactions always require the formation of a temporarily substituted enzyme intermediate.

28. The rates of utilization of substrates A and B are given by

$$V_A = \left( \frac{k_{\text{cat}}}{K_M} \right)_A [E][A]$$

and

$$V_B = \left( \frac{k_{\text{cat}}}{K_M} \right)_B [E][B]$$

Hence, the ratio of these rates is

$$V_A/V_B = \left( \frac{k_{\text{cat}}}{K_M} \right)_B [A] / \left( \frac{k_{\text{cat}}}{K_M} \right)_A [B]$$

Thus, an enzyme discriminates between competing substrates on the basis of their values of  $k_{\text{cat}}/K_M$  rather than of  $K_M$  alone.

29. The mutation slows the reaction by a factor of 100 because the activation free energy is increased by +11.42  $\text{kJ mol}^{-1}$  (+2.73  $\text{kcal mol}^{-1}$ ). Strong binding of the substrate relative to the transition state slows catalysis.

30. 11  $\mu\text{mol minute}^{-1}$

31. (a) This piece of information is necessary for determining the correct dosage of succinylcholine to administer.

(b) The duration of the paralysis depends on the ability of the serum cholinesterase to clear the drug. If there were one-eighth the amount of enzyme activity, paralysis could last eight times as long.

(c)  $K_M$  is the concentration needed by the enzyme to reach  $1/2 V_{\text{max}}$ . Consequently, for a given concentration of substrate, the reaction catalyzed by the enzyme with the lower  $K_M$  will have the higher rate. The mutant patient with the higher  $K_M$  will clear the drug at a much lower rate.

32. (a)  $K_M$  is a measure of affinity *only* if  $k_2$  is rate limiting, which is the case here. Therefore, the lower  $K_M$  means higher affinity. The mutant enzyme has a higher affinity.

(b)  $50 \mu\text{mol minute}^{-1}$ .  $10 \text{ mM}$  is  $K_M$ , and  $K_M$  yields  $\frac{1}{2} V_{\text{max}}$ .  $V_{\text{max}}$  is  $100 \mu\text{mol minute}^{-1}$ , and so . . .

(c) Enzymes do not alter the equilibrium of the reaction.

33. Enzyme 2. Despite the fact that enzyme 1 has a higher  $V_{\text{max}}$  than enzyme 2, enzyme 2 shows greater activity at the concentration of the substrate in the environment because enzyme 2 has a lower  $K_M$  for the substrate.

34. (a) The most effective means of measuring the efficiency of any enzyme–substrate complex is to determine the  $k_{\text{cat}}/K_M$  values. For the three substrates in question, the respective values of  $k_{\text{cat}}/K_M$  are: 6, 15, and 36. Thus, the enzyme exhibits a strong preference for cleaving peptide bonds in which the second amino acid is a large hydrophobic amino acid.

(b) The  $k_{\text{cat}}/K_M$  for this substrate is 2. Not very effective. This value suggests that the enzyme prefers to cleave peptide bonds with the following specificity: small R group—large hydrophobic R group.

35. If the total amount of enzyme ( $E_T$ ) is increased,  $V_{\text{max}}$  will increase, because  $V_{\text{max}} = k_2[E]_T$ . But  $K_M = (k_{-1} + k_2)/k_1$ ; that is, it is independent of substrate concentration. The middle graph describes this situation.

36.

Experimental condition	$V_{\text{max}}$	$K_M$
a. Twice as much enzyme is used	Doubles	No change
b. Half as much enzyme is used	Half as large	No change
c. A competitive inhibitor is present	No change	Increases
d. An uncompetitive inhibitor is present	Decreases	Decreases
e. A pure non-competitive inhibitor is present	Decreases	No change

37. (a)

(b) This behavior is substrate inhibition: at high concentrations, the substrate forms unproductive complexes at the active site. The adjoining drawing shows what might happen. Substrate normally binds in a defined orientation, shown in the drawing as red to red and blue to blue. At high concentrations, the substrate may bind at the active site such that the proper orientation is met for each end of the molecule, but two different substrate molecules are binding.

38. The first step will be the rate-limiting step. Enzymes  $E_B$  and  $E_C$  are operating at  $\frac{1}{2} V_{\text{max}}$ , whereas the  $K_M$  for enzyme  $E_A$  is greater than the substrate concentration.  $E_A$  would be operating at approximately  $10^{-2} V_{\text{max}}$ .

39. The fluorescence spectroscopy reveals the existence of an enzyme–serine complex and of an enzyme–serine–indole complex.

40. (a) When  $[S^+]$  is much greater than the value of  $K_M$ , pH will have a negligible effect on the enzyme because  $S^+$  will interact with  $E^-$  as soon as the enzyme becomes available.

(b) When  $[S^+]$  is much less than the value of  $K_M$ , the plot of  $V_0$  versus pH becomes essentially a titration curve for the ionizable groups, with enzyme activity being the titration marker. At low pH, the high concentration of  $H^+$  will keep the enzyme in the  $EH$  form and inactive. As the pH rises, more and more of the enzyme will be in the  $E^-$  form and active. At high pH (low  $H^+$ ), all of the enzyme is  $E^-$ .

(c) The midpoint on this curve will be the  $pK_a$  of the ionizable group, which is stated to be pH 6.

41. (a) Incubating the enzyme at  $37^\circ\text{C}$  leads to a denaturation of enzyme structure and a loss of activity. For this reason, most enzymes must be kept cool if they are not actively catalyzing their reactions.

(b) The coenzyme apparently helps to stabilize enzyme structure, because enzyme from PLP-deficient cells denatures faster. Cofactors often help stabilize enzyme structure.

42. The slow second order step occurs when complementary sequences on two different molecules bind with one another. Once the initial sequence alignment occurs, the remainder of the molecule can quickly locate complementary sequences from this nucleation site and reanneal, a first order reaction.

## Chapter 9

- For the amide substrate, the formation of the acyl-enzyme intermediate is slower than the hydrolysis of the acyl-enzyme intermediate, and so no burst is observed. A burst is observed for ester substrates; the formation of the acyl-enzyme intermediate is faster, leading to the observed burst.
- The histidine residue in the substrate can substitute to some extent for the missing histidine residue of the catalytic triad of the mutant enzyme.
- No. The catalytic triad works as a unit. After this unit has been made ineffective by the mutation of histidine to alanine, the further mutation of serine to alanine should have only a small effect.
- The substitution corresponds to one of the key differences between trypsin and chymotrypsin, and so trypsin-like specificity (cleavage after lysine and arginine) might be predicted.

In fact, additional changes are required to effect this specificity change.

5. Imidazole is apparently small enough to reach the active site of carbonic anhydrase and compensate for the missing histidine. Buffers with large molecular components cannot do so, and the effects of the mutation are more evident.

6. No. The odds of such a sequence being present are approximately  $1$  in  $4^{10} = 1,048,576$ . Because a typical viral genome has only 50,000 bp, the target sequence would be unlikely to be present.

7. No, because the enzyme would destroy the host DNA before protective methylation could take place.

8. No. The bacteria receiving the enzyme would have their own DNA destroyed because they would likely lack the appropriate protective methylase.

9. EDTA will bind to  $Zn^{2+}$  and remove the ion, which is required for enzyme activity, from the enzyme.

10. (a) The aldehyde reacts with the active-site serine. (b) A hemiacetal is formed.

11. Trypsin.

12. The reaction is expected to be slower by a factor of 10 because the rate depends on the  $pK_a$  of the zinc-bound water.

$$k_{cat} = 60,000 \text{ s}^{-1}$$

13. EDTA binds the magnesium necessary for the reaction.

14. ATP hydrolysis is reversible within the active site. ATP hydrolysis takes place within the active site with the incorporation of  $^{18}O$ , ATP is re-formed, and the ATP is released back into solution.

15. If the aspartate is mutated, the protease is inactive and the virus will not be viable.

16. Water substitutes for the hydroxyl group of serine 236 in mediating proton transfer from the attacking water and the  $\gamma$ -phosphoryl group.

17. For subtilisin, the catalytic power is approximately  $30 \text{ s}^{-1}/10^{-8} \text{ s}^{-1} = 3 \times 10^9$ . For carbonic anhydrase (at pH 7), the catalytic power is approximately  $500,000 \text{ s}^{-1}/0.15 \text{ s}^{-1} = 3.3 \times 10^6$ . Subtilisin is the more powerful enzyme by this criterion.

18. The triple mutant still catalyzes the reaction by a factor of approximately 1000-fold compared to the uncatalyzed reaction. This could be due to the enzyme binding the substrate and holding it in a conformation that is susceptible to attack by water.

19. (a) Cysteine protease: The same as Figure 9.8, except that cysteine replaces serine in the active site and no aspartate is present.

(b) Aspartyl protease:

(c) Metalloprotease:

## Chapter 10

1. The enzyme catalyzes the first step in the synthesis of pyrimidines. It facilitates the condensation of carbamoyl phosphate and aspartate to form *N*-carbamoylaspartate and inorganic phosphate.

2. The protonated form of histidine probably stabilizes the negatively charged carbonyl oxygen atom of the scissile bond (bond to be broken) in the transition state. Deprotonation would lead to a loss of activity. Hence, the rate is expected to be half maximal at a pH of about 6.5 (the  $pK$  of an unperturbed histidine side chain in a protein) and to decrease as the pH is raised.

3. The inhibition of an allosteric enzyme by the end product of the pathway controlled by the enzyme. It prevents the production of too much end product and the consumption of substrates when product is not required.

4. High concentrations of ATP might signal two overlapping situations. The high levels of ATP might suggest that some nucleotides are available for nucleic acid synthesis, and consequently, UTP and CTP should be synthesized. The high levels of ATP indicate that energy is available for nucleic acid synthesis, and so UTP and CTP should be produced.

5. All of the enzyme would be in the R form all of the time. There would be no cooperativity. The kinetics would look like that of a Michaelis–Menten enzyme.

6. The enzyme would show simple Michaelis–Menten kinetics because it is essentially always in the R state.

7. CTP is formed by the addition of an amino group to UTP. Evidence indicates the UTP is also capable of inhibiting ATCase in the presence of CTP.

8. Homotropic effectors are the substrates of allosteric enzymes. Heterotropic effectors are the regulators of allosteric enzymes.

Homotropic effectors account for the sigmoidal nature of the velocity versus substrate concentration curve, whereas heterotropic effectors alter the  $K_M$  of the curve. Ultimately, both types of effectors work by altering the T/R ratio.

9. The reconstitution shows that the complex quaternary structure and the resulting catalytic and regulatory properties are ultimately encoded in the primary structure of individual components.

10. If substrates had been used, the enzyme would catalyze the reaction. Intermediates would not accumulate on the enzyme. Consequently, any enzyme that crystallized would have been free of substrates or products.

11. (a) 100. The change in the  $[R]/[T]$  ratio on binding one substrate molecule must be the same as the ratio of the substrate affinities of the two forms.

(b) 10. The binding of four substrate molecules changes the  $[R]/[T]$  by a factor of  $100^4 = 10^8$ . The ratio in the absence of substrate is  $10^{-7}$ . Hence, the ratio in the fully liganded molecule is  $10^8 \times 10^{-7} = 10$ .

12. The fraction of molecules in the R form is  $10^{-5}$ , 0.004, 0.615, 0.998, and 1 when 0, 1, 2, 3, and 4 ligands, respectively, are bound.

13. The sequential model can account for negative cooperativity, whereas the concerted model cannot.

14.

15. The binding of PALA switches ATCase from the T to the R state because PALA acts as a substrate analog. An enzyme molecule containing bound PALA has fewer free catalytic sites than does an unoccupied enzyme molecule. However, the PALA-containing enzyme will be in the R state and, hence, have a higher affinity for the substrates. The dependence of the degree of activation on the concentration of PALA is a complex function of the allosteric constant  $L_0$  and of the binding affinities of the R and T states for the analog and substrates.

16. The net outcome of the two reactions is the hydrolysis of ATP to ADP and  $P_i$ , which has a  $\Delta G$  of  $-50 \text{ kJ mol}^{-1}$  ( $-12 \text{ kcal mol}^{-1}$ ) under cellular conditions.

17. Isozymes are homologous enzymes that catalyze the same reaction but have different kinetic or regulatory properties.

18. Although the same reaction may be required in a variety of tissues, the biochemical properties of tissues will differ according to their biological function. Isozymes allow the fine-tuning of catalytic and regulatory properties to meet the specific needs of the tissue.

19. (a) 7; (b) 8; (c) 11; (d) 6; (e) 1; (f) 12; (g) 3; (h) 4; (i) 5; (j) 2; (k) 10; (l) 9.

20. When phosphorylation takes place at the expense of ATP, sufficient energy is expended to dramatically alter the structure and hence activity of a protein. Moreover, because ATP is the cellular energy currency, protein modification is linked to the energy status of the cell.

21. Covalent modification is reversible, whereas proteolytic cleavage is irreversible.

22. Activation is independent of zymogen concentration because the reaction is intramolecular.

23. Although quite rare, cases of enteropeptidase deficiency have been reported. The affected person has diarrhea and fails to thrive because digestion is inadequate. In particular, protein digestion is impaired.

24. Add blood from the second patient to a sample from the first. If the mixture clots, the second patient has a defect different from that of the first. This type of assay is called a complementation test.

25. Activated factor X remains bound to blood-platelet membranes, which accelerates its activation of prothrombin.

26. Antithrombin III is a very slowly hydrolyzed substrate of thrombin. Hence, its interaction with thrombin requires a fully formed active site on the enzyme.

27. Replacing methionine with leucine would be a good choice. Leucine is resistant to oxidation and has nearly the same volume and degree of hydrophobicity as methionine has.

28. Inappropriate clot formation could block arteries in the brain, causing a stroke, or the heart, causing a heart attack.

29. Thrombin catalyzes the hydrolysis of fibrinogen to form active fibrin. But it also has a role in shutting down the cascade by activating protein C, a protease that digests other clotting enzymes  $V_a$  and  $VIII_a$ .

30. Tissue-type plasminogen activator, or TPA, is a serine protease that leads to the dissolution of blood clots. TPA activates plasminogen that is bound to a fibrin clot, converting it into active plasmin, which then hydrolyzes the fibrin of the clot.

31. A mature clot is stabilized by amide linkages between the side chains of lysine and glutamine that are absent in a soft clot. The linkages are formed by transglutaminase.

32. The simple sequential model predicts that the fraction of catalytic chains in the R state,  $f_R$ , is equal to the fraction containing bound substrate,  $Y$ . The concerted model, in contrast, predicts that  $f_R$  increases more rapidly than  $Y$  as the substrate concentration is increased. The change in  $f_R$  leads to the change in  $Y$  on addition of substrate, as predicted by the concerted model.

33. The binding of succinate to the functional catalytic sites of the native  $c_3$  moiety changed the visible absorption spectrum of nitrotyrosine residues in the *other*  $c_3$  moiety of the hybrid enzyme. Thus, the binding of substrate analog to the active sites of one trimer altered the structure of the other trimer.

34. According to the concerted model, an allosteric activator shifts the conformational equilibrium of all subunits toward the R state, whereas an allosteric inhibitor shifts it toward the T state. Thus, ATP (an allosteric activator) shifted the equilibrium to the R form, resulting in an absorption change similar to that obtained when substrate is bound. CTP had a different effect. Hence, this allosteric inhibitor shifted the equilibrium to the T form. Thus, the concerted model accounts for the ATP-induced and CTP-induced (heterotropic), as well as for the substrate-induced (homotropic), allosteric interactions of ATCase.

35. (a) When crowded, the control group displays gregarious behavior. (b) Inhibition of PKA appears to prevent gregarious behavior, while inhibition of PKG has no effect on the behavior. (c) The effect of PKG inhibition was investigated to establish that the effect seen with PKA inhibition is specific and not just due to the inhibition of any kinase. (d) PKA plays a role in altering behavior of insects. (e) Gregariousness in locusts that are always gregarious is not affected by PKA inhibition, suggesting that PKA may play a role in modifying behavior patterns but not in establishing the patterns.

36. Residues  $a$  and  $d$  are located in the interior of an  $\alpha$ -helical coiled coil, near the axis of the superhelix. Hydrophobic interactions between these side chains contribute to the stability of the coiled coil.

37. In the R state, ATCase expands and becomes less dense. This decrease in density results in a decrease in the sedimentation value (see the formula on p. 76).

38. The interaction between trypsin and the inhibitor is so stable that the transition state is rarely formed. Recall that maximal binding energy is released when an enzyme binds to the transition state. If the substrate-enzyme interaction is too stable, the transition state rarely forms.

39. Dicoumarol is a competitive inhibitor of  $\gamma$ -glutamyl carboxylase. Consequently,  $\gamma$ -carboxyglutamate, which is required for prothrombin to be converted into thrombin, is not formed. Amino acid composition is determined by

hydrolyzing the protein at elevated temperatures in the presence of strong acid. Under these conditions, the carboxyl group of  $\gamma$ -carboxyglutamate is removed from the normal prothrombin, leaving simply glutamate.

40.

41.

### Chapter 11

- Carbohydrates were originally regarded as *hydrates of carbon* because the empirical formula of many of them is  $(\text{CH}_2\text{O})_n$ .
- Three amino acids can be linked by peptide bonds in only six different ways. However, three different monosaccharides can be linked in a plethora of ways. The monosaccharides can be linked in a linear or branched manner, with  $\alpha$  or  $\beta$  linkages, with bonds between C-1 and C-3, between C-1 and C-4, between C-1 and C-6, and so forth. In fact, the three monosaccharides can form 12,288 different trisaccharides.
- (a) 10; (b) 6; (c) 8; (d) 9; (e) 2; (f) 4; (g) 1; (h) 5; (i) 7; (j) 3.
- (a) aldose-ketose; (b) epimers; (c) aldose-ketose (d) anomers; (e) aldose-ketose; (f) epimers.

- Erythrose: tetrose aldose; ribose: pentose aldose; glyceraldehyde: triose aldose; dihydroxyacetone: triose ketose; erythrose: tetrose ketose; ribulose: pentose ketose; fructose: hexose ketose.

6.

7.

**$\alpha$ -Glucosyl-(1  $\rightarrow$  6)-galactose**

- The proportion of the  $\alpha$  anomer is 0.36, and that of the  $\beta$  anomer is 0.64.
- Glucose is reactive because of the presence of an aldehyde group in its open-chain form. The aldehyde group slowly condenses with amino groups to form aldimine products of a type called Schiff-base adducts.

10. A pyranoside reacts with two molecules of periodate; formate is one of the products. A furanoside reacts with only one molecule of periodate; formate is not formed.

11. (a)  $\beta$ -D-Mannose; (b)  $\beta$ -D-galactose; (c)  $\beta$ -D-fructose; (d)  $\beta$ -D-glucosamine.

12. The trisaccharide itself should be a competitive inhibitor of cell adhesion if the trisaccharide unit of the glycoprotein is critical for the interaction.

13. Reducing ends would form 1,2,3,6-tetramethylglucose. The branch points would yield 2,3-dimethylglucose. The remainder of the molecule would yield 2,3,6-trimethylglucose.

14. (a) Not a reducing sugar; no open-chain forms are possible. (b) D-galactose, D-glucose, D-fructose. (c) D-galactose and sucrose (glucose + fructose).

15.  The hemiketal linkage of the  $\alpha$  anomer is broken to form the open form. Rotation about the C-1 and C-2 bonds allows the formation of the  $\beta$  anomer, and a mixture of isomers results.

16. Heating converts the very sweet pyranose form into the more-stable but less-sweet furanose form. Consequently, the sweetness of the preparation is difficult to accurately control, which also accounts for why honey loses sweetness with time. See Figure 11.5 for structures.

17. (a) Each glycogen molecule has one reducing end, whereas the number of nonreducing ends is determined by the number of branches, or  $\alpha$ -1,6 linkages. (b) Because the number of nonreducing ends greatly exceeds the number of reducing ends in a collection of glycogen molecules, all of the degradation and synthesis of glycogen takes place at the nonreducing ends, thus maximizing the rate of degradation and synthesis.

18. No, sucrose is not a reducing sugar. The anomeric carbon atom acts as the reducing agent in both glucose and fructose but, in sucrose, the anomeric carbon atoms of fructose and glucose are joined by a covalent bond and are thus not available to react.

19. Glycogen is a polymer of glucose linked by  $\alpha$ -1,4-glycosidic bonds with branches formed approximately every 10 glucose units by  $\alpha$ -1,6-glycosidic bonds. Starch consists of two polymers of glucose. Amylose is a straight-chain polymer formed by  $\alpha$ -1,4-glycosidic bonds. Amylopectin is similar to glycogen but amylopectin has fewer branches, one branch per 30 or so glucose units.

20. Cellulose is a linear polymer of glucose joined by  $\beta$ -1,4 linkages. Glycogen is a branched polymer with the main chain being formed by  $\alpha$ -1,4-glycosidic bonds. The  $\beta$ -1,4 linkages allow the formation of a linear polymer ideal for structural roles. The  $\alpha$ -1,4 linkages of glycogen form a helical structure, which allows the storage of many glucose moieties in a small space.

21. Simple glycoproteins are often secreted proteins and thus play a variety of roles. For example, the hormone EPO is a glycoprotein. Usually, the protein component constitutes the bulk of the glycoprotein by mass. In contrast, proteoglycans and mucoproteins are predominantly carbohydrates. Proteoglycans have glycosaminoglycans attached, and play structural roles as in cartilage and the extracellular matrix. Mucoproteins often serve as lubricants and have multiple carbohydrates attached through an *N*-acetylgalactosamine moiety.

22. The attachment of the carbohydrate allows the EPO to stay in circulation longer and thus to function for longer periods of time than would a carbohydrate-free EPO.

23. The glycosaminoglycan, because it is heavily charged, binds many water molecules. When cartilage is stressed, such as when

your heel hits the ground, the water is released, thus cushioning the impact. When you lift your heel, the water rebinds.

24. The lectin that binds the mannose 6-phosphate might be defective and not recognize a correctly addressed protein.

25. Asparagine, serine, and threonine.

26. Different molecular forms of a glycoprotein that differ in the amount of carbohydrate attached or the location of attachment or both.

27. The total collection of carbohydrates synthesized by a cell at particular times and under particular environmental conditions.

28. The genome comprises all of the genes present in an organism. The proteome includes all of the possible protein products and modified proteins that a cell expresses under any particular set of circumstances. The glycome consists of all of the carbohydrates synthesized by the cell under any particular set of circumstances. Because the genome is static, but any given protein can be variously expressed and modified, the proteome is more complex than the genome. The glycome, which includes not only glycoforms of proteins, but also many possible carbohydrate structures, must be even more complex.

29. An asparagine residue can be glycosylated if the residue is part of an Asn-X-Ser or Asn-X-Thr sequence, in which X can be any residue, except proline. Your roommate's hedging is because not all potential sites are glycosylated.

30. It suggests that carbohydrates are on the cell surfaces of all organisms for the purpose of recognition by other cells, organisms, or the environment.

31. A glycoprotein is a protein that is decorated with carbohydrates. A lectin is a protein that specifically recognizes carbohydrates. A lectin can also be a glycoprotein.

32. Each site either is or is not glycosylated, and so there are  $2^6 = 64$  possible proteins.

33. The 20 amino acid components of proteins and the 4 nucleotide components of nucleic acids are linked by the same type of bond—the peptide bond in proteins and the 5'-to-3' phosphodiester linkage in nucleic acids. In contrast, there are many different carbohydrates that can be modified and linked in a variety of ways. Moreover, oligosaccharides can be branched. Finally, many sugars have the same or similar chemical formula, and similar chemical properties, making specific identification and linkage difficult.

34. As discussed in Chapter 9, many enzymes display stereochemical specificity. Clearly, the enzymes of sucrose synthesis are able to distinguish between the isomers of the substrates and link only the correct pair.

35. If the carbohydrate specificity of the lectin is known, an affinity column with the appropriate carbohydrate attached could be prepared. The protein preparation containing the lectin of interest could be passed over the column. The use of this method was indeed how the glucose-binding lectin concanavalin A was purified.

36. (a) Aggrecan is heavily decorated with glycosaminoglycans. If glycosaminoglycans are released into the media, aggrecan must be undergoing degradation.

(b) Another enzyme might be present that cleaves glycosaminoglycans from aggrecan without degrading aggrecan. Other experiments not shown established that glycosaminoglycan release is an accurate measure of aggrecan destruction.

(c) The control provides a baseline of "background" degradation inherent in the assay.

(d) Aggrecan degradation is greatly enhanced.

- (e) Aggrecan degradation is reduced to the background system.  
 (f) It is an in vitro system in which not all the factors contributing to cartilage stabilization in vivo are present.

### Chapter 12

- $2.86 \times 10^6$  molecules, because each leaflet of the bilayer contains  $1.43 \times 10^6$  molecules.
- Essentially an “inside-out” membrane. The hydrophilic groups would come together on the interior of the structure, away from the solvent, whereas the hydrocarbon chains would interact with the solvent.
- $2 \times 10^{-7}$  cm,  $6 \times 10^{-6}$  cm, and  $2 \times 10^{-4}$  cm.
- The radius of this molecule is  $3.1 \times 10^{-7}$  cm, and its diffusion coefficient is  $7.4 \times 10^{-9}$  cm<sup>2</sup> s<sup>-1</sup>. The average distances traversed are  $1.7 \times 10^{-7}$  cm in 1 μs,  $5.4 \times 10^{-6}$  cm in 1 ms, and  $1.7 \times 10^{-4}$  cm in 1 s.
- The membrane underwent a phase transition from a highly fluid to a nearly frozen state when the temperature was lowered. A carrier can shuttle ions across a membrane only when the bilayer is highly fluid. A channel, in contrast, allows ions to traverse its pore even when the bilayer is quite rigid.
- The presence of a cis double bond introduces a kink in the fatty acid chain that prevents tight packing and reduces the number of atoms in van der Waals contact. The kink lowers the melting point compared with that of a saturated fatty acid. Trans fatty acids do not have the kink, and so their melting temperatures are higher, more similar to those of saturated fatty acids. Because trans fatty acids have no structural effect, they are rarely observed.
- Palmitic acid is shorter than stearic acid. Thus, when the chains pack together, there is less opportunity for van der Waals interaction and the melting point is thus lower than that of the longer stearic acid.
- Hibernators selectively feed on plants that have a high proportion of polyunsaturated fatty acids with lower melting temperature.
- The initial decrease in fluorescence with the first addition of sodium dithionite results from the quenching of NBD-PS molecules in the outer leaflet of the bilayer. Sodium dithionite does not traverse the membrane under these experimental conditions; hence, it does not quench the labeled phospholipids in the inner leaflet. A second addition of sodium dithionite has no effect, as the NBD-PS molecules in the outer leaflet remain quenched. However, after a 6.5-hour incubation, about half the NBD-PS has flipped over to the outer leaflet of the bilayer, resulting in the 50% decrease in fluorescence when sodium dithionite is added.
- The addition of the carbohydrate introduces a significant energy barrier to the flip-flop because a hydrophilic carbohydrate moiety would need to be moved through a hydrophobic environment. This energetic barrier enhances membrane asymmetry.
- The C<sub>16</sub> alkyl chain is attached by an ether linkage. The C-2 carbon atom of glycerol has only an acetyl group attached by an ester linkage instead of a fatty acid, as is the case with most phospholipids.
- In a hydrophobic environment, the formation of intrachain hydrogen bonds stabilizes the amide hydrogen atoms and carbonyl oxygen atoms of the polypeptide chain, and so an α helix forms. In an aqueous environment, these groups are stabilized by interaction with water, and so there is no energetic reason to form an α helix. Thus, the α helix would be more likely to form in a hydrophobic environment.
- The protein may contain an α helix that passes through the hydrophobic core of the protein. This helix is likely to feature a stretch of hydrophobic amino acids similar to those observed in transmembrane helices.
- The shift to the lower temperature would decrease fluidity by enhancing the packing of the hydrophobic chains by van der Waals interactions. To prevent this packing, new phospholipids having shorter chains and a greater number of cis double bonds would be synthesized. The shorter chains would reduce the number of van der Waals interactions, and the cis double bonds, which cause the kink in structure, would prevent the packing of the fatty acid tails of the phospholipids.
- Each of the 21 v-SNARE proteins could interact with each of 7 t-SNARE partners. Multiplication gives the total number of different interacting pairs:  $7 \times 21 = 147$  different v-SNARE–t-SNARE pairs.
- (a) The graph shows that, as temperature increases, the phospholipid bilayer becomes more fluid.  $T_m$  is the temperature of the transition from the predominantly less fluid state to the predominantly more fluid state. Cholesterol broadens the transition from the less-fluid to the more-fluid state. In essence, cholesterol makes membrane fluidity less sensitive to temperature changes.  
 (b) This effect is important because the presence of cholesterol tends to stabilize membrane fluidity by preventing sharp transitions. Because protein function depends on the proper fluidity of the membrane, cholesterol maintains the proper environment for membrane-protein function.
- The protein plotted in part *c* is a transmembrane protein from *C. elegans*. It spans the membrane with four α helices that are prominently displayed as hydrophobic peaks in the hydropathy plot. Interestingly, the protein plotted in part *a* also is a membrane protein, a porin. This protein is made primarily of β strands, which lack the prominent hydrophobic window of membrane helices. This example shows that, although hydropathy plots are useful, they are not infallible.
- (a) Prostaglandin H<sub>2</sub> synthase-1 recovers its activity immediately after removal of ibuprofen, suggesting that this inhibitor dissociates rapidly from the enzyme. In contrast, the enzyme remains significantly inhibited 30 minutes after removal of indomethacin, suggesting that this inhibitor dissociates slowly from its active site.  
 (b) Aspirin covalently modifies prostaglandin H<sub>2</sub> synthase-1, indicating that it would dissociate very slowly (if at all). Hence, one would anticipate that very low activity would be evident in all conditions where inhibitor has been added (columns 2, 3, and 4).
- To purify any protein, the protein must first be solubilized. For a membrane protein, solubilization usually requires a detergent—hydrophobic molecules that bind to the protein and thus replace the lipid environment of the membrane. If the detergent is removed, the protein aggregates and precipitates from solution. Often, the steps in purification, such as ion-exchange chromatography, are difficult to perform in the presence of sufficient detergent to solubilize the protein. Crystals of appropriate protein–detergent complexes must be generated.

### Chapter 13

- In simple diffusion, the substance in question can diffuse down its concentration gradient through the membrane. In facilitated diffusion, the substance is not lipophilic and cannot directly diffuse through the membrane. A channel or carrier is required to facilitate movement down the gradient.

2. The two forms are (1) ATP hydrolysis and (2) the movement of one molecule down its concentration gradient coupled with the movement of another molecule up its concentration gradient.
3. The three types of carriers are symporters, antiporters, and uniporters. Symporters and antiporters can mediate secondary active transport.
4. The free-energy cost is  $+32 \text{ kJ mol}^{-1}$  ( $+7.6 \text{ kcal mol}^{-1}$ ). The chemical work performed is  $+20.4 \text{ kJ mol}^{-1}$  ( $+4.9 \text{ kcal mol}^{-1}$ ), and the electrical work performed is  $+11.5 \text{ kJ mol}^{-1}$  ( $+2.8 \text{ kcal mol}^{-1}$ ).
5. For chloride,  $z = -1$ ; for calcium  $z = +2$ . At the concentrations given, the equilibrium potential for chloride is  $-97 \text{ mV}$  and the equilibrium potential for calcium is  $+122 \text{ mV}$ .
6. The concentration of glucose inside the cell is 66 times as great as that outside the cell [ $(c_2/c_1) = 66$ ] when the free-energy input is  $+10.8 \text{ kJ mol}^{-1}$  ( $+2.6 \text{ kcal mol}^{-1}$ ).
7. By analogy with the  $\text{Ca}^{2+}$  ATPase, with three  $\text{Na}^+$  ions binding from inside the cell to the  $E_1$  conformation and with two  $\text{K}^+$  ions binding from outside the cell to the  $E_2$  conformation, a plausible mechanism is as follows:
  - (i) A catalytic cycle could begin with the enzyme in its unphosphorylated state ( $E_1$ ) with three sodium ions bound.
  - (ii) The  $E_1$  conformation binds ATP. A conformational change traps sodium ions inside the enzyme.
  - (iii) The phosphoryl group is transferred from ATP to an aspartyl residue.
  - (iv) On ADP release, the enzyme changes its overall conformation, including the membrane domain. This new conformation ( $E_2$ ) releases the sodium ions to the side of the membrane opposite that at which they entered and binds two potassium ions from the side where sodium ions are released.
  - (v) The phosphorylaspartate residue is hydrolyzed to release inorganic phosphate. With the release of phosphate, the interactions stabilizing  $E_2$  are lost, and the enzyme everts to the  $E_1$  conformation. Potassium ions are released to the cytoplasmic side of the membrane. The binding of three sodium ions from the cytoplasmic side of the membrane completes the cycle.
8. Establish a lactose gradient across vesicle membranes that contain properly oriented lactose permease. Initially, the pH should be the same on both sides of the membrane and the lactose concentration should be higher on the "exit" side of lactose permease. As the lactose flows "in reverse" through the permease, down its concentration gradient, it can be tested whether or not a pH gradient becomes established as the lactose gradient is dissipated.
9. Ligand-gated channels open in response to the binding of a molecule by the channel, whereas voltage-gated channels open in response to changes in the membrane potential.
10. An ion channel must transport ions in either direction at the same rate. The net flow of ions is determined only by the composition of the solutions on either side of the membrane.
11. Uniporters act as enzymes do; their transport cycles include large conformational changes, and only a few molecules interact with the protein per transport cycle. In contrast, channels, after having opened, provide a pore in the membrane through which many ions may pass. As such, channels mediate transport at a much higher rate than do uniporters.
12. FCCP effectively creates a pore in the bacterial membrane through which protons can pass rapidly. Protons that are pumped out of the bacteria will pass through this pore preferentially (the "path of least resistance"), rather than participate in  $\text{H}^+$ /lactose symport.
13. Cardiac muscle must contract in a highly coordinated manner in order to pump blood effectively. Gap junctions mediate the orderly cell-to-cell propagation of the action potential through the heart during each beat.
14. The positively charged guanidinium group resembles  $\text{Na}^+$  and binds to negatively charged carboxylate groups in the mouth of the channel.
15. SERCA, a P-type ATPase, uses a mechanism by which a covalent phosphorylated intermediate (at an aspartate residue) is formed. At steady state, a subset of the SERCA molecules is trapped in the  $E_2$ -P state and, as a result, radiolabeled. The MDR protein is an ABC transporter and does not operate through a phosphorylated intermediate. Hence, a radiolabeled band would not be observed for MDR.
16. The blockage of ion channels inhibits action potentials, leading to loss of nervous function. Like tetrodotoxin, these toxin molecules are useful for isolating and specifically inhibiting particular ion channels.
17. After repolarization, the ball domains of the ion channels engage the channel pore, rendering them inactive for a short period of time. During this time, the channels cannot be reopened until the ball domains disengage and the channel returns to the "closed" state.
18. Because sodium ions are charged and because sodium channels carry only sodium ions (but not anions), the accumulation of excess positive charge on one side of the membrane dominates the chemical gradients.
19. A mutation that impairs the ability of the sodium channel to inactivate would prolong the duration of the depolarizing sodium current, thus lengthening the cardiac action potential.
20. No. Channels will likely open or close in response to an external stimulus, but the unit conductance of the open channel will be influenced very little.
21. The ratio of closed to open forms of the channel is  $10^5$ , 5000, 250, 12.5, and 0.625 when zero, one, two, three, and four ligands, respectively, are bound. Hence, the fraction of open channels is  $1.0 \times 10^{-5}$ ,  $2.0 \times 10^{-4}$ ,  $4.0 \times 10^{-3}$ ,  $7.4 \times 10^{-2}$ , and 0.62.
22. These organic phosphates inhibit acetylcholinesterase by reacting with the active-site serine residue to form a stable phosphorylated derivative. They cause respiratory paralysis by blocking synaptic transmission at cholinergic synapses.
23. (a) The binding of the first acetylcholine molecule increases the open-to-closed ratio by a factor of 240, and the binding of the second increases it by a factor of 11,700. (b) The free-energy contributions are  $+14 \text{ kJ mol}^{-1}$  ( $+3.3 \text{ kcal mol}^{-1}$ ) and  $+23 \text{ kJ mol}^{-1}$  ( $+5.6 \text{ kcal mol}^{-1}$ ), respectively. (c) No; the MWC model predicts that the binding of each ligand will have the same effect on the open-to-closed ratio.
24. Batrachotoxin blocks the transition from the open to the closed state.
25. (a) Chloride ions flow into the cell. (b) Chloride flux is inhibitory because it hyperpolarizes the membrane. (c) The channel consists of five subunits.
26. After the addition of ATP and calcium, SERCA will pump  $\text{Ca}^{2+}$  ions into the vesicle. However, the accumulation of  $\text{Ca}^{2+}$  ions inside the vesicle will rapidly lead to the formation of an electrical gradient that cannot be overcome by ATP hydrolysis. The addition of calcimycin will allow the pumped  $\text{Ca}^{2+}$  ions to flow back out of the vesicle, dissipating the charge buildup, and enabling the pump to operate continuously.
27. The catalytic prowess of acetylcholinesterase ensures that the duration of the nerve stimulus will be short.

28. See reaction below.

29. (a) Only ASIC1a is inhibited by the toxin. (b) Yes; when the toxin was removed, the activity of the acid-sensing channel began to be restored. (c) 0.9 nM.

30. This mutation is one of a class of mutations that result in slow-channel syndrome (SCS). The results suggest a defect in channel closing; so the channel remains open for prolonged periods. Alternatively, the channel may have a higher affinity for acetylcholine than does the control channel.

31. The mutation reduces the affinity of acetylcholine for the receptor. The recordings would show the channel opening only infrequently.

32. Glucose displays a transport curve that suggests the participation of a carrier because the initial rate is high but then levels off at higher concentrations, consistent with saturation of the carrier, which is reminiscent of Michaelis–Menten enzymes (Section 8.4). Indole shows no such saturation phenomenon, which implies that the molecule is lipophilic and simply diffuses across the membrane. Ouabain is a specific inhibitor the  $\text{Na}^+\text{-K}^+$  pump. If ouabain were to inhibit glucose transport, then a  $\text{Na}^+$ -glucose cotransporter would be assisting in transport.

## Chapter 14

1. The negatively charged glutamate residues mimic the negatively charged phosphoserine or phosphothreonine residues and stabilize the active conformation of the enzyme.

2. No. Phosphoserine and phosphothreonine are considerably shorter than phosphotyrosine.

3. The GTPase activity terminates the signal. Without such activity, after a pathway has been activated, it remains activated and is unresponsive to changes in the initial signal. If the GTPase activity

were more efficient, the lifetime of the GTP-bound  $G_\alpha$  subunit would be too short to achieve downstream signaling.

4. Two identical receptor molecules must recognize different aspects of the same signal molecule.

5. Growth-factor receptors can be activated by dimerization. If an antibody causes a receptor to dimerize, the signal-transduction pathway in a cell will be activated.

6. The mutated  $\alpha$  subunit will always be in the GTP form and, hence, in the active form, which would stimulate its signaling pathway.

7. A G protein is a component of the signal-transduction pathway. GTP $\gamma$ S is not hydrolyzed by the  $G_\alpha$  subunit, leading to prolonged activation.

8. Calcium ions diffuse slowly because they bind to many protein surfaces within a cell, impeding their free motion. Cyclic AMP does not bind as frequently, and so it diffuses more rapidly.

9. Fura-2 is a highly negatively charged molecule, with five carboxylate groups. Its charge prevents it from effectively crossing the hydrophobic region of the plasma membrane.

10.  $G_{\alpha s}$  stimulates adenylate cyclase, leading to the generation of cAMP. This signal then leads to glucose mobilization (Chapter 21). If cAMP phosphodiesterase were inhibited, then cAMP levels would remain high even after the termination of the epinephrine signal, and glucose mobilization would continue.

11. If the two kinase domains are forced to be within close proximity of each other, the activation loop of one kinase, in its inactivating conformation, can be displaced by the activation loop of the neighboring kinase, which acts as a substrate for phosphorylation.

12. The full network of pathways initiated by insulin includes a large number of proteins and is substantially more elaborate than indicated in Figure 14.26. Furthermore, many additional proteins take part in the termination of insulin signaling. A defect in any of the proteins in the insulin signaling pathways or in the subsequent termination of the insulin response could potentially cause problems. Therefore, it is not surprising that many different gene defects can cause type 2 diabetes.

13. The binding of growth hormone causes its monomeric receptor to dimerize. The dimeric receptor can then activate a separate tyrosine kinase to which the receptor binds. The signaling pathway can then continue in similar fashion to the pathways that are activated by the insulin receptor or other mammalian EGF receptors.

14. The truncated receptor will dimerize with the full-length monomers on EGF-binding, but cross-phosphorylation cannot take place, because the truncated receptor possesses neither the substrate for the neighboring kinase domain nor its own kinase domain to phosphorylate the C-terminal tail of the other monomer. Hence, these mutant receptors will block normal EGF signaling.

15. Insulin would elicit the response that is normally caused by EGF. Insulin binding will likely stimulate dimerization and phosphorylation of the chimeric receptor and thereby signal the downstream events that are normally triggered by EGF binding. Exposure of these cells to EGF would have no effect.

16.  $10^5$

17. The formation of diacylglycerol implies the participation of phospholipase C. A simple pathway would entail receptor activation by cross-phosphorylation, followed by the binding of phospholipase C (through its SH2 domains). The participation of phospholipase C indicates that  $\text{IP}_3$  would be formed and, hence, calcium concentrations would increase.

18. Other potential drug targets within the EGF signaling cascade include, but are not limited to, the kinase active sites of the EGF receptor, Raf, MEK, or ERK.

19. In the reaction catalyzed by adenylate cyclase, the 3'-OH group nucleophilically attacks the  $\alpha$ -phosphorus atom attached to the 5'-OH group, leading to displacement of pyrophosphate. The reaction catalyzed by DNA polymerase is similar except that the 3'-OH group is on a different nucleotide.

20. ATP-competitive inhibitors are likely to act on multiple kinases because every kinase domain contains an ATP-binding site. Hence, these drugs may not be selective for the desired kinase target.

21. (a)  $X \approx 10^{-7}$  M;  $Y \approx 5 \times 10^{-6}$  M;  $Z \approx 10^{-3}$  M. (b) Because much less X is required to fill half of the sites, X displays the highest affinity. (c) The binding affinity almost perfectly matches the ability to stimulate adenylate cyclase, suggesting that the hormone-receptor complex leads to the stimulation of adenylate cyclase. (d) Try performing the experiment in the presence of antibodies to  $G_{\alpha s}$ .

22. (a) The total binding does not distinguish binding to a specific receptor from binding to different receptors or from nonspecific binding to the membrane.

(b) The rationale is that the receptor will have a high affinity for the ligand. Thus, in the presence of excess nonradioactive ligand, the receptor will bind to nonradioactive ligand. Therefore, any binding of the radioactive ligand must be nonspecific.

(c) The plateau suggests that the number of receptor-binding sites in the cell membrane is limited.

23. Number of receptors per cell =

$$\frac{10^4 \text{ cpm}}{\text{mg of membrane protein}} \times \frac{\text{mg of membrane protein}}{10^{10} \text{ cells}} \times \frac{\text{mmol}}{10^{12} \text{ cpm}} \times \frac{6.023 \times 10^{20} \text{ molecules}}{\text{mmol}} = 600$$

## Chapter 15

1. The highly integrated biochemical reactions that take place inside the cell.

2. Anabolism is the set of biochemical reactions that use energy to build new molecules and ultimately new cells. Catabolism is the set of biochemical reactions that extract energy from fuel sources or break down biomolecules.

3. You reply that vandalism is disrespectful and expensive. Part of your tuition money will now have to pay to remove the vandalism. Plus, the fool should know that Gibbs free energy is at a minimum when a system is in equilibrium.

4. Cellular movements and the performance of mechanical work; active transport; biosynthetic reactions.

5. 1. f; 2. h; 3. i; 4. a; 5. g; 6. b; 7. c; 8. e; 9. j; 10. d.

6. These ions neutralize the charges on the ATP and also facilitate interactions with macromolecules that bind ATP.

7. Charge repulsion, resonance stabilization, increase in entropy, and stabilization by hydration.

8. Trick question. The answer is not known. Adenine appears to form more readily under prebiotic conditions, so ATP may have predominated initially.

9. Having only one nucleotide represent the available energy allows the cell to better monitor its energy status.

10. Increasing the concentration of ATP or decreasing the concentration cellular ADP or  $P_i$  (by rapid removal by other reactions, for instance) would make the reaction more exergonic. Likewise, altering the  $Mg^{2+}$  concentration could raise or lower the  $\Delta G$  of the reaction.

11. The free-energy changes of the individual steps in a pathway are summed to determine the overall free-energy change of the entire pathway. Consequently, a reaction with a positive free-energy value can be powered to take place if coupled to a sufficiently exergonic reaction.

12. Reactions in parts *a* and *c*, to the left; reactions in parts *b* and *d*, to the right.

13. None whatsoever.

14. (a)  $\Delta G^{\circ} = +31.4 \text{ kJ mol}^{-1}$  ( $+7.5 \text{ kcal mol}^{-1}$ ) and  $K'_{eq} = 3.06 \times 10^{-6}$ ; (b)  $3.28 \times 10^4$ .

15.  $\Delta G^{\circ} = +7.1 \text{ kJ mol}^{-1}$  ( $+1.7 \text{ kcal mol}^{-1}$ ). The equilibrium ratio is 17.5.

16. (a) Acetate + CoA +  $H^+$  goes to acetyl CoA +  $H_2O$ ,  $\Delta G^{\circ} = -31.4 \text{ kJ mol}^{-1}$  ( $-7.5 \text{ kcal mol}^{-1}$ ). ATP hydrolysis to AMP and  $P_i$ ,  $\Delta G^{\circ} = -45.6 \text{ kJ mol}^{-1}$  ( $-10.9 \text{ kcal mol}^{-1}$ ). Overall reaction,  $\Delta G^{\circ} = -14.2 \text{ kJ mol}^{-1}$  ( $-3.4 \text{ kcal mol}^{-1}$ ).

(b) With pyrophosphate hydrolysis,  $\Delta G^{\circ} = -33.4 \text{ kJ mol}^{-1}$  ( $-7.98 \text{ kcal mol}^{-1}$ ). Pyrophosphate hydrolysis makes the overall reaction even more exergonic.

17. (a) For an acid AH,

The pK is defined as  $pK = -\log_{10} K$ .  $\Delta G^{\circ}$  is the standard free-energy change at pH 7. Thus,  $\Delta G^{\circ} = -RT \ln K = -2.303 RT \log_{10} K = +2.303 RT pK$ .

(b)  $\Delta G^{\circ} = +27.32 \text{ kJ mol}^{-1}$  ( $+6.53 \text{ kcal mol}^{-1}$ ).

18. Arginine phosphate in invertebrate muscle, like creatine phosphate in vertebrate muscle, serves as a reservoir of high-potential phosphoryl groups. Arginine phosphate maintains a high level of ATP in muscular exertion.

19. An ADP unit.

20. (a) The rationale behind creatine supplementation is that it would be converted into creatine phosphate and thus serve as a rapid means of replenishing ATP after muscle contraction. (b) If creatine supplementation is beneficial, it would affect activities that depend on short bursts of activity; any sustained activity would require ATP generation by fuel metabolism, which, as Figure 15.7 shows, requires more time.

21. Under standard conditions,  $\Delta G^{\circ} = -RT \ln [\text{products}]/[\text{reactants}]$ . Substituting  $+23.8 \text{ kJ mol}^{-1}$  ( $+5.7 \text{ kcal mol}^{-1}$ ) for  $\Delta G^{\circ}$  and solving for  $[\text{products}]/[\text{reactants}]$  yields  $9.9 \times 10^{-5}$ . In other words, the forward reaction does not take place to a significant extent. Under intracellular conditions,  $\Delta G$  is  $-1.3 \text{ kJ mol}^{-1}$  ( $-0.3 \text{ kcal mol}^{-1}$ ). Using the equation  $\Delta G = \Delta G^{\circ} + RT \ln [\text{products}]/[\text{reactants}]$  and solving for  $[\text{products}]/[\text{reactants}]$  gives a ratio of  $5.96 \times 10^{-5}$ . Thus, a reaction that is endergonic under standard conditions can be converted into an exergonic reaction by maintaining the  $[\text{products}]/[\text{reactants}]$  ratio below the equilibrium value. This conversion is usually attained by using the products in another coupled reaction as soon as they are formed.

22. Under standard conditions,

$$K'_{eq} = \frac{[B]_{eq}}{[A]_{eq}} \times \frac{[ADP]_{eq}[P_i]_{eq}}{[ATP]_{eq}} = 10^{33/1.36} = 2.67 \times 10^2$$

At equilibrium, the ratio of [B] to [A] is given by

$$\frac{[B]_{eq}}{[A]_{eq}} = K'_{eq} \frac{[ATP]_{eq}}{[ADP]_{eq}[P_i]_{eq}}$$

The ATP-generating system of cells maintains the  $[ATP]/[ADP][P_i]$  ratio at a high level, typically about  $500 \text{ M}^{-1}$ . For this ratio,

$$\frac{[B]_{eq}}{[A]_{eq}} = 2.67 \times 10^2 \times 500 = 1.34 \times 10^5$$

This equilibrium ratio is strikingly different from the value of  $1.15 \times 10^{-3}$  for the reaction  $A \rightarrow B$  in the absence of ATP hydrolysis. In other words, coupling the hydrolysis of ATP with the conversion of A into B has changed the equilibrium ratio of B to A by a factor of about  $10^8$ .

23. Liver:  $-45.2 \text{ kJ mol}^{-1}$  ( $-10.8 \text{ kcal mol}^{-1}$ ); muscle:  $-48.1 \text{ kJ mol}^{-1}$  ( $-11.5 \text{ kcal mol}^{-1}$ ); brain:  $-48.5 \text{ kJ mol}^{-1}$  ( $-11.6 \text{ kcal mol}^{-1}$ ). The  $\Delta G$  is most negative in brain cells.

24. (a) Ethanol; (b) lactate; (c) succinate; (d) isocitrate; (e) malate.

25. Recall that  $\Delta G = \Delta G^{\circ'} + RT \ln [\text{products}]/[\text{reactants}]$ .

Altering the ratio of products to reactants will cause  $\Delta G$  to vary. In glycolysis, the concentrations of the components of the pathway result in a value of  $\Delta G$  greater than that of  $\Delta G^{\circ'}$ .

26. Higher organisms cannot make vitamins, and thus are dependent on obtaining them from other organisms.

27. Unless the ingested food is converted into molecules capable of being absorbed by the intestine, no energy can ever be extracted by the body.

28. NADH and  $\text{FADH}_2$  are electron carriers for catabolism; NADPH is the carrier for anabolism.

29. The electrons of the C–O bond cannot form resonance structures with the C–S bond that are as stable as those that they can form with the C–O bond. Thus, the thioester is not stabilized by resonance to the same degree as an oxygen ester is stabilized.

30. Oxidation–reduction reactions; ligation reactions; isomerization reactions; group-transfer reactions; hydrolytic reactions; cleavage of bonds by means other than hydrolysis or oxidation.

31. Controlling the amount of enzymes; controlling enzyme activity; controlling the availability of substrates.

32. Although the reaction is thermodynamically favorable, the reactants are kinetically stable because of the large activation energy. Enzymes lower the activation energy so that reactions take place on time scales required by the cell.

33. The activated form of sulfate in most organisms is 3'-phosphoadenosine-5'-phosphosulfate.

34. (a) As the  $\text{Mg}^{2+}$  concentration falls, the  $\Delta G$  of hydrolysis rises. Note that pMg is a logarithmic plot, and so each number on the x-axis represents a 10-fold change in  $[\text{Mg}^{2+}]$ .

(b)  $\text{Mg}^{2+}$  would bind to the phosphates of ATP and help to mitigate charge repulsion. As the  $[\text{Mg}^{2+}]$  falls, charge stabilization of ATP would be less, leading to greater charge repulsion and an increase in  $\Delta G$  on hydrolysis.

## Chapter 16

1. Two molecules of ATP are produced per molecule of glyceraldehyde 3-phosphate and, because two molecules of GAP are produced per molecule of glucose, the total ATP yield is four. However, two molecules of ATP are required to convert glucose into fructose 1,6-bisphosphate. Thus, the net yield is only two molecules of ATP.

2. (a) 4; (b) 3; (c) 1; (d) 6; (e) 8; (f) 2; (g) 10; (h) 9; (i) 7; (j) 5.

3. In both cases, the electron donor is glyceraldehyde 3-phosphate. In lactic acid fermentation, the electron acceptor is pyruvate, converting it into lactate. In alcoholic fermentation, acetaldehyde is the electron acceptor, forming ethanol.

4. (a) 3 ATP; (b) 2 ATP; (c) 2 ATP; (d) 2 ATP; (e) 4 ATP.

5. Glucokinase enables the liver to remove glucose from the blood when hexokinase is saturated, ensuring that glucose is captured for later use.

6. The GAP formed is immediately removed by subsequent reactions, resulting in the conversion of DHAP into GAP by the enzyme.

7. A thioester couples the oxidation of glyceraldehyde 3-phosphate to 3-phosphoglycerate with the formation of 1,3-bisphosphoglycerate.

1,3-Bisphosphoglycerate can subsequently power the formation of ATP.

8. Glycolysis is a component of alcoholic fermentation, the pathway that produces alcohol for beer and wine. The belief was that understanding the biochemical basis of alcohol production might lead to a more-efficient means of producing beer.

9. The conversion of glyceraldehyde 3-phosphate into 1,3-bisphosphoglycerate would be impaired. Glycolysis would be less effective.

10. Glucose 6-phosphate must have other fates. Indeed, it can be converted into glycogen (Chapter 21) or be processed to yield reducing power for biosynthesis (Chapter 20).

11. The energy needs of a muscle cell vary widely, from rest to intense exercise. Consequently, the regulation of phosphofructokinase by energy charge is vital. In other tissues, such as the liver, ATP concentration is less likely to fluctuate and will not be a key regulator of phosphofructokinase.

12. (a) 6; (b) 1; (c) 7; (d) 3; (e) 2; (f) 5; (g) 4.

13. The  $\Delta G^{\circ'}$  for the reverse of glycolysis is  $+90 \text{ kJ mol}^{-1}$  ( $+22 \text{ kcal mol}^{-1}$ ), far too endergonic to take place.

14. The conversion of glucose into glucose 6-phosphate by hexokinase; the conversion of fructose 6-phosphate into fructose 1,6-bisphosphate by phosphofructokinase; the formation of pyruvate from phosphoenolpyruvate by pyruvate kinase.

15. Lactic acid is a strong acid. If it remained in the cell, the pH of the cell would fall, which could lead to the denaturation of muscle protein and result in muscle damage.

16. GLUT2 transports glucose only when the blood concentration of glucose is high, which is precisely the condition in which the  $\beta$  cells of the pancreas secrete insulin.

17.  $\text{Fructose} + \text{ATP} \longrightarrow \text{fructose 1-phosphate} + \text{ADP}$

Fructokinase

$\text{Fructose 1-phosphate} \longrightarrow \text{dihydroxyacetone phosphate} + \text{glyceraldehyde}$ : Fructose 1-phosphate aldolase

$\text{Glyceraldehyde} + \text{ATP} \longrightarrow \text{glyceraldehyde 3-phosphate} + \text{ADP}$ : Triose kinase

The primary controlling step of glycolysis catalyzed by phosphofructokinase is bypassed by the preceding reactions. Glycolysis will proceed in an unregulated fashion.

18. (a) A, B; (b) C, D; (c) D; (d) A; (e) B; (f) C; (g) A; (h) D; (i) none; (j) A; (k) A.

19. (a) 4; (b) 10; (c) 1; (d) 5; (e) 7; (f) 8; (g) 9; (h) 2; (i) 3; (j) 6.

20. Without triose isomerase, only one of the two three-carbon molecules generated by aldolase could be used to generate ATP. Only two molecules of ATP would result from the metabolism of each glucose. But two molecules of ATP would still be required to form fructose 1,6-bisphosphate, the substrate for aldolase. The net yield of ATP would be zero, a yield incompatible with life.

21. Glucose is reactive because its open-chain form contains an aldehyde group.

22. (a) The label is in the methyl carbon atom of pyruvate. (b)  $5 \text{ mCi mM}^{-1}$ . The specific activity is halved because the number of moles of product (pyruvate) is twice that of the labeled substrate (glucose).

23. (a)  $\text{Glucose} + 2 \text{ P}_i + 2 \text{ ADP} \rightarrow 2 \text{ lactate} + 2 \text{ ATP}$ .

(b)  $\Delta G = -114 \text{ kJ mol}^{-1}$  ( $-27.2 \text{ kcal mol}^{-1}$ ).

24.  $3.06 \times 10^{-5}$

25. The equilibrium concentrations of fructose 1,6-bisphosphate, dihydroxyacetone phosphate, and glyceraldehyde 3-phosphate are  $7.8 \times 10^{-4} \text{ M}$ ,  $2.2 \times 10^{-4} \text{ M}$ , and  $2.2 \times 10^{-4} \text{ M}$ , respectively.

26. All three carbon atoms of 2,3-BPG are  $^{14}\text{C}$  labeled. The phosphorus atom attached to the C-2 hydroxyl group is  $^{32}\text{P}$  labeled.

27. Hexokinase has a low ATPase activity in the absence of a sugar because it is in a catalytically inactive conformation. The addition of xylose closes the cleft between the two lobes of the enzyme. However, xylose lacks a hydroxymethyl group, and so it cannot be phosphorylated. Instead, a water molecule at the site normally occupied by the C-6 hydroxymethyl group acts as the acceptor of the phosphoryl group from ATP.

28. (a) The fructose 1-phosphate pathway forms glyceraldehyde 3-phosphate.  
(b) Phosphofructokinase, a key control enzyme, is bypassed.

29. The reverse of glycolysis is highly endergonic under cellular conditions. The expenditure of six NTP molecules in gluconeogenesis renders gluconeogenesis exergonic.

30. (a) 2, 3, 6, 9; (b) 1, 4, 5, 7, 8.

31. Lactic acid is capable of being further oxidized and is thus useful energy. The conversion of this acid into glucose saves the carbon atoms for future combustion.

32. In glycolysis, the formation of pyruvate and ATP by pyruvate kinase is irreversible. This step is bypassed by two reactions in gluconeogenesis: (1) the formation of oxaloacetate from pyruvate and CO<sub>2</sub> by pyruvate carboxylase and (2) the formation of phosphoenolpyruvate from oxaloacetate and GTP by phosphoenolpyruvate carboxykinase. The formation of fructose 1,6-bisphosphate by phosphofructokinase is bypassed by fructose 1,6-bisphosphatase in gluconeogenesis, which catalyzes the conversion of fructose 1,6-bisphosphate into fructose 6-phosphate. Finally, the hexokinase-catalyzed formation of glucose 6-phosphate in glycolysis is bypassed by glucose 6-phosphatase, but only in the liver.

33. Reciprocal regulation at the key allosteric enzymes in the two pathways. For instance, PFK is stimulated by fructose 2,6-bisphosphate and AMP. The effect of these signals is opposite that of fructose 1,6-bisphosphatase. If both pathways were operating simultaneously, a futile cycle would result. ATP would be hydrolyzed, yielding only heat.

34. Muscle is likely to produce lactic acid during contraction. Lactic acid is a strong acid and cannot accumulate in muscle or blood. Liver removes the lactic acid from the blood and converts it into glucose. The glucose can be released into the blood or stored as glycogen for later use.

35. Glucose produced by the liver could not be released into the blood. Tissues that rely on glucose as an energy source would not function as well unless glucose was provided in the diet.

36. Glucose is an important energy source for both tissues and is essentially the only energy source for the brain. Consequently, these tissues should never release glucose. Glucose release is prevented by the absence of glucose 6-phosphatase.

37. 6 NTP (4 ATP and 2 GTP); 2 NADH.

38. (a) None; (b) none; (c) 4 (2 ATP and 2 GTP); (d) none.

39. If the amino groups are removed from alanine and aspartate, the ketoacids pyruvate and oxaloacetate are formed. Both of these molecules are components of the gluconeogenic pathway.

40. (a) Increased; (b) increased; (c) increased; (d) decreased.

41. Fructose 2,6-bisphosphate, present at high concentration when glucose is abundant, normally inhibits gluconeogenesis by blocking fructose 1,6-bisphosphatase. In this genetic disorder, the phosphatase is active irrespective of the glucose level. Hence, substrate cycling is increased. The level of fructose 1,6-bisphosphate is consequently lower than normal. Less pyruvate is formed and thus less ATP is generated.

42. Reactions in parts *b* and *e* would be blocked.

43. There will be no labeled carbons. The CO<sub>2</sub> added to pyruvate (formed from the lactate) to form oxaloacetate is lost with the conversion of oxaloacetate into phosphoenolpyruvate.

44. The net reaction in the presence of arsenate is

Glycolysis proceeds in the presence of arsenate, but the ATP normally formed in the conversion of 1,3-bisphosphoglycerate into 3-phosphoglycerate is lost. Thus, arsenate uncouples oxidation and phosphorylation by forming a highly labile acyl arsenate.

45. This example illustrates the difference between the *stoichiometric* and the *catalytic* use of a molecule. If cells used NAD<sup>+</sup> stoichiometrically, a new molecule of NAD<sup>+</sup> would be required each time a molecule of lactate was produced. As we will see, the synthesis of NAD<sup>+</sup> requires ATP. On the other hand, if the NAD<sup>+</sup> that is converted into NADH could be recycled and reused, a small amount of the molecule could regenerate a vast amount of lactate, which is the case in the cell. NAD<sup>+</sup> is regenerated by the oxidation of NADH and reused. NAD<sup>+</sup> is thus used catalytically.

46. Consider the equilibrium equation of adenylate kinase:

$$K_{\text{eq}} = [\text{ATP}][\text{AMP}] / [\text{ADP}]^2 \quad (1)$$

or

$$\text{AMP} = K_{\text{eq}} [\text{ADP}]^2 / [\text{ATP}] \quad (2)$$

Recall that  $[\text{ATP}] > [\text{ADP}] > [\text{AMP}]$  in the cell. As ATP is utilized, a small decrease in its concentration will result in a larger percentage increase in [ADP] because its concentration is greater than that of ADP. This larger percentage increase in [ADP] will result in an even greater percentage increase in [AMP] because the concentration of AMP is related to the square of [ADP]. In essence, equation 2 shows that monitoring the energy status with AMP magnifies small changes in [ATP], leading to tighter control.

47. The synthesis of glucose during intense exercise provides a good example of interorgan cooperation in higher organisms. When muscle is actively contracting, lactate is produced from glucose by glycolysis. The lactate is released into the blood and absorbed by the liver, where it is converted by gluconeogenesis into glucose. The newly synthesized glucose is then released and taken up by the muscle for energy generation.

48. The input of four additional high-phosphoryl-transfer-potential molecules in gluconeogenesis changes the equilibrium constant by a factor of 10<sup>32</sup>, which makes the conversion of pyruvate into glucose thermodynamically feasible. Without this energetic input, gluconeogenesis would not take place.

49. The mechanism is analogous to that for triose phosphate isomerase (Figure 16.5). It proceeds through an enediol intermediate. The active site would be expected to have a general base (analogous to Glu 165 in TPI) and a general acid (analogous to His 95 in TPI).

50. Galactose is a component of glycoproteins. Possibly, the absence of galactose leads to the improper formation or function of glycoproteins required in the central nervous system. More generally, the fact that the symptoms arise in the absence of galactose suggests that galactose is required in some fashion.

51. Using the Michaelis-Menten equation to solve for [S] when  $K_M = 50 \mu\text{M}$  and  $V_o = 0.9V_{\text{max}}$  shows that a substrate concentration of 0.45 mM yields 90% of  $V_{\text{max}}$ . Under normal conditions, the enzyme is essentially working at  $V_{\text{max}}$ .

52. Fructose 2,6-bisphosphate stabilizes the R state of the enzyme.

53. (a) Curiously, the enzyme uses ADP as the phosphoryl donor rather than ATP.

(b) Both AMP and ATP behave as competitive inhibitors of ADP, the phosphoryl donor. Apparently, the *P. furiosus* enzyme is not allosterically inhibited by ATP.

54. (a) If both enzymes operated simultaneously, the following reactions would take place:

The net result would be simply:

The energy of ATP hydrolysis would be released as heat.

(b) Not really. For the cycle to generate heat, both enzymes must be functional at the same time in the same cell.

(c) The species *B. terrestris* and *B. rufocinctus* might show some futile cycling because both enzymes are active to a substantial degree.

(d) No. These results simply suggest that simultaneous activity of phosphofructokinase and fructose 1,6-bisphosphatase is unlikely to be employed to generate heat in the species shown.

55. ATP initially stimulates PFK activity, as would be expected for a substrate. Higher concentrations of ATP inhibit the enzyme. Although this effect seems counterintuitive for a substrate, recall that the function of glycolysis in muscle is to generate ATP. Consequently, high concentrations of ATP signal that the ATP needs are met and glycolysis should stop. In addition to being a substrate, ATP is an allosteric inhibitor of PFK.

## Chapter 17

1. The pyruvate dehydrogenase complex catalyzes the following reaction, linking glycolysis and the citric acid cycle:

2. Pyruvate dehydrogenase catalyzes the decarboxylation of pyruvate and the formation of acetyl lipoamide. Dihydrolipoyl trans-acetylase catalyzes the formation of acetyl CoA. Dihydrolipoyl dehydrogenase catalyzes the reduction of the oxidized lipoic acid. The kinase associated with the complex phosphorylates and inactivates the complex, whereas the phosphatase dephosphorylates and activates the complex.

3. Thiamine pyrophosphate plays a role in the decarboxylation of pyruvate. Lipoic acid (as lipoamide) transfers the acetyl group. Coenzyme A accepts the acetyl group from lipoic acid to form acetyl CoA. FAD accepts the electrons and hydrogen ions when reduced lipoic acid is oxidized.  $\text{NAD}^+$  accepts electrons from  $\text{FADH}_2$ .

4. Catalytic coenzymes (TPP, lipoic acid, and FAD) are modified but regenerated in each reaction cycle. Thus, they can play a role in the processing of many molecules of pyruvate. Stoichiometric coenzymes (coenzyme A and  $\text{NAD}^+$ ) are used in only one reaction because they are the components of products of the reaction.

5. The remaining steps regenerate oxidized lipoamide, which is required to begin the next reaction cycle. Moreover, this regeneration results in the production of high-energy electrons in the form of NADH.

6. The advantages are as follows:

The reaction is facilitated by having the active sites in proximity. The reactants do not leave the enzyme until the final product is formed.

Constraining the reactants minimizes loss due to diffusion and minimizes side reactions.

All of the enzymes are present in the correct amounts.

Regulation is more efficient because the regulatory enzymes—the kinase and phosphatase—are part of the complex.

7. (a) After one round of the citric acid cycle, the label emerges in C-2 and C-3 of oxaloacetate. (b) The label emerges in  $\text{CO}_2$  in the formation of acetyl CoA from pyruvate. (c) After one round of the citric acid cycle, the label emerges in C-1 and C-4 of oxaloacetate. (d) and (e) Same fate as that in part a.

8. (a) Isocitrate lyase and malate synthase are required in addition to the enzymes of the citric acid cycle.

(b)  $2 \text{ Acetyl CoA} + 2 \text{ NAD}^+ + \text{FAD} + 3 \text{ H}_2\text{O} \longrightarrow \text{oxaloacetate} + 2 \text{ CoA} + 2 \text{ NADH} + \text{FADH}_2 + 3 \text{ H}^+$

(c) No. Hence, mammals cannot carry out the net synthesis of oxaloacetate from acetyl CoA.

9.  $-41.0 \text{ kJ mol}^{-1} (-9.8 \text{ kcal mol}^{-1})$

10. Enzymes or enzyme complexes are biological catalysts. Recall that a catalyst facilitates a chemical reaction without the catalyst itself being permanently altered. Oxaloacetate can be thought of as a catalyst because it binds to an acetyl group, leads to the oxidative decarboxylation of the two carbon atoms, and is regenerated at the completion of a cycle. In essence, oxaloacetate (and any cycle intermediate) acts as a catalyst.

11. Thiamine thiazolone pyrophosphate is a transition-state analog. The sulfur-containing ring of this analog is uncharged, and so it closely resembles the transition state of the normal coenzyme in thiamine-catalyzed reactions (e.g., the uncharged resonance form of hydroxyethyl-TPP).

12. (a) 6; (b) 10; (c) 1; (d) 7; (e) 2; (f) 8; (g) 3; (h) 4; (i) 5; (j) 9.

13. A decrease in the amount of  $\text{O}_2$  will necessitate an increase in anaerobic glycolysis for energy production, leading to the generation of a large amount of lactic acid. Under conditions of shock, the kinase inhibitor is administered to ensure that pyruvate dehydrogenase is operating maximally.

14. (a) As is stated in the previous problem, DCA inhibits pyruvate dehydrogenase kinase.

(b) The fact that inhibiting the kinase results in more dehydrogenase activity suggests that there must be some residual activity that is being inhibited by the kinase.

15. Acetyl lipoamide and acetyl CoA.

16. In muscle, the acetyl CoA generated by the complex is used for energy generation. Consequently, signals that indicate an energy-rich state (high ratios of ATP/ADP and  $\text{NADH}/\text{NAD}^+$ ) inhibit the complex, whereas the reverse conditions stimulate the enzyme. Calcium as the signal for muscle contraction (and, hence, energy need) also stimulates the enzyme. In liver, acetyl CoA derived from pyruvate is used for biosynthetic purposes, such as fatty acid synthesis. Insulin, the hormone denoting the fed state, stimulates the complex.

17. (a) Enhanced kinase activity will result in a decrease in the activity of the PDH complex because phosphorylation by the kinase inhibits the complex.

(b) Phosphatase activates the complex by removing a phosphate. If the phosphatase activity is diminished, the activity of the PDH complex also will decrease.

18. She might have been ingesting, in some fashion, the arsenite from the peeling paint or the wallpaper. Also, she might have been breathing arsine gas from the wallpaper, which would be oxidized to arsenite in her body. In any of these circumstances, the arsenite inhibited enzymes that require lipoic acid—notably, the PDH complex.

19. (a) 5; (b) 7; (c) 1; (d) 10; (e) 2; (f) 4; (g) 9; (h) 3; (i) 8; (j) 6.

20. The TCA cycle depends on a steady supply of  $\text{NAD}^+$  as an oxidant, generating NADH.  $\text{O}_2$  is never directly utilized in the cycle. However,  $\text{NAD}^+$  is regenerated via donation of electrons to  $\text{O}_2$  by way of the electron transport chain, so eventually a lack of  $\text{O}_2$  will cause the cycle to cease due to a lack of  $\text{NAD}^+$ .

## ANSWERS TO PROBLEMS

21. Succinate dehydrogenase is the only enzyme in the citric acid cycle that is embedded in the mitochondrial membrane, which makes it associated with the electron-transport chain.

22. (a) The steady-state concentrations of the products are low compared with those of the substrates. (b) The ratio of malate to oxaloacetate must be greater than  $1.57 \times 10^4$  for oxaloacetate to be formed.

23.

24. Succinate will increase in concentration, followed by  $\alpha$ -ketoglutarate and the other intermediates “upstream” of the site of inhibition. Succinate has two methylene groups that are required for the dehydrogenation, whereas malonate has but one.

25. Pyruvate carboxylase should be active only when the acetyl CoA concentration is high. Acetyl CoA might accumulate if the energy needs of the cell are not being met, because of a deficiency of oxaloacetate. Under these conditions the pyruvate carboxylase catalyzes an anaplerotic reaction. Alternatively, acetyl CoA might accumulate because the energy needs of the cell have been met. In this circumstance, pyruvate will be converted back into glucose, and the first step in this conversion is the formation of oxaloacetate.

26. The energy released when succinate is oxidized to fumarate is not sufficient to power the synthesis of NADH but is sufficient to reduce FAD.

27. Citrate is a tertiary alcohol that cannot be oxidized, because oxidation requires a hydrogen atom to be removed from the alcohol and a hydrogen atom to be removed from the carbon atom bonded to the alcohol. No such hydrogen exists in citrate. The isomerization converts the tertiary alcohol into isocitrate, which is a secondary alcohol that can be oxidized.

28. The enzyme nucleoside diphosphokinase transfers a phosphoryl group from GTP (or any nucleoside triphosphate) to ADP according to the reversible reaction:

29. The reaction is powered by the hydrolysis of a thioester. Acetyl CoA provides the thioester that is converted into citryl CoA. When this thioester is hydrolyzed, citrate is formed in an irreversible reaction.

30. It enables organisms such as plants and bacteria to convert fats, through acetyl CoA, into glucose.

31. We cannot get the net conversion of fats into glucose, because the only means to get the carbon atoms from fats into oxaloacetate, the precursor of glucose, is through the citric acid cycle. However, although two carbon atoms enter the cycle as acetyl CoA, two carbon atoms are lost as  $\text{CO}_2$  before oxaloacetate is formed. Thus, although some carbon atoms from fats may end up as carbon atoms in glucose, we cannot obtain a *net* synthesis of glucose from fats.

32. Acetyl CoA will inhibit the complex. Glucose metabolism to pyruvate will be slowed because acetyl CoA is being derived from an alternative source.

33. The enol intermediate of acetyl CoA attacks the carbonyl carbon atom of glyoxylate to form a C–C bond. This reaction is like the condensation of oxaloacetate with the enol intermediate of acetyl CoA in the reaction catalyzed by citrate synthase. Glyoxylate contains a hydrogen atom in place of the  $-\text{CH}_2\text{COO}^-$  group of oxaloacetate; the reactions are otherwise nearly identical.

34. Citrate is a symmetric molecule. Consequently, the investigators assumed that the two  $-\text{CH}_2\text{COO}^-$  groups in it would react identically. Thus, for every citrate molecule undergoing the reactions shown in path 1, they thought that another citrate molecule would react as shown in path 2. If so, then only *half* the label should have emerged in the  $\text{CO}_2$ .

35. Call one hydrogen atom A and the other B. Now suppose that an enzyme binds three groups of this substrate—X, Y, and H—at three complementary sites. The adjoining diagram shows X, Y, and  $\text{H}_A$  bound to three points on the enzyme. In contrast, X, Y, and  $\text{H}_B$  cannot be bound to this active site; two of these three groups can be bound, but not all three. Thus,  $\text{H}_A$  and  $\text{H}_B$  will have different fates.

Sterically nonequivalent groups such as  $H_A$  and  $H_B$  will almost always be distinguished in enzymatic reactions. The essence of the differentiation of these groups is that the enzyme holds the substrate in a specific orientation. Attachment at three points, as depicted in the diagram, is a readily visualized way of achieving a particular orientation of the substrate, but it is not the only means of doing so.

36. (a) The complete oxidation of citrate requires  $4.5 \mu\text{mol}$  of  $\text{O}_2$  for every micromole of citrate.

Thus,  $13.5 \mu\text{mol}$  of  $\text{O}_2$  would be consumed by  $3 \mu\text{mol}$  of citrate.

(b) Citrate led to the consumption of far more  $\text{O}_2$  than can be accounted for simply by the oxidation of citrate itself. Citrate thus facilitated  $\text{O}_2$  consumption.

37. (a) In the absence of arsenite, the amount of citrate remained constant. In its presence, the concentration of citrate fell, suggesting that it was being metabolized.

(b) The action of arsenite is not altered. Citrate still disappears.

(c) Arsenite is preventing the regeneration of citrate. Recall (pp. 515–516) that arsenite inhibits the pyruvate dehydrogenase complex.

38. (a) The initial infection is unaffected by the absence of isocitrate lyase, but the absence of this enzyme inhibits the latent phase of the infection.

(b) Yes.

(c) A critic could say that, in the process of deleting the isocitrate lyase gene, some other gene was damaged, and it is the absence of this other gene that prevents latent infection. Reinserting the isocitrate lyase gene into the bacteria from which it had been removed renders the criticism less valid.

(d) Isocitrate lyase enables the bacteria to synthesize carbohydrates that are necessary for survival, including carbohydrate components of the cell membrane.

## Chapter 18

1. In fermentations, organic compounds are both the donors and the acceptors of electrons. In respiration, the electron donor is usually an organic compound, whereas the electron acceptor is an inorganic molecule, such as oxygen.

2. Biochemists use  $E'_0$ , the value at pH 7, whereas chemists use  $E_0$ , the value in  $1 \text{ M H}^+$ . The prime denotes that pH 7 is the standard state.

3. The reduction potential of  $\text{FADH}_2$  is less than that of  $\text{NADH}$  (Table 18.1). Consequently, when those electrons are passed along to oxygen, less energy is released. The consequence of the difference is that electron flow from  $\text{FADH}_2$  to  $\text{O}_2$  pumps fewer protons than do the electrons from  $\text{NADH}$ .

4. The  $\Delta G'^0$  for the reduction of oxygen by  $\text{FADH}_2$  is  $-200 \text{ kJ mol}^{-1}$  ( $-48 \text{ kcal mol}^{-1}$ ).

5.  $\Delta G'^0$  is  $+67 \text{ kJ mol}^{-1}$  ( $+16.1 \text{ kcal mol}^{-1}$ ) for oxidation by  $\text{NAD}^+$  and  $-3.8 \text{ kJ mol}^{-1}$  ( $-0.92 \text{ kcal mol}^{-1}$ ) for oxidation by  $\text{FAD}$ . The oxidation of succinate by  $\text{NAD}^+$  is not thermodynamically feasible.

6. An oxidizing agent, or oxidant, accepts electrons in oxidation–reduction reactions. A reducing reagent, or reductant, donates electrons in such reactions.

7. Pyruvate accepts electrons and is thus the oxidant.  $\text{NADH}$  gives up electrons and is the reductant.

8.  $\Delta G'^0 = -nF\Delta E'_0$

9. The  $\Delta E'_0$  value of iron can be altered by changing the environment of the ion.

10. c, e, b, a, d.

11. (a) 4; (b) 5; (c) 2; (d) 10; (e) 3; (f) 8; (g) 9; (h) 7; (i) 1; (j) 6.

12. (a) 4; (b) 3; (c) 1; (d) 5; (e) 2.

13. The 10 isoprene units render coenzyme Q soluble in the hydrophobic environment of the inner mitochondrial membrane. The two oxygen atoms can reversibly bind two electrons and two protons as the molecule transitions between the quinone form and quinol form.

14. Rotenone:  $\text{NADH}$ ,  $\text{NADH-Q}$  oxidoreductase will be reduced. The remainder will be oxidized. Antimycin A:  $\text{NADH}$ ,  $\text{NADH-Q}$  oxidoreductase and coenzyme Q will be reduced. The remainder will be oxidized. Cyanide: All will be reduced.

15. Complex I would be reduced, whereas Complexes II, III, and IV would be oxidized. The citric acid cycle would halt because it has no way to oxidize  $\text{NADH}$ .

16. The respirasome is another example of the use of supramolecular complexes in biochemistry. Having the three complexes that are proton pumps associated with one another will enhance the efficiency of electron flow from complex to complex, which in turn will cause more-efficient proton pumping.

17. Succinate dehydrogenase is a component of Complex II.

18. Hydroxyl radical ( $\text{OH}\cdot$ ), hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), superoxide ion ( $\text{O}_2^{\cdot-}$ ), and peroxide ( $\text{O}_2^{2-}$ ). These small molecules react with a host of macromolecules—including proteins, nucleotides, and membranes—to disrupt cell structure and function.

19. The ATP is recycled by ATP-generating processes, most notably oxidative phosphorylation.

20. (a) 12.5; (b) 14; (c) 32; (d) 13.5; (e) 30; (f) 16.

21. (a) It blocks electron transport and proton pumping at Complex IV. (b) It blocks electron transport and ATP synthesis by inhibiting the exchange of ATP and ADP across the inner mitochondrial membrane. (c) It blocks electron transport and proton pumping at Complex I. (d) It blocks ATP synthesis without inhibiting electron transport by dissipating the proton gradient. (e) It blocks electron transport and proton pumping at Complex IV. (f) It blocks electron transport and proton pumping at Complex III.

22. If the proton gradient is not dissipated by the influx of protons into a mitochondrion with the generation of ATP, eventually the outside of the mitochondrion develops such a large positive charge that the electron-transport chain can no longer pump protons against the gradient.

23. The subunits are jostled by background thermal energy (Brownian motion). The proton gradient makes clockwise rotation more likely because that direction results in protons flowing down their concentration gradient.

24. Dicyclohexylcarbodiimide reacts readily with carboxyl groups. Hence, the most likely targets are aspartate and glutamate side chains. In fact, Asp 61 of subunit c of *E. coli*  $\text{F}_0$  is specifically modified by this reagent. The conversion of Asp 61 into asparagine by site-specific mutagenesis eliminates proton conduction.

25. In the presence of poorly functioning mitochondria, the only means of generating ATP is by anaerobic glycolysis, which will lead to an accumulation of lactic acid in blood.

26. If ADP cannot get into mitochondria, the electron-transport chain will cease to function because there will be no acceptor for

the energy. NADH will build up in the matrix. Recall that NADH inhibits some citric acid cycle enzymes and that  $\text{NAD}^+$  is required by several citric acid cycle enzymes. Glycolysis will switch to lactic acid fermentation so that the NADH can be reoxidized to  $\text{NAD}^+$  by lactate dehydrogenase.

27. (a) No effect; mitochondria cannot metabolize glucose.  
 (b) No effect; no fuel is present to power the synthesis of ATP.  
 (c) The  $[\text{O}_2]$  falls because citrate is a fuel and ATP can be formed from ADP and  $\text{P}_i$ .  
 (d) Oxygen consumption stops because oligomycin inhibits ATP synthesis, which is coupled to the activity of the electron-transport chain.  
 (e) No effect, for the reasons given in part d.  
 (f)  $[\text{O}_2]$  falls rapidly because the system is uncoupled and does not require ATP synthesis to lower the proton-motive force.  
 (g)  $[\text{O}_2]$  falls, though at a lower rate. Rotenone inhibits Complex I, but the presence of succinate will enable electrons to enter at Complex II.

- (h) Oxygen consumption ceases because Complex IV is inhibited and the entire chain backs up.  
 28. (a) The P : O ratio is equal to the product of  $(\text{H}^+ / 2 e^-)$  and  $(\text{P} / \text{H}^+)$ . Note that the P : O ratio is identical with the P :  $2 e^-$  ratio.  
 (b) 2.5 and 1.5, respectively.  
 29. Cyanide can be lethal because it binds to the ferric form of cytochrome oxidase and thereby inhibits oxidative phosphorylation. Nitrite converts ferrihemoglobin into ferrihemoglobin, which also binds cyanide. Thus, ferrihemoglobin competes with cytochrome *c* oxidase for cyanide. This competition is therapeutically effective because the amount of ferrihemoglobin that can be formed without impairing oxygen transport is much greater than the amount of cytochrome *c* oxidase.  
 30. Such a defect (called Luft syndrome) was found in a 38-year-old woman who was incapable of performing prolonged physical work. Her basal metabolic rate was more than twice normal, but her thyroid function was normal. A muscle biopsy showed that her mitochondria were highly variable and atypical in structure. Biochemical studies then revealed that oxidation and phosphorylation were not tightly coupled in these mitochondria. In this patient, much of the energy of fuel molecules was converted into heat rather than ATP.  
 31. Triose phosphate isomerase converts dihydroxyacetone phosphate (a potential dead end) into glyceraldehyde 3-phosphate (a mainstream glycolytic intermediate).

32. This inhibitor (like antimycin A) blocks the reduction of cytochrome  $c_1$  by  $\text{QH}_2$ , the crossover point.  
 33. If oxidative phosphorylation were uncoupled, no ATP could be produced. In a futile attempt to generate ATP, much fuel would be consumed. The danger lies in the dose. Too much uncoupling would lead to tissue damage in highly aerobic organs such as the brain and heart, which would have severe consequences for the organism as a whole. The energy that is normally transformed into ATP would be released as heat. To maintain body temperature, sweating might increase, although the very process of sweating itself depends on ATP.  
 34. If ATP and ADP cannot exchange between the matrix and the mitochondria, ATP synthase will cease to function because its substrate ADP is absent. The proton gradient will eventually become so large that the energy released by the electron-transport chain will not be great enough to pump protons against the larger-than-normal gradient.

35. Add the inhibitor with and without an uncoupler, and monitor the rate of  $\text{O}_2$  consumption. If the  $\text{O}_2$  consumption increases again in the presence of inhibitor and uncoupler, the inhibitor must be inhibiting ATP synthase. If the uncoupler has no effect on the inhibition, the inhibitor is inhibiting the electron-transport chain.

36. Presumably, because the muscle has greater energy needs, especially during exercise, it will require more ATP. This requirement means that more sites of oxidative phosphorylation are called for, and these sites can be provided by an increase in the amount of cristae.  
 37. The arginine residue, with its positive charge, will facilitate proton release from aspartic acid by stabilizing the negatively charged aspartate.  
 38. 4; 4.7  
 39. The ATP synthase would pump protons at the expense of ATP hydrolysis, thus maintaining the proton-motive force. The synthase would function as an ATPase. There is some evidence that damaged mitochondria use this tactic to maintain, at least temporarily, the proton-motive force.  
 40. It suggests that malfunctioning mitochondria may play a role in the development of Parkinson disease. Specifically, it implicates Complex I.  
 41. The extra negative charge on ATP relative to that on ADP accounts for ATP's more-rapid translocation out of the mitochondrial matrix. If the charge differences between ATP and ADP were lessened by the binding of  $\text{Mg}^{2+}$ , ADP might more readily compete with ATP for transport to the cytoplasm.  
 42. When all of the available ADP has been converted into ATP, ATP synthase can no longer function. The proton gradient becomes large enough that the energy of the electron-transport chain is not enough to pump against the gradient, and electron transport and, hence, oxygen consumption falls.  
 43. The effect on the proton gradient is the same in each case.  
 44. ATP export from the matrix. Phosphate import into the matrix.  
 45. Recall from the discussion of enzyme-catalyzed reactions that the direction of a reaction is determined by the  $\Delta G$  difference between substrate and products. An enzyme speeds up the rate of both the forward and the backward reactions. The hydrolysis of ATP is exergonic, and so ATP synthase will enhance the hydrolytic reaction.  
 46. The cytoplasmic kinases thereby obtain preferential access to the exported ATP.  
 47. The organic acids in the blood are indications that the mice are deriving a large part of their energy needs through anaerobic glycolysis. Lactate is the end product of anaerobic glycolysis. Alanine is an aminated transport form of pyruvate, which is formed from lactate. Alanine formation plays a role in succinate formation, which is caused by the reduced state of the mitochondria.

The electron-transport chain is slowed because the inner mitochondrial membrane is hyperpolarized. Without ADP to accept the energy of the proton-motive force, the membrane becomes polarized to such an extent that protons can no longer be pumped. The excess  $\text{H}_2\text{O}_2$  is probably due to the fact that the superoxide radical is present in higher concentration because the oxygen can no longer be effectively reduced.

Indeed, these mice display evidence of such oxidative damage.

48. (a) Vitamins C and E.  
 (b) Exercise induces superoxide dismutase, which converts ROS in hydrogen peroxide and oxygen.

(c) The answer to this question is not fully established. Two possibilities are (1) the suppression of ROS by vitamins prevents the expression of more superoxide dismutase and (2) some ROS may be signal molecules required to stimulate insulin-sensitivity pathways.

49. (a) DNP is an uncoupler that prevents the use of the proton-motive force for ATP synthesis. Consequently, the rate of oxygen consumption rises (reflecting the rate of the electron transport chain) in a futile attempt to synthesize ATP. Because mitochondrial ATP synthesis is inhibited, the rate of glycolysis, as measured by ECAR, increases in an attempt to meet the cell's ATP needs. (b) Because glycolysis is now inhibited, no lactic acid will be produced and the rate of extracellular acidification will fall. Because DNP is still present, oxygen consumption will still occur at a high rate.

(c) A key step in glycolysis is the isomerization of glucose 6-phosphate to fructose 6-phosphate. 2-Deoxyglucose is incapable of undergoing the isomerization.

(d) Rotenone inhibits electron flow through Complex I, the electron transport chain is inhibited and oxygen consumption ceases.

50. (a) Succinate is oxidized by Complex II, and the electrons are used to establish a proton-motive force that powers ATP synthesis.

(b) The ability to synthesize ATP is greatly reduced.

(c) The goal was to measure ATP hydrolysis. If succinate had been added in the presence of ATP, no reaction would have taken place, because of respiratory control.

(d) The mutation has little effect on the ability of the enzyme to catalyze the hydrolysis of ATP.

(e) They suggest two things: (1) the mutation did not affect the catalytic site on the enzyme, because ATP synthase is still capable of catalyzing the reverse reaction, and (2) the mutation did not affect the amount of enzyme present, given that the controls and patients had similar amounts of activity.

51. The absolute configuration of thiophosphate indicates that inversion at phosphorus has taken place in the reaction catalyzed by ATP synthase. This result is consistent with an inline phosphoryl-transfer reaction taking place in a single step. The retention of configuration in the  $\text{Ca}^{2+}$ -ATPase reaction points to two phosphoryl-transfer reactions—inversion by the first and a return to the starting configuration by the second. The  $\text{Ca}^{2+}$ -ATPase reaction proceeds by a phosphorylated enzyme intermediate.

## Chapter 19

1. Ultimately, all of the carbon atoms of which we are made, not just carbohydrates, enter the biosphere through the process of photosynthesis. Moreover, the oxygen that we require is produced by photosynthesis.

2.  $2 \text{NADP}^+ + 3 \text{ADP}^{3-} + 3 \text{P}_i^{2-} + \text{H}^+ \rightarrow \text{O}_2 + 2 \text{NADPH} + 3 \text{ATP}^{4-} + \text{H}_2\text{O}$

3. (a) 7; (b) 5; (c) 4; (d) 10; (e) 1; (f) 2; (g) 9; (h) 3; (i) 8; (j) 6.

4. Photosystem II, in conjunction with the oxygen-generating complex, powers oxygen release. The reaction center of photosystem II absorbs light maximally at 680 nm.

5. Oxygen consumption will be maximal when photosystems I and II are operating cooperatively. Oxygen will be efficiently generated when electrons from photosystem II fill the electron holes in photosystem I, which were generated when the reaction center of photosystem I was illuminated by light of 700 nm.

6. Photosystem I generates ferredoxin, which reduces  $\text{NADP}^+$  to NADPH, a biosynthetic reducing power. Photosystem II activates the water-oxidizing complex, generating electrons for photosynthesis, and generating protons to form a proton gradient and to reduce ferredoxin and  $\text{O}_2$ .

7. The light reactions take place on thylakoid membranes. Increasing the membrane surface increases the number of ATP- and NADPH-generating sites.

8. These complexes absorb more light than can a reaction center alone. The light-harvesting complexes funnel light to the reaction centers.

9.  $\text{NADP}^+$  is the acceptor.  $\text{H}_2\text{O}$  is the donor. Light energy.

10. The charge gradient, a component of the proton-motive force in mitochondria, is neutralized by the influx of  $\text{Mg}^{2+}$  into the lumen of the thylakoid membranes.

11. Chlorophyll is readily inserted into the hydrophobic interior of the thylakoid membranes.

12. Protons released by the oxidation of water; protons pumped into the lumen by the cytochrome *bf* complex; protons removed from the stroma by the reduction of  $\text{NADP}^+$  and plastoquinone.

13. 700-nm photons have an energy content of  $+172 \text{ kJ mol}^{-1}$ . The absorption of light by photosystem I results in a  $\Delta E'_0$  of  $-1.0 \text{ V}$ . Recall that  $\Delta G'_0 = -nF\Delta E'_0$ , where  $F = 96.48 \text{ kJ mol}^{-1} \text{ V}^{-1}$ . Under standard conditions, the energy change for the electrons is 96.5 kJ. Thus, the efficiency is  $96.5/172 = 56\%$ .

14. The electron flow from photosystem II to photosystem I is uphill, or exergonic. For this uphill flow, ATP would need to be consumed, defeating the purpose of photosynthesis.

15.  $\Delta E'_0 = 10.11 \text{ V}$ , and  $\Delta G'^{\circ} = -21.3 \text{ kJ mol}^{-1}$  ( $-5.1 \text{ kcal mol}^{-1}$ ).

16. (a) All ecosystems require an energy source from outside the system, because the chemical energy sources will ultimately be limited. The photosynthetic conversion of sunlight is one example of such a conversion.

(b) Not at all. Spock would point out that chemicals other than water can donate electrons and protons.

17. DCMU inhibits electron transfer in the link between photosystems II and I.  $\text{O}_2$  can evolve in the presence of DCMU if an artificial electron acceptor such as ferricyanide can accept electrons from Q.

18. DCMU will have no effect, because it blocks photosystem II, and cyclic photophosphorylation uses photosystem I and the cytochrome *bf* complex.

19. (a)  $+120 \text{ kJ einstein}^{-1}$  ( $+28.7 \text{ kcal einstein}^{-1}$ )

(b) 1.24 V

(c) One 1000-nm photon has the free energy content of 2.4 molecules of ATP. A minimum of 0.42 photon is needed to drive the synthesis of a molecule of ATP.

20. At this distance, the expected rate is one electron per second.

21. The distance doubles, and so the rate should decrease by a factor of 64 to 640 ps.

22. The cristae.

23. In eukaryotes, both processes take place in specialized organelles. Both depend on high-energy electrons to generate ATP. In oxidative phosphorylation, the high-energy electrons originate in fuels and are extracted as reducing power in the form of NADH. In photosynthesis, the high-energy electrons are generated by light and are captured as reducing power in the form of NADPH. Both processes use redox reactions to generate a proton gradient, and the enzymes that convert the proton gradient into ATP are very similar in both processes. In both systems, electron transport takes place in membranes inside organelles.

24. We need to factor in the NADPH because it is an energy-rich molecule. Recall from Chapter 18 that NADH is worth 2.5 ATP if oxidized by the electron-transport chain.  $12 \text{ NADPH} = 30 \text{ ATP}$ . Eighteen molecules of ATP are used directly, and so the equivalent of 48 molecules of ATP is required for the synthesis of glucose.

25. Both photosynthesis and cellular respiration are powered by high-energy electrons flowing toward a more-stable state. In cellular respiration, the high-energy electrons are derived from the oxidation of carbon fuels as NADH and  $\text{FADH}_2$ . They release their energy as they reduce oxygen. In photosynthesis, high-energy electrons are generated by absorbing light energy, and they find stability in photosystem I and ferredoxin.

26. The electrons flow through photosystem II directly to ferri-cyanide. No other steps are required.
27. (a) Thioredoxin  
 (b) The control enzyme is unaffected, but the mitochondrial enzyme with part of the chloroplast  $\gamma$  subunit increases activity as the concentration of DTT increases.  
 (c) The increase was even larger when thioredoxin was present. Thioredoxin is the natural reductant for the chloroplast enzyme, and so it presumably operates more efficiently than would DTT, which probably functions to keep the thioredoxin reduced.  
 (d) They seem to have done so.  
 (e) The enzyme is susceptible to control by the redox state. In plant cells, reduced thioredoxin is generated by photosystem I. Thus, the enzyme is active when photosynthesis is taking place.  
 (f) Cysteine.  
 (g) Group-specific modification or site-specific mutagenesis.

### Chapter 20

1. The Calvin cycle is the primary means of converting gaseous  $\text{CO}_2$  into organic matter—that is, biomolecules. Essentially, every carbon atom in your body passed through rubisco and the Calvin cycle at some time in the past.
2. Autotrophs can use the energy of sunlight, carbon dioxide, and water to synthesize carbohydrates, which can subsequently be used for catabolic or anabolic purposes. Heterotrophs require chemical fuels and are thus ultimately dependent on autotrophs.
3. Nothing grim or secret about these reactions. They are sometimes called the dark reactions because they do not directly depend on light.
- 4.

Calvin cycle	Krebs cycle
Stroma	Matrix
Carbon chemistry for photosynthesis	Carbon chemistry for oxidative phosphorylation
Fixes $\text{CO}_2$	Releases $\text{CO}_2$
Requires high-energy electrons (NADPH)	Generates high-energy electrons (NADH)
Regenerates starting compound (ribulose 1,5-bisphosphate)	Regenerates starting compound (oxaloacetate)
Requires ATP	Generates ATP
Complex stoichiometry	Simple stoichiometry

5. (a) 3-Phosphoglycerate. (b) The other members of the Calvin cycle.
6. Stage 1 is the fixation of  $\text{CO}_2$  with ribulose 1,5-bisphosphate and the subsequent formation of 3-phosphoglycerate. Stage 2 is the conversion of some of the 3-phosphoglycerate into hexose. Stage 3 is the regeneration of ribulose 1,5-bisphosphate.
7. It catalyzes a crucial reaction, but it is highly inefficient. Consequently, it is required in large amounts to overcome its slow catalysis.
8. Because carbamate forms only in the presence of  $\text{CO}_2$ , this property prevents rubisco from catalyzing the oxygenase reaction exclusively when  $\text{CO}_2$  is absent.
9. Because NADPH is generated in the chloroplasts by the light reactions.
10. The concentration of 3-phosphoglycerate would increase, whereas that of ribulose 1,5-bisphosphate would decrease.
11. The concentration of 3-phosphoglycerate would decrease, whereas that of ribulose 1,5-bisphosphate would increase.
12. Aspartate + glyoxylate  $\longrightarrow$  oxaloacetate + glycine
13. The oxygenase activity of rubisco increases with temperature. Crabgrass is a  $\text{C}_4$  plant, whereas most grasses lack this capability.

- Consequently, the crabgrass will thrive at the hottest part of the summer because the  $\text{C}_4$  pathway provides an ample supply of  $\text{CO}_2$ .
14. The  $\text{C}_4$  pathway allows the  $\text{CO}_2$  concentration to increase at the site of carbon fixation. High concentrations of  $\text{CO}_2$  inhibit the oxygenase reaction of rubisco. This inhibition is important for tropical plants because the oxygenase activity increases more rapidly with temperature than does the carboxylase activity.
15. ATP is required to form phosphoenolpyruvate (PEP) from pyruvate. The PEP combines with  $\text{CO}_2$  to form oxaloacetate and, subsequently, malate. Two ATP molecules are required because a second ATP molecule is required to phosphorylate AMP to ADP.
16. Photorespiration is the consumption of oxygen by plants with the production of  $\text{CO}_2$ , but it does not generate energy. Photorespiration is due to the oxygenase activity of rubisco. It is wasteful because, instead of fixing  $\text{CO}_2$  for conversion into hexoses, rubisco is generating  $\text{CO}_2$ .
17. As global warming progresses,  $\text{C}_4$  plants will invade the higher latitudes, and  $\text{C}_3$  plants will retreat to cooler regions.
18. The light reactions lead to an increase in the stromal concentrations of NADPH, reduced ferredoxin, and  $\text{Mg}^{2+}$ , as well as an increase in pH.
19. (a) 5; (b) 1; (c) 7; (d) 2; (e) 10; (f) 3; (g) 6; (h) 4; (i) 8; (j) 9.
20. The enzymes catalyze the transformation of the five-carbon sugar formed by the oxidative phase of the pentose phosphate pathway into fructose 6-phosphate and glyceraldehyde 3-phosphate, intermediates in glycolysis (and gluconeogenesis).
21. (a) C; (b) B and F; (c) G; (d) F; (e) E; (f) H; (g) I; (h) D; (i) A; (j) F; (k) B.
22. The label emerges at C-5 of ribulose 5-phosphate.
23. Oxidative decarboxylation of isocitrate to  $\alpha$ -ketoglutarate. A  $\beta$ -ketoacid intermediate is formed in both reactions.
24. (a)  $5 \text{ Glucose 6-phosphate} + \text{ATP} \longrightarrow 6 \text{ ribose 5-phosphate} + \text{ADP} + \text{H}^+$   
 (b)  $\text{Glucose 6-phosphate} + 12 \text{ NADP}^+ + 7\text{H}_2\text{O} \longrightarrow 6 \text{ CO}_2 + 12 \text{ NADPH} + 12 \text{ H}^+ + \text{P}_i$
25. The nonoxidative phase of the pentose phosphate pathway can be used to convert three molecules of ribose 5-phosphate into two molecules of fructose 6-phosphate and one molecule of glyceraldehyde 3-phosphate. These molecules are components of the glycolytic pathway.
26. The conversion of fructose 6-phosphate into fructose 1,6-bisphosphate by phosphofructokinase requires ATP.
27. When much NADPH is required. The oxidative phase of the pentose phosphate pathway is followed by the nonoxidative phase. The resulting fructose 6-phosphate and glyceraldehyde 3-phosphate are used to generate glucose 6-phosphate through gluconeogenesis, and the cycle is repeated until the equivalent of one glucose molecule is oxidized to  $\text{CO}_2$ .
28. Fava beans contain vicine, a purine glycoside that can lead to the generation of peroxides—reactive oxygen species that can damage membranes as well as other biomolecules. Glutathione is used to detoxify the ROS. The regeneration of glutathione depends on an adequate supply of NADPH, which is synthesized by the oxidative phase of the pentose phosphate pathway. People with low levels of the dehydrogenase are especially susceptible to vicine toxicity.
29. Because red blood cells do not have mitochondria and the only means to obtain NADPH is through the pentose phosphate pathway. There are biochemical means to convert mitochondrial NADH into cytoplasmic NADPH.
30. Reactive peroxides are a type of reactive oxygen species. The enzyme glutathione peroxidase uses reduced glutathione to neutralize peroxides by converting them into alcohols while generating

oxidized glutathione. Reduced glutathione is regenerated by glutathione reductase with the use of NADPH, the product of the oxidative phase of the pentose phosphate pathway.

31.  $\Delta E'_0$  for the reduction of glutathione by NADPH is +0.09 V. Hence,  $\Delta G'^0$  is  $-17.4 \text{ kJ mol}^{-1}$  ( $-4.2 \text{ kcal mol}^{-1}$ ), which corresponds to an equilibrium constant of 1126. The required  $[\text{NADPH}]/[\text{NADP}^+]$  ratio is  $8.9 \times 10^{-5}$ .

32.

33.

34. Incubate an aliquot of a tissue homogenate with glucose labeled with  $^{14}\text{C}$  at C-1, and incubate another with glucose labeled with  $^{14}\text{C}$  at C-6. Compare the radioactivity of the  $\text{CO}_2$  produced by the two samples. The rationale of this experiment is that only C-1 is decarboxylated by the pentose phosphate pathway, whereas C-1 and C-6 are decarboxylated equally when glucose is metabolized by the glycolytic pathway, the pyruvate dehydrogenase complex, and the citric acid cycle. The reason for the equivalence of C-1 and C-6 in the latter set of reactions is that glyceraldehyde 3-phosphate and dihydroxyacetone phosphate are rapidly interconverted by triose phosphate isomerase.

35. Lacking mitochondria, red blood cells metabolize glucose to lactate to obtain energy in the form of ATP. The  $\text{CO}_2$  results from extensive use of the pentose phosphate pathway coupled with gluconeogenesis. This coupling allows the generation of much

NADPH with the complete oxidation of glucose by the oxidative branch of the pentose phosphate pathway.

36. (a)  $k_{\text{cat}}^{\text{CO}_2}/K_M^{\text{CO}_2} = 3 \times 10^6 \text{ s}^{-1}\text{M}^{-1}$

$$k_{\text{cat}}^{\text{O}_2}/K_M^{\text{O}_2} = 4 \times 10^3 \text{ s}^{-1}\text{M}^{-1}$$

(b) Despite the fact that the specificity constant for  $\text{CO}_2$  as a substrate is much greater than that of  $\text{O}_2$ , the concentration of  $\text{O}_2$  in the atmosphere is higher than that of  $\text{CO}_2$ , allowing the oxygenation reaction to occur.

37. The reduction of each mole of  $\text{CO}_2$  to the level of a hexose requires two moles of NADPH. The reduction of  $\text{NADP}^+$  is a two-electron process. Hence, the formation of two moles of NADPH requires the pumping of four moles of electrons by photosystem I. The electrons given up by photosystem I are replenished by photosystem II, which needs to absorb an equal number of photons. Hence, eight photons are needed to generate the required NADPH. The energy input of eight moles of photons is  $+1594 \text{ kJ}$  ( $+381 \text{ kcal}$ ). Thus, the overall efficiency of photosynthesis under standard conditions is at least  $477/1594$ , or 30%.

38. It is neither a violation nor a miracle. The equation on page 597 requires not only 18 ATP, but also 12 NADPH. These electrons, if transferred to  $\text{NAD}^+$  and used in the electron-transport chain, would yield 30 ATP. Thus, the synthesis of glucose requires the equivalent of 48 ATP.

39. (a) The curve on the right in graph A was generated by the  $\text{C}_4$  plant. Recall that the oxygenase activity of rubisco increases with temperature more rapidly than does the carboxylase activity. Consequently, at higher temperatures, the  $\text{C}_3$  plants would fix less carbon. Because  $\text{C}_4$  plants can maintain a higher  $\text{CO}_2$  concentration, the rise in temperature is less deleterious.

(b) The oxygenase activity will predominate. Additionally, when the temperature rise is very high, the evaporation of water might become a problem. The higher temperatures can begin to damage protein structures as well.

(c) The  $\text{C}_4$  pathway is a very effective active-transport system for concentrating  $\text{CO}_2$ , even when environmental concentrations are very low.

(d) With the assumption that the plants have approximately the same capability to fix  $\text{CO}_2$ , the  $\text{C}_4$  pathway is apparently the rate-limiting step in  $\text{C}_4$  plants.

### Chapter 21

1. Step 1 is the release of glucose 1-phosphate from glycogen by glycogen phosphorylase. Step 2 is the formation of glucose 6-phosphate from glucose 1-phosphate, a reaction catalyzed by phosphoglucomutase. Step 3 is the remodeling of the glycogen by the transferase and the glucosidase.

2. (a) 8; (b) 3; (c) 6; (d) 5; (e) 9; (f) 2; (g) 10; (h) 1; (i) 4; (j) 7.

3. Glycogen is an important fuel reserve for several reasons. The controlled breakdown of glycogen and release of glucose increase the amount of glucose that is available between meals. Hence, glycogen serves as a buffer to maintain blood-glucose levels. Glycogen's role in maintaining blood-glucose levels is especially important because glucose is virtually the only fuel used by the brain, except during prolonged starvation. Moreover, the glucose from glycogen is readily mobilized and is therefore a good source of energy for sudden, strenuous activity. Unlike fatty acids, the released glucose can provide energy in the absence of oxygen and can thus supply energy for anaerobic activity.

4. As an unbranched polymer,  $\alpha$ -amylose has only one nonreducing end. Therefore, only one glycogen phosphorylase molecule could degrade each  $\alpha$ -amylose molecule. Because glycogen is highly branched, there are many nonreducing ends per molecule.

Consequently, many phosphorylase molecules can release many glucose molecules per glycogen molecule.

5. The patient has a deficiency of the branching enzyme.

6. In muscle, the *b* form of phosphorylase is activated by AMP. In the liver, the *a* form is inhibited by glucose. The difference corresponds to the difference in the metabolic role of glycogen in each tissue. Muscle uses glycogen as a fuel for contraction, whereas the liver uses glycogen to maintain blood-glucose levels.

7. Cells maintain the  $[P_i]/[\text{glucose 1-phosphate}]$  ratio at greater than 100, substantially favoring phosphorolysis. We see here an example of how the cell can alter the free-energy change to favor a reaction taking place by altering the ratio of substrate and product.

8. The high level of glucose 6-phosphate in von Gierke disease, resulting from the absence of glucose 6-phosphatase or the transporter, shifts the allosteric equilibrium of phosphorylated glycogen synthase toward the active form.

9. The phosphoryl donor is glucose 1,6-bisphosphate, which is formed from glucose 1-phosphate and ATP in a reaction catalyzed by phosphoglucokinase.

10. The different manifestations correspond to the different roles of the liver and muscle. Liver glycogen phosphorylase plays a crucial role in the maintenance of blood-glucose levels. Recall that glucose is the primary fuel for the brain. Muscle glycogen phosphorylase provides glucose only for the muscle and, even then, only when the energy needs of the muscle are high, as during exercise. The fact that there are two different diseases suggests that there are two different isozymic forms of the glycogen phosphorylase—a liver-specific isozyme and a muscle-specific isozyme.

11. Water is excluded from the active site to prevent hydrolysis. The entry of water could lead to the formation of glucose rather than glucose 1-phosphate. A site-specific mutagenesis experiment is revealing in this regard. In phosphorylase, Tyr 573 is hydrogen bonded to the 2'-OH group of a glucose residue. The ratio of glucose 1-phosphate to glucose product is 9000 : 1 for the wild-type enzyme, and 500 : 1 for the Phe 573 mutant. Model building suggests that a water molecule occupies the site normally filled by the phenolic OH group of tyrosine and occasionally attacks the oxocarbanion ion intermediate to form glucose.

12. The amylase activity was necessary to remove all of the glycogen from the glycogenin. Recall that glycogenin synthesizes oligosaccharides of about eight glucose units, and then activity stops. Consequently, if the glucose residues are not removed by extensive amylase treatment, glycogenin will not function.

13. The substrate can be handed directly from the transferase site to the debranching site.

14. During exercise, [ATP] falls and [AMP] rises. Recall that AMP is an allosteric activator of glycogen phosphorylase *b*. Thus, even in the absence of covalent modification by phosphorylase kinase, glycogen is degraded.

15. Although glucose 1-phosphate is the actual product of the phosphorylase reaction, glucose 6-phosphate is a more versatile molecule with respect to metabolism. Among other fates, glucose-6-phosphate can be processed to yield energy or building blocks. In the liver, glucose 6-phosphate can be converted into glucose and released into the blood.

16. Epinephrine binds to its G-protein-coupled receptor. The resulting structural changes activate a  $G_\alpha$  protein, which in turn activates adenylate cyclase. Adenylate cyclase synthesizes cAMP, which activates protein kinase A. Protein kinase A partly activates phosphorylase kinase, which phosphorylates and activates glycogen phosphorylase. The calcium released during muscle contraction also activates the phosphorylase kinase, leading to further stimulation of glycogen phosphorylase.

17. First, the signal-transduction pathway is shut down when the initiating hormone is no longer present. Second, the inherent

GTPase activity of the G protein converts the bound GTP into inactive GDP. Third, phosphodiesterases convert cyclic AMP into AMP. Fourth, PP1 removes the phosphoryl group from glycogen phosphorylase, converting the enzyme into the usually inactive *b* form.

18. It prevents both from operating simultaneously, which would lead to a useless expenditure of energy.

19. All these symptoms suggest central nervous system problems. If exercise is exhaustive enough or the athlete has not prepared well enough or both, liver glycogen also can be depleted. The brain depends on glucose derived from liver glycogen.

The symptoms suggest that the brain is not getting enough fuel (hypoglycemia).

20. Liver phosphorylase *a* is inhibited by glucose, which facilitates the R  $\rightarrow$  T transition. This transition releases PP1, which inactivates glycogen breakdown and stimulates glycogen synthesis. Muscle phosphorylase is insensitive to glucose.

21. (a) 4; (b) 1; (c) 5; (d) 10; (e) 7; (f) 2; (g) 8; (h) 9; (i) 6; (j) 3.

22. Phosphoglucomutase, UDP-glucose pyrophosphorylase, pyrophosphatase, glycogenin, glycogen synthase, and branching enzyme.

23. The enzyme pyrophosphatase converts the pyrophosphate into two molecules of inorganic phosphate. This conversion renders the overall reaction irreversible.

24. The presence of high concentrations of glucose 6-phosphate indicates that glucose is abundant and that it is not being used by glycolysis. Therefore, this valuable resource is saved by incorporation into glycogen.

25. Free glucose must be phosphorylated at the expense of a molecule of ATP. Glucose 6-phosphate derived from glycogen is formed by phosphorolytic cleavage, sparing one molecule of ATP. Thus, the net yield of ATP when glycogen-derived glucose is processed to pyruvate is three molecules of ATP compared with two molecules of ATP from free glucose.

26. Breakdown: Phosphoglucomutase converts glucose 1-phosphate, liberated from glycogen breakdown, into glucose 6-phosphate, which can be released as free glucose (liver) or processed in glycolysis (muscle and liver). Synthesis: Converts glucose 6-phosphate into glucose 1-phosphate, which reacts with UTP to form UDP-glucose, the substrate for glycogen synthase.

27.  $\text{Glycogen}_n + \text{P}_i \longrightarrow \text{glycogen}_{n-1} + \text{glucose 6-phosphate}$

Glucose 6-phosphate  $\longrightarrow$  glucose 1-phosphate

$\text{UTP} + \text{glucose 1-phosphate} \longrightarrow \text{UDP-glucose} + 2\text{P}_i$

$\text{Glycogen}_{n-1} + \text{UDP-glucose} \longrightarrow \text{glycogen}_n + \text{UDP}$

Sum:  $\text{Glycogen}_n + \text{UTP} \longrightarrow \text{glycogen}_n + \text{UDP} + \text{P}_i$

28. In principle, having glycogen be the only primer for the further synthesis of glycogen should be a successful strategy. However, if the glycogen granules were not evenly divided between daughter cells, glycogen stores for future generations of cells might be compromised. Glycogenin synthesizes the primer for glycogen synthase.

29. Insulin binds to its receptor and activates the tyrosine kinase activity of the receptor, which in turn triggers a pathway that activates protein kinases. The kinases phosphorylate and inactivate glycogen synthase kinase. Protein phosphatase 1 then removes the phosphate from glycogen synthase and thereby activates the synthase.

30.

31. In the liver, glucagon stimulates the cAMP-dependent pathway that activates protein kinase A. Epinephrine binds to a 7TM  $\alpha$ -adrenergic receptor in the liver plasma membrane, which activates phospholipase C and the phosphoinositide cascade. This activation causes calcium ions to be released from the endoplasmic reticulum, which bind to calmodulin, and further stimulates phosphorylase kinase and glycogen breakdown.

32.  $\text{Galactose} + \text{ATP} + \text{UTP} + \text{H}_2\text{O} + \text{glycogen}_n \longrightarrow \text{glycogen}_{n+1} + \text{ADP} + \text{UDP} + 2 \text{P}_i + \text{H}^+$

33. Phosphorylase, transferase, glucosidase, phosphoglucomutase, and glucose 6-phosphatase.

34. Glucose is an allosteric inhibitor of phosphorylase *a*. Hence, crystals grown in its presence are in the T state. The addition of glucose 1-phosphate, a substrate, shifts the R-to-T equilibrium toward the R state. The conformational differences between these states are sufficiently large that the crystal shatters unless it is stabilized by chemical cross-links.

35. Galactose is converted into UDP-galactose to eventually form glucose 6-phosphate.

36. This disease can also be produced by a mutation in the gene that encodes the glucose 6-phosphate transporter. Recall that glucose 6-phosphate must be transported into the lumen of the endoplasmic reticulum to be hydrolyzed by phosphatase. Mutations in the other three essential proteins of this system can likewise lead to von Gierke disease.

37. (a) Apparently, the glutamate, with its negatively charged R group, can mimic to some extent the presence of a phosphoryl group on serine. That the stimulation is not as great is not surprising in that the carboxyl group is smaller and not as charged as the phosphate. (b) Substitution of aspartate would give some stimulation, but because it is smaller than the glutamate, the stimulation would be smaller.

38. (a) Glycogen was too large to enter the gel and, because analysis was by western blot with the use of an antibody specific to glycogenin, we would not expect to see background proteins.

(b)  $\alpha$ -Amylase degrades glycogen, releasing the protein glycogenin, which can be visualized by a western blot.

(c) Glycogen phosphorylase, glycogen synthase, and protein phosphatase 1. These proteins might be visible if the gel were stained for protein, but a western analysis reveals the presence of glycogenin only.

39. (a) The smear was due to molecules of glycogenin with increasingly large amounts of glycogen attached to them.

(b) In the absence of glucose in the medium, glycogen is metabolized, resulting in a loss of the high-molecular-weight material.

(c) Glycogen could have been resynthesized and added to the glycogenin when the cells were fed glucose again.

(d) No difference between lanes 3 and 4 suggests that, by 1 hour, the glycogen molecules had attained maximum size in this cell line. Prolonged incubation does not apparently increase the amount of glycogen.

(e)  $\alpha$ -Amylase removes essentially all of the glycogen, and so only the glycogenin remains.

## Chapter 22

1. (a) 5; (b) 11; (c) 1; (d) 10; (e) 2; (f) 6; (g) 9; (h) 3; (i) 4; (j) 7; (k) 8.

2.  $\text{Glycerol} + 2 \text{NAD}^+ + \text{P}_i + \text{ADP} \longrightarrow \text{pyruvate} + \text{ATP} + \text{H}_2\text{O} + 2 \text{NADH} + \text{H}^+$

Glycerol kinase and glycerol phosphate dehydrogenase

3. The ready reversibility is due to the high-energy nature of the thioester in the acyl CoA.

4. To return the AMP to a form that can be phosphorylated by oxidative phosphorylation or substrate-level phosphorylation, another molecule of ATP must be expended in the reaction:

5. b, c, a, g, h, d, e, f.

6. The citric acid cycle. The reactions that take succinate to oxaloacetate, or the reverse, are similar to those of fatty acid metabolism (Section 17.2).

7. The next-to-last degradation product, acetoacetyl CoA, yields two molecules of acetyl CoA with the thiolysis by only one molecule of CoA.

8. Palmitic acid yields 106 molecules of ATP. Palmitoleic acid has a double bond between carbons C-9 and C-10. When palmitoleic acid is processed in  $\beta$  oxidation, one of the oxidation steps (to introduce a double bond before the addition of water) will not take place, because a double bond already exists. Thus,  $\text{FADH}_2$  will not be generated, and palmitoleic acid will yield 1.5 fewer molecules of ATP than palmitic acid, for a total of 104.5 molecules of ATP.

9.

Activation fee to form the acyl CoA -2 ATP

Seven rounds of yield:

7 acetyl CoA at 10 ATP/acetyl CoA	+ 70 ATP
7 NADH at 2.5 ATP/NADH	+ 17.5 ATP
7 $\text{FADH}_2$ at 1.5 ATP/ $\text{FADH}_2$	+ 10.5 ATP
Propionyl CoA, which requires an ATP to be converted into succinyl CoA	- 1 ATP
Succinyl CoA $\rightarrow$ succinate	+ 1 ATP
Succinate $\rightarrow$ fumarate + $\text{FADH}_2$	+ 1.5 ATP
$\text{FADH}_2$ at 1.5 ATP/ $\text{FADH}_2$	
Fumarate $\rightarrow$ malate	
Malate $\rightarrow$ oxaloacetate + NADH	+ 2.5 ATP
NADH at 2.5 ATP/NADH	

Total 120 ATP

## ANSWERS TO PROBLEMS

10. You might hate yourself in the morning, but at least you won't have to worry about energy. To form stearoyl CoA requires the equivalent of 2 molecules of ATP.

9 acetyl CoA at 10 ATP/acetyl CoA	+ 90 ATP
8 NADH at 2.5 ATP/NADH	+ 20 ATP
8 FADH <sub>2</sub> at 1.5 ATP/FADH <sub>2</sub>	+ 12 ATP
Activation fee	-2.0
<b>Total</b>	<b>122 ATP</b>

11. Keep in mind that, in the citric acid cycle, 1 molecule of FADH<sub>2</sub> yields 1.5 ATP, 1 molecule of NADH yields 2.5 ATP, and 1 molecule of acetyl CoA yields 10 ATP. Two molecules of ATP are produced when glucose is degraded to 2 molecules of pyruvate. Two molecules of NADH also are produced, but the electrons are transferred to FADH<sub>2</sub> to enter the electron transport chain. Each molecule of FADH<sub>2</sub> can generate 1.5 ATP. Each molecule of pyruvate will produce 1 molecule of NADH. Each molecule of acetyl CoA generates 3 molecules of NADH, 1 molecule of FADH<sub>2</sub>, and 1 molecule of ATP. So, we have a total of 10 ATP per acetyl CoA, or 20 for the 2 molecules of acetyl CoA. The total for glucose is 30 ATP. Now, what about hexanoic acid? Caproic acid is activated to caproic CoA at the expense of 2 ATP, and so we are 2 ATP in the hole. The first cycle of β oxidation generates 1 FADH<sub>2</sub>, 1 NADH, and 1 acetyl CoA. After the acetyl CoA has been run through the citric acid cycle, this step will have generated a total of 14 ATP. The second cycle of β oxidation generates 1 FADH<sub>2</sub> and 1 NADH but 2 acetyl CoA. After the acetyl CoA has been run through the citric acid cycle, this step will have generated a total of 24 ATP. The total is 36 ATP. Thus, the foul-smelling caproic acid has a net yield of 36 ATP. So on a per carbon basis, this fat yields 20% more ATP than does glucose, a manifestation of the fact that fats are more reduced than carbohydrates.

12.  $\text{Stearate} + \text{ATP} + 13.5 \text{ H}_2\text{O} + 8 \text{ FAD} + 8 \text{ NAD}^+ \rightarrow 4.5 \text{ acetoacetate} + 14.5 \text{ H}^+ + 8 \text{ FADH}_2 + 8 \text{ NADH} + \text{AMP} + 2 \text{ P}_i$

13. Palmitate is activated and then processed by β oxidation according to the following reactions.

The eight molecules of acetyl CoA combine to form four molecules of acetoacetate for release into the blood, and so they do not contribute to the energy yield in the liver. However, the FADH<sub>2</sub> and NADH generated in the preparation of acetyl CoA can be processed by oxidative phosphorylation to yield ATP.

$$1.5 \text{ ATP/FADH}_2 \times 7 = 10.5 \text{ ATP}$$

$$2.5 \text{ ATP/NADH} \times 7 = 17.5 \text{ ATP}$$

The equivalent of 2 ATP were used to form palmitoyl CoA. Thus, 26 ATP were generated for use by the liver.

14. NADH produced with the oxidation to acetoacetate = 2.5 ATP. Acetoacetate is converted into acetoacetyl CoA. Two molecules of acetyl CoA result from the hydrolysis of acetoacetyl CoA, each worth 10 ATP when processed by the citric acid cycle. Total ATP yield is 22.5.

15. Because a molecule of succinyl CoA is used to form acetoacetyl CoA. Succinyl CoA could be used to generate one molecule of ATP, and so someone could argue that the yield is 21.5.

16. For fats to be combusted, not only must they be converted into acetyl CoA, but the acetyl CoA must be processed by the citric acid cycle. In order for acetyl CoA to enter the citric acid cycle, there must be a supply of oxaloacetate. Oxaloacetate can be formed by the metabolism of glucose to pyruvate and the subsequent carboxylation of pyruvate to form oxaloacetate.

17. (a)

The problem with phytanic acid is that, as it undergoes β oxidation, we encounter the dreaded pentavalent carbon atom. Because the pentavalent carbon atom doesn't exist, β oxidation cannot take place and phytanic acid accumulates.

(b) Removing methyl groups, though theoretically possible, would be time consuming and lacking in elegance. What would we do with the methyl groups? Our livers solve the problem by inventing α oxidation.

One round of α oxidation rather than β oxidation converts phytanic acid into a β-oxidation substrate.

18. The first oxidation removes two tritium atoms. The hydration adds nonradioactive H and OH. The second oxidation removes another tritium atom from the β-carbon atom. Thiolysis removes an acetyl CoA with only one tritium atom; so the tritium-to-carbon ratio is 1/2. This ratio will be the same for two of the acetates. The last one, however, does not undergo oxidation, and so all tritium remains. The ratio for this acetate is 3/2. The ratio for the entire molecule is then 5/6.

19. In the absence of insulin, lipid mobilization will take place to an extent that it overwhelms the ability of the liver to convert the lipids into ketone bodies.
20. (a) 10; (b) 1; (c) 5; (d) 8; (e) 3; (f) 9; (g) 6; (h) 7; (i) 4; (j) 2.
21. (a) Oxidation in mitochondria; synthesis in the cytoplasm.  
 (b) Coenzyme A in oxidation; acyl carrier protein for synthesis.  
 (c) FAD and NAD<sup>+</sup> in oxidation; NADPH for synthesis.  
 (d) The L isomer of 3-hydroxyacyl CoA in oxidation; the D isomer in synthesis.  
 (e) From carboxyl to methyl in oxidation; from methyl to carboxyl in synthesis.  
 (f) The enzymes of fatty acid synthesis, but not those of oxidation, are organized in a multienzyme complex.
22. Bicarbonate is required for the synthesis of malonyl CoA from acetyl CoA by acetyl CoA carboxylase.
23.  $7 \text{ acetyl CoA} + 6 \text{ ATP} + 12 \text{ NADPH} + 12 \text{ H}^+ \rightarrow$   
 $\text{myristate} + 7 \text{ CoA} + 6 \text{ ADP} + 6 \text{ P}_i + 12 \text{ NADP}^+ + 5 \text{ H}_2\text{O}$ .
24. We will need six acetyl CoA units. One acetyl CoA unit will be used directly to become the two carbon atoms farthest from the acid end. The other five units must be converted into malonyl CoA. The synthesis of each malonyl CoA molecule costs a molecule of ATP; so 5 molecules of ATP will be required. Each round of elongation requires 2 molecules of NADPH, 1 molecule to reduce the keto group to an alcohol and 1 molecule to reduce the double bond. As a result, 10 molecules of NADPH will be required. Therefore, 5 molecules of ATP and 10 molecules of NADPH are required to synthesize lauric acid.
25. e, b, d, a, c.
26. Such a mutation would inhibit fatty acid synthesis because the enzyme cleaves cytoplasmic citrate to yield acetyl CoA for fatty acid synthesis.
27. (a) False. Biotin is required for acetyl CoA carboxylase activity.  
 (b) True.  
 (c) False. ATP is required to synthesize malonyl CoA.  
 (d) True.  
 (e) True.  
 (f) False. Fatty acid synthase is a dimer.  
 (g) True.  
 (h) False. Acetyl CoA carboxylase is stimulated by citrate, which is cleaved to yield its substrate acetyl CoA.
28. Fatty acids with odd numbers of carbon atoms are synthesized starting with propionyl ACP (instead of acetyl ACP), which is formed from propionyl CoA by acetyl transacetylase.
29. All of the labeled carbon atoms will be retained. Because we need 8 acetyl CoA molecules and only 1 carbon atom is labeled in the acetyl group, we will have 8 labeled carbon atoms. The only acetyl CoA used directly will retain 3 tritium atoms. The 7 acetyl CoA molecules used to make malonyl CoA will lose 1 tritium atom on addition of the CO<sub>2</sub> and another one at the dehydration step. Each of the 7 malonyl CoA molecules will retain 1 tritium atom. Therefore, the total retained tritium is 10 atoms. The ratio of tritium to carbon is 1.25.
30. With a diet rich in raw eggs, avidin will inhibit fatty acid synthesis by reducing the amount of biotin required by acetyl CoA carboxylase. Cooking the eggs will denature avidin, and so it will no longer bind biotin.
31. The only acetyl CoA used directly, not in the form of malonyl CoA, provides the two carbon atoms at the ω end of the fatty acid chain. Because palmitic acid is a C<sub>16</sub> fatty acid, acetyl CoA will have provided carbons 15 and 16.
32. HCO<sub>3</sub><sup>-</sup> is attached to acetyl CoA to form malonyl CoA. When malonyl CoA condenses with acetyl CoA to form the four-carbon ketoacyl CoA, the HCO<sub>3</sub><sup>-</sup> is lost as CO<sub>2</sub>.
33. Phosphofruktokinase controls the flux down the glycolytic pathway. Glycolysis functions to generate ATP or building blocks for biosynthesis, depending on the tissue. The presence of citrate in the cytoplasm indicates that those needs are met, and there is no need to metabolize glucose.
34. C-1 is more radioactive.
35. The mutant enzyme will be persistently active because it cannot be inhibited by phosphorylation. Fatty acid synthesis will be abnormally active. Such a mutation might lead to obesity.
36. (a) Palmitoleate; (b) linoleate; (c) linoleate; (d) oleate; (e) oleate; (f) linolenate.
37. Decarboxylation drives the condensation of malonyl ACP and acetyl ACP. In contrast, the condensation of two molecules of acetyl ACP is energetically unfavorable. In gluconeogenesis, decarboxylation drives the formation of phosphoenolpyruvate from oxaloacetate.
38. Fat mobilization in adipocytes is activated by phosphorylation. Hence, overproduction of the cAMP-activated kinase will lead to an accelerated breakdown of triacylglycerols and a depletion of fat stores.
39. Carnitine translocase deficiency and glucose 6-phosphate transporter deficiency.
40. In the fifth round of β oxidation, *cis*-Δ<sup>2</sup>-enoyl CoA is formed. Dehydration by the classic hydratase yields D-3-hydroxyacyl CoA, the wrong isomer for the next enzyme in β oxidation. This dead end is circumvented by a second hydratase that removes water to give *trans*-Δ<sup>2</sup>-enoyl CoA. The addition of water by the classic hydratase then yields L-3-hydroxyacyl CoA, the appropriate isomer. Thus, hydratases of opposite stereospecificities serve to epimerize (invert the configuration of) the 3-hydroxyl group of the acyl CoA intermediate.
41. An advantage of this arrangement is that the synthetic activity of different enzymes is coordinated. In addition, intermediates can be efficiently handed from one active site to another without leaving the assembly. Furthermore, a complex of covalently joined enzymes is more stable than one formed by noncovalent attractions. Each of the component enzymes is recognizably homologous to its bacterial counterpart.
42. The probability of synthesizing an error-free polypeptide chain decreases as the length of the chain increases. A single mistake can make the entire polypeptide ineffective. In contrast, a defective subunit can be spurned in the formation of a noncovalent multienzyme complex; the good subunits are not wasted.
43. The absence of ketone bodies is due to the fact that the liver, the source of ketone bodies in the blood, cannot oxidize fatty acids to produce acetyl CoA. Moreover, because of the impaired fatty acid oxidation, the liver becomes more dependent on glucose as an energy source. This dependency results in a decrease in gluconeogenesis and a drop in blood-glucose levels, which is exacerbated by the lack of fatty acid oxidation in muscle and a subsequent increase in glucose uptake from the blood.
44. Peroxisomes enhance the degradation of very long chain fatty acids. Consequently, increasing the activity of peroxisomes could help to lower levels of blood triglycerides. In fact, clofibrate is rarely used because of serious side effects.
45. Citrate works by facilitating, in cooperation with the protein MIG12, the formation of active filaments from inactive monomers. In essence, it increases the number of active sites available, or the concentration of enzyme. Consequently, its effect is visible as an increase in the value of V<sub>max</sub>. Allosteric enzymes that alter their V<sub>max</sub> values in response to regulators are sometimes called V-class enzymes. The more common type of allosteric enzyme, in which K<sub>m</sub> is altered, comprises K-class enzymes. Palmitoyl CoA causes depolymerization and thus inactivation.

46. The thiolate anion of CoA attacks the 3-keto group to form a tetrahedral intermediate. This intermediate collapses to form acyl CoA and the enolate anion of acetyl CoA. Protonation of the enolate yields acetyl CoA.

47.

48. (a) Fats burn in the flame of carbohydrates. Without carbohydrates, there would be no anapleurotic reactions to replenish the components of the citric acid cycle. With a diet of fats only, the acetyl CoA from fatty acid degradation would build up.

(b) Acetone from ketone bodies.

(c) Yes. Odd-chain fatty acids would lead to the production of propionyl CoA, which can be converted into succinyl CoA, a citric acid cycle component. It would serve to replenish the citric acid cycle, allow glucose synthesis and mitigate the halitosis.

49. A labeled fat can enter the citric acid cycle as acetyl CoA and yield labeled oxaloacetate, but only after two carbon atoms have been lost as  $\text{CO}_2$ . Consequently, even though oxaloacetate may be labeled, there can be no net synthesis of oxaloacetate and hence no net synthesis of glucose or glycogen.

50. (a) Glucose is the primary fuel used by the brain. Lack of pyruvate dehydrogenase would prevent complete oxidation of glucose-derived pyruvate by cellular respiration. (b) Because ATP cannot be generated aerobically, glucose would be metabolized to lactate to obtain some ATP. (c) Such a diet would generate ketone bodies for use as fuel by the brain.

51. I-cell disease (Section 11.3) results when lysosomal enzymes are secreted instead of imported into the lysosome.

52. (a) The  $V_{\max}$  is decreased and the  $K_m$  is increased.  $V_{\max}$  (wild type) =  $13 \text{ nmol minute}^{-1} \text{ mg}^{-1}$ ;  $K_m$  (wild type) =  $45 \text{ } \mu\text{M}$ ;  $V_{\max}$  (mutant) =  $8.3 \text{ nmol minute}^{-1} \text{ mg}^{-1}$ ;  $K_m$  (mutant) =  $74 \text{ } \mu\text{M}$ . (b) Both the  $V_{\max}$  and the  $K_m$  are decreased.  $V_{\max}$  (wild type) =  $41 \text{ nmol minute}^{-1} \text{ mg}^{-1}$ ;  $K_m$  (wild type) =  $104 \text{ } \mu\text{M}$ ;  $V_{\max}$  (mutant) =  $23 \text{ nmol minute}^{-1} \text{ mg}^{-1}$ ;  $K_m$  (mutant) =  $69 \text{ } \mu\text{M}$ .

(c) The wild type is significantly more sensitive to malonyl CoA.

(d) With respect to carnitine, the mutant displays approximately 65% of the activity of the wild type; with respect to palmitoyl CoA, approximately 50% activity. On the other hand,  $10 \text{ } \mu\text{M}$  of malonyl CoA inhibits approximately 80% of the wild type but has essentially no effect on the mutant enzyme.

(e) The glutamate appears to play a more prominent role in regulation by malonyl CoA than in catalysis.

53. (a) Leucine is changed to alanine.

(b) No change relative to control.

(c) Tyrosine to alanine.

(d) Greatly reduced lipase binding compared to the control.

(e) Lipase activity was diminished.

(f) This suggests that they are separate. The L16A mutation allows binding of the lipase but apparently does not allow activation of the lipase.

(g) This mutation decreased both binding and activity, suggesting that the tyrosine is involved in both aspects of colipase activity.

54. (a) Sorafen A inhibits fatty acid synthesis in a dose-dependent manner.

(b) Fatty acid oxidation is increased in the presence of sorafen A.

(c) Recall that acetyl CoA carboxylase 2 synthesizes malonyl CoA to inhibit the transport of fatty acids into the mitochondria, thereby preventing fatty acid oxidation. Sorafen A apparently inhibits both forms of the carboxylase.

(d) Phospholipid synthesis was inhibited in a dose-dependent manner.

(e) Phospholipids are required for membrane synthesis.

(f) Sorafen A inhibits cell proliferation, especially at higher concentrations.

## Chapter 23

1. When the proteins are denatured, all of the peptide bonds are accessible to proteolytic enzymes. If the three-dimensional structure of a protein is maintained, access to many peptide bonds is denied to the proteolytic enzymes.

2. First, the ubiquitin-activating enzyme (E1) links ubiquitin to a sulfhydryl group on E1 itself. Next, the ubiquitin is transferred to a cysteine residue on the ubiquitin-conjugating enzyme (E2) by E2. The ubiquitin-protein ligase (E3), using the ubiquitinated E2 as a substrate, transfers the ubiquitin to the target protein.

3. (a) 7; (b) 4; (c) 2; (d) 10; (e) 5; (f) 3; (g) 9; (h) 1; (i) 6; (j) 8.

4. (a) The ATPase activity of the 26S proteasome resides in the 19S subunit. The energy of ATP hydrolysis is used to unfold the substrate, which is too large to enter the catalytic barrel. ATP may also be required for translocation of the substrate into the barrel.

(b) Substantiates the answer in part a. Because they are small, the peptides do not need to be unfolded. Moreover, small peptides could probably enter all at once and not require translocation.

5. (a) Pyruvate; (b) oxaloacetate; (c)  $\alpha$ -ketoglutarate; (d)  $\alpha$ -ketoisocaproate; (e) phenylpyruvate; (f) hydroxyphenylpyruvate.

6. (a)  $\text{Aspartate} + \alpha\text{-ketoglutarate} + \text{GTP} + \text{ATP} + 2 \text{H}_2\text{O} + \text{NADH} + \text{H}^+ \rightarrow \frac{1}{2} \text{glucose} + \text{glutamate} + \text{CO}_2 + \text{ADP} + \text{GDP} + \text{NAD}^+ + 2 \text{P}_i$ .

The required coenzymes are pyridoxal phosphate in the transamination reaction and  $\text{NAD}^+/\text{NADH}$  in the redox reactions.

(b)  $\text{Aspartate} + \text{CO}_2 + \text{NH}_4^+ + 3 \text{ATP} + \text{NAD}^+ + 4 \text{H}_2\text{O} \rightarrow \text{oxaloacetate} + \text{urea} + 2 \text{ADP} + 4 \text{P}_i + \text{AMP} + \text{NADH} + \text{H}^+$ .

7. In the eukaryotic proteasome, the distinct  $\beta$  subunits have different substrate specificities, allowing proteins to be more thoroughly degraded.

8. The six subunits probably exist as a heterohexamer. Cross-linking experiments could test the model and help determine which subunits are adjacent to one another.

9. Thiamine pyrophosphate.

10. Aminotransferases transfer the  $\alpha$ -amino group to  $\alpha$ -ketoglutarate to form glutamate. Glutamate is oxidatively deaminated to form an ammonium ion.

11. Aspartate (oxaloacetate), glutamate ( $\alpha$ -ketoglutarate), alanine (pyruvate).

12. Serine and threonine.

13. They are either fuels for the citric acid cycle, components of the citric acid cycle, or molecules that can be converted into a fuel for the citric acid cycle in one step.

14. It acts as an electron sink.  
 15. Carbamoyl phosphate and aspartate.  
 16. (a) 4; (b) 5; (c) 1; (d) 6; (e) 7; (f) 3; (g) 2.  
 17. A, arginine; B, citrulline; C, ornithine; D, arginosuccinate.  
 The order of appearance: C, B, D, A.  
 18.  $\text{CO}_2 + \text{NH}_4^+ + 3 \text{ATP} + \text{NAD}^+ + \text{aspartate} + 3 \text{H}_2\text{O} \rightarrow$   
 $\text{urea} + 2 \text{ADP} + 2 \text{P}_i + \text{AMP} + \text{PP}_i + \text{NADH} + \text{H}^+ +$   
 $\text{oxaloacetate}.$

Four high-transfer-potential phosphoryl groups are spent. Note, however, that an NADH is generated if fumarate is converted into oxaloacetate. NADH can generate 2.5 ATP in the electron-transport chain. Taking these ATP into account, only 1.5 high-transfer-potential phosphoryl groups are spent.

19. The synthesis of fumarate by the urea cycle is important because it links the urea cycle and the citric acid cycle. Fumarate is hydrated to malate, which, in turn, is oxidized to oxaloacetate. Oxaloacetate has several possible fates: (1) transamination to aspartate, (2) conversion into glucose by the gluconeogenic pathway, (3) condensation with acetyl CoA to form citrate, or (4) conversion into pyruvate. You can collect.

20. Ornithine transcarbamoylase (Compound A is analogous to PALA; Chapter 10).

21. Ammonia could lead to the amination of  $\alpha$ -ketoglutarate, producing a high concentration of glutamate in an unregulated fashion.  $\alpha$ -Ketoglutarate for glutamate synthesis could be removed from the citric acid cycle, thereby diminishing the cell's respiration capacity.

22. The mass spectrometric analysis strongly suggests that three enzymes—pyruvate dehydrogenase,  $\alpha$ -ketoglutarate dehydrogenase, and the branched-chain  $\alpha$ -ketoacid dehydrogenase—are deficient. Most likely, the common  $E_3$  component of these enzymes is missing or defective. This proposal could be tested by purifying these three enzymes and assaying their ability to catalyze the regeneration of lipoamide.

23. Benzoate, phenylacetate, and arginine would be given to supplement a protein-restricted diet. Nitrogen would emerge in hippurate, phenylacetylglutamine, and citrulline.

24. The liver is the primary tissue for capturing nitrogen as urea. If the liver is damaged (for instance, by hepatitis or the excessive consumption of alcohol), free ammonia is released into the blood.

25. This defect can be partly bypassed by providing a surplus of arginine in the diet and restricting the total protein intake. In the liver, arginine is split into urea and ornithine, which then reacts with carbamoyl phosphate to form citrulline. This urea-cycle intermediate condenses with aspartate to yield argininosuccinate, which is then excreted. Note that two nitrogen atoms—one from carbamoyl phosphate and the other from aspartate—are eliminated from the body per molecule of arginine provided in the diet. In essence, argininosuccinate substitutes for urea in carrying nitrogen out of the body. The formation of argininosuccinate removes the nitrogen, and the restriction on protein intake relieves the aciduria.

26. Aspartame, a dipeptide ester (L-aspartyl-L-phenylalanine methyl ester), is hydrolyzed to L-aspartate and L-phenylalanine. High levels of phenylalanine are harmful in phenylketonurics.

27. N-Acetylglutamate is synthesized from acetyl CoA and glutamate. Once again, acetyl CoA serves as an activated acetyl donor. This reaction is catalyzed by N-acetylglutamate synthase.

28. Not all proteins are created equal: some are more important than others. Some proteins would be degraded to provide the missing amino acid. The nitrogen from the other amino acids would be excreted as urea. Consequently, more nitrogen would be excreted than ingested.

29. The carbon skeletons of ketogenic amino acids can be converted into ketone bodies or fatty acids. Only leucine and lysine are purely ketogenic. Glucogenic amino acids are those whose carbon skeletons can be converted into glucose.

30. As shown in Figure 23.28, alanine, a gluconeogenic amino acid, is released during the metabolism of tryptophan to acetyl CoA and acetoacetyl CoA.

31. The branched-chain amino acids leucine, isoleucine, and valine. The required enzyme is the branched-chain  $\alpha$ -ketoacid dehydrogenase complex.

32. Pyruvate (glycolysis and gluconeogenesis), acetyl CoA (citric acid cycle and fatty acid synthesis), acetoacetyl CoA (ketone-body formation),  $\alpha$ -ketoglutarate (citric acid cycle), succinyl CoA (citric acid cycle), fumarate (citric acid cycle), and oxaloacetate (citric acid cycle and gluconeogenesis).

33.

34.

The equilibrium constant for the interconversion of L-serine and D-serine is exactly 1.

35. Double-displacement. A substituted enzyme intermediate is formed.

36. Exposure of such a domain suggests that a component of a multiprotein complex has failed to form properly or that one component has been synthesized in excess. This exposure leads to rapid degradation and the restoration of appropriate stoichiometries.

37. (a) Depletion of glycogen stores. When they are gone, proteins must be degraded to meet the glucose needs of the brain. The resulting amino acids are deaminated, and the nitrogen atoms are excreted as urea.

(b) The brain has adapted to the use of ketone bodies, which are derived from fatty acid catabolism. In other words, the brain is being powered by fatty acid breakdown.

(c) When the glycogen and lipid stores are gone, the only available energy source is protein.

38. The precise cause of all of the symptoms is not firmly established, but a likely explanation depends on the centrality of oxaloacetate to metabolism. A lack of pyruvate carboxylase would reduce the amount of oxaloacetate. The lack of oxaloacetate would reduce the activity of the citric acid cycle and so ATP would be generated by lactic acid formation. If the concentration of oxaloacetate is low, aspartate cannot be formed and the urea cycle would be compromised. Oxaloacetate is also required to form citrate, which transports acetyl CoA to the cytoplasm for fatty acid synthesis. Finally, oxaloacetate is required for gluconeogenesis.

39. Deamination to  $\alpha$ -keto- $\beta$ -methylvalerate; oxidative decarboxylation to  $\alpha$ -methylbutyryl CoA; oxidation to tiglyl CoA; hydration, oxidation, and thiolysis yield acetyl CoA and propionyl CoA; propionyl CoA to succinyl CoA.

40. Glycogen phosphorylase. The coenzyme serves as an acid-base catalyst.

41. In the Cori cycle, the carbon atoms are transferred from muscle to liver as lactate. For lactate to be of any use, it must be reduced to pyruvate. This reduction requires high-energy electrons in the form of NADH. When the carbon atoms are transferred as alanine, transamination yields pyruvate directly.

42. (a) Virtually no digestion in the absence of nucleotides.

(b) Protein digestion is greatly stimulated by the presence of ATP.

(c) AMP-PNP, a nonhydrolyzable analog of ATP, is no more effective than ADP.

(d) The proteasome requires neither ATP nor PAN to digest small substrates.

(e) PAN and ATP hydrolysis may be required to unfold the peptide and translocate it into the proteasome.

(f) Although *Thermoplasma* PAN is not as effective with the other proteasomes, it nonetheless results in threefold to fourfold stimulation of digestion.

(g) In light of the fact that the archaea and eukarya diverged several billion years ago, the fact that *Thermoplasma* PAN can stimulate rabbit muscle suggests homology not only between the proteasomes, but also between PAN and the 19S subunit (most likely the ATPases) of the mammalian 26S proteasome.

## Chapter 24

1. Nitrogen fixation is the conversion of atmospheric  $N_2$  into  $NH_4^+$ . Diazotrophic (nitrogen-fixing) microorganisms are able to fix nitrogen.

2. (a) 4; (b) 8; (c) 10; (d) 6; (e) 7; (f) 9; (g) 3; (h) 5; (i) 2; (j) 1.

3. The reductase provides electrons with high reducing power, whereas the nitrogenase, which requires ATP hydrolysis, uses the electrons to reduce  $N_2$  to  $NH_3$ .

4. False. Nitrogen is thermodynamically favored. ATP expenditure by the nitrogenase is required to make the reaction kinetically possible.

5. The bacteria provide the plant with ammonia by reducing atmospheric nitrogen. This reduction is energetically expensive, and the bacteria use ATP from the plant.

6. Oxaloacetate, pyruvate, ribose-5-phosphate, phosphoenolpyruvate, erythrose-4-phosphate,  $\alpha$ -ketoglutarate, and 3-phosphoglycerate.

7. Human beings do not have the biochemical pathways to synthesize certain amino acids from simpler precursors. Consequently, these amino acids are "essential" and must be obtained from the diet.

8.  $\text{Glucose} + 2 \text{ADP} + 2 \text{P}_i + 2 \text{NAD}^+ + 2 \text{glutamate} \rightarrow 2 \text{alanine} + 2 \alpha\text{-ketoglutarate} + 2 \text{ATP} + 2 \text{NADH} + 2 \text{H}_2\text{O} + 2 \text{H}^+$ .

9.  $\text{N}_2 \rightarrow \text{NH}_4^+ \rightarrow \text{glutamate} \rightarrow \text{serine} \rightarrow \text{glycine} \rightarrow \delta\text{-aminolevulinic acid} \rightarrow \text{porphobilinogen} \rightarrow \text{heme}$ .

10. Pyridoxal phosphate (PLP).

11. S-Adenosylmethionine, tetrahydrofolate, and methylcobalamin.

12. (a)  $N^5, N^{10}$ -Methylenetetrahydrofolate;

(b)  $N^5$ -methyltetrahydrofolate.

13.  $\gamma$ -Glutamyl phosphate is a likely reaction intermediate.

14. The synthesis of asparagine from aspartate passes through an acyl-adenylate intermediate. One of the products of the reaction will be  $^{18}\text{O}$ -labeled AMP.

15. The administration of glycine leads to the formation of isovalerylglycine. This water-soluble conjugate, in contrast with isovaleric acid, is excreted very rapidly by the kidneys.

16. The nitrogen atom shaded red is derived from glutamine. The carbon atom shaded blue is derived from serine.

17. They carry out nitrogen fixation. The absence of photosystem II provides an environment in which  $\text{O}_2$  is not produced. Recall that the nitrogenase is very rapidly inactivated by  $\text{O}_2$ .

18. The cytoplasm is a reducing environment, whereas the extracellular milieu is an oxidizing environment.

19. (a) None; (b) D-glutamate and oxaloacetate.

20. Succinyl CoA is formed in the mitochondrial matrix as part of the citric acid cycle.

21. Alanine from pyruvate; aspartate from oxaloacetate; glutamate from  $\alpha$ -ketoglutarate.

22. Lysine cyclodeaminase converts L-lysine into the six-membered ring analog of proline, also referred to as L-homoproline or L-pipecolate:

23. Y could inhibit the  $\text{C} \rightarrow \text{D}$  step, Z could inhibit the  $\text{C} \rightarrow \text{F}$  step, and C could inhibit  $\text{A} \rightarrow \text{B}$ . This scheme is an example of sequential feedback inhibition. Alternatively, Y could inhibit the  $\text{C} \rightarrow \text{D}$  step, Z could inhibit the  $\text{C} \rightarrow \text{F}$  step, and the  $\text{A} \rightarrow \text{B}$  step would be inhibited only in the presence of both Y and Z. This scheme is called concerted feedback inhibition.

24. The rate of the  $\text{A} \rightarrow \text{B}$  step in the presence of high levels of Y and Z would be  $24 \text{ s}^{-1}$  ( $0.6 \times 0.4 \times 100 \text{ s}^{-1}$ ).

25. Lysine 258 is absolutely essential for the activity of aspartate aminotransferase, as it is responsible both for the formation of the internal aldimine with the pyridoxal phosphate cofactor and for transferring the proton between the ketimine and quinonoid intermediates. Mutation of this residue to cysteine would be expected to dramatically impair catalysis, as cysteine cannot occupy the same space as lysine and also exhibits differing  $\text{pK}_a$  properties. Upon treatment with 2-bromoethylamine, however, the resulting thioether now has a shape and  $\text{pK}_a$  similar to the original lysine side chain. Hence, some catalytic activity is restored.

26. An external aldimine forms with SAM, which is deprotonated to form the quinonoid intermediate. The deprotonated carbon

atom attacks the carbon atom adjacent to the sulfur atom to form the cyclopropane ring and release methylthioadenosine, the other product.

27. An external aldimine forms with L-serine, which is deprotonated to form the quinonoid intermediate. This intermediate is reprotonated on its opposite face to form an aldimine with D-serine. This compound is cleaved to release D-serine. The equilibrium constant for a racemization reaction is 1 because the reactant and product are exact mirror images of each other.

28. (a) In the first step, histidine attacks the methylene group from the methionine subgroup of SAM (rather than the usual methyl substituent), resulting in the transfer of an aminocarboxypropyl group. Three subsequent conventional SAM-mediated methylations of the primary amine yield diphthine.

(b) In this chapter, we have observed two examples of an ATP-dependent conversion of a carboxylate into an amide: glutamine synthetase, which uses an acyl-phosphate intermediate, and asparagine synthetase, which uses an acyl-adenylate intermediate. Either mechanism is possible in formation of diphthamide from diphthine.

29. Biotin.

30. Synthesis from oxaloacetate and  $\alpha$ -ketoglutarate would deplete the citric acid cycle, which would decrease ATP production. Anapleurotic reactions would be required to replenish the citric acid cycle.

31. SAM is the donor for DNA methylation reactions that protect a host from digestion by its own restriction enzymes. A lack of SAM would render the bacterial DNA susceptible to digestion by the cell's own restriction enzymes.

32. Acetate  $\rightarrow$  acetyl-CoA  $\rightarrow$  citrate  $\rightarrow$  isocitrate  $\rightarrow$   $\alpha$ -ketoglutarate  $\rightarrow$  succinyl-CoA.
33. The value of  $K_M$  of glutamate dehydrogenase for  $\text{NH}_4^+$  is high ( $\gg 1$  mM), and so this enzyme is not saturated when  $\text{NH}_4^+$  is limiting. In contrast, glutamine synthetase has very high affinity for  $\text{NH}_4^+$ . Thus, ATP hydrolysis is required to capture ammonia when it is scarce.
34. (a) Asparagine is much more abundant in the dark. More glutamine is present in the light. These amino acids show the most dramatic effects. Glycine also is more abundant in the light.
- (b) Glutamine is a more metabolically reactive amino acid, used in the synthesis of many other compounds. Consequently, when energy is available as light, glutamine will be preferentially synthesized. Asparagine, which carries more nitrogen per carbon atom and is thus a more-efficient means of storing nitrogen when energy is short, is synthesized in the dark. Glycine is more prevalent in the light because of photorespiration.
- (c) White asparagus has an especially high concentration of asparagine, which accounts for its intense taste. All asparagus has a large amount of asparagine. In fact, as suggested by its name, asparagine was first isolated from asparagus.

### Chapter 25

1. In de novo synthesis, the nucleotides are synthesized from simpler precursor compounds, in essence from scratch. In salvage pathways, preformed bases are recovered and attached to riboses.
2. Carbon 2 and nitrogen 3 come from carbamoyl phosphate. Nitrogen 1 and carbons 4, 5, and 6 are derived from aspartate.
3. Nitrogen 1: aspartate; carbon 2:  $N^{10}$ -formyltetrahydrofolate; nitrogen 3: glutamine; carbons 4 and 5 and nitrogen 7: glycine; carbon 6:  $\text{CO}_2$ ; carbon 8:  $N^{10}$ -formyltetrahydrofolate; nitrogen 9: glutamine.
4. Energy currency: ATP; signal transduction: ATP and GTP; RNA synthesis: ATP, GTP, CTP, and UTP; DNA synthesis: dATP, dCTP, dGTP, and TTP; components of coenzymes: ATP in CoA, FAD, and  $\text{NAD(P)}^+$ ; carbohydrate synthesis: UDP-glucose. These are just some of the uses.
5. A nucleoside is a base attached to ribose. A nucleotide is a nucleoside with the ribose bearing one or more phosphates.
6. (a) 9; (b) 7; (c) 6; (d) 10; (e) 2; (f) 4; (g) 1; (h) 11; (i) 8; (j) 3; (k) 5.
7. Substrate channeling is the process whereby the product of one active site moves to become a substrate at another active site without ever leaving the enzyme. A channel connects the active sites. Substrate channeling greatly enhances enzyme efficiency and minimizes the diffusion of a substrate to an active site.
8.  $\text{Glucose} + 2 \text{ATP} + 2 \text{NADP}^+ + \text{H}_2\text{O} \rightarrow \text{PRPP} + \text{CO}_2 + \text{ADP} + \text{AMP} + 2 \text{NADPH} + 3 \text{H}^+$ .
9.  $\text{Glutamine} + \text{aspartate} + \text{CO}_2 + 2 \text{ATP} + \text{NAD}^+ \rightarrow \text{orotate} + 2 \text{ADP} + 2 \text{P}_i + \text{glutamate} + \text{NADH} + \text{H}^+$ .
10. (a, c, and d) PRPP; (b) carbamoyl phosphate.
11. PRPP and formylglycinamide ribonucleotide
12.  $\text{dUMP} + \text{serine} + \text{NADPH} + \text{H}^+ \rightarrow \text{TMP} + \text{NADP}^+ + \text{glycine}$ .
13. There is a deficiency of  $N^{10}$ -formyltetrahydrofolate. Sulfanilamide inhibits the synthesis of folate by acting as an analog of *p*-aminobenzoate, one of the precursors of folate.
14. (a) Cell A cannot grow in a HAT medium, because it cannot synthesize TMP either from thymidine or from dUMP. Cell B cannot grow in this medium, because it cannot synthesize purines by either the de novo pathway or the salvage pathway. Cell C can grow in a HAT medium because it contains active thymidine

- kinase from cell B (enabling it to phosphorylate thymidine to TMP) and hypoxanthine guanine phosphoribosyltransferase from cell A (enabling it to synthesize purines from hypoxanthine by the salvage pathway).
- (b) Transform cell A with a plasmid containing foreign genes of interest and a functional thymidine kinase gene. The only cells that will grow in a HAT medium are those that have acquired a thymidylate kinase gene; nearly all of these transformed cells will also contain the other genes on the plasmid.
15. The folate derivative  $N^5, N^{10}$ -methylene tetrahydrofolate is required by thymidylate synthase to add a methyl group to dUMP, forming TMP. Insufficient folate could result in spina bifida.
16. The reciprocal substrate relation refers to the fact that AMP synthesis requires GTP, whereas GMP synthesis requires ATP. These requirements tend to balance the synthesis of ATP and GTP.
17. Ring carbon 6 in cytosine will be labeled. In guanine, only carbon 5 will be labeled with  $^{13}\text{C}$ .
18. UTP is first converted into UDP. Ribonucleotide reductase generates dUDP. DeoxyUDP is converted to dUMP. Thymidylate synthase generates TMP from dUMP. Monophosphate and diphosphate kinases subsequently form TTP.
19. These patients have a high level of urate because of the breakdown of nucleic acids. Allopurinol prevents the formation of kidney stones and blocks other deleterious consequences of hyperuricemia by preventing the formation of urate.
20. The free energies of binding are  $-57.7$  (wild type),  $-49.8$  (Asn 27), and  $-38.1$  (Ser 27)  $\text{kJ mol}^{-1}$  ( $-13.8$ ,  $-11.9$ , and  $-9.1$   $\text{kcal mol}^{-1}$ , respectively). The loss in binding energy is  $+7.9$   $\text{kJ mol}^{-1}$  ( $+1.9$   $\text{kcal mol}^{-1}$ ) and  $+19.7$   $\text{kJ mol}^{-1}$  ( $+4.7$   $\text{kcal mol}^{-1}$ ).
21. By their nature, cancer cells divide rapidly and thus require frequent DNA synthesis. Inhibitors of TMP synthesis will impair DNA synthesis and cancer growth.
22. Uridine and cytidine are administered to by-pass the defective enzyme in orotic aciduria.
23. Inosine or hypoxanthine could be administered.
24. N-1 in both cases, and the amine group linked to C-6 in ATP.
25. Nitrogen atoms 3 and 9 in the purine ring
26. Allopurinol, an analog of hypoxanthine, is a suicide inhibitor of xanthine oxidase.
27. An oxygen atom is added to allopurinol to form alloxanthine.

**Alloxanthine**

28.

The synthesis of carbamoyl phosphate requires 2 ATP	2 ATP
The formation of PRPP from ribose 5-phosphate yields an AMP*	2 ATP
The conversion of UMP to UTP requires 2 ATP	2 ATP
The conversion of UTP to CTP requires 1 ATP	1 ATP
Total	7 ATP

\*Remember that AMP is the equivalent of 2 ATP because an ATP must be expended to generate ADP, the substrate for ATP synthesis.

29. (a) Carboxyaminoimidazole ribonucleotide; (b) glycinamide ribonucleotide; (c) phosphoribosyl amine; (d) formylglycinamide ribonucleotide.

30. The first reaction proceeds by phosphorylation of glycine to form an acyl phosphate followed by nucleophilic attack by the amine of phosphoribosylamine to displace orthophosphate. The second reaction consists of adenylation of the carbonyl group of xanthylate followed by nucleophilic attack by ammonia to displace AMP.

31. The  $\text{-NH}_2$  group attacks the carbonyl carbon atom to form a tetrahedral intermediate. Removal of a proton leads to the elimination of water to form inosinate.

32. The enzyme that uses ammonia, carbamoyl phosphate synthetase I, forms carbamoyl phosphate for a reaction with ornithine, the first step of the urea cycle. The enzyme that uses glutamine, carbamoyl phosphate synthetase II, generates carbamoyl phosphate for use in the first step of pyrimidine biosynthesis.

33. PRPP is the activated intermediate in the synthesis of phosphoribosylamine in the de novo pathway of purine formation; of purine nucleotides from free bases by the salvage pathway; of orotidylate in the formation of pyrimidines; of nicotinate ribonucleotide; of phosphoribosyl ATP in the pathway leading to histidine; and of phosphoribosylanthranilate in the pathway leading to tryptophan.

34. (a) cAMP; (b) ATP; (c) UDP-glucose; (d) acetyl CoA; (e)  $\text{NAD}^+$ , FAD; (f) dideoxynucleotides; (g) fluorouracil; (h) CTP inhibits ATCase.

35. In vitamin  $\text{B}_{12}$  deficiency, methyltetrahydrofolate cannot donate its methyl group to homocysteine to regenerate methionine. Because the synthesis of methyltetrahydrofolate is irreversible, the cell's tetrahydrofolate will ultimately be converted into this form. No formyl or methylene tetrahydrofolate will be left for nucleotide synthesis. Vitamin  $\text{B}_{12}$  is also required to metabolize propionyl CoA generated in the oxidation of odd-chain fatty acids and in the degradation of methionine.

36. Because folate is required for nucleotide synthesis, cells that are dividing rapidly would be most readily affected. They would include cells of the intestine, which are constantly replaced, and precursors to blood cells. A lack of intestinal cells and blood cells would account for the symptoms often observed.

37. In patients with glucose 6-phosphatase deficiency, the cytoplasmic level of ATP in the liver falls as a result of increased glycogenolysis. In all three conditions, AMP rises above normal, and the excess AMP is degraded to urate.

38. Succinate  $\rightarrow$  malate  $\rightarrow$  oxaloacetate by the citric acid cycle. Oxaloacetate  $\rightarrow$  aspartate by transamination, followed by pyrimidine synthesis. Carbons 4, 5, and 6 are labeled.

39. Glucose will most likely be converted into two molecules of pyruvate, one of which will be labeled in the 2 position:

Now consider two common fates of pyruvate—conversion into acetyl CoA and subsequent processing by the citric acid cycle or carboxylation by pyruvate carboxylase to form oxaloacetate. Formation of citrate by condensing the labeled pyruvate with oxaloacetate will yield labeled citrate:

The labeled carbon will be retained through one round of the citric acid cycle but, on the formation of the symmetric succinate, the label will appear in two different positions. Thus, when succinate is metabolized to oxaloacetate, which may be aminated to form aspartate, two carbons will be labeled:

When this aspartate is used to form uracil, the labeled  $\text{COO}^-$  attached to the  $\alpha$ -carbon is lost and the other  $\text{COO}^-$  becomes incorporated into uracil as carbon 4.

Suppose, instead, that labeled 2- $^{14}\text{C}$ pyruvate is carboxylated to form oxaloacetate and processed to form aspartate. In this case, the  $\alpha$ -carbon of aspartate bears the label.

When this aspartate is used to synthesize uracil, carbon 6 bears the label:

40. HGPRT, which is nonfunctional in Lesch–Nyhan patients, is required to form 6-mercaptopurine ribose monophosphate. Consequently, de novo purine synthesis continues.

41. (a) Some ATP can be salvaged from the ADP that is being generated. (b) There are equal numbers of high-phosphoryl-transfer-potential groups on each side of the equation. (c) Because the adenylate kinase reaction is at equilibrium, the removal of AMP would lead to the formation of more ATP. (d) Essentially, the cycle serves as an anaplerotic reaction for the generation of the citric acid cycle intermediate fumarate.

42. (i) The formation of 5-aminoimidazole-4-(*N*-succinylcarboxamide) ribonucleotide from 5-aminoimidazole-4-(*N*-succinylcarboxamide) ribonucleotide in the synthesis of IMP. (ii) The formation of AMP from adenylosuccinate. (iii) The formation of arginine from argininosuccinate in the urea cycle.

43. Allopurinol is an inhibitor of xanthine oxidase, which is on the pathway for urate synthesis. In your pet duck, this pathway is the

means by which excess nitrogen is excreted. If xanthine oxidase were inhibited in your duck, nitrogen could not be excreted, with severe consequences such as the formation of a dead duck.

44. (a) The enzyme from the LND 2 patient showed much less activity than the normal enzyme, suggesting that the defect in the enzyme impaired its catalytic ability. The results for LND 1 are puzzling. The enzyme displays activity similar to the enzyme from the normal cell line, and yet the patient was suffering from Lesch-Nyhan disease.

(b) Possible explanations include: there may be an inhibitor in the cells that prevents the enzyme from acting *in vivo* but is lost during the purification procedure; the enzyme may be degraded more rapidly *in vivo* than the normal enzyme; the enzyme may be inherently less stable than the normal enzyme.

(c) The enzyme from LND 1 lost activity much faster than the normal enzyme, suggesting that the enzyme was structurally unstable and would lose enzyme activity in the cell, accounting for the appearance of the disease.

### Chapter 26

1. Glycerol 3-phosphate is the foundation for both triacylglycerol and phospholipid synthesis. Glycerol 3-phosphate is acylated twice to form phosphatidate. In triacylglycerol synthesis, the phosphoryl group is removed from glycerol 3-phosphate to form diacylglycerol, which is then acylated to form triacylglycerol. In phospholipid synthesis, phosphatidate commonly reacts with CTP to form CDP-diacylglycerol, which then reacts with an alcohol to form a phospholipid. Alternatively, diacylglycerol may react with a CDP-alcohol to form a phospholipid.

2. Glycerol 3-phosphate is formed primarily by the reduction of dihydroxyacetone phosphate, a gluconeogenic intermediate, and to a lesser extent by the phosphorylation of glycerol.

3.  $\text{Glycerol} + 4 \text{ ATP} + 3 \text{ fatty acids} + 4 \text{ H}_2\text{O} \longrightarrow \text{triacylglycerol} + \text{ADP} + 3 \text{ AMP} + 7 \text{ P}_i + 4 \text{ H}^+$

4.  $\text{Glycerol} + 3 \text{ ATP} + 2 \text{ fatty acids} + 2 \text{ H}_2\text{O} + \text{CTP} + \text{ethanolamine} \longrightarrow \text{phosphatidylethanolamine} + \text{CMP} + \text{ADP} + 2 \text{ AMP} + 6 \text{ P}_i + 3 \text{ H}^+$

5. Three. One molecule of ATP to form phosphorylethanolamine and two molecules of ATP to regenerate CTP from CMP.

6. All are synthesized from ceramide. In sphingomyelin, the terminal hydroxyl group of ceramide is modified with phosphorylcholine. In a cerebroside, the hydroxyl group has a glucose or galactose attached. In a ganglioside, oligosaccharide chains are attached to the hydroxyl group.

7. (i) Activate the diacylglycerol as CDP-DAG. (ii) Activate the alcohol as CDP-alcohol. (iii) Use the base-exchange reaction.

8. (a) CDP-diacylglycerol; (b) CDP-ethanolamine; (c) acyl CoA; (d) phosphatidylcholine; (e) UDP-glucose or UDP-galactose; (f) UDP-galactose; (g) geranyl pyrophosphate.

9. Such mutations are seen in mice. The amount of adipose tissue would decrease severely because diacylglycerol could not be formed. Normally, diacylglycerol is acylated to form triacylglycerols. If there were deficient phosphatidic acid phosphatase activity, no triacylglycerols would form.

10. (a) 8; (b) 4; (c) 1; (d) 9; (e) 3; (f) 10; (g) 5; (h) 2; (i) 6; (j) 7.

11. (i) The synthesis of activated isoprene units (isopentyl pyrophosphate), (ii) the condensation of six of the activated isoprene units to form squalene, and (iii) cyclization of the squalene to form cholesterol.

12. The amount of reductase and its activity control the regulation of cholesterol biosynthesis. Transcriptional control is mediated by SREBP. Translation of the reductase mRNA also is controlled. The reductase itself may undergo regulated proteolysis. Finally,

the activity of the reductase is inhibited by phosphorylation by AMP kinase when ATP levels are low.

13. (a and b) None, because the label is lost as  $\text{CO}_2$ .

14. The hallmark of this genetic disease is elevated cholesterol levels in the blood of even young children. The excess cholesterol is taken up by macrophages, which eventually results in the formation of plaques and heart disease. There are many mutations that cause the disease, but all result in malfunctioning of the LDL receptor.

15. The categories of mutations are: (i) no receptor is synthesized; (ii) receptors are synthesized but do not reach the plasma membrane, because they lack signals for intracellular transport or do not fold properly; (iii) receptors reach the cell surface, but they fail to bind LDL normally because of a defect in the LDL-binding domain; (iv) receptors reach the cell surface and bind LDL, but they fail to cluster in coated pits because of a defect in their carboxyl-terminal regions.

16. "None of your business" and "I don't talk biochemistry until after breakfast" are appropriate but rude and uninformative answers. A better answer might be: "Although it is true that cholesterol is a precursor to steroid hormones, the rest of the statement is oversimplified. Cholesterol is a component of membranes, and membranes literally define cells, and cells make up tissues. But to say that cholesterol 'makes' cells and tissues is wrong."

17. Statins are competitive inhibitors of HMG-CoA reductase. They are used as drugs to inhibit cholesterol synthesis in patients with high levels of cholesterol.

18. No. Cholesterol is essential for membrane function and as a precursor for bile salts and steroid hormones. The complete lack of cholesterol would be lethal.

19. Deamination of cytidine to uridine changes CAA (Gln) into UAA (stop).

20. The LDL contains apolipoprotein B-100, which binds to an LDL receptor on the cell surface in a region known as a coated pit. On binding, the complex is internalized by endocytosis to form an internal vesicle. The vesicle is separated into two components. One, with the receptor, is transported back to the cell surface and fuses with the membrane, allowing continued use of the receptor. The other vesicle fuses with lysosomes inside the cell. The cholesterol esters are hydrolyzed, and free cholesterol is made available for cellular use. The LDL protein is hydrolyzed to free amino acids.

21. Benign prostatic hypertrophy can be treated by inhibiting  $5\alpha$ -reductase. Finasteride, the 4-azasteroid analog of dihydrotestosterone, competitively inhibits the reductase but does not act on androgen receptors. Patients taking finasteride have a markedly lower plasma level of dihydrotestosterone and a nearly normal level of testosterone. The prostate gland becomes smaller, whereas testosterone-dependent processes such as fertility, libido, and muscle strength appear to be unaffected.

**Finasteride**

22. Patients who are most sensitive to debrisoquine have a deficiency of a liver P450 enzyme encoded by a member of the CYP2 subfamily. This characteristic is inherited as an autosomal recessive

trait. The capacity to degrade other drugs may be impaired in people who hydroxylate debrisoquine at a slow rate, because a single P450 enzyme usually handles a broad range of substrates.

23. Many hydrophobic odorants are deactivated by hydroxylation. Molecular oxygen is activated by a cytochrome P450 monooxygenase. NADPH serves as the reductant. One oxygen atom of O<sub>2</sub> goes into the odorant substrate, whereas the other is reduced to water.

24. Recall that dihydrotestosterone is crucial for the development of male characteristics in the embryo. If a pregnant woman were to be exposed to Propecia, the 5 $\alpha$ -reductase of the male embryo would be inhibited, which could result in severe developmental abnormalities.

25. The oxygenation reactions catalyzed by the cytochrome P450 family permit greater flexibility in biosynthesis. Because plants are not mobile, they must rely on physical defenses, such as thorns, and chemical defenses, such as toxic alkaloids. The larger P450 array might permit greater biosynthetic versatility.

26. This knowledge might enable clinicians to characterize the likelihood of a patient's having an adverse drug reaction or being susceptible to chemical-induced illnesses. It might also permit a personalized and especially effective drug-treatment regime for diseases such as cancer.

27. The honeybees may be especially sensitive to environmental toxins, including pesticides, because these chemicals are not readily detoxified, owing to the minimal P450 system.

28. A deficiency of the hydroxylase will cause a build-up of progesterone, which will then be converted into estradiol and testosterone.

29. The core structure of a steroid is four fused rings: three cyclohexane rings and one cyclopentane ring. In vitamin D, the B ring is split by ultraviolet light.

30. The negatively charged phosphoserine residue interacts with the positively charged protonated histidine residue and decreases its ability to transfer a proton to the thiolate.

31. The methyl group is first hydroxylated. The hydroxymethylamine eliminates formaldehyde to form methylamine.

32. Note that a cytidine nucleotide plays the same role in the synthesis of these phosphoglycerides as a uridine nucleotide does in the formation of glycogen (Section 21.4). In all of these biosyntheses, an activated intermediate (UDP-glucose, CDP-diacylglycerol, or CDP-alcohol) is formed from a phosphorylated substrate (glucose 1-phosphate, phosphatidate, or a phosphoryl alcohol) and a nucleoside triphosphate (UTP or CTP). The activated intermediate then reacts with a hydroxyl group (the terminus of glycogen, the side chain of serine, or a diacylglycerol).

33. The attachment of isoprenoid side chains confers hydrophobic character. Proteins having such a modification are targeted to membranes.

34. 3-Hydroxy-3-methylglutaryl CoA is also a precursor for ketone-body synthesis. If fuel is needed elsewhere in the body, as might be the case during a fast, 3-hydroxy-3-methylglutaryl CoA is converted into the ketone body acetoacetate. If energy needs are met, the liver will synthesize cholesterol. Remember also that cholesterol synthesis occurs in the cytoplasm while ketone bodies are synthesized in the mitochondria.

35. One way in which phosphatidylcholine can be synthesized is by the addition of three methyl groups to phosphatidylethanolamine. The methyl donor is a modified form of methionine, S-adenosylmethionine or SAM (Section 24.2).

36. Mutations could occur in the gene encoding the sodium channel that would prevent the action of DDT. Alternatively, P450 enzyme synthesis could be increased to accelerate metabolism of the insecticide to inactive metabolites. In fact, both types of responses to insecticides have been observed.

37. Citrate is transported out of the mitochondria in times of plenty. ATP-citrate lyase yields acetyl CoA and oxaloacetate. The acetyl CoA can then be used to synthesize cholesterol.

38. (a) There is no effect. (b) Because actin is not controlled by cholesterol, the amount isolated should be the same in both experimental groups; a difference would suggest a problem in the RNA isolation. (c) The presence of cholesterol in the diet dramatically reduces the amount of HMG-CoA reductase protein. (d) A common means of regulating the amount of a protein present is to regulate transcription, which is clearly not the case here. (e) The translation of mRNA could be inhibited, and the protein could be rapidly degraded.

39. (a) The activity of the enzyme from the GD patient is the same as that from the control. This suggests that GD is not caused by a mutation that impairs enzyme activity.

(b) There is much less GCCase in the GD sample. Because the same number of cells were used in the two samples (confirmed by the identical levels of actin in both samples), we know that the difference in amount of GCCase is not due to different quantities of cells. Two possible explanations are that transcription is impaired in the GD sample or that the enzyme in GD is more readily destroyed than the control.

(c) Apparently, the enzyme is being synthesized but then degraded. (d) The defect in the enzyme from the GD patient seems to result in more rapid degradation of the enzyme by the proteasome. The fact that the amount of GCCase present in the control increased upon proteasomal inhibition suggests that GCCase may undergo rapid turnover under normal conditions.

## Chapter 27

1. Over the 40 years under consideration, our test subject will have consumed

$$40 \text{ years} \times 365 \text{ days year}^{-1} \times 8400 \text{ kJ (2000 kcal) day}^{-1} \\ = 1.2 \times 10^8 \text{ kJ (} 2.9 \times 10^7 \text{ kcal) in 40 years}$$

Thus, over the 40-year span, our subject has ingested

$$1.2 \times 10^8 (2.9 \times 10^7 \text{ kcal}) / 38 \text{ kJ (9 kcal g}^{-1}\text{)} \\ = 3.2 \times 10^6 \text{ g} = 3200 \text{ kg of food}$$

which is equivalent to more than 6 tons of food!

2. 55 pounds = 25 kg = 25,000 g = total weight gain

$$40 \text{ years} \times 365 \text{ days year}^{-1} = 14,600 \text{ days} \\ 25,000 \text{ g} / 14,600 \text{ days} = 1.7 \text{ g day}^{-1}$$

which is equivalent to an extra pat of butter per day. Her BMI is 26.5, and she would be considered overweight but not obese.

3. Adipose tissue is now known to be an active endocrine organ, secreting signal molecules called adipokines.

4. Caloric homeostasis is the condition in which the energy expenditure of an organism is equal to the energy intake.

5. Leptin and insulin.

6. CCK produces a feeling of satiety and stimulates the secretion of digestive enzymes by the pancreas and the secretion of bile salts

by the gall bladder. GLP-1 also produces a feeling of satiety; in addition, it potentiates the glucose-induced secretion of insulin by the  $\beta$  cells of the pancreas.

7. Obviously, something is amiss. Although the answer is not known, the leptin-signaling pathway appears to be inhibited by suppressors of cytokine signaling, the regulatory proteins.

8. 1: a, b; 2: f; 3: c, d, f; 4: c, d; 5: c; 6: f; 7: e; 8: e; 9: e.

9. Phosphorylation of dietary glucose after it enters the liver; gluconeogenesis; glycogen breakdown.

10. Type 1 diabetes is due to autoimmune destruction of the insulin-producing cells of the pancreas. Type 1 diabetes is also called insulin-dependent diabetes because affected people require insulin to survive. Type 2 diabetes is characterized by insulin resistance. Insulin is produced, but the tissues that should respond to insulin, such as muscle, do not.

11. Leptin stimulates processes impaired in diabetes. For instance, leptin stimulates fatty acid oxidation, inhibits triacylglycerol synthesis, and increases the sensitivity of muscle and the liver to insulin.

12. (a) A watt is equal to 1 joule (J) per second (0.239 calorie per second). Hence, 70 W is equivalent to  $0.07 \text{ kJ s}^{-1}$  ( $0.017 \text{ kcal s}^{-1}$ ).

(b) A watt is a current of 1 ampere (A) across a potential of 1 volt (V). For simplicity, let us assume that all the electron flow is from NADH to  $\text{O}_2$  (a potential drop of 1.14 V). Hence, the current is 61.4 A, which corresponds to  $3.86 \times 10^{20}$  electrons per second ( $1 \text{ A} = 1 \text{ coulomb s}^{-1} = 6.28 \times 10^{18} \text{ charge s}^{-1}$ ).

(c) About 2.5 molecules of ATP are formed per molecule of NADH oxidized (two electrons). Hence, 1 molecule of ATP is formed per 0.8 electron transferred. A flow of  $3.86 \times 10^{20}$  electrons per second therefore leads to the generation of  $4.83 \times 10^{20}$  molecules of ATP per second, or  $0.80 \text{ mmol s}^{-1}$ .

(d) The molecular weight of ATP is 507. The total body content of ATP of 50 g is equal to 0.099 mol. Hence, ATP turns over about once in 125 seconds when the body is at rest.

13. (a) The stoichiometry of the complete oxidation of glucose is

$$\text{C}_6\text{H}_{12}\text{O}_6 + 6 \text{O}_2 \longrightarrow 6 \text{CO}_2 + 6 \text{H}_2\text{O}$$

and that of tripalmitoylglycerol is

Hence, the RQ values are 1.0 and 0.703, respectively.

(b) An RQ value reveals the relative use of carbohydrates and fats as fuels. The RQ of a marathon runner typically decreases from 0.97 to 0.77 in the course of a race. The lowering of the RQ indicates the shift in fuel from carbohydrates to fat.

14. One gram of glucose (molecular weight 180.2) is equal to 5.55 mmol, and one gram of tripalmitoylglycerol (molecular weight 807.3) is equal to 1.24 mmol. The reaction stoichiometries (Problem 13) indicate that 6 mol of  $\text{H}_2\text{O}$  is produced per mole of glucose oxidized, and 49 mol of  $\text{H}_2\text{O}$  is produced per mole of tripalmitoylglycerol oxidized. Hence, the  $\text{H}_2\text{O}$  yields per gram of fuel are 33.3 mmol (0.6 g) for glucose and 60.8 mmol (1.09 g) for tripalmitoylglycerol. Thus, complete oxidation of this fat gives 1.82 times as much water as does glucose. Another advantage of triacylglycerols is that they can be stored in essentially anhydrous form, whereas glucose is stored as glycogen, a highly hydrated polymer. A hump consisting mainly of glycogen would be an intolerable burden—far more than the straw that broke the camel's back.

15. The starved–fed cycle is the nightly hormonal cycle that humans experience during sleep and on eating. The cycle maintains adequate amounts of blood glucose. The starved part—sleep—is characterized by increased glucagon secretion and decreased insulin secretion. After a meal, glucagon concentration falls and insulin concentration rises.

16. Ethanol is oxidized to yield acetaldehyde by alcohol dehydrogenase, which is subsequently oxidized to acetate and acetaldehyde. Ethanol is also metabolized to acetaldehyde by the P450 enzymes, with the subsequent depletion of NADPH.

17. First, fatty liver develops owing to the increased amounts of NADH that inhibit fatty acid oxidation and stimulate fatty acid synthesis. Second, alcoholic hepatitis begins owing to oxidative damage and damage due to excess acetaldehyde that results in cell death. Finally, fibrous tissues form, creating scars that impair blood flow and biochemical function. Ammonia cannot be converted into urea, and its toxicity leads to coma and death.

18. A typical macadamia nut has a mass of about 2 g. Because it consists mainly of fats ( $\sim 37 \text{ kJ g}^{-1}$ ,  $\sim 9 \text{ kcal g}^{-1}$ ), a nut has a value of about 75 kJ (18 kcal). The ingestion of 10 nuts results in an intake of about 753 kJ (180 kcal). As stated in the answer to Problem 12, a power consumption of 1 W corresponds to  $1 \text{ J s}^{-1}$  ( $0.239 \text{ cal s}^{-1}$ ), and so 400-W running requires  $0.4 \text{ kJ s}^{-1}$  ( $0.0956 \text{ kcal s}^{-1}$ ). Hence, a person would have to run 1882 s, or about 31 minutes, to spend the calories provided by 10 nuts.

19. A high blood-glucose level triggers the secretion of insulin, which stimulates the synthesis of glycogen and triacylglycerols. A high insulin level would impede the mobilization of fuel reserves during the marathon.

20. A lack of adipose tissue leads to an accumulation of fats in the muscle, with the generation of insulin resistance. The experiment shows that adipokines secreted by the adipose tissue, here leptin, facilitate in some fashion the action of insulin in muscle.

21. Such a mutation would increase the phosphorylation of the insulin receptor and IRS in muscle and would improve insulin sensitivity. Indeed, PTP1B is an attractive therapeutic target for type 2 diabetes.

22. Lipid mobilization can be so rapid that it exceeds the ability of the liver to oxidize the lipids or convert them into ketone bodies. The excess is reesterified and released into the blood as VLDLs.

23. A role of the liver is to provide glucose for other tissues. In the liver, glycolysis is used not for energy production but for biosynthetic purposes. Consequently, in the presence of glucagon, liver glycolysis stops so that the glucose can be released into the blood.

24. The urea cycle and gluconeogenesis.

25. (a) Insulin inhibits lipid utilization.

(b) Insulin stimulates protein synthesis, but there are no amino acids in the children's diet. Moreover, insulin inhibits protein breakdown. Consequently, muscle proteins cannot be broken down and used for the synthesis of essential proteins.

(c) Because proteins cannot be synthesized, blood osmolarity is too low. Consequently, fluid leaves the blood. An especially important protein for maintaining blood osmolarity is albumin.

26. During strenuous exercise, muscle converts glucose into pyruvate through glycolysis. Some of the pyruvate is processed by cellular respiration. However, some of it is converted into lactate and released into the blood. The liver takes up the lactate and converts it into glucose through gluconeogenesis. Muscle may process the carbon skeletons of branched-chain amino acids aerobically. The nitrogens of these amino acids are transferred to pyruvate to form alanine, which is released into the blood and taken up by the liver. After the transamination of the amino group to  $\alpha$ -ketoglutarate, the resulting pyruvate is converted into glucose. Finally, muscle glycogen may be mobilized, and the released glucose can be used by muscle.

27. This conversion allows muscle to function anaerobically.  $\text{NAD}^+$  is regenerated when pyruvate is reduced to lactate, and so energy can continue to be extracted from glucose during strenuous exercise. The liver converts the lactate into glucose.

28. Fatty acids and glucose, respectively.
29. This practice is called carbo-loading. Depleting the glycogen stores will initially cause the muscles to synthesize a large amount of glycogen when dietary carbohydrates are provided and will lead to the supercompensation of glycogen stores.
30. The oxygen consumption at the end of exercise is used to replenish ATP and creatine phosphate and to oxidize any lactate produced.
31. Oxygen is used in oxidative phosphorylation to resynthesize ATP and creatine phosphate. The liver converts lactate released by the muscle into glucose. Blood must be circulated to return the body temperature to normal, and so the heart cannot return to its resting rate immediately. Hemoglobin must be reoxygenated to replace the oxygen used in exercise. The muscles that power breathing must continue working at the same time as the exercised muscles are returning to resting states. In essence, all the biochemical systems activated in intense exercise need increased oxygen to return to the resting state.
32. Ethanol may replace water that is hydrogen bonded to proteins and membrane surfaces. This alteration of the hydration state of the protein would alter its conformation and hence function. Ethanol may also alter phospholipid packing in membranes. The two effects suggest that integral membrane proteins would be most sensitive to ethanol, as indeed seems to be the case.
33. Cells from the type I fiber would be rich in mitochondria, whereas those of the type II fiber would have few mitochondria.
34. (a) The ATP expended during this race amounts to about 8380 kg, or 18,400 pounds. (b) The cyclist would need about \$1,260,000,000 to complete the race.
35. Exercise greatly enhances the ATP needs of muscle cells. To more efficiently meet these needs, more mitochondria are synthesized.
36. AMPK activity increases as ATP is used for muscle contraction. AMPK inactivates acetyl CoA carboxylase. Recall that malonyl CoA, the product of acetyl CoA carboxylase, inhibits transport of fatty acids into the mitochondria. The decrease in muscle malonyl CoA allows fatty acid oxidation in muscle.
37. After the first several days of starvation, most tissues are using fatty acids. Ketone bodies provide much of the brain's energy, decreasing glucose requirement. The low insulin/high glucagon ration stimulates lipolysis and gluconeogenesis. However, gluconeogenesis will not occur because the increase in fatty acid oxidation increases acetyl CoA and NADH. The high concentration of NADH inhibits the TCA cycle as well as gluconeogenesis. The acetyl CoA forms ketone bodies.
38. (a) The increase in all of the ratios is due to the NADH glut caused by the metabolism of alcohol.
- (b) The increased amounts of lactate and D-3-hydroxybutyrate are released into the blood, accounting for the acidosis.
- (c) Drinking on an empty stomach suggests that glycogen stores are low. Because of the NADH glut, gluconeogenesis cannot occur. Consequently, hypoglycemia results. A well-fed drinker will have glucose in the blood from the meal and thus will not experience hypoglycemia.
39. If glucose is always provided, even in small amounts, the brain will use glucose as a fuel rather than adapting to ketone body use. During the fast, muscle protein will be broken down to meet the brain's glucose needs. This protein degradation will lead to organ failure sooner than if the brain had adapted to ketone body utilization.
40. The inability of muscle mitochondria to process all of the fatty acids produced by overnutrition leads to excessive levels of diacylglycerol and ceramide in the muscle cytoplasm. These

second-messenger molecules activate enzymes that impair insulin signaling.

41. Both are due to a lack of thiamine (vitamin B<sub>1</sub>). Thiamine, which is sometimes called aneurin, is required most notably for the proper functioning of pyruvate dehydrogenase.

42. (a) Red blood cells always produce lactate, and fast-twitch or type II, muscle fibers (Problem 33) also produce a large amount of lactate.

(b) At that point, the athlete is beginning to move into anaerobic exercise, in which most energy is produced by anaerobic glycolysis.

(c) The lactate threshold is essentially the point at which the athlete switches from aerobic exercise, which can be done for extended periods, to anaerobic exercise, essentially sprinting, which can be done for only short periods. The idea is to race at the extreme of his or her aerobic capacity until the finish line is in sight and then to switch to anaerobic.

(d) Training increases the amount of blood vessels and the number of muscle mitochondria. Together, they increase the ability to process glucose aerobically. Consequently, a greater effort can be expended before the switch to anaerobic energy production.

43. Consider the graph of lactate production as a function of effort shown in Problem 42. For an athlete racing at her lactate threshold or just below it, the RQ value will be 1. With the finish line in sight, our runner ups her pace so that she is now also processing glucose to lactic acid in addition to processing glucose aerobically; that is, she begins running above her lactate threshold. The lactic acid released into the blood will ionize

The increase in H<sup>+</sup> will alter the blood buffer system, leading to the formation of carbonic acid

The carbonic acid will dissociate into water and carbon dioxide

This carbon dioxide will be superimposed on the carbon dioxide generated by the combustion of glucose aerobically, leading to an RQ greater than 1.

44. The increase in ATP resulting from the processing of glucose in the β cells closes a potassium channel. The closing of the potassium channel alters the voltage across the cell membrane, which leads to an opening of a calcium channel. The influx of calcium causes the insulin-containing secretory granules to fuse with the cell membrane, resulting in the release of insulin.

### Chapter 28

- DNA polymerase I uses deoxyribonucleoside triphosphates; pyrophosphate is the leaving group. DNA ligase uses DNA-adenylate (AMP joined to the 5'-phosphoryl group) as a reaction partner; AMP is the leaving group. Topoisomerase I uses a DNA-tyrosyl intermediate (5'-phosphoryl group linked to the phenolic OH group); the tyrosine residue of the enzyme is the leaving group.
- Positive supercoiling resists the unwinding of DNA. The melting temperature of DNA increases in proceeding from negatively supercoiled to relaxed to positively supercoiled DNA. Positive supercoiling is probably an adaptation to high temperature.
- The nucleotides used for DNA synthesis have the triphosphate attached to the 5'-hydroxyl group with free 3'-hydroxyl groups. Such nucleotides can be utilized only for 5'-to-3' DNA synthesis.

15. (a) Because cordycepin lacks a 3'-OH group, it cannot participate in 3' → 5' bond formation. (b) Because the poly(A) tail is a long stretch of adenosine nucleotides, the likelihood that a molecule of cordycepin would become incorporated is higher than with most RNA. (c) Yes, it must be converted into cordycepin 5'-triphosphate.
16. There are  $2^8 = 256$  possible products.
17. The relationship between the -10 and -35 sequences could be affected by torsional strain. Since topoisomerase II introduces negative supercoils in DNA, this prevents this enzyme from overstimulating the expression of its own gene.
18. Ser-Ile-Phe-His-Pro-Stop
19. A mutation that disrupted the normal AAUAAA recognition sequence for the endonuclease could account for this finding. In fact, a change from U to C in this sequence caused this defect in a thalassemic patient. Cleavage occurred at the AAUAAA 900 nucleotides downstream from this mutant AACAAA site.
20. One possibility is that the 3' end of the poly(U) donor strand cleaves the phosphodiester bond on the 5' side of the insertion site. The newly formed 3' terminus of the acceptor strand then cleaves the poly(U) strand on the 5' side of the nucleotide that initiated the attack. In other words, a uridine residue could be added by two transesterification reactions. This postulated mechanism is similar to the one in RNA splicing.
21. Alternative splicing, RNA editing. Covalent modification of the proteins subsequent to synthesis.
22. Attach an oligo(dT) or oligo(U) sequence to an inert support to create an affinity column. When RNA is passed through the column, only poly(A)-containing RNA will be retained.
23. (a) Different amounts of RNA are present for the various genes. (b) Although all of the tissues have the same genes, the genes are expressed to different extents in different tissues. (c) These genes are called housekeeping genes—genes that most tissues express. They might include genes for glycolysis or citric acid cycle enzymes. (d) The point of the experiment is to determine which genes are initiated in vivo. The initiation inhibitor is added to prevent initiation at start sites that may have been activated during the isolation of the nuclei.
24. DNA is the single strand that forms the trunk of the tree. Strands of increasing length are RNA molecules; the beginning of transcription is where growing chains are the smallest; the end of transcription is where chain growth stops. Direction is left to right. Many enzymes are actively transcribing each gene.

### Chapter 30

1. The Oxford English Dictionary defines translation as the action or process of turning from one language into another. Protein synthesis converts nucleic acid sequence information into amino acid sequence information.
2. An error frequency of 1 incorrect amino acid every  $10^4$  incorporations allows for the rapid and accurate synthesis of proteins as large as 1000 amino acids. Higher error rates would result in too many defective proteins. Lower error rates would likely slow the rate of protein synthesis without a significant gain in accuracy.
3. (i) Each is a single chain. (ii) They contain unusual bases. (iii) Approximately half of the bases are base-paired to form double helices. (iv) The 5' end is phosphorylated and is usually pG. (v) The amino acid is attached to the hydroxyl group of the A residue of the CCA sequence at the 3' end of the tRNA. (vi) The anticodon is located in a loop near the center of the tRNA sequence. (vii) The molecules are L-shaped.
4. First is the formation of the aminoacyl adenylate, which then reacts with the tRNA to form the aminoacyl-tRNA. Both steps are catalyzed by aminoacyl-tRNA synthetase.
5. Unique features are required so that the aminoacyl-tRNA synthetases can distinguish among the tRNAs and attach the correct amino acid to the proper tRNA. Common features are required because all tRNAs must interact with the same protein-synthesizing machinery.
6. An activated amino acid is one linked to the appropriate tRNA.
7. (a) No; (b) no; (c) yes.
8. The ATP is cleaved to AMP and  $PP_i$ . Consequently, a second ATP is required to convert AMP into ADP, the substrate for oxidative phosphorylation.
9. Amino acids larger than the correct amino acid cannot fit into the active site of the tRNA. Smaller but incorrect amino acids that become attached to the tRNA fit into the editing site and are cleaved from the tRNA.
10. Recognition sites on both faces of the tRNAs may be required to uniquely identify the 20 different tRNAs.
11. The first two bases in a codon form Watson-Crick base pairs that are checked for fidelity by bases of the 16S rRNA. The third base is not inspected for accuracy, and so some variation is tolerated.
12. Four bands: light, heavy, a hybrid of light 30S and heavy 50S, and a hybrid of heavy 30S and light 50S.
13. Two hundred molecules of ATP are converted into 200 AMP + 400  $P_i$  to activate the 200 amino acids, which is equivalent to 400 molecules of ATP. One molecule of GTP is required for initiation, and 398 molecules of GTP are needed to form 199 peptide bonds.
14. The reading frame is a set of contiguous, nonoverlapping three-nucleotide codons that begins with a start codon and ends with a stop codon.
15. A mutation caused by the insertion of an extra base can be suppressed by a tRNA that contains a fourth base in its anticodon. For example, UUUC rather than UUU is read as the codon for phenylalanine by a tRNA that contains 3'-AAAG-5' as its anticodon.
16. One approach is to synthesize a tRNA that is acylated with a reactive amino acid analog. For example, bromoacetyl-phenylalanyl-tRNA is an affinity-labeling reagent for the P site of *E. coli* ribosomes.
17. The sequence GAGGU is complementary to a sequence of five bases at the 3' end of 16S rRNA and is located several bases upstream of an AUG start codon. Hence, this region is a start signal for protein synthesis. The replacement of G by A would be expected to weaken the interaction of this mRNA with the 16S rRNA and thereby diminish its effectiveness as an initiation signal. In fact, this mutation results in a 10-fold decrease in the rate of synthesis of the protein specified by this mRNA.
18. The peptide would be Phe-Cys-His-Val-Ala-Ala. The codons UGC and UGU encode cysteine but, because the cysteine was modified to alanine, alanine is incorporated in place of cysteine.
19. Proteins are synthesized from the amino to the carboxyl end on ribosomes, whereas they are synthesized in the reverse direction in the solid-phase method. The activated intermediate in ribosomal synthesis is an aminoacyl-tRNA; in the solid-phase method, it is the adduct of the amino acid and dicyclohexylcarbodiimide.
20. GTP is not hydrolyzed until aminoacyl-tRNA is delivered to the A site of the ribosome. An earlier hydrolysis of GTP would be wasteful because EF-Tu-GDP has little affinity for aminoacyl-tRNA.
21. The translation of an mRNA molecule can be blocked by antisense RNA, an RNA molecule with the complementary sequence. The antisense-sense RNA duplex cannot serve as a template for translation; single-stranded mRNA is required. Furthermore, the antisense-sense duplex is degraded by nucleases. Antisense RNA added to the external medium is spontaneously taken up by

many cells. A precise quantity can be delivered by microinjection. Alternatively, a plasmid encoding the antisense RNA can be introduced into target cells.

22. (a)  $A_5$ . (b)  $A_5 > A_4 > A_3 > A_2$ . (c) Synthesis is from the amino terminus to the carboxyl terminus.

23. These enzymes convert nucleic acid information into protein information by interpreting the tRNA and linking it to the proper amino acid.

24. The rate would fall because the elongation step requires that the GTP be hydrolyzed before any further elongation can take place.

25. Protein factors modulate the initiation of protein synthesis. The role of IF1 and IF3 is to prevent premature binding of the 30S and 50S ribosomal subunits, whereas IF2 delivers Met-tRNA<sub>f</sub> to the ribosome. Protein factors are also required for elongation (EF-G and EF-Tu), for termination (release factors, RFs), and for ribosome dissociation (ribosome release factors, RRFs).

26. The signal sequence, signal-recognition particle (SRP), the SRP receptor, and the translocon.

27. The formation of peptide bonds, which in turn are powered by the hydrolysis of the aminoacyl-tRNAs.

28. The Shine-Dalgarno sequence of the mRNA base-pairs with a part of the 16S rRNA of the 30S subunit, which positions the subunit so that the initiator AUG is recognized.

29.

	Bacteria	Eukaryote
Ribosome size	70S	80S
mRNA	Polycistronic	Not polycistronic
Initiation	Shine-Dalgarno is required	First AUG is used
Protein factors	Required	Many more required
Relation to transcription	Translation can start before transcription is completed	Transcription and translation are spatially separated
First amino acid	fMet	Met

30. The SRP binds to the signal sequence and inhibits further translation. The SRP ushers the inhibited ribosome to the ER, where it interacts with the SRP receptor (SR). The SRP-SR complex binds the translocon and simultaneously hydrolyzes GTP. On GTP hydrolysis, SRP and SR dissociate from each other and from the ribosome. Protein synthesis resumes and the nascent protein is channeled through the translocon.

31. The alternative would be to have a single ribosome translating a single mRNA molecule. The use of polysomes allows more protein synthesis per mRNA molecule in a given period of time and thus the production of more protein.

32. (a) 1, 2, 3, 5, 6, 10; (b) 1, 2, 7, 8; (c) 1, 4, 8, 9.

33. Transfer RNAs have roles in several recognition processes. A tRNA must be recognized by the appropriate aminoacyl-tRNA synthetase, and the tRNA must interact with the ribosome and, in particular, with the peptidyl transferase.

34. The aminoacyl-tRNA can be initially synthesized. However, the side-chain amino group attacks the ester linkage to form a six-membered amide, releasing the tRNA.

35. (a, d, and e) Type 2; (b, c, and f) Type 1.

36. The error rates of DNA, RNA, and protein synthesis are of the order of  $10^{-10}$ ,  $10^{-5}$ , and  $10^{-4}$ , respectively, per nucleotide (or amino acid) incorporated. The fidelity of all three processes depends on the precision of base-pairing to the DNA or mRNA template. Few errors are corrected in RNA synthesis. In contrast, the fidelity of DNA synthesis is markedly increased by the

$3' \rightarrow 5'$  proofreading nuclease activity and by postreplicative repair. In protein synthesis, the mischarging of some tRNAs is corrected by the hydrolytic action of aminoacyl-tRNA synthetase. Proofreading also takes place when aminoacyl-tRNA occupies the A site on the ribosome; the GTPase activity of EF-Tu sets the pace of this final stage of editing.

37. EF-Ts catalyzes the exchange of GTP for GDP bound to EF-Tu. In G-protein cascades, an activated 7TM receptor catalyzes GTP-GDP exchange in a G protein.

38. The  $\alpha$  subunits of G proteins are inhibited by a similar mechanism in cholera and whooping cough (Section 14.5).

39. Glu-tRNA<sup>Gln</sup> is formed by misacylation. The activated glutamate is subsequently amidated to form Gln-tRNA<sup>Gln</sup>. Ways in which glutamine is formed from glutamate were discussed in Section 24.2. In regard to *H. pylori*, a specific enzyme, Glu-tRNA<sup>Gln</sup> amidotransferase, catalyzes the following reaction:

Glu-tRNA<sup>Glu</sup> is not a substrate for the enzyme; so the transferase must also recognize aspects of the structure of tRNA<sup>Gln</sup>.

40. The primary structure determines the three-dimensional structure of the protein. Thus, the final phase of information transfer from DNA to RNA to protein synthesis is the folding of the protein into its functional state.

41. (a) eIF-4H has two effects: (1) the extent of unwinding is increased and (2) the rate of unwinding is increased, as indicated by the increased rise in activity at early reaction times.

(b) To firmly establish that the effect of eIF-4H was not due to any inherent helicase activity.

(c) Half-maximal activity was achieved at 0.11  $\mu\text{M}$  of eIF-4H.

Therefore, maximal stimulation would be achieved at a ratio of 1:1.

(d) eIF-4H enhances the rate of unwinding of all helices, but the effect is greater as the helices increase in stability.

(e) The results in graph C suggest that eIF-4H increases the processivity.

42. (a) The three peaks represent, from left to right, the 40S ribosomal subunit, the 60S ribosomal subunit, and the 80S ribosome.

(b) Not only are ribosomal subunits and the 80S ribosome present, but polysomes of various lengths also are apparent. The individual peaks in the polysome region represent polysomes of discrete length.

(c) The treatment significantly inhibited the number of polysomes while increasing the number of free ribosomal subunits. This outcome could be due to inhibited protein-synthesis initiation or inhibited transcription.

### Chapter 31

1. (a) Cells will express  $\beta$ -galactosidase, *lac* permease, and thiogalactoside transacetylase even in the absence of lactose. (b) Cells will express  $\beta$ -galactosidase, *lac* permease, and thiogalactoside transacetylase even in the absence of lactose. (c) The levels of catabolic enzymes such as  $\beta$ -galactosidase and arabinose isomerase will remain low even at low levels of glucose.

2. The concentration is  $1/(6 \times 10^{23})$  moles per  $10^{-15}$  liter =  $1.7 \times 10^{-9}$  M. Because  $K_d = 10^{-13}$  M, the single molecule should be bound to its specific binding site.

3. The number of possible 8-bp sites is  $4^8 = 65,536$ . In a genome of  $4.6 \times 10^6$  base pairs, the average site should appear  $4.6 \times 10^6/65,536 = 70$  times. Each 10-bp site should appear 4 times. Each 12-bp site should appear 0.27 times (many 12-bp sites will not appear at all).

4. The *lac* repressor does not bind DNA when the repressor is bound to a small molecule (the inducer), whereas the *pur* repressor binds

DNA only when the repressor is bound to a small molecule (the corepressor). The *E. coli* genome contains only a single *lac* repressor-binding region, whereas it has many sites for the *pur* repressor.

5. Anti-inducers bind to the conformation of repressors, such as the *lac* repressor, that are capable of binding DNA. They occupy a site that overlaps that for the inducer and, therefore, compete for binding to the repressor.

6. The inverted repeat may be a binding site for a dimeric DNA-binding protein or it may correspond to a stem-loop structure in the encoded RNA.

7. Bacteriophage  $\lambda$  would be more likely to enter the lytic phase because the cooperative binding of the  $\lambda$  repressor to  $O_R2$  and  $O_R1$ , which supports the lysogenic pathway, would be disrupted.

8.  $\lambda$  repressor gene  $-10$  region GATTTA  $-35$  region TAGATA  
Cro gene  $-10$  region TAATGG  $-35$  region TTGACT

There are four differences in the  $-10$  region and three differences in the  $-35$  region.

9. Increased Cro concentration reduces the expression of the  $\lambda$  repressor gene. Increased  $\lambda$  repressor concentration reduces the expression of the Cro gene. At low  $\lambda$  repressor concentrations, increased  $\lambda$  repressor concentration increases the expression of the  $\lambda$  repressor gene. At higher  $\lambda$  repressor concentrations, increased  $\lambda$  repressor concentration decreases the expression of the  $\lambda$  repressor gene.

10. Normally, bacterial mRNAs have a leader sequence in which a Shine–Dalgarno sequence precedes the AUG start codon. The absence of a leader would be expected to lead to inefficient translation.

11. Add each compound to a culture of *V. fischeri* at low density and look for the development of luminescence.

12. ACC, 7; ACA, 1; ACU, 0; ACG, 0.

13. Retention. The reaction likely proceeds in two steps: Attack of Glu 537 on the carbon of the galactose moiety (with inversion) followed by attack of water on this carbon (with a second inversion) to release the galactose from the enzyme.

14. The footprint appears to have approximately 50% of its intensity near 3.7 nM so that the dissociation constant is approximately 3.7 nM, corresponding to a standard free energy of binding of  $-48$  kJ/mol ( $-11$  kcal/mol) at  $T = 298$ K.

### Chapter 32

1. The distribution of charged amino acids is H2A (13 K, 13 R, 2 D, 7 E, charge = +17), H2B (20 K, 8 R, 3 D, 7 E, charge = +18), H3 (13 K, 18 R, 4 D, 7 E, charge = +20), H4 (11 K, 14 R, 3 D, 4 E, charge = +18). The total charge of the histone octamer is estimated to be  $2 \times (17 + 18 + 20 + 18) = +146$ . The total charge on 150 base pairs of DNA is  $-300$ . Thus, the histone octamer neutralizes approximately one-half of the charge.

2. The presence of a particular DNA fragment could be detected by hybridization, by PCR, or by direct sequencing.

3. The total length of the DNA is estimated to be  $145 \text{ bp} \times 3.4 \text{ \AA/bp} = 493 \text{ \AA}$ , which represents 1.75 turns or  $1.75 \times 2\pi r = 11.0r$ . Thus, the radius is estimated to be  $r = 493 \text{ \AA}/11.0 = 44.8 \text{ \AA}$ .

4. 5-Azacytidine cannot be methylated. Some genes, normally repressed by methylation, will be active. 5-Azacytidine is also an inhibitor of DNA methyltransferase, resulting in lower levels of methylation and, hence, lower levels of gene repression.

5. Proteins containing these domains will be targeted to methylated DNA in repressed promoter regions. They would likely bind in the major groove because that is where the methyl group is located.

6. Gene expression is not expected to respond to the presence of estrogen. However, genes for which expression normally responds to estrogen will respond to the presence of progesterone.

7. The acetylation of lysine will reduce the charge from +1 to 0. The methylation of lysine will not reduce the charge.

8. On the basis of the pattern of cysteine and histidine residues, this region appears to contain three zinc-finger domains.

9.  $10/4000 = 0.25\%$ .  $0.25\%$  of 12 Mb = 30 kilobase pairs.

10. Monomethylated-activated; Trimethylated-repressed.

11. The addition of an IRE to the 5' end of the mRNA is expected to block translation in the absence of iron. The addition of an IRE to the 3' end of the mRNA is not expected to block translation, but it might affect mRNA stability.

12. The sequences of all of the mRNAs would be searched for sequences that are fully or nearly complementary to the sequence of the miRNA. These sequences would be candidates for regulation by this mRNA.

13. The amino group of the lysine residue, formed from the protonated form by a base, attacks the carbonyl group of acetyl CoA to generate a tetrahedral intermediate. This intermediate collapses to form the amide bond and release CoA.

14. In mouse DNA, most of the HpaII sites are methylated and therefore not cut by the enzyme, resulting in large fragments. Some small fragments are produced from CpG islands that are unmethylated. For *Drosophila* and *E. coli* DNA, there is no methylation and all sites are cut.

### Chapter 33

1. The transgenic nematode would avoid the compound. The identity of the ligand is determined by the receptor, whereas the behavioral response is dictated by the neuron in which the receptor is expressed.

2. Only a mixture of compounds  $C_5$ -COOH and  $HOOC-C_7$ -COOH is predicted to yield this pattern.

3. Bitter and sweet sensations are mediated by G proteins coupled to 7TM receptors, leading to millisecond time resolution. Salty and sour sensations are mediated directly by ion channels, which may lead to faster time resolution.

4. Sound travels 0.15 m in 428  $\mu$ s. The human hearing system is capable of sensing time differences of close to a microsecond, and so the difference in arrival times at the two ears is substantial. A system based on G proteins is unlikely to be able to reliably distinguish between signals arriving at the two ears, because G proteins typically respond in milliseconds.

5. If a plant tastes bitter, animals will avoid eating it even if it is nontoxic, which may provide a selective advantage to the plant.

6. Using mice in which either the gene for T1R1 or the gene for T1R3 has been disrupted, test the taste responses of these mice to glutamate, aspartate, and a wide variety of other amino acids.

7. 530 nm light will be absorbed to some degree by all three photoreceptors, with the largest absorption from the "green" receptor.

8. These women have four functional color receptors: blue, red, green, and a red–green hybrid. The additional color receptor allows some colors that appear identical to most people to be distinguished.

9. 380 (one for each receptor); there are  $(380 \times 379)/2! = 72,010$  combinations of two receptors;  $(380 \times 379 \times 378)/3! = 9,073,260$  combinations of three receptors.

10. The absorption of light converts 11-*cis*-retinal into all-*trans*-retinal.

11. These compounds are enantiomers and must bind to protein receptors to elicit a smell. Even these subtle structural differences can affect relative receptor binding affinities and, hence, the elicited odor.

12. Vision: cGMP-gated channel; taste: amiloride-sensitive sodium channel; hearing: tip-link channel.

13. For all senses, ATP hydrolysis is required to generate and maintain ion gradients and membrane potential. Olfaction: ATP is required for the synthesis of cAMP. Gustation: ATP is required for the synthesis of cyclic nucleotides, and GTP is required for the action of gustducin in the detection of bitter and sweet tastes. Vision: GTP is required for the synthesis of cGMP and for the action of transducin. Hearing and touch: ATP hydrolysis is required to generate and maintain ion gradients and membrane potential and may be required for other roles as well.

14.

### Chapter 34

1. The innate immune system responds rapidly to common features present in many pathogens. The genes for the innate immune system's key molecules are expressed without substantial modification. In contrast, the adaptive immune system responds to specific features present only in a given pathogen. Its genes undergo significant rearrangement and mutation to enable specific recognition of a vast number of potential binding surfaces.

2. VJ and V(D)J recombination; variability in segment joining by the action of terminal deoxyribonucleotidyl transferase; somatic mutation.

3. *Affinity* refers to the strength of a single interaction; *avidity* refers to the cumulative strength of multiple independent binding interactions. Avidity may play a significant role in the interaction between IgM and antigen because this immunoglobulin class features 10 binding sites.

4. The intracellular signaling domain common to each of the TLRs is responsible for docking other proteins and reporting that a targeted pathogen-associated molecular pattern (PAMP), such as LPS, has been detected. If a mutation within this domain interfered with the intracellular docking and signal transduction, then TLR4 would not respond to LPS.

5. Viruses that contain dsRNA genomes would be expected to stimulate a TLR3-mediated immune response.

6. (a)  $\Delta G^{\circ'} = -37 \text{ kJ mol}^{-1} (-8.9 \text{ kcal mol}^{-1})$   
 (b)  $K_a = 3.3 \times 10^6 \text{ M}^{-1}$   
 (c)  $k_{\text{on}} = 4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ . This value is close to the diffusion-controlled limit for the combination of a small molecule with a protein (p. 231). Hence, the extent of structural change is likely to be small; extensive conformational transitions take time.

7. The fluorescence enhancement and the shift to blue indicate that water is largely excluded from the binding site when the hapten is bound. Hydrophobic interactions contribute significantly to the formation of most antigen-antibody complexes.

8. (a) An antibody combining site is formed by CDRs from both the H and the L chains. The  $V_H$  and  $V_L$  domains are essential. A small proportion of  $F_{\text{ab}}$  fragments can be further digested to produce  $F_{\text{v}}$ , a fragment that contains just these two domains.  $C_{H1}$  and  $C_L$  contribute to the stability of  $F_{\text{ab}}$  but not to antigen binding.

(b) A synthetic  $F_{\text{v}}$  analog 248 residues long was prepared by expressing a synthetic gene consisting of a  $V_H$  gene joined to a  $V_L$  gene through a linker. [J. S. Huston et al., *Proc. Natl. Acad. Sci. U.S.A.* 85:5879–5883, 1988.]

9. (a) Multivalent antigens lead to the dimerization or oligomerization of transmembrane immunoglobulins, an essential step in their activation. This mode of activation is reminiscent of that of receptor tyrosine kinases (Section 14.2).

(b) An antibody specific for a transmembrane immunoglobulin will activate a B cell by cross-linking these receptors. This experiment can be carried out by using, for example, a goat antibody to cross-link receptors on a mouse B cell.

10. B cells do not express T-cell receptors. The hybridization of T-cell cDNAs with B-cell mRNAs removes cDNAs that are expressed in both cells. Hence, the mixture of cDNAs subsequent to this hybridization are enriched in those encoding T-cell receptors. This procedure, called subtractive hybridization, is generally useful in isolating low-abundance cDNAs. Hybridization should be carried out by using mRNAs from a closely related cell that does not express the gene of interest. [See S. M. Hedrick, D. I. Cohen, E. A. Nielsen, and M. M. Davis, *Nature* 308:149–153, 1984, for an interesting account of how this method was used to obtain genes for T-cell receptors.]

11. TLR4 is the receptor for LPS, a toxin found specifically in the walls of Gram-negative bacteria. Mutations that inhibit the function of TLR4 impair an affected person's defenses against this class of bacteria.

12. If the HLA alleles are not matched, then the recipient's T cell receptors will identify the MHC proteins of the transplanted tissue as nonself and transplant rejection is likely.

13. Purify an antibody with a specificity to one antigen. Unfold the antibody and allow it to re-fold either in the presence of the antigen or in the absence of the antigen. Test the re-folded antibodies for antigen-binding ability.

14. In some cases, V–D–J rearrangement will result in combining V, D, and J segments out of frame. mRNA molecules produced from such rearranged genes will produce truncated molecules if translated. This possibility is excluded by degrading the mRNA.

15. The mutant bacteria may still stimulate an immune response without causing disease. Hence, they may be valuable starting points for the design of a live attenuated vaccine for the original pathogenic strain.

16. The peptide is LLQATYSAV (L in second position, V in last).

17. Catalysis is likely to require a base for removing a proton from a water molecule. A histidine, glutamate, or aspartate residue is most likely. In addition, a potential hydrogen-bond donor may be present and will interact with the negatively charged oxygen atom that forms in the transition state.

18. A phosphotyrosine residue in the carboxyl terminus of Src and related protein tyrosine kinases binds to its own SH2 domain to generate the inhibited form of Src (Section 14.5). Removal of the phosphoryl group from this residue will activate the kinase.

19. (a)  $K_d = 10^{-7} \text{ M}$ ; (b)  $K_d = 10^{-9} \text{ M}$ . The gene was probably generated by a point mutation in the gene for antibody A rather than by de novo rearrangement.

### Chapter 35

1. (a) Skeletal muscle and eukaryotic cilia derive their free energy from ATP hydrolysis; the bacterial flagellar motor uses a proton-motive force.

(b) Skeletal muscle requires myosin and actin. Eukaryotic cilia require microtubules and dynein. The bacterial flagellar motor requires MotA, MotB, and FliG, as well as many ancillary components.

2.  $6400 \text{ \AA}/80 \text{ \AA} = 80$  body lengths per second. For a 10-foot automobile, this body-length speed corresponds to a speed of  $80 \times 10 \text{ feet} = 800 \text{ feet per second}$ , or 545 miles per hour.

3.  $4 \text{ pN} = 8.8 \times 10^{-13} \text{ pounds}$ . The weight of a single motor domain is  $100,000 \text{ g mol}^{-1}/(6.023 \times 10^{23} \text{ molecules mol}^{-1}) = 1.7 \times 10^{-19} \text{ g} = 3.7 \times 10^{-22} \text{ pounds}$ . Thus, a motor domain can lift  $(8.8 \times 10^{-13}/3.7 \times 10^{-22}) = 2.4 \times 10^9$  times its weight.

4. Both actin filaments and microtubules are built from subunits and these subunits bind and hydrolyze nucleoside triphosphates. Actin filaments are built of a single type of subunit and these subunits bind ATP. Microtubules are built of two different types of subunits and these subunits bind GTP.

5. The light chains in myosin stiffen the lever arm. The light chains in kinesin bind cargo to be transported.

6. After death, the ratio of ADP to ATP increases rapidly. In the ADP form, myosin motor domains bind tightly to actin. Myosin-actin interactions are possible because the drop in ATP concentration also allows the calcium concentration to rise, clearing the blockage of actin by tropomyosin through the action of the troponin complex.

7. Above its critical concentration, ATP-actin will polymerize. The ATP will hydrolyze through time to form ADP-actin, which has a higher critical concentration. Thus, if the initial subunit concentration is between the critical concentrations of ATP-actin and ADP-actin, filaments will form initially and then disappear on ATP hydrolysis.

8. A one-base step is approximately  $3.4 \text{ \AA} = 3.4 \times 10^{-4} \text{ \mu m}$ . If a stoichiometry of one molecule of ATP per step is assumed, this distance corresponds to a velocity of  $0.017 \text{ \mu m s}^{-1}$ . Kinesin moves at a velocity of  $6400 \text{ \AA per second}$ , or  $0.64 \text{ \mu m s}^{-1}$ .

9. A proton-motive force across the plasma membrane is necessary to drive the flagellar motor. Under conditions of starvation, this proton-motive force is depleted. In acidic solution, the pH difference across the membrane is sufficient to power the motor.

10. The mean distance between tumbles would be longer when the bacterium is moving up a gradient of a chemoattractant.

11. (a)  $1.13 \times 10^{-9} \text{ dyne}$

(b)  $6.8 \times 10^{14} \text{ erg}$

(c)  $6.6 \times 10^{-11} \text{ erg per 80 molecules of ATP}$ . A single kinesin motor provides more than enough free energy to power the transport of micrometer-size cargoes at micrometer-per-second velocities.

12. The spacing between identical subunits on microtubules is 8 nm. Thus, a kinesin molecule with a step size that is not a multiple of 8 nm would have to be able to bind at more than one type of site on the microtubule surface.

13. KIF1A must be tethered to an additional microtubule-binding element that retains an attachment to the microtubule when the motor domain releases.

14. Filaments built from subunits can be arbitrarily long, can be dynamically assembled and disassembled, and require only a small amount of genetic information to encode.

15. Protons still flow from outside to inside the cell. Each proton might pass into the outer half-channel of one MotA-MotB complex, bind to the MS ring, rotate clockwise, and pass into the inner half-channel of the neighboring MotA-MotB complex.

16. At a high concentration of calcium ion,  $\text{Ca}^{2+}$  binds to calmodulin. In turn, calmodulin binds to a protein kinase that phosphorylates myosin light chains and activates it. At low calcium ion concentration, the light chains are dephosphorylated by a  $\text{Ca}^{2+}$ -independent phosphatase.

17. (a) The value of  $k_{\text{cat}}$  is approximately 13 molecules per second, whereas the  $K_{\text{M}}$  value for ATP is approximately  $12 \text{ \mu M}$ .

(b) The step size is approximately  $(380 - 120)/7 = 37 \text{ nm}$ .

(c) The step size is very large, which is consistent with the presence of six light-chain-binding sites and, hence, very long lever arms.

The rate of ADP release is essentially identical with the overall  $k_{\text{cat}}$ ; so ADP release is rate limiting, which suggests that both motor domains can bind to sites 37 nm apart simultaneously. ADP release from the hindmost domain allows ATP to bind, leading to actin release and lever-arm motion.

### Chapter 36

1. (a) Before; (b) after; (c) after; (d) after; (e) before; (f) after.

2. (a) Yes; (b) yes; (c) no ( $\text{MW} > 600$ ).

3. If computer programs could estimate  $\log(P)$  values on the basis of chemical structure, then the required laboratory time for drug development could be shortened. The determination of the relative solubilities of pharmaceutical candidates by allowing each compound to equilibrate between water and an organic phase would no longer be necessary.

4. Perhaps *N*-acetylcysteine would conjugate to some of the *N*-acetyl-*p*-benzoquinone imine that is produced by the metabolism of acetaminophen, thereby preventing the depletion of the liver's supply of glutathione.

5. In Phase I clinical trials, approximately 10 to 100 usually healthy volunteers are typically enrolled in a study designed to assess safety. In contrast, a larger number of subjects are enrolled in a typical Phase II trial. Moreover, these persons may benefit from the drug administered. In a Phase II trial, efficacy, dosage, and safety can be assessed.

6. The binding of other drugs to albumin could cause extra coumadin to be released. (Albumin is a general carrier for hydrophobic molecules.)

7. A drug that inhibits a P450 enzyme may dramatically affect the disposition of another drug that is metabolized by that same enzyme. If this inhibited metabolism is not accounted for when dosing, the second drug may reach very high, and sometimes toxic, levels in the blood.

8. Unlike competitive inhibition, noncompetitive inhibition cannot be overcome with additional substrate. Hence, a drug that acts by a noncompetitive mechanism will be unaffected by changing levels of the physiological substrate.

9. An inhibitor of MDR could prevent the efflux of a chemotherapeutic drug from tumor cells. Hence, this type of an inhibitor could be useful in averting resistance to cancer chemotherapy.

10. Agents that inhibit one or more enzymes of the glycolytic pathway could act to deprive trypanosomes of energy and thus be useful for treating sleeping sickness. A difficulty is that glycolysis in the host cells also would be inhibited.

11. Imatinib is an inhibitor of the Bcr-Abl kinase, a mutant kinase present only in tumor cells that have undergone a translocation between chromosomes 9 and 22 (Figure 14.34). Before initiating treatment with imatinib, we could sequence the DNA of the tumor cells and determine (a) whether this translocation has taken place and (b) whether the sequence of *bcr-abl* carries any mutations that would render the kinase resistant

## ANSWERS TO PROBLEMS

to imatinib. If the translocation has not taken place or if the gene carries resistance mutations, then imatinib would likely not be an effective treatment for the patient carrying this particular tumor.

12. Sildenafil increases cGMP levels by inhibiting the phosphodiesterase-mediated breakdown of cGMP to GMP. Intracellular cGMP levels can also be increased by activating its synthesis. This activation can be achieved with the use of NO donors (such as sodium nitroprusside and nitroglycerin) or compounds that activate guanylate cyclase activity. Drugs that act by the latter mechanism are currently in clinical trials.

13. A reasonable mechanism would be an oxidative deamination following an overall mechanism similar to that in Figure 36.10, with release of ammonia.

14.  $K_1 \approx 0.3$  nM.  $IC_{50} \approx 2.0$  nM. Yes, compound A should be effective when taken orally because 400 nM is much greater than the estimated values of  $K_1$  and  $IC_{50}$ .

### Amyotrophic Lateral Sclerosis

Siddique, T., Figlewicz, D. A., Pericak-Vance, M. A., Haines, J. L., Rouleau, G., Jeffers, A. J., Sapp, P., Hung, W.-Y., Bebout, J., McKenna-Yasek, D., et al. 1991. Linkage of a gene causing familial amyotrophic lateral sclerosis to chromosome 21 and evidence of genetic-locus heterogeneity. *New Engl. J. Med.* 324:1381–1384.

Rosen, D. R., Siddique, T., Patterson, D., Figlewicz, D. A., Sapp, P., Hentati, A., Donaldson, D., Goto, J., O'Regan, J. P., Deng, H.-X., et al. 1993. Mutations in Cu/Zn superoxide dismutase gene are associated with familial amyotrophic lateral sclerosis. *Nature* 362:59–62.

Gurney, M. E., Pu, H., Chiu, A. Y., Dal Canto, M. C., Polchow, C. Y., Alexander, D. D., Caliendo, J., Hentati, A., Kwon, Y. W., Deng, H.-X., et al. 1994. Motor neuron degeneration in mice that express a human Cu, Zn superoxide dismutase mutation. *Science* 264:1772–1774.

Borchelt, D. R., Lee, M. K., Slunt, H. S., Guarnieri, M., Xu, Z.-S., Wong, P. C., Brown, R. H., Jr., Price, D. L., Sisodia, S. S., and Cleveland, D. W. 1994. Superoxide dismutase 1 with mutations linked to familial amyotrophic lateral sclerosis possesses significant activity. *Proc. Natl. Acad. Sci. U.S.A.* 91:8292–8296.

## Chapter 6

### Where to Start

Hogewer, P. 2011. The roots of bioinformatics in theoretical biology. *PLoS Comp. Biol.* 7:e1002021.

Searls, D. B. 2010. The roots of bioinformatics. *PLoS Comp. Biol.* 6: e1000809.

### Books

Claverie, J.-M., and Notredame, C. 2003. *Bioinformatics for Dummies*. Wiley.

Pevsner, J. 2003. *Bioinformatics and Functional Genomics*. Wiley-Liss.

Doolittle, R. F. 1987. *Of URFS and ORFS*. University Science Books.

### Sequence Alignment

Schaffer, A. A., Aravind, L., Madden, T. L., Shavirin, S., Spouge, J. L., Wolf, Y. I., Koonin, E. V., and Altschul, S. F. 2001. Improving the accuracy of PSI-BLAST protein database searches with composition-based statistics and other refinements. *Nucleic Acids Res.* 29: 2994–3005.

Henikoff, S., and Henikoff, J. G. 1992. Amino acid substitution matrices from protein blocks. *Proc. Natl. Acad. Sci. U.S.A.* 89:10915–10919.

Johnson, M. S., and Overington, J. P. 1993. A structural basis for sequence comparisons: An evaluation of scoring methodologies. *J. Mol. Biol.* 233:716–738.

Eddy, S. R. 2004. Where did the BLOSUM62 alignment score matrix come from? *Nat. Biotechnol.* 22:1035–1036.

Aravind, L., and Koonin, E. V. 1999. Gleaning non-trivial structural, functional and evolutionary information about proteins by iterative database searches. *J. Mol. Biol.* 287:1023–1040.

Altschul, S. F., Madden, T. L., Schaffer, A. A., Zhang, J., Zhang, Z., Miller, W., and Lipman, D. J. 1997. Gapped BLAST and PSI-BLAST: A new generation of protein database search programs. *Nucleic Acids Res.* 25:3389–3402.

### Structure Comparison

Orengo, C. A., Bray, J. E., Buchan, D. W., Harrison, A., Lee, D., Pearl, F. M., Sillitoe, I., Todd, A. E., and Thornton, J. M. 2002. The CATH protein family database: A resource for structural and functional annotation of genomes. *Proteomics* 2:11–21.

Bashford, D., Chothia, C., and Lesk, A. M. 1987. Determinants of a protein fold: Unique features of the globin amino acid sequences. *J. Mol. Biol.* 196:199–216.

Harutyunyan, E. H., Safonova, T. N., Kuranova, I. P., Popov, A. N., Teplyakov, A. V., Obmolova, G. V., Rusakov, A. A., Vainshtein, B. K., Dodson, G. G., Wilson, J. C., et al. 1995. The structure of deoxy- and oxy-leghaemoglobin from lupin. *J. Mol. Biol.* 251:104–115.

Flaherty, K. M., McKay, D. B., Kabsch, W., and Holmes, K. C. 1991. Similarity of the three-dimensional structures of actin and the ATPase fragment of a 70-kDa heat shock cognate protein. *Proc. Natl. Acad. Sci. U.S.A.* 88:5041–5045.

Murzin, A. G., Brenner, S. E., Hubbard, T., and Chothia, C. 1995. SCOP: A structural classification of proteins database for the investigation of sequences and structures. *J. Mol. Biol.* 247:536–540.

Hadley, C., and Jones, D. T. 1999. A systematic comparison of protein structure classification: SCOP, CATH and FSSP. *Struct. Fold. Des.* 7:1099–1112.

### Domain Detection

Marchler-Bauer, A., Anderson, J. B., DeWeese-Scott, C., Fedorova, N. D., Geer, L. Y., He, S., Hurwitz, D. I., Jackson, J. D., Jacobs, A. R., Lanczycki, C. J., et al. 2003. CDD: A curated Entrez database of conserved domain alignments. *Nucleic Acids Res.* 31:383–387.

Ploegman, J. H., Drent, G., Kalk, K. H., and Hol, W. G. 1978. Structure of bovine liver rhodanese I: Structure determination at 2.5 Å resolution and a comparison of the conformation and sequence of its two domains. *J. Mol. Biol.* 123:557–594.

Nikolov, D. B., Hu, S. H., Lin, J., Gasch, A., Hoffmann, A., Horikoshi, M., Chua, N. H., Roeder, R. G., and Burley, S. K. 1992. Crystal structure of TFIID TATA-box binding protein. *Nature* 360:40–46.

Doolittle, R. F. 1995. The multiplicity of domains in proteins. *Annu. Rev. Biochem.* 64:287–314.

Heger, A., and Holm, L. 2000. Rapid automatic detection and alignment of repeats in protein sequences. *Proteins* 41:224–237.

### Evolutionary Trees

Wolf, Y. I., Rogozin, I. B., Grishin, N. V., and Koonin, E. V. 2002. Genome trees and the tree of life. *Trends Genet.* 18:472–479.

Doolittle, R. F. 1992. Stein and Moore Award address. Reconstructing history with amino acid sequences. *Protein Sci.* 1:191–200.

Zuckermandl, E., and Pauling, L. 1965. Molecules as documents of evolutionary history. *J. Theor. Biol.* 8:357–366.

Schönknecht, G., Chen, W.-H., Ternes, C. M., Barbier, G. G., Shrestha, R. P., Stanke, M., Bräutigam, A., Baker, B. J., Banfield, J. F., Garavito, R. M., et al. 2013. Gene transfer from bacteria and archaea facilitated evolution of an extremophilic eukaryote. *Science* 339:1207–1210.

### Ancient DNA

Prüfer, K., Racimo, F., Patterson, N., Jay, F., Sankararaman, S., Sawyer, S., Heinze, A., Renaud, G., Sudmant, P. H., de Filippo, C., et al. 2014. The complete genome sequence of a Neanderthal from the Altai Mountains. *Nature* 505:43–49.

Meyer, M., Kircher, M., Gansauge, M. T., Li, H., Racimo, F., Mallick, S., Schraiber, J. G., Jay, F., Prüfer, K., de Filippo, C., et al. 2012. A high-coverage genome sequence from an archaic Denisovan individual. *Science* 338:222–226.

Green, R. E., Malaspina, A.-S., Krause, J., Briggs, A. W., Johnson, P. L. F., Uhler, C., Meyer, M., Good, J. M., Maricic, T., Stenzel, U., et al. 2008. A complete Neanderthal mitochondrial genome sequence determined by high-throughput sequencing. *Cell* 134:416–426.

## SELECTED READINGS

Pääbo, S., Poinar, H., Serre, D., Jaenicke-Despres, V., Hebler, J., Rohland, N., Kuch, M., Krause, J., Vigilant, L., and Hofreiter, M. 2004. Genetic analyses from ancient DNA. *Annu. Rev. Genet.* 38:645–679.

**Evolution in the Laboratory**

- ADME properties, of drugs, 1036–1040,  
 1037f
- ADP (adenosine diphosphate), **275**  
 ATP hydrolyzed to, 426  
 in citric acid cycle, 406f, 506  
 formation of, 275  
 in kinesin movement, 1025, 1025f  
 in oxidative phosphorylation, 550–551,  
 551f, 553–554, 554f  
 in random sequential reaction, 232  
 structure of, 426, **427**
- Adrenocorticotrophic hormone, 59
- Aerobic glycolysis, 474–476, 510
- Affinity chromatography, 70–71, 70f
- Affinity maturation, 993
- Affinity tags, 78, 237–238, 237f, 238f
- Aflatoxin activation, 846f
- A-form DNA, 111–112, 111f, 112f, 112t
- Aggrecan, 328
- $\alpha$ -glucosidase, 450
- Agonists, 951
- Agouti-related peptide (AgRP),  
 805–806, 806f
- Agre, Peter, 1
- Agrobacterium tumefaciens*, 163, 163f
- Alanine  
 defined, 30  
 formation of, 720–721  
 in gluconeogenesis, 486  
 in muscle contraction, 486, 486f  
 structure of, 31f  
 tryptophan in, 700
- Alanine aminotransferase, 688
- Alanyl-tRNA, 895, 895f
- Albinism, 705t
- Albumin, 137f, 1037
- Alcaptonuria, 705
- Alcohol dehydrogenase, 820
- Alcoholic fermentation, 449, 463, 463f
- Alcoholic scurvy, 821
- Alcohols  
 fermentation of, 462–464, 463f  
 formation from pyruvate, 462–464, 463f  
 metabolism of, 819–822  
 monosaccharides and, 322  
 toxicity of, 821–822
- Aldehyde dehydrogenase, 228
- Aldehydes, oxidation of energy, 457–458
- Alder, Julius, 1026
- Aldimine, 690
- Aldolase, 455  
 in Calvin cycle, 595  
 in transaldolase reaction, 606–607
- Aldoses  
 conversion to ketoses, 454  
 defined, 316
- Aldosterone, 789, 792, **793**
- Allolactose, 930
- Allopurinol, 761
- Allosteric constant, 290
- Allosteric control, 285
- Allosteric effector, 200–201
- Allosteric enzymes, 233, 233f  
 allosteric constant, 290  
 concerted model, 290  
 control of, 443  
 homotropic effects on, 290  
 sequential model, 290–291  
 sigmoidal kinetics, 287, 287f  
 substrate concentration and, 291  
 threshold effects, 291, 291f  
 T-to-R equilibrium in, 291–292,  
 291f, 292f  
 T-to-R state transition, 290–291, 290f
- Allosteric sites, 287
- Alloxanthine, 761
- $\alpha$  helix  
 of membrane proteins, 355–356,  
 355f, 355t  
 pitch of, 40  
 as right-handed, 41  
 schematic view of, 41f  
 screw sense, 40–41, 40f  
 structure of, 41f, **41**
- $\alpha$ -stabilizing protein (AHSP), 207–208, 207f
- $\alpha_1$ -antiproteinase, 303
- $\alpha$ -amino acids, 29, 35
- $\alpha$ -helical coiled coil, 44
- $\alpha$ -hemoglobin, 207, 207f  
 alignment with gap insertion, 173f  
 amino acid sequences, 171–172, 171f, 172f
- $\alpha$ -thalassemia, 207
- Alternative splicing, 128, 129f, 877  
 defects in, 885t  
 defined, 885  
 example of, 885f  
 pre-mRNA, 885–886
- Altman, Sidney, 859, 870
- Alu sequences, 154
- Alzheimer's disease, 56–57
- Amanita phalloides*, 873, 873f

 in liver, 622–623, 637  
 metabolism of, 607–610, 618, 618f  
 in pentose phosphate pathway, 602, 603f,  
 607–610  
 transporter, 637
- Glucose 6-phosphate dehydrogenase  
 (G6PD)  
 deficiency, 610–612  
 in pentose phosphate pathway, 602,  
 610–612  
 in reactive oxygen species protection,  
 610–612
- Glucose homeostasis  
 in diabetes, 807–812  
 in starvation, 818–819  
 starved-fed cycle in, 816–817
- Glucose transporters (GLUTs), 368  
 families, 473, 474t  
 in glycolysis, 473–474, 474t
- Glucose-alanine cycle, 692–693
- Glucose-stimulated insulin secretion  
 (GSIS), 810–812
- $\alpha$ -1,6-glucosidase, 638
- Glutamate, 233, 700  
 chirality of, 717, 718f  
 formation of, 687, 692, 720–721  
 in nitrogen fixation, 717–718  
 oxidative deamination of, 687–689  
 structure of, 33, 34f  
 synthesis of, 722, 722f
- Glutamate dehydrogenase, 688–689,  
 717, 718
- Glutamate synthase, 718

- Glutamine, 717–718  
 degradation, 701  
 in nitrogen transport, 693  
 in pyrimidine synthesis, 745  
 structure of, 32f, 33  
 synthesis of, 722
- Glutamine phosphoribosyl  
 amidotransferase, 749
- Glutamine synthetase, 717, 718, 732–733  
 regulation of, 732–733, 733f  
 structure of, 732–733
- Glutathione, 610, 611  
 conjugation reaction, 1038, **1039**  
 defined, 734  
 structure of, **734**
- Glutathione peroxidase, 611, 735, 735f, **735**
- Glutathione reductase, 611, 734
- Glycan-binding proteins, 334
- Glyceraldehyde, 316, **316**, 317, 317f
- Glyceraldehyde 3-phosphate (GAP), 323  
 in Calvin cycle, 595  
 catalytic mechanism of, 458, 459f  
 free-energy profiles for, 458, 458f  
 in glycolysis, 452f, 454–455, 455f, 456, 456f, 457–460, 458f, 459f  
 oxidation of, 432–433, 458–459, 459f  
 in pentose phosphate pathway, 603, 604, 604f  
 structure of, 458f, **458**
- Glycerol  
 generation by lipolysis, 648, 648f  
 in gluconeogenesis, 476–478  
 in liver, 648  
 in phosphoglycerides, 344
- Glycerol 3-phosphate  
 in lipid synthesis, 768  
 reoxidation of, 549
- Glycerol 3-phosphate shuttle, 549–550, 549f
- Glycerol phosphate acyltransferase, 768
- Glycine  
 in Calvin cycle, 593  
 conversion into serine, 700  
 defined, 30  
 in liposomes, 349, 349f  
 porphyrins from, 736–737, 737f  
 structure of, 31f  
 synthesis of, 722–723, 723f
- Glycine synthase, 724
- Glycine-glycine-glutamine (GGQ)  
 sequence, 911
- Glycoaminoglycans, 326
- Glycocholate, 646f
- Glycogen, 333  
 branch point in, 324, 324f  
 defined, 324, 617  
 glucose storage in, 617, 618–619  
 in glycogen metabolism, 627–629, 628f, 633  
 in liver, 618, 618f, 627  
 molecules, 617, 618f, 632f  
 in muscle, 618, 618f  
 phosphorolytic cleavage of, 620–621  
 remodeling, 622, 622f  
 storage efficiency, 632  
 storage sites of, 618, 618f  
 structure of, 618f
- Glycogen lakes, 638f
- Glycogen metabolism  
 branching enzyme in, 631–632, 632f  
 cAMP in, 628–629  
 coordinate control of, 632–633, 633f  
 degradation of, 618–629  
 enzyme breakdown, 619–623  
 epinephrine in, 627–629, 628f, 633  
 evolution of, 629  
 G proteins in, 627–629  
 glycogen in, 627–629, 628f, 633  
 glycogen phosphorylase in, 619–626  
 glycogen synthase in, 630–632, 631f  
 glycogen synthase kinase (GSK) in, 632, 633, 633f  
 glycogenin in, 631  
 $\alpha$ -1,6-glucosidase in, 621–622  
 hormones in, 627–629, 628f  
 insulin in, 635, 635f  
 in liver, 635–637, 636f  
 overview of, 617–619  
 pathway integration, 628f  
 phosphoglucomutase in, 622, 623f  
 phosphoglycerate mutase in, 622  
 phosphorolysis in, 619–623  
 phosphorylase in, 619–627, 621f, 636, 636f  
 protein kinase A (PKA) in, 629, 633, 633f  
 protein phosphatase 1 (PP1) in, 629, 633–635, 634f, 636  
 pyridoxal phosphate (PLP) in, 621, 621f  
 regulation of, 618–619, 632–638  
 regulatory cascade for, 627–629, 628f  
 7TM receptors in, 627–629, 628f  
 termination of, 629  
 transferase in, 622, 622f  
 UDP-glucose and, 630–631
- Glycogen phosphorylase  
*a*, 623–624, 624f, 626, 627f  
 allosteric regulation of, 624, 624f, 625, 625t  
 amino-terminal domain of, 620–621, 620f  
*b*, 623, 624f, 625, 626, 627f  
 carboxyl-terminal domain of, 620–621, 620f  
 defined, 623  
 evolution of, 629  
 in glycogen metabolism, 619–626  
 glycogen-binding site of, 620–621, 620f  
 in liver, 623–624, 634f  
 in muscle, 625, 625f  
 regulation of, 623–627, 624f, 625t, 629  
 structure of, 620
- Glycogen synthase  
 $\alpha$ -1,6 linkages, 631–632, 631f  
 defined, 630  
 in glycogen synthesis, 632  
 isozymes of, 630–631
- Glycogen synthase kinase (GSK)  
 defined, 632  
 in glycogen metabolism, 633, 633f
- Glycogenin, 631
- Glycogen-storage diseases, 637–638, 637t, 638f
- Glycolate, 593–594, 593f
- Glycolipids, 344, 345–346, 348–350
- N*-glycolylneuraminate, 772
- Glycolysis  
 aerobic, 474–476, 510  
 aldehyde oxidation in, 457–458  
 anaerobic mode, 510, 814  
 ATP formation in, 459–462  
 1,3-bisphosphoglycerate (1,3-BPG) in, 433, 457–460, 459f  
 in cancer, 474–476  
 citric acid cycle and, 497–501, 497f  
 covalent enzyme-bound intermediate in, 458  
 defined, 449  
 dihydroxyacetone phosphate (DHAP) in, 452f, 454–455, 455f, 456, 456f  
 as Embden-Meyerhof pathway, 450  
 enediol intermediate in, 455, 456f  
 energy charge and, 482–483  
 as energy-conversion pathway, 451–469  
 in eukaryotic cells, 451  
 fermentation in, 462–464  
 first stage of, 451, 451f, 452f  
 fructose 1,6-bisphosphate in, 452f, 453–454, 454f  
 fructose 1-phosphate in, 466  
 fructose 2,6-bisphosphate in, 472, 472f  
 fructose 6-phosphate in, 452f, 453, 454f, 472  
 fructose in, 465–466, 466f  
 galactose in, 466–467, 466f  
 gluconeogenesis and, 478, 482–487  
 glucose 6-phosphate (G-6P) in, 452f  
 glucose transporters in, 473–474, 474t  
 glucose trapping in, 451–453  
 glyceraldehyde 3-phosphate (GAP) in, 452f, 454–455, 455f, 456, 456f, 457–460, 458f, 459f  
 hexokinase in, 451–453, 453f, 470–471, 473  
 historical perspective on, 450  
 insulin in, 816  
 isomerization of carbon sugars in, 453–454, 454f  
 in liver, 472–473, 483–485  
 in muscle, 469–471, 471f  
 NAD<sup>+</sup> in, 458, 459f, 462–464, 465  
 NADH in, 458, 462–464  
 overview of, 449, 451  
 pathway integration, 486, 486f  
 pentose phosphate pathway and, 602–610  
 phosphofructokinase (PFK) in, 469–470, 470f, 472, 472f  
 phosphoglycerate kinase in, 459  
 phosphoglycerate mutase in, 460  
 2-phosphoglycerate in, 460–461, 460f  
 3-phosphoglycerate in, 460–461, 460f  
 pyruvate in, 452f, 459–464

- Glycolysis—(continued)  
 pyruvate kinase in, 471, 473, 473f  
 reactions of, 462t–463t  
 reciprocal regulation in, 482–487  
 regulation of, 812, 812f  
 second stage of, 451, 452f, 457f  
 stages of, 451, 451f, 452f, 457f  
 thioester intermediate in, 457–458, 458f  
 triose phosphate isomerase (TPI) in,  
 455–456, 455f, 456f
- Glycolytic intermediates, 610
- Glycolytic pathway  
 glucokinase in, 473

# ACIDITY CONSTANTS

## pK<sub>a</sub> values of some acids

Acid	pK' (at 25°C)	Acid	pK' (at 25°C)
Acetic acid	4.76	Malic acid, pK <sub>1</sub>	3.40
Acetoacetic acid	3.58	pK <sub>2</sub>	5.11
Ammonium ion	9.25	Phenol	9.89
Ascorbic acid, pK <sub>1</sub>	4.10	Phosphoric acid, pK <sub>1</sub>	2.12
pK <sub>2</sub>	11.79	pK <sub>2</sub>	7.21
Benzoic acid	4.20	pK <sub>3</sub>	12.67
<i>n</i> -Butyric acid	4.81	Pyridinium ion	5.25
Cacodylic acid	6.19	Pyrophosphoric acid, pK <sub>1</sub>	0.85
Citric acid, pK <sub>1</sub>	3.14	pK <sub>2</sub>	1.49
pK <sub>2</sub>	4.77	pK <sub>3</sub>	5.77
pK <sub>3</sub>	6.39	pK <sub>4</sub>	8.22
Ethylammonium ion	10.81	Succinic acid, pK <sub>1</sub>	4.21
Formic acid	3.75	pK <sub>2</sub>	5.64
Glycine, pK <sub>1</sub>	2.35	Trimethylammonium ion	9.79
pK <sub>2</sub>	9.78	Tris (hydroxymethyl) aminomethane	8.08
Imidazolium ion	6.95	Water*	15.74
Lactic acid	3.86		
Fumaric acid, pK <sub>1</sub>	3.03		
pK <sub>2</sub>	4.44		

\*[H<sup>+</sup>][OH<sup>-</sup>] = 10<sup>-14</sup>; [H<sub>2</sub>O] = 55.5 M.

## Typical pK<sub>a</sub> values of ionizable groups in proteins

Group	Acid	⇌	Base	Typical pK <sub>a</sub>	Group	Acid	⇌	Base	Typical pK <sub>a</sub>
Terminal α-carboxyl group				3.1	Cysteine				8.3
Aspartic acid Glutamic acid				4.1	Tyrosine				10.4
Histidine				6.0	Lysine				10.0
Terminal α-amino group				8.0	Arginine				12.5

Note: pK<sub>a</sub> values depend on temperature, ionic strength, and the microenvironment of the ionizable group.

# STANDARD BOND LENGTHS

---

Bond	Structure	Length (Å)
C—H	R <sub>2</sub> CH <sub>2</sub>	1.07
	Aromatic	1.08
	RCH <sub>3</sub>	1.10
C—C	Hydrocarbon	1.54
	Aromatic	1.40
C=C	Ethylene	1.33
C≡C	Acetylene	1.20
C—N	RNH <sub>2</sub>	1.47
	O=C—N	1.34
C—O	Alcohol	1.43
	Ester	1.36
C=O	Aldehyde	1.22
	Amide	1.24
C—S	R <sub>2</sub> S	1.82
N—H	Amide	0.99
O—H	Alcohol	0.97
O—O	O <sub>2</sub>	1.21
P—O	Ester	1.56
S—H	Thiol	1.33
S—S	Disulfide	2.05
